$\mathbf{S}^l \in \mathbb{R}^{m \times d}$ is the sequence representation of the l-th decoder layer. Input $\mathbf{S}^0$ is defined similar to $\mathbf{H}^0$. To ensure auto-regressive decoding, the attention weights in Eq. 6 are masked to prevent attention to future target tokens.

The Transformer's parameters are typically initialized by sampling from a uniform distribution:

$$\mathbf{W} \in \mathbb{R}^{d_i \times d_o} \sim \mathcal{U}(-\gamma, \gamma), \gamma = \sqrt{\frac{6}{d_i + d_o}}, \quad (9)$$

where d_i and d_o indicate input and output dimension separately. This initialization has the advantage of maintaining activation variances and back-propagated gradients variance and can help train deep neural networks (Glorot and Bengio, 2010).

4 Vanishing Gradient Analysis

One natural way to deepen Transformer is simply enlarging the layer number L. Unfortunately, Figure 1 shows that this would give rise to gradient vanishing on both the encoder and the decoder at the lower layers, and that the case on the decoder side is worse. We identified a structural problem in the Transformer architecture that gives rise to this issue, namely the interaction of RC and LN, which we will here discuss in more detail.

Given an input vector $\mathbf{z} \in \mathbb{R}^d$, let us consider the general structure of RC followed by LN:

$$\mathbf{r} = \textsc{Rc}\left(\mathbf{z}, f(\mathbf{z})\right), \tag{10}$$

$$\mathbf{o} = \textsc{Ln}\left(\mathbf{r}\right), \tag{11}$$

where $\mathbf{r}, \mathbf{o} \in \mathbb{R}^d$ are intermediate outputs. $f(\cdot)$ represents any neural network, such as recurrent, convolutional or attention network, etc. Suppose during back-propagation, the error signal at the output of LN is δ_o. Contributions of RC and LN to the error signal are as follows:

$$\delta_r = \frac{\partial \mathbf{o}}{\partial \mathbf{r}}\delta_o = \text{diag}(\frac{\mathbf{g}}{\sigma_r})(\mathbf{I} - \frac{1 - \bar{\mathbf{r}}\bar{\mathbf{r}}^T}{d})\delta_o \tag{12}$$

$$\delta_z = \frac{\partial \mathbf{r}}{\partial \mathbf{z}}\delta_r = (1 + \frac{\partial f}{\partial \mathbf{z}})\delta_r, \tag{13}$$

where $\bar{\mathbf{r}}$ denotes the normalized input. $\mathbf{I}$ is the identity matrix and $\text{diag}(\cdot)$ establishes a diagonal matrix from its input. The resulting δ_r and δ_z are error signals arrived at output $\mathbf{r}$ and $\mathbf{z}$ respectively.

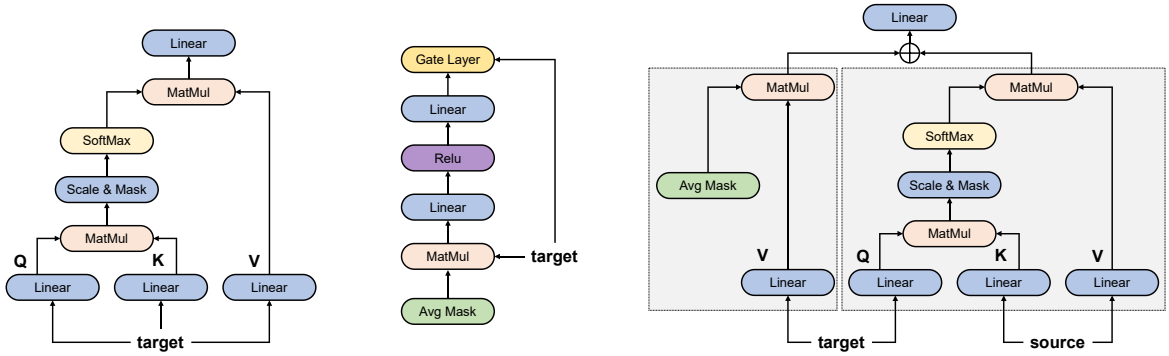
We define the change of error signal as follows:

$$\beta = \beta_{\textsc{Ln}} \cdot \beta_{\textsc{Rc}} = \frac{\|\delta_z\|_2}{\|\delta_r\|_2} \cdot \frac{\|\delta_r\|_2}{\|\delta_o\|_2}, \tag{14}$$

where β (or model ratio), $\beta_{\textsc{Ln}}$ (or LN ratio) and $\beta_{\textsc{Rc}}$ (or RC ratio) measure the gradient norm ratio[2] of the whole residual block, the layer normalization and the residual connection respectively. Informally, a neural model should preserve the gradient norm between layers ($\beta \approx 1$) so as to allow training of very deep models (see Zaeemzadeh et al., 2018).

We resort to empirical evidence to analyze these ratios. Results in Table 1 show that LN weakens error signal ($\beta_{\textsc{Ln}} < 1$) but RC strengthens it ($\beta_{\textsc{Rc}} > 1$). One explanation about LN's decay effect is the large output variance of RC ($\text{Var}(\mathbf{r}) >$ 1) which negatively affects δ_r as shown in Eq. 12. By contrast, the short-cut in RC ensures that the error signal at higher layer δ_r can always be safely carried on to lower layer no matter how complex $\frac{\partial f}{\partial \mathbf{z}}$ would be as in Eq. 13, increasing the ratio.

[2]Model gradients depend on both error signal and layer activation. Reduced/enhanced error signal does not necessarily result in gradient vanishing/explosion, but strongly contributes to it.



Method	Module		Self	Cross	FFN
Base	Enc	$\beta_{\textsc{Ln}}$	0.86	-	0.84
		$\beta_{\textsc{Rc}}$	1.22	-	1.10
		β	1.05	-	0.93
		$\text{Var}(\mathbf{r})$	1.38	-	1.40
	Dec	$\beta_{\textsc{Ln}}$	0.82	0.74	0.84
		$\beta_{\textsc{Rc}}$	1.21	1.00	1.11
		β	0.98	0.74	0.93
		$\text{Var}(\mathbf{r})$	1.48	1.84	1.39
Ours	Enc	$\beta_{\textsc{Ln}}$	0.96	-	0.95
		$\beta_{\textsc{Rc}}$	1.04	-	1.02
		β	1.02	-	0.98
		$\text{Var}(\mathbf{r})$	1.10	-	1.10
	Dec	$\beta_{\textsc{Ln}}$	0.95	0.94	0.94
		$\beta_{\textsc{Rc}}$	1.05	1.00	1.02
		β	1.10	0.95	0.98
		$\text{Var}(\mathbf{r})$	1.13	1.15	1.11

Table 1: Empirical measure of output variance $\text{Var}(\mathbf{r})$ of RC and error signal change ratio $\beta_{\textsc{Ln}}$, $\beta_{\textsc{Rc}}$ and β (Eq. 14) averaged over 12 layers. These values are estimated with $\sim$3k target tokens at the beginning of training using 12-layer Transformer. "*Base*": the baseline Transformer. "*Ours*": the Transformer with DS-Init. *Enc* and *Dec* stand for encoder and decoder respectively. *Self*, *Cross* and *FFN* indicate the self-attention, encoder-decoder attention and the feed-forward sublayer respectively.

5 Depth-Scaled Initialization

Results on the model ratio show that self-attention sublayer has a (near) increasing effect ($\beta > 1$) that intensifies error signal, while feed-forward sublayer manifests a decreasing effect ($\beta < 1$). In particular, though the encoder-decoder attention sublayer and the self-attention sublayer share the same attention formulation, the model ratio of the former is smaller. As shown in Eq. 7 and 1, part of the reason is that encoder-decoder attention can only back-propagate gradients to lower layers through the query representation $\mathbf{Q}$, bypassing gradients at the key $\mathbf{K}$ and the value $\mathbf{V}$ to the encoder side. This negative effect explains why the decoder suffers from more severe gradient vanishing than the encoder in Figure 1.

The gradient norm is preserved better through the self-attention layer than the encoder-decoder attention, which offers insights on the successful training of the deep Transformer in BERT (Devlin et al., 2019) and GPT (Radford et al., 2018), where encoder-decoder attention is not involved. However, results in Table 1 also suggests that the self-attention sublayer in the encoder is not strong

(a) Self-Attention (b) AAN (c) Merged attention with simplified AAN

Figure 2: An overview of self-attention, AAN and the proposed merged attention with simplified AAN.

enough to counteract the gradient loss in the feed-forward sublayer. That is why BERT and GPT adopt a much smaller standard deviation (0.02) for initialization, in a similar spirit to our solution.

We attribute the gradient vanishing issue to the large output variance of RC (Eq. 12). Considering that activation variance is positively correlated with parameter variance (Glorot and Bengio, 2010), we propose DS-Init and change the original initialization method in Eq. 9 as follows:

$$\mathbf{W} \in \mathbb{R}^{d_i \times d_o} \sim \mathcal{U}\left(-\gamma\frac{\alpha}{\sqrt{l}}, \gamma\frac{\alpha}{\sqrt{l}}\right), \quad (15)$$

where α is a hyperparameter in the range of $[0, 1]$ and l denotes layer depth. Hyperparameter α improves the flexibility of our method. Compared with existing approaches (Vaswani et al., 2018; Bapna et al., 2018), our solution does not require modifications in the model architecture and hence is easy to implement.

According to the property of uniform distribution, the variance of model parameters decreases from $\frac{\gamma^2}{3}$ to $\frac{\gamma^2\alpha^2}{3l}$ after applying DS-Init. By doing so, a higher layer would have smaller output variance of RC so that more gradients can flow back. Results in Table 1 suggest that DS-Init narrows both the variance and different ratios to be $\sim$1, ensuring the stability of gradient back-propagation. Evidence in Figure 1 also shows that DS-Init helps keep the gradient norm and slightly increases it on the encoder side. This is because DS-Init endows lower layers with parameters of larger variance and activations of larger norm. When error signals at different layers are of similar scale, the gradient norm at lower layers would be larger. Nevertheless, this increase does not hurt model training based on our empirical observation.

DS-Init is partially inspired by the *Fixup* initialization (Zhang et al., 2019). Both of them try to reduce the output variance of RC. The difference is that Fixup focuses on overcoming gradient explosion cased by consecutive RCs and seeks to enable training without LN but at the cost of carefully handling parameter initialization of each matrix transformation, including manipulating initialization of different bias and scale terms. Instead, DS-Init aims at solving gradient vanishing in deep Transformer caused by the structure of RC followed by LN. We still employ LN to standardize layer activation and improve model convergence. The inclusion of LN ensures the stability and simplicity of DS-Init.

6 Merged Attention Model

With large model depth, deep Transformer unavoidably introduces high computational overhead. This brings about significantly longer training and decoding time. To remedy this issue, we propose a merged attention model for decoder that integrates a simplified average-based self-attention sublayer into the encoder-decoder attention sublayer. Figure 2 highlights the difference.

The AAN model (Figure 2(b)), as an alternative to the self-attention model (Figure 2(a)), accelerates Transformer decoding by allowing decoding in linear time, avoiding the $\mathcal{O}(n^2)$ complexity of the self-attention mechanism (Zhang et al., 2018). Unfortunately, the gating sublayer and the feed-forward sublayer inside AAN reduce the empirical performance improvement. We propose a simplified AAN by removing all matrix computation except for two linear projections:

$$\mathrm{SAAN}(\mathbf{S}^{l-1}) = \left[\mathbf{M}_a(\mathbf{S}^{l-1}\mathbf{W}_v)\right]\mathbf{W}_o, \quad (16)$$

Dataset	#Src	#Tgt	#Sent	#BPE
WMT14 En-De	116M	110M	4.5M	32K
WMT14 En-Fr	1045M	1189M	36M	32K
WMT18 En-Fi	73M	54M	3.3M	32K
WMT18 Zh-En	510M	576M	25M	32K
IWSLT14 De-En	3.0M	3.2M	159K	30K

Table 2: Statistics for different training datasets. *#Src* and *#Tgt* denote the number of source and target tokens respectively. *#Sent*: the number of bilingual sentences. *#BPE*: the number of merge operations in BPE. *M*: million, *K*: thousand.

where $\mathbf{M}_a$ denotes the average mask matrix for parallel computation (Zhang et al., 2018). This new model is then combined with the encoder-decoder attention as shown in Figure 2(c):

$$\begin{aligned} \text{MATT}(\mathbf{S}^{l-1}) &= \text{SAAN}(\mathbf{S}^{l-1}) + \text{ATT}(\mathbf{S}^{l-1}, \mathbf{H}^{L}) \\ \bar{\mathbf{S}}^{l} &= \text{LN}\left(\text{RC}\left(\mathbf{S}^{l-1}, \text{MATT}(\mathbf{S}^{l-1})\right)\right). \end{aligned} \quad (17)$$

The mapping $\mathbf{W}_o$ is shared for SAAN and ATT. After combination, MAtt allows for the parallelization of AAN and encoder-decoder attention.

7 Experiments

7.1 Datasets and Evaluation

We take WMT14 English-German translation (En-De) (Bojar et al., 2014) as our benchmark for model analysis, and examine the generalization of our approach on four other tasks: WMT14 English-French (En-Fr), IWSLT14 German-English (De-En) (Cettolo et al., 2014), WMT18 English-Finnish (En-Fi) and WMT18 Chinese-English (Zh-En) (Bojar et al., 2018). Byte pair encoding algorithm (BPE) (Sennrich et al., 2016) is used in preprocessing to handle low frequency words. Statistics of different datasets are listed in Table 2.

Except for IWSLT14 De-En task, we collect subword units independently on the source and target side of training data. We directly use the preprocessed training data from the WMT18 website[3] for En-Fi and Zh-En tasks, and use newstest2017 as our development set, newstest2018 as our test set. Our training data for WMT14 En-De and WMT14 En-Fr is identical to previous setups (Vaswani et al., 2017; Wu et al., 2019). We use newstest2013 as development set for WMT14 En-De and newstest2012+2013 for WMT14 En-Fr. Apart from newstest2014 test set[4], we also evaluate our model on all WMT14-18 test sets for WMT14 En-De translation. The settings for IWSLT14 De-En are as in Ranzato et al. (2016), with 7584 sentence pairs for development, and the concatenated dev sets for IWSLT 2014 as test set (tst2010, tst2011, tst2012, dev2010, dev2012).

We report tokenized case-sensitive BLEU (Papineni et al., 2002) for WMT14 En-De and WMT14 En-Fr, and provide detokenized case-sensitive BLEU for WMT14 En-De, WMT18 En-Fi and Zh-En with *sacreBLEU* (Post, 2018)[5]. We also report chrF score for En-Fi translation which was found correlated better with human evaluation (Bojar et al., 2018). Following previous work (Wu et al., 2019), we evaluate IWSLT14 De-En with tokenized case-insensitive BLEU.

7.2 Model Settings

We experiment with both *base* (layer size 512/2048, 8 heads) and *big* (layer size 1024/4096, 16 heads) settings as in Vaswani et al. (2017). Except for the vanilla Transformer, we also compare with the structure that is currently default in tensor2tensor (T2T), which puts layer normalization before residual blocks (Vaswani et al., 2018). We use an in-house toolkit for all experiments.

Dropout is applied to the residual connection (dp_r) and attention weights (dp_a). We share the target embedding matrix with the softmax projection matrix but not with the source embedding matrix. We train all models using Adam optimizer (0.9/0.98 for base, 0.9/0.998 for big) with adaptive learning rate schedule (warm-up step 4K for base, 16K for big) as in (Vaswani et al., 2017) and label smoothing of 0.1. We set α in DS-Init to 1.0. Sentence pairs containing around 25K$\sim$50K (bs) target tokens are grouped into one batch. We use relatively larger batch size and dropout rate for deeper and bigger models for better convergence. We perform evaluation by averaging last 5 checkpoints. Besides, we apply mixed-precision training to all big models. Unless otherwise stated, we train base and big model with 300K maximum steps, and decode sentences using beam search with a beam size of 4 and length penalty of 0.6. Decoding is implemented with cache to save redundant computations. Other settings for specific translation tasks are explained in the individual subsections.

[3] http://www.statmt.org/wmt18/translation-task.html

[4] We use the filtered test set consisting of 2737 sentence pairs. The difference of translation quality on filtered and full test sets is marginal.

Bold indicates best BLEU score. dp_a and dp_r: dropout rate on attention weights and residual connection. bs: batch size in tokens.

7.3 WMT14 En-De Translation Task

Table 3 summarizes translation results under different settings. Applying DS-Init and/or MAtt to Transformer with 6 layers slightly decreases translation quality by ∼0.2 BLEU (27.59→27.35). However, they allow scaling up to deeper architectures, achieving a BLEU score of 28.55 (12 layers) and 28.67 (20 layers), outperforming all baselines. These improvements can not be obtained via enlarging the training batch size (⑧), confirming the strength of deep models.

We also compare our simplified AAN in MAtt (④) with two variants: a self-attention network (⑥), and the original AAN (⑦). Results show minor differences in translation quality, but improvements in training and decoding speed, and a reduction in the number of model parameters. Compared to the baseline, MAtt improves decoding speed by 50%, and training speed by 10%, while having 9% fewer parameters.

Result ⑨ indicates that the gradient vanishing issue prevents training of deep vanilla Transformers, which cannot be solved by only simplifying the decoder via MAtt (⑩). By contrast, both T2T and DS-Init can help. Our DS-Init improves norm preservation through specific parameter initialization, while T2T reschedules the LN position. Results in Table 3 show that T2T underperforms DS-Init by 0.2 BLEU on average, and slightly increases training and decoding time (by 2%) compared to the original Transformer due to additional LN layers. This suggests that our solution is more effective and efficient.

ID	BLEU		PPL	
	Train	Dev	Train	Dev
1	28.64	26.16	5.23	4.76

16	30.25	**26.56**	4.62	4.58

Table 4: Tokenized case-sensitive BLEU (BLEU) and perplexity (PPL) on training (Train) and development (newstest2013, Dev) set. We randomly select 3K sentence pairs as our training data for evaluation. Lower PPL is better.

Surprisingly, training deep Transformers with both DS-Init and MAtt improves not only running efficiency but also translation quality (by 0.2 BLEU), compared with DS-Init alone. To get an improved understanding, we analyze model performance on both training and development set. Results in Table 4 show that models with DS-Init yield the best perplexity on both training and development set, and those with T2T achieve the best BLEU on the training set. However, DS-Init+MAtt performs best in terms of BLEU on the development set. This indicates that the success of DS-Init+MAtt comes from its better generalization rather than better fitting training data.

We also attempt to apply DS-Init on the encoder alone or the decoder alone for 12-layer models. Unfortunately, both variants lead to unstable optimization where gradients tend to explode at the

middle of training. We attempt to solve this issue with gradient clipping of rate 1.0. Results show that this fails for decoder and achieves only 27.89 BLEU for encoder, losing 0.66 BLEU compared with the full variant (28.55). We leave further analysis to future work and recommend using DS-Init on both the encoder and the decoder.

Effect of Model Depth We empirically compare a wider range of model depths for Transformer+DS-Init+MAtt with up to 30 layers. Hyperparameters are the same as for 14 except that we use 42K and 48K batch size for 18 and 30 layers respectively. Figure 3 shows that deeper Transformers yield better performance. However, improvements are steepest going from 6 to 12 layers, and further improvements are small.

7.3.1 Comparison with Existing Work

Table 6 lists the results in big setting and compares with current SOTA. Big models are trained with $dp_a = 0.1$ and $dp_r = 0.3$. The 6-layer baseline and the deeper ones are trained with batch size of 48K and 54K respectively. Deep Transformer with our method outperforms its 6-layer counterpart by over 0.4 points on newstest2014 and around 0.1 point on newstest2014∼newstest2018. Our model outperforms the transparent model (Bapna et al., 2018) (+1.58 BLEU), an approach for the deep encoder. Our model performs on par with current SOTA, the dynamic convolution model (DCNN) (Wu et al., 2019). In particular, though DCNN achieves encouraging performance on newstest2014, it falls behind the baseline on other test sets. By contrast, our model obtains more consistent performance improvements.

In work concurrent to ours, Wang et al. (2019) discuss how the placement of layer normalization affects deep Transformers, and compare the original *post-norm* (which we consider our baseline) and a *pre-norm* layout (which we call T2T). Their results also show that pre-norm allows training of deeper Transformers. Our results show that deep post-norm Transformers are also trainable with appropriate initialization, and tend to give slightly better results.

7.4 Results on Other Translation Tasks

We use 12 layers for our model in these tasks. We enlarge the dropout rate to $dp_a = 0.3, dp_r = 0.5$ for IWSLT14 De-En task and train models on WMT14 En-Fr and WMT18 Zh-En with 500K steps. Other models are trained with the same settings as in WMT14 En-De.

We report translation results on other tasks in Table 5. Results show that our model beats the baseline on all tasks with gains of over 1 BLEU,

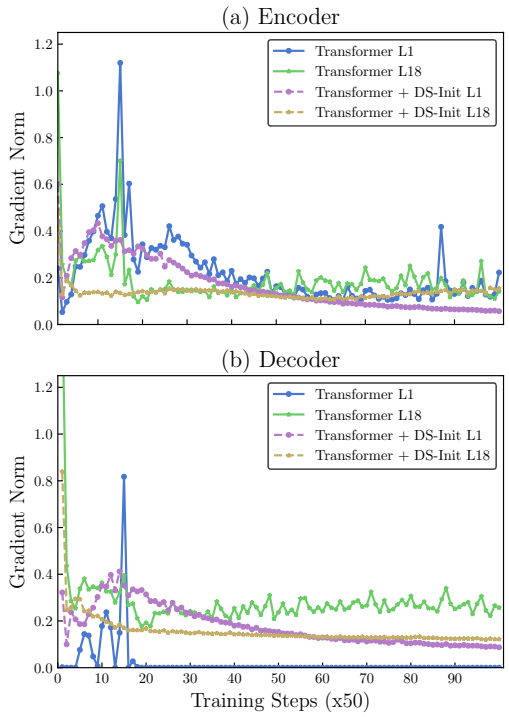

Figure 4: Gradient norm (y-axis) of the first and the last encoder layers (top) and decoder layers (bottom) in 18-layer deep Transformer over the fist 5k training steps. We use around 25k source/target tokens in each training batch. Each point in this plot is averaged over 50 training steps. "*L1*/*L18*" denotes the first/last layer. DS-Init helps stabilize the gradient norm during training.

except the WMT18 En-Fi where our model yields marginal BLEU improvements (+0.3 BLEU). We argue that this is due to the rich morphology of Finnish, and BLEU's inability to measure improvements below the word level. We also provide the chrF score in which our model gains 0.6 points. In addition, speed measures show that though our model consumes 50+% more training time, there is only a small difference with respect to decoding time thanks to MAtt.

7.5 Analysis of Training Dynamics

Our analysis in Figure 1 and Table 1 is based on gradients estimated exactly after parameter initialization without considering training dynamics. Optimizers with adaptive step rules, such as Adam, could have an adverse effect that enables gradient scale correction through the accumulated first and second moments. However, results in Figure 4 show that without DS-Init, the encoder gradients are less stable and the decoder gradients still suffer from the vanishing issue, particularly at the first layer. DS-Init makes the training more stable and robust.[6]

8 Conclusion and Future Work

This paper discusses training of very deep Transformers. We show that the training of deep Transformers suffers from gradient vanishing, which we mitigate with depth-scaled initialization. To improve training and decoding efficiency, we propose a merged attention sublayer that integrates a simplified average-based self-attention sublayer into the encoder-decoder attention sublayer. Experimental results show that deep models trained with these techniques clearly outperform a vanilla Transformer with 6 layers in terms of BLEU, and outperforms other solutions to train deep Transformers (Bapna et al., 2018; Vaswani et al., 2018). Thanks to the more efficient merged attention sublayer, we achieve these quality improvements while matching the decoding speed of the baseline model.

In the future, we would like to extend our model to other sequence-to-sequence tasks, such as summarization and dialogue generation, as well as adapt the idea to other generative architectures (Zhang et al., 2016, 2018). We have trained models with up to 30 layers each for the encoder and decoder, and while training was successful and improved over shallower counterparts, gains are relatively small beyond 12 layers. An open question is whether there are other structural issues that limit the benefits of increasing the depth of the Transformer architecture, or whether the benefit of very deep models is greater for other tasks and dataset.

Acknowledgments

We thank the reviewers for their insightful comments. This project has received funding from the grant H2020-ICT-2018-2-825460 (ELITR) by the European Union. Biao Zhang also acknowledges the support of the Baidu Scholarship. This work has been performed using resources provided by the Cambridge Tier-2 system operated by the University of Cambridge Research Computing Service (http://www.hpc.cam.ac.uk) funded by EPSRC Tier-2 capital grant EP/P020259/1.

[6] We observe this both in the raw gradients and after taking the Adam step rules into account.

A Discriminative Neural Model for Cross-Lingual Word Alignment

{post, vandurme}@cs.jhu.edu

Abstract

We introduce a novel discriminative word alignment model, which we integrate into a Transformer-based machine translation model. In experiments based on a small number of labeled examples (∼1.7K–5K sentences) we evaluate its performance intrinsically on both English-Chinese and English-Arabic alignment, where we achieve major improvements over unsupervised baselines (11–27 F1). We evaluate the model extrinsically on data projection for Chinese NER, showing that our alignments lead to higher performance when used to project NER tags from English to Chinese. Finally, we perform an ablation analysis and an annotation experiment that jointly support the utility and feasibility of future manual alignment elicitation.

1 Introduction

Neural-network-based models for Machine Translation (MT) have set new standards for performance, especially when large amounts of parallel text (bitext) are available. However, explicit word-to-word alignments, which were foundational to pre-neural statistical MT (SMT) (Brown et al., 1993), have largely been lost in neural MT (NMT) models. This is unfortunate: while alignments are not necessary for NMT systems, they have a wealth of applications in downstream tasks, such as transferring input formatting, incorporating lexica, and human-in-the-loop translation. Crucially, they are central to cross-lingual dataset creation via projection (Yarowsky et al., 2001), where token-level annotations in a high-resource language are projected across alignments to a low-resource language; using projection, datasets have been created for a variety of natural language processing tasks, including named-entity recognition (NER), part-of-speech tagging, parsing, information extraction (IE), and semantic role labeling (Yarowsky et al., 2001; Hwa et al., 2005; Riloff et al., 2002; Padó and Lapata, 2009; Xi and Hwa, 2005). This paradigm allows researchers to address a lack of annotated multilingual resources and changing ontologies with minimal annotation effort.

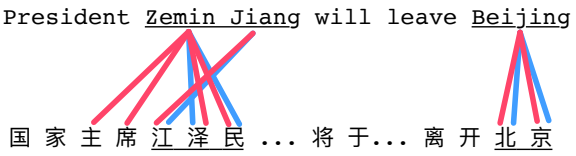

Figure 1: One application of alignments is to project annotations (e.g., Named Entities) across bitexts. Here we see a lack of correspondence between FastAlign (red) alignments and gold alignments (blue).

The introduction of attention (Bahdanau et al., 2014) has allowed NMT to advance past decoding from a single sentence-level vector representation and has been crucial in supporting fluent, meaningful translations, especially of longer sentences. However, despite their intuitive analogy to word alignments, attention-based alignments typically do not correspond very closely to gold-standard human annotations and suffer from systematic errors (Koehn and Knowles, 2017; Ghader and Monz, 2017), falling short of the promise to jointly learn to align and translate. This problem has only been exacerbated by the introduction of deeper models containing multiple attention layers and heads (e.g. Vaswani et al. (2017)). There have been several attempts to mitigate this discrepancy, mostly with a view to improving the quality of output translations (Alkhouli et al., 2016, 2018; Chen et al., 2016; Liu et al., 2016) – though some work has focused specifically on alignment (Legrand et al., 2016; Zenkel et al., 2019). We confirm that the poor performance of encoder-decoder attention for Recurrent Neural Networks (RNNs) found by Koehn and Knowles (2017) and Ghader and Monz (2017) can also be observed in the self-attentional Transformer model (Vaswani et al., 2017), further motivating an

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 910–920, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

approach focusing explicitly on alignment quality.

We introduce a novel alignment module that learns to produce high-quality alignments after training on 1.7K to 4.9K human-annotated alignments for Arabic and Chinese, respectively. While our module is integrated into the state-of-the-art Transformer model (Vaswani et al., 2017), the implementation is architecture-neutral, and can therefore be applied to RNN-based models (Schwenk, 2012; Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014) or fully convolutional models (Gehring et al., 2017). Our experiments on English-Chinese and English-Arabic bitext show that our model yields major improvements of 11 and 27 alignment F1 points (respectively) over baseline models; ablation experiments indicate with only half the data minor improvements can be observed for Chinese, and that the amount of annotated alignment data has a far greater impact on alignment score than the amount of unlabelled bitext used for pre-training.

Furthermore, our NER projection trials demonstrate a major downstream improvement when using our alignments over FastAlign. Taken together, these results motivate the further annotation of small amounts of quality alignment data in a variety of languages. We demonstrate that such annotation can be performed rapidly by untrained L2 (second language) speakers.

2 Related work

Statistical Alignment Generative alignment (Brown et al., 1993) models the posterior over a target sequence $\mathbf{t}$ given a source sequence $\mathbf{s}$ as:

$$p(\mathbf{t}|\mathbf{s}) = \sum_a \prod_i \underbrace{p(t_i|a_i, \mathbf{t}_{<i}, \mathbf{s})}_{\text{lexical model}} \underbrace{p(a_i|\mathbf{a}_{<i}, \mathbf{t}_{<i}, \mathbf{s})}_{\text{alignment model}}$$

Such models are asymmetrical: they are learned in both directions and then heuristically combined.

Discriminative alignment models, on the other hand, directly model $p(\mathbf{a}|\mathbf{s}, \mathbf{t})$, usually by extracting features from the source and target sequences and training a supervised classifier using labelled data. A comprehensive account of methods and features for discriminative alignment can be found in Tomeh (2012).

Neural Machine Translation The attentional encoder-decoder proposed by Bahdanau et al. (2014) greatly improved the initial sequence-to-sequence architecture; rather than conditioning each target word on the final hidden unit of the encoder, each target word prediction is conditioned on a weighted average of all the encoder hidden units. However, the weights in the average do not constitute a soft alignment, as confirmed by Koehn and Knowles (2017) and Ghader and Monz (2017). Our findings align with those of Ghader and Monz (2017), who provide a detailed analysis of where attention and alignment diverge, offering possible explanations for the modest results obtained when attempting to bias attention weights towards alignments. For example, Chen et al. (2016) introduce a loss over the attention weight that penalizes the model when the attention deviates from alignments; this yields only minor BLEU score improvements.[1]

Neural Alignment Models Legrand et al. (2016) develop a neural alignment model that uses a convolutional encoder for the source and target sequences and a negative-sampling-based objective. Tamura et al. (2014) introduce a supervised RNN-based aligner which conditions each alignment decision on the source and target sequences as well as previous alignment decisions. Alkhouli et al. (2018) extend the Transformer architecture for alignment by adding an additional alignment head to the multi-head encoder-decoder attention, biasing the attention weights to correspond with alignments. Similarly, Zenkel et al. (2019) introduce a single-layer attention module (akin to the standard Transformer decoder) which predicts the target word conditioned on the encoder and decoder states, following the intuition that a source word should be aligned to a target word if it is highly predictive of the target word. Unlike our model, all of these models are asymmetrical and are trained without explicit alignment data.

Following the generative formulation of the alignment problem, Alkhouli et al. (2016) present neural lexical translation and alignment models, which they train using silver-standard alignments obtained from GIZA++. A similar training strategy is used in Alkhouli and Ney (2017), who bias an RNN attention module with silver-standard alignments for use as a lexical model. In the same vein, Peter et al. (2017) improve the attention module by allowing it to peek at the next target word.

Note that unlike our framework, none of the models mentioned make use of existing gold-standard labeled data. Following Legrand et al. (2016) and Zenkel et al. (2019) we focus exclusively on alignment quality. A similar approach is taken

[1] This may also be a result of noisy training data, as they use unsupervised alignments as training data for their models.

by Ouyang and McKeown (2019), who introduce a pointer network-based model for monolingual phrase alignment which allows for the alignment of variable-length phrases.

3 Model

NMT systems typically use an encoder-decoder architecture, where one neural network (the encoder) learns to provide another network (the decoder) with a continuous representation of the input sequence of words in the source language, $s_1, \ldots, s_N$, from which the decoder can accurately predict the target sequence $t_1, \ldots, t_M$. The intermediate representations of the encoder and decoder are known as hidden states. After training, the hidden states of the encoder $(S_1, \ldots, S_N)$ and decoder $(T_1, \ldots, T_M)$ contain information about their co-indexed source and target words as well as their respective contexts; this can be thought of as a rough approximation of the semantic content of the source and target words. In an MT model (such as the Transformer-based model used here) the states of the encoder and decoder networks also bear information on cross-lingual correspondence.

From these representations, we can derive a natural formulation of the alignment problem: words of the source language should be aligned to the words in the target language that convey roughly the same meaning in the translated sentence i.e. their contextual vector-based meaning representations are similar.

We use the dot product as an unnormalized measure of distance between each pair of vectors S_i and T_j. In order to apply a distance metric, the two vectors are projected into a shared space via a shared three-layer feed-forward neural network with *tanh* activations and a linear output layer, producing source and target matrices $S'_1, \ldots, S'_N$ and $T'_1, \ldots, T'_M$.[2] This is given by:

$$S'_i = W_3(tanh(W_2(tanh(W_1 S_i))))$$
$$T'_j = W_3(tanh(W_2(tanh(W_1 T_j))))$$

Taking the matrix product of the projected source and target sequences along their shared dimension yields a matrix A of $N \times M$ semantic "links", where each element A_{ij} is an un-normalized distance between vectors S'_i and T'_j, i.e. $A = [S'_1, \ldots, S'_N] \cdot [T'_1, \ldots, T'_M]^T$

These distances will be passed through a sigmoid function, normalizing them to probabilities $p(a_{ij}|\mathbf{s}, \mathbf{t})$. However, alignments are context-sensitive: the decision to align source word i to target word j may affect the probability of aligning the neighbors of i and j. Therefore, before applying the sigmoid function to the matrix A we convolve it with a shared weight matrix, yielding a matrix A', which encodes the relationships between alignments; this is given by $A' = W_{conv} * A$, where $*$ is the convolution operator. This can be thought of as a way of conditioning each alignment decision on its neighbors, modeling $p(a_{i,j}|\mathbf{s}, \mathbf{t}, a_{i' \neq i, j' \neq j})$. This step is crucial—without a 3×3 convolution, F1 results hover below 50.

Finally, we apply the sigmoid function to A' and treat each alignment decision as a separate binary classification problem, using binary cross entropy loss:

$$\sum_{i<N, j<M} \Big(\hat{a}_{ij} \log \big(p(a_{ij}|\mathbf{s}, \mathbf{t})\big) + \big(1 - \hat{a}_{ij}\big) \log \big(1 - p(a_{ij}|\mathbf{s}, \mathbf{t})\big) \Big)$$

where $\hat{a}_{ij} = 1$ if source word i is aligned to target word j in the gold-standard data, and 0 otherwise. Note that the convolution step ensures these are not independent alignment decisions.

When training our model, we begin by pre-training an MT model on unlabelled bitext; the weights of this model are used to initialize the encoder and decoder in the alignment model. To obtain an alignment at test time, the source and target word sequences are encoded and presented to the aligner.

4 Alignment Experiments

4.1 Baselines

We compare against two baselines: alignments obtained from FastAlign (Dyer et al., 2013), and attention-based alignments. FastAlign is a fast log-linear reparameterization of IBM Model 2 (Brown et al., 1993).

Unlike in the RNN case, where a single attention layer intervenes between the encoder and decoder, Transformers make use of multi-head and multi-layer attention. Our attentional alignments are obtained by averaging across all heads of the final multi-head encoder-decoder attention layer.

Both of these methods allow for fast online decoding, making them comparable to our model, and both have been used for word alignment; moreover, FastAlign is a standard choice for projection (Arthur et al., 2016; Fu et al., 2014; Eger et al., 2018; Agić et al., 2016; Sharoff, 2018).

[2] We use 512 hidden units in each layer.

Our model extends the Sockeye implementation of the Transformer model (Hieber et al., 2017).[3]

Following Dyer et al. (2013), FastAlign hyperparameters were tuned by training on 10K training examples, evaluating on a 100-sentence subset of the validation split. The *grow-diag-final-and* heuristic was used for symmetrization. Thresholds for both attention alignment and our model were tuned on the same 100-sentence validation subset.

4.2 Data

Chinese character-tokenized bitext and alignments were sourced from the GALE Chinese-English Parallel Aligned Treebank (Li et al., 2015); Arabic data was obtained from the GALE Arabic-English Parallel Aligned Treebank (Li et al., 2013). Both GALE datasets are based on broadcast news corpora; gold-standard alignments were produced by multiple trained human annotators, with several checks for quality including redundant annotation, review by senior annotators, and automatic heuristics. The GALE corpora satisfy the following criteria:

1. *Quality*: although some problems were detected in the GALE alignments (e.g. mismatched bitext, formatting errors, etc.), the multiple levels of quality control suggest a high level of overall quality.
2. *Size*: while other gold-standard alignment corpora exist (Europarl, etc.) these are typically on the order of ∼500 sentences; conversely, GALE is large enough to be used as a training set in a neural setting.
3. *Annotations*: GALE is annotated with a variety of labels, and a subset of the Chinese portion of GALE was annotated for NER as part of the OntoNotes corpus (Weischedel et al., 2013).

Sentences were split into train, test, and validation portions and cleaned by removing extraneous annotations (e.g. timestamp tags, etc.). Corpus statistics are given in Table 1.

The discriminative models (referred to as DiscAlign) were initialized with weights from an MT model pre-trained on 4 million sentences, which were tokenized using the Moses tokenizer (Koehn et al., 2007). Chinese data was drawn from the WMT 2017 En-Zh bitext, while the Arabic data was sourced from local resources; both Chinese and Arabic models were trained with a 60K-word vocabulary. For FastAlign, the GALE train split was concatenated to the pretraining bitext, while for both the discriminative and attentional models the GALE data was used to finetune a model pre-trained on bitext alone.

Language	train	dev	test
AR	1687	299	315
ZH	4871	596	636

Table 1: Num. annotated alignment sentence pairs.

Contemporary MT systems use subword units to tackle the problem of out-of-vocabulary low-frequency words. This is often implemented by byte-pair encoding (BPE) (Sennrich et al., 2016). We applied a BPE model with 30K merge operations to all of our data for the BPE experimental condition. Training alignments were expanded by aligning all subwords of a given source word to all the subwords of the target word to which the source word aligns. At test time, following Zenkel et al. (2019), to reduce BPE alignments to regular alignments, we considered a source and target word to be aligned if *any* of their subwords were aligned.[4] This heuristic was used to evaluate all BPE models.

With the task of projection for NER data in mind (Yarowsky et al., 2001), we evaluate all models on Chinese NER spans. These spans were obtained from the OntoNotes corpus, which subsumes the GALE Chinese corpus. Due to formatting differences, only a subset of the GALE sentences (287 validation, 189 test) were recoverable from OntoNotes.

We evaluate our models using macro-F1 score, as Fraser and Marcu (2007) showed that alignment error rate does not match human judgments. F1 scores were obtained using the macro-F1 scorer provided by FastAlign.

4.3 Results

Our model outperforms both baselines for all languages and experimental conditions. Table 2 shows that our model performs especially well in the NER setting, where we observe the largest improve-

[3] We pre-train a 6-layer model with the Adam optimizer (Kingma and Ba, 2014) using a learning rate of 0.0002, 8-headed multi-head attention, 2048-dimensional feed-forward layers, and 512-dimensional encoder/decoder output layers. We include weight-tying (Press and Wolf, 2017) between the source and target embedding layers. All other MT hyperparameters were set to the Sockeye defaults.

[4] Note that this step is necessary in order to make the produced and reference alignments comparable; to evaluate alignments, the sequences must be identical, or the evaluation is ill-posed.

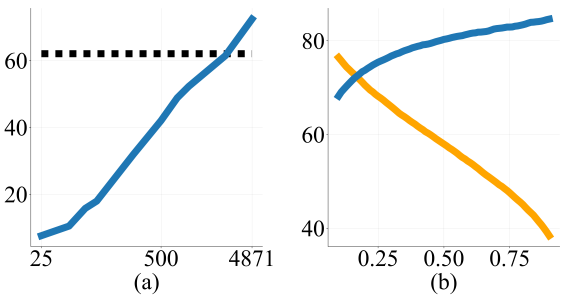

Figure 2: (a) Dev. F1 as function of training corpus size (log scale), contrast against FastAlign F1 (dashed). (b) Dev. precision (blue) and recall (orange) at different thresholds.

Method	P	R	F1

DiscAlign (BPE)	87.05	76.98	**81.71**

Table 3: Precision, Recall, and F1 on Arabic GALE test data.

ment over FastAlign ($\Delta = 14$). By increasing the threshold α above which $p(a_{i,j}|\mathbf{s}, \mathbf{t})$ is considered an alignment we can obtain high-precision alignments, exceeding FastAlign's precision and recall. The best threshold values on the development set were $\alpha = 0.13$ and $\alpha = 0.14$ for average attention on data with and without BPE (respectively) and $\alpha = 0.15$ for the discriminative settings ($\alpha = 0.5$ was used for the high-precision "+prec" setting).

Table 3 further underscores these findings; we observe an even more dramatic increase in performance on Arabic, despite the fact that the model is trained on only 1.7K labelled examples. Furthermore, we see that average attention performs abysmally in Arabic. The best thresholds for Arabic differed substantially from those for Chinese: for average attention (with and without BPE) the values were $\alpha = 0.05$ and $\alpha = 0.1$, while for the discriminative aligner they were $\alpha = 0.94$ and $\alpha = 0.99$ (compared to 0.15 for Chinese). This is reflected in the high precision of the discriminative aligner.

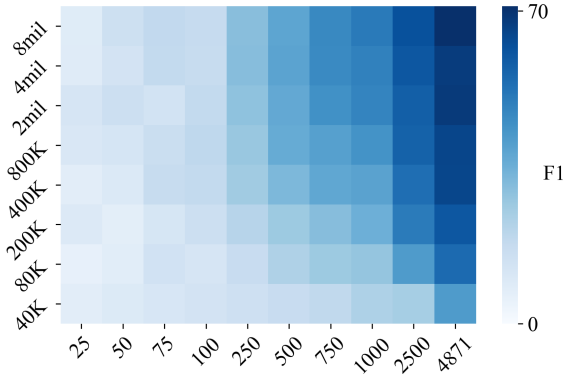

Figure 3: Chinese F1 performance with respect to the amount of unlabelled pretraining bitext (y axis) and the number of sentences annotated for alignment (x axis); increasing the number of annotated sentences has a far greater impact on the F1 score than increasing the amount of bitext.

Figure 2(a) shows the relationship between the number of training examples and validation F1 performance for Chinese, with the performance of FastAlign overlaid as a benchmark. We observe that with a little over half the training examples (2500), we perform comparably to FastAlign.

In Figure 3, we demonstrate that labelled alignment data has a greater impact than the amount of pre-training bitext. For example, halving the number of pre-training examples from 8 million to 4 million only reduces F1 by 3.69, but halving the number of labelled finetuning examples while keeping the number of pre-training sentences constant at 8 million lowers the performance by 9.44 F1.

Analysis Taken together, Table 2 and Figure 2 support the use of discriminative alignment models in settings where test data is presented in an online fashion as well as in cases where high-quality alignments matter. Most importantly, the results in the NER condition highlight the applicability of our model to dataset projection for NER.

Figure 2(b) also shows that by varying the minimum threshold α on $p(a_{ij}|\mathbf{s}, \mathbf{t})$, we can manipulate the precision-recall tradeoff, giving our model an advantage in scenarios where high precision alignments are required (e.g., dataset projection) as well as in ones where high recall is preferred (e.g., correction by human annotators).

Our results underscore the poor performance of attentional alignments. One factor driving the low F1 scores observed may be the Transformer's design: each attention head in the Transformer's multi-head attention layer learns to attend to different aspects of the encoder states; thus, averaging across all heads is likely to yield even noisier results than the RNN model, where there is effectively only one attention head. Another reason attention performs poorly may be that attention heads are learning task- and dataset- specific patterns that do not match alignments but nevertheless provide useful cues for translation. This would support the observations of Ghader and Monz (2017), who find that for certain parts of speech (e.g. verbs) alignment is very poorly correlated with translation loss.

These findings illustrate the benefit of supervised training for alignment, suggesting further annotation of gold-standard alignments is warranted, with an emphasis on alignment quality.[5] In particular, Figure 3 indicates that labelled alignment data is far more valuable than bitext, meaning that efforts should be focused on annotating existing bitext for alignment; FastAlign's performance (when trained on the entire 4 million-sentence training bitext and the alignment bitext) can be surpassed after pre-training the translation model on only 400K sentences of unlabelled bitext and the full alignment set (4871 sentences).

5 NER Experiments

In Table 2 we evaluated the quality of our model's alignments intrinsically, showing that they dramatically outperform the baseline models, especially for NER spans. To show that these improvements translate to downstream performance, we conduct projection experiments for NER using the Chinese and English data from the OntoNotes 5.0 corpus.

Projection Dataset projection, as defined by Yarowsky et al. (2001), is a method of obtaining data in a low resource language by leveraging existing bitext and high-resource annotations. As shown (for a single sentence) in Figure 1, a set of sentences in a high-resource language for which there exist task-specific token-level annotations (e.g. an English NER dataset) is translated into the target language. Using alignments, the annotations are "projected" from the source text to the target; each target token receives the label of the source token it is aligned to (or a default label if the token is unaligned). This produces an annotated resource in the target language which can be used to train or pre-train a model.

Data We project the English OntoNotes NER training data (53K sentences) by first translating it to Chinese using our BPE translation model, and then aligning the source and target sequences using FastAlign and our best discriminative model. We create two datasets, one where the tags have been projected using FastAlign alignments and another using the higher-quality DiscAlign alignments. OntoNotes contains gold-labelled NER data for 18 tag types in both Chinese and English. The official splits[6] were used. Because there are fewer training examples for Chinese than English, two NER models were trained, one with the same number of projected sentences as there were gold Chinese sentences (36K), and the second using the full English dataset (53K sentences) projected to Chinese. The data was pre-processed in following the same procedure as §4

NER Model Given the recent successes of contextual encoders for sequence modeling, especially for NER, we make use of a pre-trained BERT model (Devlin et al., 2018), where the NER label is determined by the softmax output of a linear layer situated on top of the encoder.[7] Each model was trained for 4 to 8 epochs.

We explore the performance of the BERT NER model when trained on both gold-standard and projected datasets. In addition, we analyze its performance when trained on decreasing amounts of gold data, and contrast those results with the performance of a model pre-trained on projected data and fine-tuned with gold data.

[5] In addition to the preprocessing steps required to clean the data, a bilingual speaker pointed out several systematic deviations from the alignment protocol by GALE annotators.

5.1 Results & Analysis

Table 4 shows that while NER systems trained on projected data do categorically worse than an NER system trained on gold-standard data, the higher-quality alignments obtained from DiscAlign lead to a major improvement in F1 when compared to FastAlign.

For many tasks, an English resource (i.e. the English portion of the OntoNotes data) exists along with bitext between English and a given target language, but very few resources are available in the target language. Table 5 shows that projection outperforms a system trained on gold data when there is very little gold data available (500 sentences); as the amount of data increases, these gains disappear. However, Table 6 indicates that projected data provides a useful pre-training objective for NER, making low-data NER models perform about as well as if they had been trained on twice as much gold data.

Figure 4 shows that for nearly all classes, especially rare ones, pre-training on projected data improves downstream results when there is little annotated data. This is partly due to the fact some classes (e.g. LANGUAGE, ORDINAL, etc.) may appear very rarely in the 500-sentence training set ($\leq$ 21 times). Note that all classes appear at least 5 times in the training data. However, these classes are far more common in the much larger projected dataset. In addition, the major gains seen in tags with higher support in the gold data (e.g. MONEY, LOCATION) suggest that pre-training the NER model on projected data does more than merely expose the model to unseen classes.

6 Human Evaluation

In §4 we established that our discriminatively-trained neural aligner outperforms unsupervised baselines, especially on NER spans; in §5 we verified that the alignments it produces can be productively applied a downstream IE task (NER) via dataset projection.

However, unlike these unsupervised baselines, our aligner requires labelled data on the order of thousands of sentences, and thus cannot be applied to language pairs for which no labelled alignment data exists (most languages). We contend that using a web-based crowdsourcing interface [8], alignment annotation can be performed rapidly by annotators with minimal experience; to justify this claim, we conduct a small timed experiment using untrained human annotators. Six L2 Chinese speakers (L1 English) were asked to annotate English-Chinese bitext for alignment. These sentences were taken from the GALE development portion of the OntoNotes dataset. Note that these annotators had no experience in annotating data for alignment, and had approximately equivalent amounts of Chinese instruction. Annotators were introduced to the task and the alignment interface, and then given 50 minutes to align the sentences as accurately as possible. They were divided into two groups, with each group annotating a different partition of sentences.

6.1 Results & Analysis

Table 7 shows that alignment can be performed rapidly, at 4.4 sentences per minute. The annotators achieve high overall precision for alignment, but fall short on recall. When only alignments of

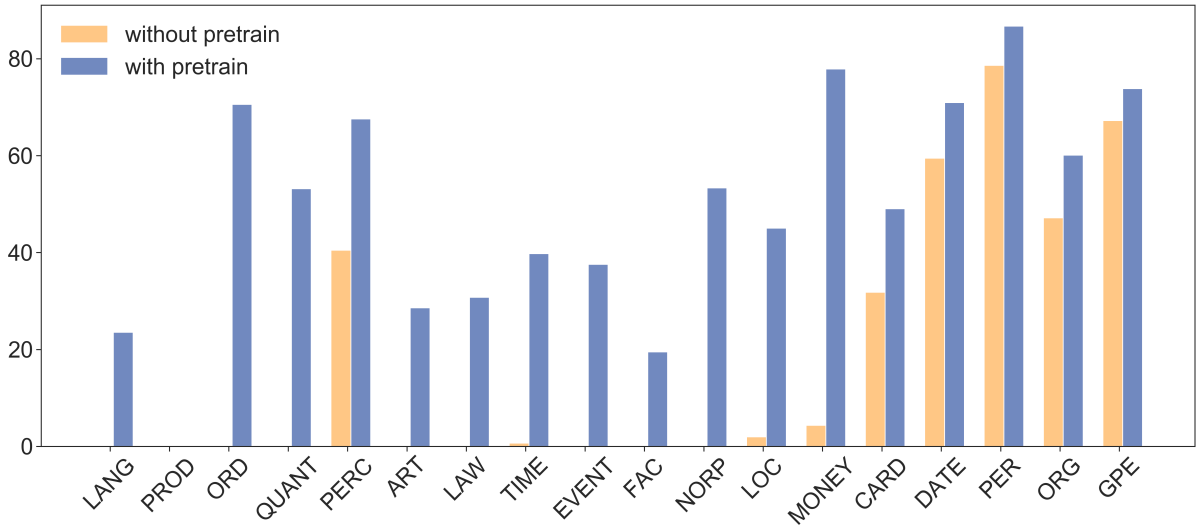

Figure 4: Comparing F1 across different tag types when a model is trained on 500 gold NER sentences to when it is pre-trained on projected data and then finetuned on 500 gold sentences, ranked by number of train examples.

Model	sents/m	P	R	F1
Human	4.4	90.09	62.85	73.92
DiscAlign	-	74.54	72.15	73.31
Hu. (NER)	-	87.73	71.02	78.24
DA (NER)	-	77.37	67.69	71.94

Table 7: Sentences per minute and average scores against gold-labelled data for sentences annotated for alignment by human annotators (Hu.), compared to DiscAlign (DA) on the same sentences.

NER spans are considered, their F1 score improves considerably. Additionally, human annotators outperform DiscAlign when evaluated on the same sentences.

These are promising results, as they indicate that entirely untrained L2 annotators can rapidly annotate data. Their relatively low recall scores might be due to their lack of training, and given more extensive training and guidelines we would expect them to improve.

7 Conclusion & Future Work

We described a model extension to NMT which supports discriminative alignment, where fewer than 5K Chinese and 1.7K Arabic labelled sentences lead to better F1 scores in all tested scenarios than standardly employed mechanisms. By evaluating the model on both Arabic and Chinese we demonstrated that our model's improvements generalize across typologically divergent languages. We showed that in Chinese our model's performance is particularly strong for NER spans.

We projected a dataset for NER from English to Chinese using our alignments, verifying that our model's higher alignment quality led to downstream improvements; our aligner's intrinsic improvements result in major gains over FastAlign in a downstream NER evaluation. Comparing the performance of our projected dataset with a gold-standard dataset, we showed that a large projected dataset can outperform a small labelled one, and that projection can be leveraged as a method of data augmentation for low-resource settings.

Finally, we showed that untrained L2 annotators can rapidly annotate bitext for alignment, and yield promising results for both full alignment and NER-specific annotation, confirming that we can collect additional data in a variety of languages.

Based on our findings that:

- discriminative alignments outperform common unsupervised baselines in two typologically divergent languages
- this performance boost leads to major downstream improvements on NER
- only a small amount of labelled data is needed to realize these improvements
- and that these labelled examples can be obtained from L2 speakers with minimal training

we conclude with a call for additional annotation efforts in a wider variety of languages. While multilingual datasets directly annotated for a given task typically lead to the highest-performing systems (see Table 4) these datasets are task-specific and not robust to ontology changes. In contrast, the framework of projection via discriminatively-trained alignments which we present is task-agnostic (any

token-level annotations can be projected) and requires only one source-side dataset to be annotated.

Future work will explore different sets of languages paired with new, higher-quality elicited alignments of existing bitext. We will also explore architecture modifications to allow for task-specific annotation, training, and inference for a given IE task, where only certain spans are of interest (i.e. training our aligner only on NER-span alignments). We expect that asking annotators to only align Named Entities (or some other token type) will greatly increase the annotation speed. These experiments will extend beyond NER to other token-level tasks such as coreference resolution and event detection.

Abstract

Zero pronouns (ZPs) are frequently omitted in pro-drop languages, but should be recalled in non-pro-drop languages. This discourse phenomenon poses a significant challenge for machine translation (MT) when translating texts from pro-drop to non-pro-drop languages. In this paper, we propose a unified and discourse-aware ZP translation approach for neural MT models. Specifically, we jointly learn to predict and translate ZPs in an end-to-end manner, allowing both components to interact with each other. In addition, we employ hierarchical neural networks to exploit discourse-level context, which is beneficial for ZP prediction and thus translation. Experimental results on both Chinese⇒English and Japanese⇒English data show that our approach significantly and accumulatively improves both translation performance and ZP prediction accuracy over not only baseline but also previous works using external ZP prediction models. Extensive analyses confirm that the performance improvement comes from the alleviation of different kinds of errors especially caused by subjective ZPs.

1 Introduction

Zero anaphora is a discourse phenomenon, where pronouns can be omitted when they are pragmatically or grammatically inferable from intra- and inter-sentential context (Li and Thomson, 1979). However, translating such implicit information (i.e. zero pronoun, ZP) poses various difficulties for machine translation (MT) in terms of completeness and correctness. Although neural models are getting better at learning representations, it is still difficult to implicitly learn complex ZPs in a general model. Actually, ZP prediction and translation need to not only understand the semantics or intentions of a single sentence, but also utilize its discourse-level context.

Two technological advances in the field of ZP and MT, have seen vast progress over the last decades, but they have been developed very much in isolation. Early studies (Chung and Gildea, 2010; Le Nagard and Koehn, 2010; Xiang et al., 2013) fed MT systems with the results of ZP prediction models, which are trained on a small-scale and non-homologous data compared to MT models. To narrow the data-level gap, Wang et al. (2016) proposed an automatic method to annotate ZPs by utilizing the parallel corpus of MT. The homologous data for both ZP prediction and translation leads to significant improvements on translation performances for both statistical MT (Wang et al., 2016) and neural MT models (Wang et al., 2018a). However, such approaches still require external ZP prediction models, which have a low accuracy of 66%. The numerous errors of ZP prediction errors will be propagated to translation models, which leads to new translation problems. In addition, relying on external ZP prediction models in decoding makes these approaches unwieldy in practice, due to introducing more computation cost and pipeline complexity.

In this work, we try to further bridge the model-level gap by jointly modeling ZP prediction and translation. Joint learning has proven highly effective on alleviating the error propagation problem, such as joint parsing and translation (Liu and Liu, 2010), as well as joint tokenization and translation (Xiao et al., 2010). Similarly, we expect that ZP prediction and translation could interact with each other: prediction offers more ZP information beyond 1-best result to translation and translation helps prediction resolve ambiguity. Specifically, we first cast ZP prediction as a sequence labeling task with a neural model, which is trained jointly with a standard neural machine translation (NMT) model in an end-to-end manner. We leverage the auto-annotated ZPs to supervise the learning of ZP

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 921–930, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

prediction component, which releases the reliance on external ZP knowledge in decoding phase.

In addition, previous studies revealed that discourse-level information can better tackle ZP resolution, because around 23% of ZPs appear two or more sentences away from their antecedents (Zhao and Ng, 2007; Chen and Ng, 2013). Inspired by these findings, we exploit inter-sentential context to further improve ZP prediction and thus translation. Concretely, we employ hierarchical neural networks (Sordoni et al., 2015; Wang et al., 2017) to summarize the context of previous sentences in a text, which is integrated to the joint model for ZP prediction.

We validate the proposed approach on the widely-used data for ZP translation (Wang et al., 2018a), which consist of 2.15M Chinese–English sentence pairs. Experimental results show that the joint model indeed improves performances on both ZP prediction and translation. Incorporating discourse-level context further improves performances, and outperforms ther external ZP prediction model (Wang et al., 2018a) by +2.29 BLEU points in translation and +11% in prediction accuracy. Experimental results on a further Japanese–English translation task show that our model consistently outperforms both the baseline and the external ZP prediction model, demonstrating the universality of the proposed approach.

The key contributions of this paper are:

1. We propose a single model to jointly learn ZP prediction and translation, which improves performances on both tasks by allowing the two components to interact with each other.

2. Our study demonstrates the effectiveness of discourse-level context for ZP prediction.

3. Based on our manually-annotated testset, we conduct extensive analyses to assess ZP prediction and translation.

2 Background

2.1 Zero Pronoun

In pro-drop languages such as Chinese and Japanese, ZPs occur much more frequently compared to non-pro-drop languages such as English (Zhao and Ng, 2007). As seen in Table 1, the subject pronoun ("我") and the object pronoun ("它") are omitted in Chinese sentences ("Inp.") while these pronouns are all compulsory in their English translations ("Ref."). This is not a problem for human beings since we can easily recall these missing pronoun from the context. Taking the second sentence for example, the pronoun "它" is an anaphoric ZP that refers to the antecedent ("蛋糕") in previous sentence, while the non-anaphoric pronoun "我" can still be inferred from the whole sentence. The first example also indicates the necessity of intra-sentential information for ZP prediction.

Inp.	等 我 搬进来，**(我)** 能 买 台 电视 吗?
Ref.	Can **I** get a TV when I move in?
Out.	When I move in **to buy** a TV.
Inp.	这块 蛋糕 很 美味！ 你 烤 的 **(它)** 吗?
Ref.	The cake is very tasty! Did you bake **it**?
Out.	The cake is delicious! **Are you baked**?

Table 1: Examples of ZPs and translations where words in brackets are ZPs that are invisible in decoding and underlined words are antecedents of anaphoric ZPs. This leads to problems for NMT in respect of completeness (first case) and correctness (second case). "Inp." and "Ref." indicate Chinese input and English translation, respectively. "Out." represents the output of a NMT model.

However, ZP poses a significant challenge for translation models from pro-drop to non-pro-drop languages, where ZPs are normally omitted in the source side but should be generated overly in the target side. As shown in Table 1, even a strong NMT model fails to recall the implicit information, which lead to problems like *incompleteness* and *incorrectness*. The first case is translated into "When I move in to buy a TV", which makes the output miss subject element (incompleteness). The second case is translated into "Are you baked?", while the correct translation should be "Did you bake it?" (incorrectness).

2.2 Bridging Data Gap Between ZP Prediction and Translation

Recent efforts have explored ways to bridge the gap of ZP prediction and translation (Wang et al., 2016, 2018a,b) by training both models on the homologous data. The pipeline involves two phases, as described below.

Translation-Oriented ZP Prediction Its goal is to recall the ZPs in the source sentence (i.e. pro-drop language) with the information of the target sentence (i.e. non-pro-drop language) in a paral-

lel corpus. Taking the second case (assuming that Inp. and Ref. are sentence pair in a parallel corpus) in Table 1 for instance, the ZP "它 (*it*)" is dropped in the Chinese side while its equivalent "it" exists in the English side. It is possible to identify the ZP position (between "的" and "吗") by alignment information, and then recover the ZP word "它" by a language model (scoring all possible pronoun candidates and select the one with the lowest perplexity). Wang et al. (2016) proposed a novel approach to automatically annotate ZPs using alignment information from bilingual data, and the auto-annotation accuracy can achieve above 90%. Thus, a large amount of ZP-annotated sentences were available to train an external ZP prediction model, which was further used to annotate source sentences in test sets during the decoding phase. They integrated the ZP predictor into SMT and showed promising results on both Chinese–English and Japanese–English data.

However, their neural-based ZP prediction model still produce low accuracies on predicting ZPs, which is 66% in F1 score. This is a key problem for the pipeline framework, since numerous errors would be propagated to the subsequent translation process.

Translation with ZP-Annotated Data An intuitive way to exploit the annotated data is to train a standard NMT model on the annotated parallel corpus, which decodes the input sentence annotated by the external ZP prediction model. Wang et al. (2018a) leveraged the encoder-decoder-reconstructor framework (Tu et al., 2017) for this task, which reconstructs the intermediate representations of NMT model back to the ZP-annotated input. The auxiliary loss on ZP reconstruction can guide the intermediate representations to learn critical information relevant to ZPs. However, their best model still needs external ZP prediction at decoding time. In response to this problem, Wang et al. (2018b) leveraged the prediction results of the ZP positions, which have relatively higher accuracy (e.g. 88%). Accordingly, they jointly learn the partial ZP prediction (*i.e.*, predict the ZP word given the externally annotated ZP position) and ZP translation.

In this work, we follow this direction with the encoder-decoder-reconstructor framework, and show our approach outperforms both strategies of using externally annotated data.

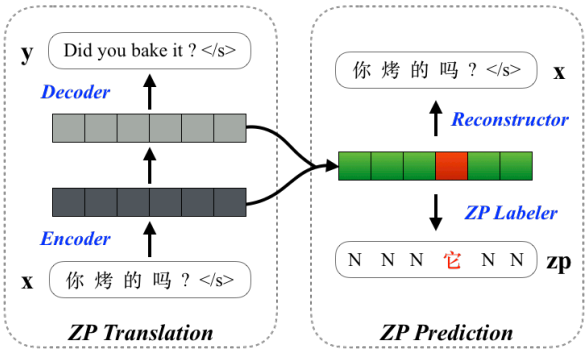

Figure 1: Architecture of the joint ZP prediction and translation model, in which ZP prediction is casted as a sequence labelling problem.

3 Approach

In this study, we propose a joint model to learn ZP prediction and translation, which can be further improved by leveraging discourse-level context.

- *Joint ZP Prediction and Translation* (Section 3.1) We cast ZP prediction as a sequence labeling problem, which can be trained together with ZP translation model in an end-to-end manner. This releases the reliance on external ZP prediction models (e.g. 66% or 88% accuracy), since no ZP-annotated sentence is required any more in decoding. Instead, only the high-quality annotated bilingual data (e.g. 93% accuracy) are needed.

- *Discourse-Aware ZP Prediction* (Section 3.2) We further improve ZP prediction and thus its translation with discourse-level context, which is summarized by hierarchical neural networks. The contextual representation is integrated into the reconstructor, based on which ZP prediction is conducted.

3.1 Joint ZP Prediction and Translation

Figure 1 illustrates the architecture of the joint model, which consists of two main components. The ZP translation component is a standard encoder-decoder NMT model, while an additional reconstructor is introduced for ZP prediction. To guarantee the reconstructor states contain enough information for ZP prediction, the reconstructor reads both the encoder and decoder states and the reconstruction score is computed by

$$R(\hat{\mathbf{x}}|\mathbf{h}^{enc}, \mathbf{h}^{dec}) = \prod_{t=1}^{T} g_r(\hat{x}_{t-1}, \mathbf{h}_t^{rec}, \hat{\mathbf{c}}_t^{enc}, \hat{\mathbf{c}}_t^{dec})$$

where $\mathbf{h}_t^{rec}$ is the hidden state in the reconstructor:

$$\mathbf{h}_t^{rec} = f_r(\hat{x}_{t-1}, \mathbf{h}_{t-1}^{rec}, \hat{\mathbf{c}}_t^{enc}, \hat{\mathbf{c}}_t^{dec}) \quad (1)$$

Here $g_r(\cdot)$ and $f_r(\cdot)$ are respective softmax and activation functions for the reconstructor. The context vectors $\hat{\mathbf{c}}_t^{enc}$ and $\hat{\mathbf{c}}_t^{dec}$ are the weighted sum of $\mathbf{h}^{enc}$ and $\mathbf{h}^{dec}$, and the weights are calculated by two interactive attention models:

$$\hat{\alpha}^{enc} = \text{ATT}_{enc}(x_{t-1}, \mathbf{h}_{t-1}^{rec}, \mathbf{h}^{enc}) \quad (2)$$
$$\hat{\alpha}^{dec} = \text{ATT}_{dec}(x_{t-1}, \mathbf{h}_{t-1}^{rec}, \mathbf{h}^{dec}, \hat{\mathbf{c}}_t^{enc}) \quad (3)$$

The interaction between two attention models leads to a better exploitation of the encoder and decoder representations (Wang et al., 2018b).

ZP Prediction as Sequence Labelling We cast ZP prediction as a sequence labelling task, where each word is labelled if there is a pronoun missing before it. Given the input $\mathbf{x} = \{x_1, x_2, \ldots, x_T\}$ with the last word x_T being the end-of-sentence tag " ⟨eos⟩",[1] the output to be labelled is a sequence of labels $\mathbf{zp} = \{zp_1, zp_2, \ldots, zp_T\}$ with $zp_t \in \{N\} \cup \mathbb{V}_{zp}$. Among the label set, "$N$" denotes no ZP, and $\mathbb{V}_{zp}$ is the vocabulary of pronouns.[2] Taking Figure 1 as an example, the label sequence "N N N 它 N N" indicates that the pronoun "它" is missing before the fourth word "吗" in the source sentence "你 烤 的 吗？ ". More specifically, we model the probability of generating the label sequence $\mathbf{zp}$ as:

$$P(\mathbf{zp}|\mathbf{h}^{rec}) = \prod_{t=1}^{T} P(zp_t|\mathbf{h}_t^{rec}) = \prod_{t=1}^{T} g_l(zp_t, \mathbf{h}_t^{rec}) \quad (4)$$

where $g_l(\cdot)$ is softmax for the ZP labeler. As seen, we integrate the ZP generation component into the ZP translation model. There is no reliance on external ZP prediction models in decoding phase.

Training and Testing The newly introduced prediction component is trained together with the encoder-decoder-reconstructor:

$$J(\theta, \gamma, \psi) = \arg\max_{\theta,\gamma,\psi} \Big\{ \underbrace{\log L(\mathbf{y}|\mathbf{x};\theta)}_{\textit{likelihood}} + \underbrace{\log R(\mathbf{x}|\mathbf{h}^{enc}, \mathbf{h}^{dec};\theta)}_{\textit{reconstruction}} + \underbrace{\log P(\mathbf{zp}|\mathbf{h}^{rec};\theta,\gamma)}_{\textit{ZP labeling}} \Big\} \quad (5)$$

where $\{\theta, \gamma\}$ are respectively the parameters associated with the encoder-decoder-reconstructor and the ZP prediction component. The auxiliary prediction loss $P(\cdot)$ guides the hidden states of both the encoder-decoder and the reconstructor to embed the ZPs in the source sentence. Although the calculation of labeling loss relies on explicitly annotated labels, it is only used in training to guide the parameters to learn ZP-enhanced representations. Benefiting from the implicit integration of ZP information, we release the reliance on external ZP prediction model in testing.

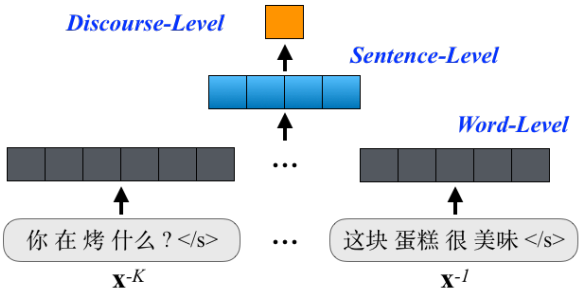

Figure 2: Architecture of hierarchical neural encoder. $\mathbf{x}^{-K}, \ldots, \mathbf{x}^{-1}$ are K previous sentences before the current source sentence "你 烤 的 吗 ?" in a text.

3.2 Discourse-Aware ZP Prediction

Discourse information have proven useful for predicting antecedents, which may occur in previous sentences (Zhao and Ng, 2007; Chen and Ng, 2013). Therefore, we further improve ZP prediction with discourse-level context, which is learned together with the joint model.

Encoding Discourse-Level Context Hierarchical structure networks are usually used for modelling discourse context on various natural language processing tasks such query suggestion (Sordoni et al., 2015), dialogue modeling (Serban et al., 2016) and MT (Wang et al., 2017). Therefore, we employ hierarchical encoder (Wang et al., 2017) to encoder discourse-

[1] We introduce " ⟨eos⟩" to cover the case that a pronoun is missing at the end of a sentence.

[2] We employ the pronoun vocabulary used in Wang et al. (2016), which contains 30 distinct Chinese pronouns.

level context for NMT. More specifically, we use the previous K source sentences $\mathbf{X} = \{\mathbf{x}^{-K}, \ldots, \mathbf{x}^{-1}\}$ as the discourse information, which is summarized with a two-layer hierarchical encoder, as shown in Figure 2. For each sentence $\mathbf{x}^{-k}$, we employ a *word-level encoder* to summarize the representation of the whole sentence:

$$\mathbf{h}^{-k} = \text{ENCODER}_{word}(\mathbf{x}^{-k}) \quad (6)$$

After we can obtain all sentence-level representations $\mathbf{H}^X = \{\mathbf{h}^{-K}, \ldots, \mathbf{h}^{-1}\}$, we feed them into a *sentence-level encoder* to produce a vector that represents the discourse-level context:

$$\mathbf{C} = \text{ENCODER}_{sentence}(\mathbf{H}^X) \quad (7)$$

Here the summary C consists of not only the dependencies between words, but also the relations between sentences. Following Voita et al. (2018), we share the parameters of word-level encoder ENCODER_{word} with the encoder component in standard NMT model. Note that, ENCODER_{word} and $\text{ENCODER}_{sentence}$ can be implemented as arbitrary networks, such as recurrent networks (Cho et al., 2014), convolutional networks (Gehring et al., 2017), or self-attention networks (Vaswani et al., 2017). In this study, we used recurrent networks to implement our ENCODER.

Integrating Discourse into ZP Prediction We directly feed the discourse-level context to the reconstructor to improve ZP prediction. Specifically, we combine the context vector and the reconstructor state:

$$\widehat{\mathbf{h}}_t^{rec} = f_c(\mathbf{h}_t^{rec}, \mathbf{C}) \quad (8)$$

Here $f_c(\cdot)$ is a function for combining reconstructor states and the context vector, which is a simple concatenation (CONCAT) in this work. The revised reconstructor state $\widehat{\mathbf{h}}_t^{rec}$ is then used in Equations (1) and (4).

4 Experiments

4.1 Setup

We conducted translation experiments on both Chinese⇒English and Japanese⇒English translation tasks, since Chinese and Japanese are pro-drop languages while English is not. For Chinese⇒English translation task, we used the data of auto-annotated ZPs (Wang et al., 2018a).[3] The training, validation, and test sets contain 2.15M, 1.09K, and 1.15K sentence pairs, respectively. In the training data, there are 27% of Chinese pronouns are ZPs, which poses difficulties for NMT models. For Japanese⇒English translation task, we respectively selected 1.03M, 1.02K, and 1.02K sentence pairs from Opensubtitle2016[4] as training, validation, and test sets (Tiedemann, 2012). We used case-insensitive 4-gram NIST BLEU (Papineni et al., 2002) as evaluation metrics, and *sign-test* (Collins et al., 2005) to test for statistical significance.

To make fair comparison with Wang et al. (2018a), we also implemented our approach on top of the RNN-based NMT model, which incorporates dropout (Hinton et al., 2012) on the output layer and improves the attention model by feeding the most recently generated word. For training the models, we limited the source and target vocabularies to the most frequent 30K words for Chinese⇒English and 20K for Japanese⇒English. Each model was trained on sentences of length up to a maximum of 20 words with early stopping. Mini-batches were shuffled during processing with a mini-batch size of 80. The dimension of word embedding was 620 and the hidden layer size was 1,000. We trained for 20 epochs using Adadelta (Zeiler, 2012), and selected the model that yielded best performances on validation sets. For training the proposed models, the hidden layer sizes of hierarchical model and reconstruction model are 1,000 and 2,000, respectively. We modeled previous three sentences as discourse-level context.[5]

4.2 Results on Chinese⇒English Task

Table 2 lists the performance of ZP translation and prediction on Chinese⇒English data.

The baseline (Row 1) is trained on the standard NMT model using the original parallel data ($\mathbf{x}$, $\mathbf{y}$). In addition, we implemented two comparative models (Row 2-3), which differ with respect to the training data used. The "+ ZP-Annotated Data" model was still trained on standard NMT model but using new training instances ($\hat{\mathbf{x}}$, $\mathbf{y}$) whose source-side sentences are auto-annotated with ZPs. The "+ Reconstruction" is the best model reported in Wang et al. (2018a), which employs two reconstructors to reconstruct the $\hat{\mathbf{x}}$ from

[5] We followed Wang et al. (2017) and Tu et al. (2018) to use 3 previous sentences as discourse context.

#	Model	Translation		Prediction		
		#Params	*BLEU*	*P*	*R*	*F1*
1	Baseline	86.7M	31.80	n/a	n/a	n/a
External ZP Prediction (Wang et al., 2018a)						
2	+ ZP-Annotated Data	+0M	32.67	0.67	0.65	0.66
3	+ Reconstruction	+73.8M	35.08			
This Work: Joint ZP Prediction and Translation						
4	Joint Model	+35.6M	36.04†	0.72	0.68	0.70
5	+ Discourse-Level Context	+56.6M	**37.11**†	0.76	0.77	**0.77**

Table 2: Evaluation of ZP translation and prediction on the Chinese–English data. "#Params" represents the number of parameters used in different models. "†" indicates statistically significant difference ($p < 0.01$) from the best external ZP prediction model for translation performance. As seen, the proposed joint models improve performances in both ZP translation and prediction, over the external ZP prediction models.

hidden representations of encoder and decoder. At decoding time, ZPs can not be annotated by alignment method since target sentences are not available. Thus, source sentences are annotated by an external ZP prediction model, which is trained on monolingual training instances $\hat{\mathbf{x}}$. Finally, we evaluated two proposed models (Row 4-5) which are introduced in Section 3.1 and 3.2, respectively.

Translation Quality Benefiting from the explicitly annotated ZPs in the source language, the "+ ZP-Annotated Data" model (Row 2) outperforms the baseline system built on the original data where the pronouns are missing (*i.e.,* +0.87 BLEU point). This illustrates that explicitly recalling translation of ZPs at training time helps produce better translations. Furthermore, the "+ Reconstuction" approach (Row 3) respectively outperforms the baseline and "+ ZP-Annotated Data" models by +3.28 and +2.41 BLEU points, which indicates that explicitly handling ZPs with reconstruction model can better address ZP problems.

The proposed models consistently outperform other models in all cases, demonstrating the superiority of the joint learning of ZP prediction and translation. Specifically, the "Joint Model" (Row 4) significantly improves translation performance by +4.24 over baseline model. In addition, this joint approach also outperforms two comparative models "+ ZP-Annotated Data" and "+ Reconstruction" by +3.37 and +0.96 BLEU points, respectively. We attribute the improvement over external ZP prediction to: 1) releasing the reliance on external ZP prediction models can greatly alleviate error propagation problems; and 2) joint learning of ZP prediction and translation is able to guide the related parameters to learn better latent representations. Furthermore, introducing discourse-level context (Row 5) accumulatively improves translation performance, and significantly outperform the joint model by +1.07 BLEU points.

Model	BLEU	△
Baseline	19.94	–
External ZP Prediction	20.86	+0.92
Joint Model	21.39	+1.45
+ Discourse-Level Context	**22.00**	+2.06

Table 3: Translation quality on Japanese–English data. As seen, the proposed models can also significantly improve translation performance, which shares the same trend with that on Chinese–English translation.

More parameters may capture more information, at the cost of posing difficulties to training. Wang et al. (2018a) leverage two separate reconstructors with hidden state size being 2000 and 1000 respectively. Accordingly, their models introduce a large number of parameters. In contrast, we set the hidden size of the reconstructor be 1000, which greatly reduce the newly introduced parameters (+35.6M vs. +73.8M). Modeling discourse-level context further introduces +21M new parameters, which is reasonable comparing with previous work. Our best model variation outperform that of external ZP prediction by over 2 BLEU points with less parameters (143.3M vs. 160.5M), showing that the improvements are attributed to the stronger modeling capacity rather than more parameters.

ZP Prediction Accuracy The joint model improves prediction accuracy as expected, which we

Model	ZP-Annotated Input		
	✓	×	▽
Baseline	31.80		–
External ZP Predict.	35.08	34.02	-1.06
Joint Model	36.04	35.93	-0.11
+ Discourse	**37.11**	**36.51**	-0.60

Model	BLEU	△
Baseline	31.80	–
+ Discourse⇒Decoder	32.34	+0.54
Baseline + ZP-Anno.	32.67	
+ Discourse⇒Decoder	32.55	-0.12
Joint Model	36.04	–
+ Discourse⇒Decoder	34.66	-1.38

Table 5: Translation results when transforming the contextual representation to decoder of different models. Incorporating discourse-level context does not always lead to improvement of translation performance.

attribute to the leverage of useful translation information. Incorporating the discourse-level context further improves ZP prediction, and the best performance is 11% higher than external ZP prediction model. These results confirm our claim that joint learning of ZP prediction and translation can benefit both components by allowing them to interact with each other.

4.3 Results on Japanese⇒English Task

Table 3 lists the results. We compare our models and the best external ZP prediction approach. As seen, our models also significantly improve translation performance, demonstrating the effectiveness and universality of the proposed approach.

This improvement on Japanese⇒English translation is lower than that on Chinese⇒English, showing that ZP prediction and translation are more challenging for Japanese. The reason may be two folds: 1) Japanese language has a larger number of pronoun variations borrowed from archaism, which leads to more difficulties in learning ZPs; 2) Japanese language is subject-object-verb (SOV) while English has subject-verb-object (SVO) structure, and this poses difficulties for ZP annotation via alignment method.

4.4 Analysis

We conducted extensive analyses on Chinese ⇒English to better understand our models in terms of the effect of external ZP annotation and different types of ZPs errors.

Reliance on Externally ZP-Annotated Input Some researchers may argue that previous approaches (Wang et al., 2018a) are also able to release the reliance of externally annotated input by removing the reconstructor component. Table 4 lists the results. Without ZP-annotated input in decoding, all approaches can still outperform the baseline model, by benefiting better intermediate representations that contain necessary ZP information. Compared with reconstruction-based models, however, removing the reconstruction components leads to decrease on translation quality. As seen, the BLEU score of best "External ZP prediction" model dramatically drops by -1.06 points, showing that this approach is heavily dependent on the results of external ZP annotations. The performances of proposed models only decrease by -0.1∼-0.6 BLEU point. It indicates that our models are compatible with the standard encoder-decoder-reconstructor framework, thus enjoy an additional benefit of re-scoring translation hypotheses in testing with reconstruction scores. All the results together prove the superiority of the proposed unified framework for ZP translation.

Effect of Discourse-Level Context Recent studies revealed that inter-sentential context can implicitly help to tackle anaphora resolution in NMT architecture (Jean et al., 2017b; Bawden et al., 2018; Voita et al., 2018). Some may argue that document-level architectures are strong enough to alleviate ZP problems for NMT. To answer this concern, we compared with "+ Discourse⇒Decoder" models, which transform the contextual representation to the decoder part of different models. In this way, the discourse-level context can benefit both the generation of translation and ZP prediction.

As shown in Table 5, directly incorporating inter-sentential context into standard NMT model (one of document-level NMT architectures) can improve translation quality by +0.54 BLEU point than baseline. However, this integration mechanism does not work well in "Baseline + ZP-Annotation" and our "Joint" models, which de-

Model	Error	Sub.	Obj.	Dum.	All
BASE.	Total	112	41	45	198
EXTE.	Fixed	50	34	33	117
	New	11	14	7	32
	Total	73	21	19	113
JOIN.	Fixed	61	35	37	133
	New	8	11	7	26
	Total	59	17	15	91
+DIS.	Fixed	70	39	38	147
	New	7	9	7	23
	Total	**49**	**11**	**14**	**74**

Table 6: Translation error statistics. The ZP types "Sub.", "Obj." and "Dum." denote errors caused by subjective, objective and dummy pronouns, respectively. The models "Base.", "Exte.", "Join." and "+Dis." denote "Baseline", "+ Reconstruction", "Joint Model" and "+ Discourse-Level context" models. **Bold** numbers denote the least errors in each category.

creasing by -0.12 and -1.38 BLEU points, respectively. One potential problem with this strategy is that the propagation path is longer: $\mathbf{C} \rightarrow \mathbf{h}^{dec} \rightarrow \mathbf{h}^{rec} \rightarrow \mathbf{zp}$, which may suffer from the vanishing effect. This also confirms our hypothesis that discourse-level context benefits ZP prediction more than ZP translation. Therefore, we incorporate the discourse-level context into reconstructor instead of the decoder.

Manual Evaluation on Translation Errors We finally investigate how the proposed approaches improve the translation by human evaluation. We randomly select 500 sentences from the test set. As shown in Table 6, we count how many translation errors caused by different types of ZPs (*i.e.,* "Subjective", "Objective" and "Dummy"[6]) are fixed ("Fixed") and newly generated ("New") by different models.

All the models can fix different amount of ZP problems in terms of completeness and correctness, which is consistent with the translation results reported in Table 2. This confirms that our improvement in terms of BLEU scores indeed comes from alleviating translation errors caused by ZPs. Among them, the proposed model "+DIS." performs best, which fixes 74% of the ZP errors, and only introduces 12% of new errors.

In addition, we found that subjective ZPs are more difficult to predict and translate since they usually occur in imperative sentences, and ZP prediction needs to understand intention of speakers. The "EXTE." model only fixes 45% of subjective ZP errors but made 10% new errors by predicting wrong ZPs. However, the proposed joint model works better, which fixes 54% error with only introducing 7% new errors. Predicting objective ZPs needs inter-sentential context, thus our "+DIS." model is able to fix more objective ZP errors (95% vs. 82%) by introducing less new errors (22% vs. 34%) than "EXTE.".

Case Study Table 7 shows two typical examples, of which pronouns are mistakenly translated by the strong baseline ("External ZP Prediction") model (Wang et al., 2018a) while fixed by our model and failed to be fix. In "Fixed Error" case, the dropped word "它 (*it*)" is an anaphoric ZP whose antecedent is the noun "电视 (*television*)" in previous sentence while the dropped word "你 (*you*)" is a non-anaphoric ZP that depends upon speaker or listener. As seen, our "JOIN." model performs better than the "EXTE." model because two ZP positions are syntactically recalled in the target side, showing that the joint approach have better capability of utilizing intra-sentential information for identifying ZPs. Besides, our "+DIS." model can semantically fix the error by predicting correct ZP words, demonstrating that inter-sentential context can aid to recovering such complex ZPs. However, as shown in "Non-Fixed Error" case, there are still some ZPs can not be precisely predicted due to the misunderstanding of intentions of utterances. Thus, exploiting dialogue focus for ZP translation is our future work (Rao et al., 2015).

5 Related Work

ZP Prediction and Translation ZP resolution is a challenging task which needs lexical, syntactic, discourse knowledge. Previous studies have been conducted to improves the performance of ZP resolution for different pro-drop languages (Kong and Zhou, 2010; Chen and Ng, 2013; Park et al., 2015; Yin et al., 2017). However, directly using results of external ZP resolution systems for translation task shows limited improvements (Chung and Gildea, 2010; Le Nagard and Koehn, 2010; Taira et al., 2012; Xiang et al., 2013), since such external systems are trained on small-scale data that is non-homologous to MT. To

[6]In pro-drop languages, it is used to fulfill the syntactical requirements without providing explicit meaning (e.g. "it").

Table 7: Example translations where pronouns in brackets are dropped in original inputs ("INP.") but labeled by humans according to references ("REF.") and previous sentence ("PRE."). We italicize some *mistranslated* errors and highlight the **correct** ones in bold.

overcome the data-level gap, Wang et al. (2016) proposed an automatic approach of ZP annotation by utilizing an alignment matrix from a large parallel data. By using the translation-oriented ZP corpus, they exploited different approaches to alleviate ZP problems for translation models (Wang et al., 2016, 2018a,b). Note that Wang et al. (2018b) also explored to address the problem of error propagation by jointly predicting ZP words given ZP position information. However, this method still relies an external model that predicting ZP positions at decoding time. Instead, this work proposes a unified model without any additional ZP annotations in decoding, thus release reliance on external ZP prediction in practice.

Discourse-Aware NMT Recent years, context-aware architecture has been well studied for NMT (Wang et al., 2017; Jean et al., 2017a; Tu et al., 2018). Wang et al. (2017) proposed hierarchical recurrent neural networks to summarize inter-sentential context from previous sentences and then integrate it into a standard NMT model with difference strategies. Jean et al. (2017a) introduced an additional set of an encoder and attention to encode and select part of the previous source sentence for generating each target word. Besides, Tu et al. (2018) proposed to augment NMT models with a cache-like memory network, which stores the translation history in terms of bilingual hidden representations at decoding steps of previous sentences. They also evaluated the above three models on different domains of data, showing that the hierarchical encoder performs comparable with the multi-attention model. More recently, some researchers began to investigate the effects of context-aware NMT on cross-lingual pronoun prediction (Jean et al., 2017b; Bawden et al., 2018; Voita et al., 2018). They mainly exploited general anaphora in non-pro-drop languages such as English⇒Russian.

6 Conclusion

In this work, we proposed a unified model to learn jointly predict and translate ZPs by leveraging multi-task learning. We also employed hierarchical neural networks to exploit discourse-level information for better ZP prediction. Experimental results on both Chinese⇒English and Japanese⇒English data show that the two proposed approaches accumulatively improve both the translation performance and ZP prediction accuracy. Our models also outperform the existing ZP translation models in previous work, and achieve a new state-of-the-art on the widely-used subtitle corpus. Manual evaluation confirms that the performance improvement comes from the alleviation of translation errors, which are mainly caused by subjective, objective as well as discourse-aware ZPs.

There are two potential extensions to our work. First, we will evaluate our method on other implication phenomena (or called unaligned words (Takeno et al., 2017)) such as tenses and article words for NMT. Second, we will investigate the impact of different context-aware models on ZP translation, including multi-attention (Jean et al., 2017b) and context-aware Transformer(Voita et al., 2018).

Abstract

Previous studies have shown that neural machine translation (NMT) models can benefit from explicitly modeling translated (PAST) and untranslated (FUTURE) source contents as recurrent states (Zheng et al., 2018). However, this less interpretable recurrent process hinders its power to model the dynamic updating of PAST and FUTURE contents during decoding. In this paper, we propose to model the *dynamic principles* by explicitly separating source words into groups of translated and untranslated contents through parts-to-wholes assignment. The assignment is learned through a novel variant of routing-by-agreement mechanism (Sabour et al., 2017), namely *Guided Dynamic Routing*, where the translating status at each decoding step *guides* the routing process to assign each source word to its associated group (i.e., translated or untranslated content) represented by a capsule, enabling translation to be made from holistic context. Experiments show that our approach achieves substantial improvements over both RNMT and Transformer by producing more adequate translations. Extensive analysis demonstrates that our method is highly interpretable, which is able to recognize the translated and untranslated contents as expected.[1]

1 Introduction

Neural machine translation (NMT) generally adopts an *attentive encoder-decoder* framework (Sutskever et al., 2014; Vaswani et al., 2017), where the encoder maps a source sentence into a sequence of contextual representations (*source contents*), and the decoder generates a target sentence word-by-word based on part of the source content assigned by an attention model (Bahdanau et al., 2015). Like human translators, NMT systems should have the ability to know the relevant source-side context for the current word (PRESENT), as well as recognize what parts in the source contents have been translated (PAST) and what parts have not (FUTURE), at each decoding step. Accordingly, the PAST, PRESENT and FUTURE are three *dynamically* changing states during the whole translation process.

Previous studies have shown that NMT models are likely to face the illness of inadequate translation (Kong et al., 2019), which is usually embodied in over- and under-translation problems (Tu et al., 2016, 2017). This issue may be attributed to the poor ability of NMT of recognizing the dynamic translated and untranslated contents. To remedy this, Zheng et al. (2018) first demonstrate that explicitly tracking PAST and FUTURE contents helps NMT models alleviate this issue and generate better translation. In their work, the running PAST and FUTURE contents are modeled as recurrent states. However, the recurrent process is still non-trivial to determine which parts of the source words are the PAST and which are the FUTURE, and to what extent the recurrent states represent them respectively, this less interpretable nature is probably not the best way to model and exploit the dynamic PAST and FUTURE.

We argue that an explicit separation of the source words into two groups, representing PAST and FUTURE respectively (Figure 1), could be more beneficial not only for easy and direct recognition of the translated and untranslated source contents, but also for better interpretation of model's behavior of the recognition. We formulate the explicit separation as a procedure of parts-to-wholes assignment: the representation of each source words (parts) should be assigned to its associated group of either PAST or FUTURE (wholes).

In this paper, we implement this idea using Cap-

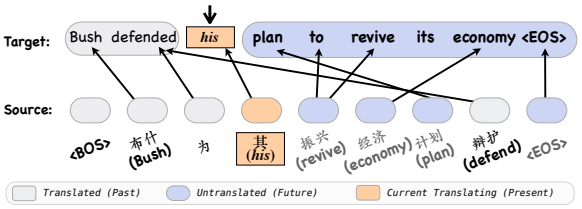

Figure 1: An example of separation of PAST and FUTURE in machine translation. When generating the current translation "his", the source tokens "⟨BOS⟩", "布什(Bush)" and phrase "为...辩护(defend)" are the translated contents (PAST), while the remaining tokens are untranslated contents (FUTURE).

sule Network (Hinton et al., 2011) with routing-by-agreement mechanism (Sabour et al., 2017), which has demonstrated its appealing strength of solving the problem of parts-to-wholes assignment (Hinton et al., 2018; Gong et al., 2018; Dou et al., 2019; Li et al., 2019), to model the separation of the PAST and FUTURE:

1. We first cast the PAST and FUTURE source contents as two groups of capsules.
2. We then design a novel variant of the routing-by-agreement mechanism, called *Guided Dynamic Routing* (GDR), which is *guided* by the current translating status at each decoding step to assign each source word to its associated capsules by assignment probabilities for several routing iterations.
3. Finally, the PAST and FUTURE capsules accumulate their expected contents from representations, and are fed into the decoder to provide a time-dependent holistic view of context to decide the prediction.

In addition, two auxiliary learning signals facilitate GDR's acquiring of our expected functionality, other than implicit learning within the training process of the NMT model.

We conducted extensive experiments and analysis to verify the effectiveness of our proposed model. Experiments on Chinese-to-English, English-to-German, and English-to-Romanian show consistent and substantial improvements over the Transformer (Vaswani et al., 2017) or RNMT (Bahdanau et al., 2015). Visualized evidence proves that our approach does acquire the expected ability to separate the source words into PAST and FUTURE, which is highly interpretable. We also observe that our model does alleviate the inadequate translation problem: Human subjective evaluation reveals that our model produces more adequate and high-quality translations than Transformer. Length analysis regarding source sentences shows that our model generates not only longer but also better translations.

2 Neural Machine Translation

Neural models for sequence-to-sequence tasks such as machine translation often adopt an *encoder-decoder* framework. Given a source sentence $\mathbf{x} = \langle x_1, \ldots, x_I \rangle$, a NMT model learns to predict a target sentence $\mathbf{y} = \langle y_1, \ldots, y_T \rangle$ by maximizing the conditional probabilities $p(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T} p(y_t|y_{<t}, \mathbf{x})$. Specifically, an encoder first maps the source sentence into a sequence of encoded representations:

$$\mathbf{h} = \langle \boldsymbol{h}_1, \ldots, \boldsymbol{h}_I \rangle = f_e(\mathbf{x}), \quad (1)$$

where f_e is the encoder's transformation function. Given the encoded representations of the source words, a decoder generates the sequence of target words $\mathbf{y}$ autoregressively:

$$\boldsymbol{z}_t = f_d(y_{<t}, \boldsymbol{a}_t), \quad (2)$$

$$p(y_t|y_{<t}, \mathbf{x}) = \mathrm{softmax}(E(y_t)^\top \boldsymbol{z}_t), \quad (3)$$

where $E(y_t)$ is the embedding of y_t. The current word is predicted based on the decoder state $\boldsymbol{z}_t$. f_d is the transformation function of decoder, which determines $\boldsymbol{z}_t$ based on the target translation trajectory $y_{<t}$, and the lexical-level source content $\boldsymbol{a}_t$ that is most relevant to PRESENT translation by an attention model (Bahdanau et al., 2015). Ideally, with all the source encoded representations in the encoder, NMT models should be able to update translated and untranslated source contents and keep them in mind. However, most of existing NMT models lack an explicit functionality to maintain the translated and untranslated contents, failing to distinguish the source words being of either PAST or FUTURE (Zheng et al., 2018), which is likely to suffer from severe inadequate translation problem (Tu et al., 2016; Kong et al., 2019).

3 Approach

Motivation Our intuition arises straightforwardly: if we could tell the translated and untranslated source contents apart by directly separating the source words into PAST and FUTURE categories at each decoding step, the PRESENT translation could benefit from the dynamically holistic context (i.e., PAST+ PRESENT+ FUTURE). To this

purpose, we should design a mechanism by which each word could be recognized and assigned to a distinct category, i.e., PAST or FUTURE contents, subject to the translation status at present. This procedure can be seen as a parts-to-wholes assignment, in which the encoder hidden states of the source words (parts) are supposed to be assigned to either PAST or FUTURE (wholes).

Capsule network (Hinton et al., 2011) has shown its capability of solving the problem of assigning parts to wholes (Sabour et al., 2017). A capsule is a vector of neurons which represents different properties of the same entity from the input (Sabour et al., 2017). The functionality relies on a fast iterative process called routing-by-agreement, whose basic idea is to iteratively refine the proportion of how much a part should be assigned to a whole, based on the agreement between the part and the whole (Dou et al., 2019). Therefore, it is appealing to investigate if this mechanism could be employed for our intuition.

3.1 Guided Dynamic Routing (GDR)

Dynamic routing (Sabour et al., 2017) is an implementation of routing-by-agreement, where it runs intrinsically without any external guidance. However, what we expect is a mechanism driven by the decoding status at present. Here we propose a variant of dynamic routing mechanism called *Guided Dynamic Routing* (GDR), where the routing process is *guided* by the translating information at each decoding step (Figure 2).

Formally, we cast the source encoded representations $\mathbf{h}$ of I source words to be input capsules, while we denote $\mathbf{\Omega}$ as output capsules, which consist of J entries. Initially, we assume that $J/2$ of them ($\mathbf{\Omega}^P$) represent the PAST contents, and the rest $J/2$ capsules ($\mathbf{\Omega}^F$) represent the FUTURE:

$$\mathbf{\Omega}^P = \langle \Omega_1^P, \cdots, \Omega_{J/2}^P \rangle, \quad \mathbf{\Omega}^F = \langle \Omega_1^F, \cdots, \Omega_{J/2}^F \rangle.$$

where each capsule is represented by a d_c-dimension vector. We assemble these PAST and FUTURE capsules together, which are expected to competing for source information, i.e., we now have $\mathbf{\Omega} = \mathbf{\Omega}^P \cup \mathbf{\Omega}^F$. We will describe how to teach these capsules to retrieve their relevant parts from source contents in the Section 3.3. ***Note*** that we employ GDR at every decoding step t to obtain the time-dependent PAST and FUTURE and omit the subscript t for simplicity.

In the dynamic routing process, each vector output of capsule j is calculated with a non-linear

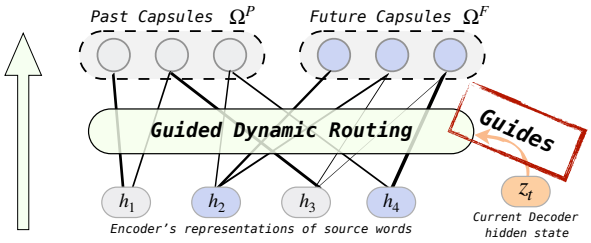

Figure 2: Illustration of the Guided Dynamic Routing.

squashing function (Sabour et al., 2017):

$$\Omega_j = \frac{\|\boldsymbol{s}_j\|^2}{1+\|\boldsymbol{s}_j\|^2}\frac{\boldsymbol{s}_j}{\|\boldsymbol{s}_j\|}, \quad \boldsymbol{s}_j = \sum_i^I c_{ij}\boldsymbol{v}_{ij}, \quad (4)$$

where $\boldsymbol{s}_j$ is the accumulated input of capsule Ω_j, which is a weighted sum over all *vote vectors* $\boldsymbol{v}_{ij}$. $\boldsymbol{v}_{ij}$ is transformed from the input capsule $\boldsymbol{h}_i$:

$$\boldsymbol{v}_{ij} = \boldsymbol{W}_j \boldsymbol{h}_i, \quad (5)$$

where $\boldsymbol{W}_j \in \mathbb{R}^{d \times d_c}$ is a trainable matrix for j-th output capsule[2]. c_{ij} is the assignment probability (i.e. the agreement) that is determined by the iterative dynamic routing. The assignment probabilities $c_{i\cdot}$ associated with each input capsule $\boldsymbol{h}_i$ sum to 1: $\sum_j c_{ij} = 1$, and are computed by:

$$c_{ij} = \mathrm{softmax}(b_{ij}), \quad (6)$$

where routing logit b_{ij} is initialized as all 0s, which measures the degree that $\boldsymbol{h}_i$ should be sent to Ω_j. The initial assignment probabilities are then iteratively updated by measuring the agreement between the vote vector $\boldsymbol{v}_{ij}$ and capsule Ω_j by an MLP, considering the current decoding state $\boldsymbol{z}_t$:

$$b_{ij} \leftarrow b_{ij} + \boldsymbol{w}^\top \tanh(\boldsymbol{W}_b[\boldsymbol{z}_t; \boldsymbol{v}_{ij}; \Omega_j]), \quad (7)$$

where $\boldsymbol{W}_b \in \mathbb{R}^{d+d_c*2}$ and $\boldsymbol{w} \in \mathbb{R}^{d_c}$ are learnable parameters. Instead of using simple scalar product, i.e., $b_{ij} = \boldsymbol{v}_{ij}^\top \Omega_j$ (Sabour et al., 2017), which could not consider the current decoding state as a condition signal, we resort to the MLP to take $\boldsymbol{z}_i$ into account inspired by MLP-based attention mechanism (Bahdanau et al., 2015; Luong et al., 2015). That is why we call it "guided" dynamic routing.

[2]Note that unlike Sabour et al. (2017), where each pair of input capsule i and output capsule j has a distinct transformation matrix $\boldsymbol{W}_{ij}$ as their numbers are predefined ($I \times J$ transformation matrices in total), here we share the transformation matrix $\boldsymbol{W}_j$ of output capsule j among all the input capsules due to the varied amount of the source words. So there are J transformation matrices in our model.

Algorithm 1 Guided Dynamic Routing (GDR)

Input: Encoder hidden state $\mathbf{h}$, current decoding hidden state $\boldsymbol{z}_t$, and number of routing iterations r.
Output: PAST, FUTURE, and redundant capsules.
procedure: GDR($\mathbf{h}$, $\boldsymbol{z}_t$, r)
$\forall i \in \mathbf{h}, j \in \boldsymbol{\Omega} : b_{ij} \leftarrow 0, \boldsymbol{v}_{ij} \leftarrow \boldsymbol{W}_j \boldsymbol{h}_i$ ▷ *Initializing routing logits, and vote vectors.*
for r iterations **do**
  $\forall i \in \mathbf{h}, j \in \boldsymbol{\Omega}$: Compute assign. probs. c_{ij} by Eq. 6
  $\forall j \in \boldsymbol{\Omega}$: Compute capsules Ω_j by Eq. 4
  $\forall i \in \mathbf{h}, j \in \boldsymbol{\Omega}$: Update routing logits b_{ij} by Eq. 7
end for
$[\boldsymbol{\Omega}^P; \boldsymbol{\Omega}^F; \boldsymbol{\Omega}^R] = \boldsymbol{\Omega}$ ▷ *Return past, future, and redundant capsules*
return $\boldsymbol{\Omega}^P, \boldsymbol{\Omega}^F, \boldsymbol{\Omega}^R$

Now with the awareness of the current decoding status, the hidden state (input capsule) of a source word prefers to send its representation to the output capsules, which have large routing agreements associated with the input capsule. After a few rounds of iterations, the output capsules are able to ignore all but the most relevant information from the source hidden states, representing a distinct aspect of either PAST or FUTURE.

Redundant Capsules In some cases, some parts of the source sentence may belong to neither past contents nor future contents. For example, function words in English (e.g., "the") could not find its counterpart translation in Chinese. Therefore, we add additional Redundant Capsules $\boldsymbol{\Omega}^R$ (also known as "orphan capsules" in Sabour et al. (2017)), which are expected to receive higher routing assignment probabilities when a source word should not belong to either PAST or FUTURE.

We show the algorithm of our guided dynamic routing in Algorithm 1.

3.2 Integrating into NMT

The proposed GDR can be applied on the top of any sequence-to-sequence architecture, which does not require any specific modification. Let us take a Transformer-fashion architecture as example (Figure 3). Given a sentence $\mathbf{x} = \langle x_1, \ldots, x_I \rangle$, the encoder leverages N stacked identical layers to map the sentence into contextual representations:

$$\mathbf{h}^{(l)} = \text{EncoderLayer}(\mathbf{h}^{(l-1)}),$$

where the superscript l indicates layer depth. Based on the encoded source representations $\mathbf{h}^N$, a decoder generates translation word by word. The

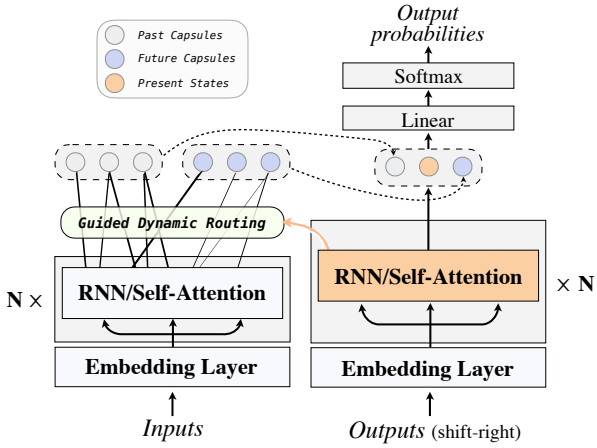

Figure 3: Illustration of our architecture.

decoder also has N stacked identical layers:

$$\mathbf{z}^{(l)} = \text{DecoderLayer}(\mathbf{z}^{(l-1)}, \mathbf{a}^{(l)}),$$
$$\mathbf{a}^{(l)} = \text{Attention}(\mathbf{z}^{(l-1)}, \mathbf{h}^{(N)}),$$

where $\mathbf{a}^{(l)}$ is the lexical-level source context assigned by an attention mechanism between current decoder layer and the last encoder layer. Given the hidden states of the last decoder layer $\mathbf{z}^{(N)}$, we perform our proposed guided dynamic routing (GDR) mechanism to compute the PAST and FUTURE contents from the source side and obtain the holistic context of each decoding step:

$$\boldsymbol{\Omega}^P, \boldsymbol{\Omega}^F, \boldsymbol{\Omega}^R = \text{GDR}(\mathbf{z}^{(N)}, \mathbf{h}^{(N)}),$$
$$\mathbf{o} = \text{FeedForward}(\mathbf{z}^{(N)}, \boldsymbol{\Omega}^P, \boldsymbol{\Omega}^F) + \mathbf{z}^{(N)},$$

where $\mathbf{o} = \langle \boldsymbol{o}_1, \cdots, \boldsymbol{o}_T \rangle$ is the sequence of the holistic context of each decoding step. Based on the holistic context, the output probabilities are computed as:

$$p(y_t | y_{<t}, \mathbf{x}) = \text{softmax}(g(\boldsymbol{o}_t)).$$

The NMT model is now able to employ the dynamic holistic context for better generation.

3.3 Learning PAST and FUTURE as Expected Auxiliary Guided Losses

To ensure that the dynamic routing process runs as expected, we introduce the following auxiliary guided signals to assist the learning process.

Bag-of-Word Constraint Weng et al. (2017) propose a multitasking scheme to boost NMT by predicting the bag-of-words of target sentence using the Word Predictions approach. Inspired by

this work, we introduce a BOW constraint to encourage the PAST and FUTURE capsules to be predictive of the preceding and subsequent bag-of-words regarding each decoding step respectively:

$$\mathcal{L}_{\text{BOW}} = \frac{1}{T}\sum_{t=0}^{T}\big(-\log p_{\text{PRE}}(y_{\leq t}|\mathbf{\Omega}_t^P) - \log p_{\text{SUB}}(y_{\geq t}|\mathbf{\Omega}_t^F)\big),$$

where $p_{pre}(y_{\leq t}|\mathbf{\Omega}_t^P)$ and $p_{sub}(y_{\geq t}|\mathbf{\Omega}_t^F)$ are the predicted probabilities of the preceding bag-of-words and subsequent words at decoding step t, respectively. For instance, the probabilities of the preceding bag-of-words are computed by:

$$p_{\text{PRE}}(y_{<t}|\mathbf{\Omega}_t^P) = \prod_{\tau\in[1,t]} p_{\text{PRE}}(y_\tau|\mathbf{\Omega}_t^P) \propto \prod_{\tau\in[1,t]} \exp(\boldsymbol{E}(y_\tau)^\top \boldsymbol{W}_{\text{BOW}}^P \mathbf{\Omega}_t^P).$$

The computation of $p_{\text{SUB}}(y_{\geq t}|\mathbf{\Omega}_t^F)$ is similar. By applying the BOW constraint, the PAST and FUTURE capsules can learn to reflect the target-side past and future bag-of-words information.

Bilingual Content Agreement Intuitively, the translated source contents should be semantically equivalent to the translated target contents, and so do untranslated contents. Thus, a natural idea is to encourage the source PAST contents, modeled by the PAST capsule to be close to the target PAST representation at each decoding step, and the same for the FUTURE. Hence, we introduce a Bilingual Content Agreement (BCA) to require the bilingual semantic-equivalent contents to be predictive to each other by Minimum Square Estimation (MSE) loss:

$$\mathcal{L}_{\text{BCA}} = \frac{1}{T}\sum_{t=1}^{T}\|\mathbf{\Omega}_t^P - \boldsymbol{W}_{\text{BCA}}^P(\frac{1}{t}\sum_{\tau=1}^{t}\boldsymbol{z}_\tau)\|^2 + \|\mathbf{\Omega}_t^F - \boldsymbol{W}_{\text{BCA}}^F(\frac{1}{T-t+1}\sum_{\tau=t}^{T}\boldsymbol{z}_\tau)\|^2,$$

where the target-side past information is represented by the averaged results of the decoder hidden states of all preceding words, while the average of subsequent decoder hidden states represents the target-side future information.

Training

Given the dataset of parallel training examples $\{\langle \mathbf{x}^{(m)}, \mathbf{y}^{(m)}\rangle\}_{m=1}^{M}$, the model parameters are trained by minimizing the loss $\mathcal{L}(\boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is the set of all the parameter of the proposed model:

$$\mathcal{L}(\boldsymbol{\theta}) = \frac{1}{M}\sum_{m=1}^{M}\big(-\log p(\mathbf{y}^{(m)}|\mathbf{x}^{(m)}) + \lambda_1\cdot\mathcal{L}_{\text{BOW}} + \lambda_2\cdot\mathcal{L}_{\text{BCA}}\big),$$

where λ_1 and λ_2 are hyper-parameters.

4 Experiment

We mainly evaluated our approaches on the widely used NIST Chinese-to-English (Zh-En) translation task. We also conducted translation experiments on WMT14 English-to-German (En-De) and WMT16 English-to-Romanian (En-Ro):

1. NIST Zh-En. The training data consists of 1.09 million sentence pairs extracted from LDC[3]. We used NIST MT03 as the development set (Dev); MT04, MT05, MT06 as the test sets.

2. WMT14 En-De. The training data consists of 4.5 million sentence pairs from WMT14 news translation task. We used newstest2013 as the development set and newstest2014 as the test set.

3. WMT16 En-Ro. The training data consists of 0.6 million sentence pairs from WMT16 news translation task. We used newstest2015 as the development set and newstest2016 as the test set.

We used `transformer_base` configuration (Vaswani et al., 2017) for all the models. We run the dynamic routing for r=3 iterations. The dimension d_c of a single capsule is 256. Either PAST or FUTURE content was represented by $\frac{J}{2} = 2$ capsules. Our proposed models were trained on the top of pre-trained baseline models[4]. λ_1 and λ_2 in training objective were set to 1. In Appendix, we provide details for the training settings.

4.1 NIST Zh-En Translation

We list the results of our experiments on NIST Zh-En task in Table 1 concerning two different architectures, i.e., Transformer and RNMT. As we can see, all of our models substantially outperform the baselines in terms of averaged BLEU score of all the test sets. Among them, our best model achieves 45.65 BLEU based on Transformer architecture. We also find that redundant capsules are helpful while discarding them leads to -0.35 BLEU degradation (45.65 vs 45.30).

[3]The corpora includes LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06

[4]Pre-training is only for efficiency purpose. Our approach could also learn from scratch.

+AOL (Kong et al., 2019)	N/A	0.57×	1.00×	37.61	40.05	37.58	36.87	38.16 (+1.55)
OURS	53.9m	0.62×	0.90×	**38.10**	**40.87**	**37.50**	**37.00**	**38.45 (+1.84)**

Table 1: Experiment ressuts on NIST Zh-En task, including number of parameters ($|\boldsymbol{\theta}|$, excluding word embeddings), training/testing speeds (v_{train}/v_{test}), and translation results in case-insensitive BLEU.

Architectures Our approach shows consistent effects on both Transformer and RNMT architectures. In comparison to the Transformer baseline, our model achieves at most +1.59 BLEU improvement (45.65 v.s 44.06), while +1.84 BLEU improvement over RNMT baselines (38.45 v.s 36.61). These results indicate the compatibility of our approach to different architectures.

Auxiliary Guided Losses Both the auxiliary guided losses help our model for better learning. The BOW constraint leads to a +0.67 improvement compared to the vanilla GDR, while the benefit is +0.62 for BCA. Combination of both gains the most margins (+0.84), which means that they can supplement each other.

Efficiency To examine the efficiency of the proposed approach, we also list the relative speed of both training and testing. Our approach is 0.67× slower than the Transformer baseline in training phase, however, it does not hurt the speed of testing too much (0.94×). It is because the most extra computation in training phrase is related to the softmax operations of BOW losses, the degradation of the testing efficiency is moderate.

Comparison to Other Work On the experiments on RNMT architecture, we list two related works. Zheng et al. (2018) use extra PAST and FUTURE RNNs to capture translated and untranslated contents recurrently (PFRNN), while Kong et al. (2019) directly leverage translation adequacy as learning reward by their proposed Adequacy-oriented Learning (AOL). Compared to them, our model also enjoys competitive improvements due to the explicit separation of source contents. In addition, PFRNN is non-trivial to adapt to Transformer, because it requires a recurrent process which fails to be compatible with parallel training of Transformer, scarifying Transformer's efficiency advantage.

Model	En-De	En-Ro
GNMT+RL (Wu et al., 2016)	24.6	N/A
ConvS2S (Gehring et al., 2017)	25.2	29.88
Transformer (Vaswani et al., 2017)	27.3	N/A

Transformer (Gu et al., 2017)	N/A	31.91
Transformer	27.14	32.10
OURS	**28.10**	**32.96**

Table 2: Case-sensitive BLEU on WMT14 En-De and WMT16 En-Ro tasks.

4.2 WMT En-De and En-Ro Translation

We evaluated our approach on WMT14 En-De and WMT16 En-Ro tasks. As shown in Table 2, our reproduced Transformer baseline systems are close to the state-of-the-art results in previous work, which guarantee the comparability of our experiments. The results show a consistent trend of improvements as NIST Zh-En task on WMT14 En-De (+0.96 BLEU) and WMT16 En-Ro (+0.86 BLEU) benchmarks. We also list the results of other published research for comparison, where our model outperforms the previous results in both language pairs. Note that our approach also surpasses Kong et al. (2019) on WMT14 En-De task. These experiments demonstrate the effectiveness of our approach across different language pairs.

4.3 Analysis and Discussion

***Our model learns* PAST *and* FUTURE.** We visualize the assignment probabilities in the last routing iteration (Figure 4). Interestingly, there is a clear trend that the assignment probabilities to the PAST capsules gradually raise up, while

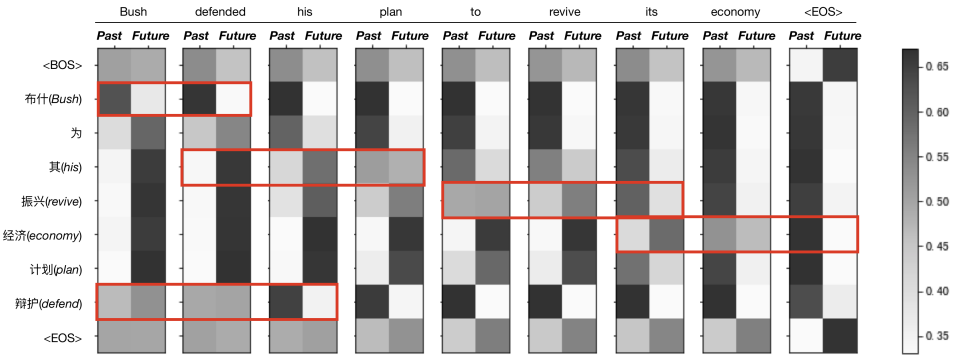

Figure 4: Visualization of the assignment probabilities of iterative routing. Each sub-heatmap is associated with a target word, where the left column is the probabilities of each source words routing to the PAST capsules, and the right one is to the FUTUREExamples in the red frame indicate the changes before and after the generation of the central word. We omit the assignment probabilities associated with the redundant capsules for simplicity. For instance, after the target word "defended" was generated, the assignment probabilities of its source translation "辩护" changed from FUTURE to PAST. Results of "Bush", "his", "revive" and "economy" are similar, except a adverse case ("plan").

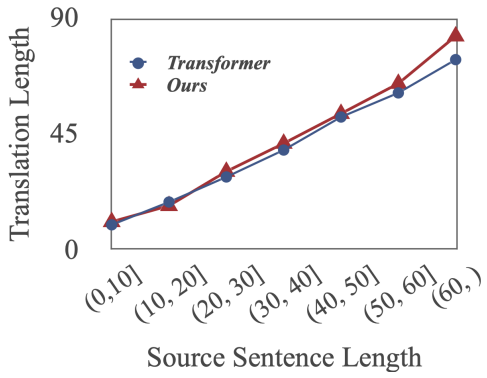
those to the FUTURE capsules reduce to around zeros. This phenomenon is consistent with the intuition that the translated contents should aggregate and the untranslated should decline (Zheng et al., 2018). The assignment weights of a specific word change from FUTURE to PAST after being generated. These pieces of evidence give a strong verification that our GDR mechanism indeed has learned to distinguish the PAST contents and FUTURE contents in the source-side.

Moreover, we measure how well our capsules accumulate the expected contents by comparison between the BOW predictions and ground-truth target words. Accordingly, we define a *top-5 overlap rate* (r_{OL}) for predicting preceding and subsequent words are defined as follow, respectively: $r^P_{\text{OL}} = \frac{1}{T}\sum_{t=1}^{T}\frac{|\text{Top}_{5\text{t}}(p_{pre}(\mathbf{\Omega}^P_t)) \cap y_{<=t}|}{|y_{<=t}|}$, $r^F_{\text{OL}} = \frac{1}{T}\sum_{t=1}^{T}\frac{|\text{Top}_{5(\text{T}-\text{t})}(p_{sub}(\mathbf{\Omega}^F_t)) \cap y_{>=t}|}{|y_{>=t}|}$. The PAST capsules achieves r^P_{OL} of 0.72, while r^F_{OL} of 0.70 for the FUTURE capsules. The results indicate that the capsules could predict the corresponding words to a certain extent, which implies the capsules contain the expected information of PAST or FUTURE contents.



Translations become better and more adequate. To validate the translation adequacy of our model, we use Coverage Difference Ratio (CDR) proposed by Kong et al. (2019), i.e., $\text{CDR} = 1 - \frac{|C_{\text{ref}} \backslash C_{\text{gen}}|}{|C_{\text{ref}}|}$, where C_{ref} and C_{gen} are the set of source words covered by the reference and translation, respectively. The CDR reflects the translation adequacy by comparing the source coverages between reference and translation. As shown in Table 3, our approach achieves a better CDR than the Transformer baseline, which means superiority in translation adequacy.

Model	Transformer	OURS
CDR	0.73	**0.79**
HUMAN EVALUATION		
QUALITY	4.39±.11	**4.66±.10**
OVER(%)	0.03±.01	**0.01±.01**
UNDER(%)	3.83±.97	**2.41±.80**

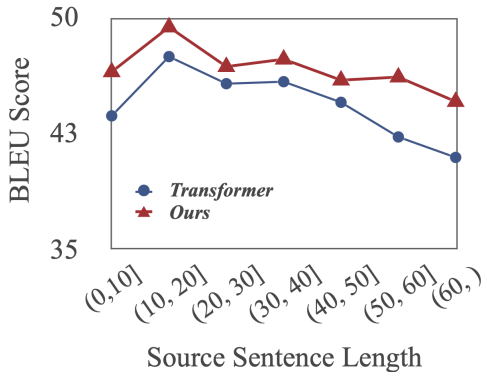


Table 3: Evaluation on translation quality and adequacy. For HUMAN evaluation, we asked three evaluators to score translations from 100 source sentences, which are randomly sampled from the testsets from anonymous systems, the QUALITY from 1 to 5 (higher is better), and the proportions of source words concerning OVER- and UNDER-translation, respectively.

Following Zheng et al. (2018), we also conduct subjective evaluations to validate the benefit of modeling PAST and FUTURE (the last three rows of Table 3). Surprisingly, we find that the modern NMT model, i.e., Transformer, rarely produces over-translation but still suffers from under-translation. Our model obtains the highest human rating on translation quality while substantially alleviates the under-translation problem than Transformer.

Longer sentences benefit much more. We report the comparison with sentence lengths (Figure 5). In all the intervals of length, our model does generate better (Figure 5b) and longer (Figure 5a) translations. Interestingly, our approach

(a) Translation length v.s source length

(b) BLEU v.s source length

Figure 5: Comparison regarding source length.

gets a larger improvement when the input sentences become longer, which are commonly thought hard to translate. We attribute this to the less number of under-translation cases in our model, meaning that our model learns better translation quality and adequacy, especially for long sentences.

Does guided dynamic routing really matter? Despite the promising numbers of the GDR and the auxiliary guided losses, a straightforward question rises: will other more simple models also work if they are just equipped with the guided losses to recognize PAST and FUTURE contents? In other word, does the proposed guided dynamic routing really matter?

To answer this question, we integrate the proposed auxiliary losses into two simple baselines to guide the recognition of past and future: A MLP classifier model (CLF) that determines if a source word is a past word, otherwise future[5]; and an attention-based model (ATTN) that uses two individual attention modules to retrieve past or future parts from the source words. As shown in Table 6, surprisingly, the simple baselines can obtain improvements, emphasizing the function of the proposed guided losses, while there remain a considerable gaps between our model and them. In fact, the CLF is essentially a *one-iteration* variant of GDR, and iterative refinement by multiple iterations is necessary and effective[6]. And the attention mechanism is used for feature pooling, not suitable for parts-to-wholes assignment[7]. These experiments reveal that our guided dynamic routing is a better choice to model and exploit the dynamic PAST and FUTURE.

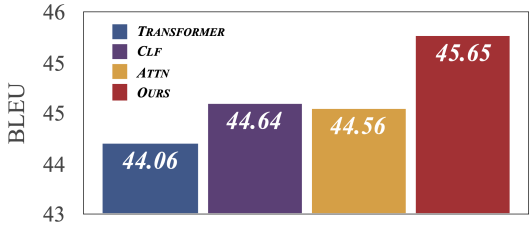

Figure 6: Comparison with simple baselines with the same auxiliary guided loss on NIST Zh-En.

5 Related Work

Inadequate translation problem is a widely known weakness of NMT models, especially when translating long sentences (Kong et al., 2019; Tu et al., 2016; Lei et al., 2019). To alleviate this problem, one direction is to recognize the translated and untranslated contents, and pay more attention to untranslated parts. Tu et al. (2016), Mi et al. (2016) and Li et al. (2018) employ coverage vector or coverage ratio to indicate the lexical-level coverage of source words. Meng et al. (2018) influence the attentive vectors by translated/untranslated information. Our work mainly follows the path of Zheng et al. (2018), which introduce two extra recurrent layers in the decoder to maintain the representations of the past and future translation contents. However, it may be not easy to show the direct correspondence between the source contents and learned representations in the past/future

[5]CLF is a 3-way classifier that computes the probabilities $p^P(x_i)$, $p^F(x_i)$ and $p^R(x_i)$ (they sum to 1) as past, future and redundant weights, which is similar to Equation 6. The PAST and FUTURE representations are computed by weighted summation, which is similar to Equation 4.

[6]See Appendix for analysis of iteration numbers.

[7]Consider an extreme case that in the end of translation, there is no FUTURE content left, but the attention model still produces a *weighted average* over all the source representations, which is nonsense. In contrast, the GDR is able to assign zero probabilities to the FUTURE capsules, solving the source of the problem.

RNN layers, nor compatible with the state-of-the-art Transformer for the additional recurrences prevent Transformer decoder from being parallelized.

Another direction is to introduce global representations. Lin et al. (2018) model a global source representation by deconvolution networks. Xia et al. (2017); Zhang et al. (2018); Geng et al. (2018) propose to provide a holistic view of target sentence by multi-pass decoding. Zhou et al. (2019) improve Zhang et al. (2018) to a synchronous bidirectional decoding fashion. Similarly, Weng et al. (2019) deploy bidirectional decoding in interactive translation setting. Different from these work aiming at providing static global information in the whole translation process, our approach models a dynamically global (holistic) context by using capsules network to separate source contents at every decoding steps.

Other efforts explore exploiting future hints. Serdyuk et al. (2018) design a Twin Regularization to encourage the hidden states in forward decoder RNN to estimate the representations of a backward RNN. Weng et al. (2017) require the decoder states to not only generate the current word but also predict the remain untranslated words. Actor-critic algorithms are employed to predict future properties (Li et al., 2017; Bahdanau et al., 2017; He et al., 2017) by estimating the future rewards for decision making. Kong et al. (2019) propose a policy gradient based adequacy-oriented approach to improve translation adequacy. These methods use future information only at the training stage, while our model could also exploit past and future information at inference, which provides accessible clues of translated and untranslated contents.

Capsule networks (Hinton et al., 2011) and its associated assignment policy of dynamic routing (Hinton et al., 2011) and EM-routing (Hinton et al., 2018) aims at addressing the limited expressive ability of the parts-to-wholes assignment in computer vision. In natural language processing community, however, the capsule network has not yet been widely investigated. Zhao et al. (2018) testify capsule network on text classification and Gong et al. (2018) propose to aggregate a sequence of vectors via dynamic routing for sequence encoding. Dou et al. (2019) first propose to employ capsule network in NMT using routing-by-agreement mechanism for layer representation aggregation. Wang (2019) develops a constant time NMT model using capsule networks. These studies mainly use capsule network for information aggregation, where the capsules could have a less interpretable meaning. In contrast, our model learns what we expect by the aid of auxiliary learning signals, which endows our model with better interpretability.

6 Conclusion

In this paper, we propose to recognize the translated PAST and untranslated FUTURE contents via parts-to-wholes assignment in neural machine translation. We propose the guided dynamic routing, a novel mechanism that explicitly separates source words into PAST and FUTURE guided by PRESENT target decoding status at each decoding step. We empirically demonstrate that such explicit separation of source contents benefit neural machine translation with considerable and consistent improvements on three language pairs. Extensive analysis shows that our approach learns to model the PAST and FUTURE as expected, and alleviates the inadequate translation problem. It is interesting to apply our approach to other sequence-to-sequence tasks, e.g., text summarization (as listed in Appendix).

Abstract

While achieving great fluency, current machine translation (MT) techniques are bottlenecked by adequacy issues. To have a closer study of these issues and accelerate model development, we propose automatic detecting adequacy errors in MT hypothesis for MT model evaluation. To do that, we annotate missing and wrong translations, the two most prevalent issues for current neural machine translation model, in 15000 Chinese-English translation pairs. We build a supervised alignment model for translation error detection (*AlignDet*) based on a simple *Alignment Triangle* strategy to set the benchmark for automatic error detection task. We also discuss the difficulties of this task and the benefits of this task for existing evaluation metrics.

1 Introduction

Different translation errors impact translation comprehensibility and adequacy differently. For example, wrong product or terminology translation can be considered more severe than missing translation in the eCommerce domain. Though many machine translation evaluation (MTE) metrics have been proposed, most of them are not able to provide a direct connection between the score and the error class to emphasize the different impact on translation comprehension and adequacy. Most MTE scores measure the similarity between the MT hypothesis and the reference using n-gram and are useful in providing immediate feedback on model performance for system development and objective evaluation for system comparison. To further analyse the MT hypothesis, fine-grained translation analysis is normally conducted manually which involves expensive human effort (Popović and Ney, 2011; Popović, 2011b; Fishel et al., 2012; Vilar et al., 2006).

This motivates early unsupervised error detection methods (Popović and Ney, 2011). Such methods find the erroneous words by calculating the edit distance between the MT hypothesis and its corresponding reference. However, such unsupervised methods suffer from low accuracy and inability to provide and distinguish certain error classes like *Missing words* and *Wrong translation*[1] (c.f. Sec 3). On the other hand, the works on supervised methods are few due to limited training resources available. The annotated corpus are mainly collected from outputs of Phrase-based Machine Translation systems and usually suffer from small quantity (around 200 instances per language pair) (Fishel et al., 2012), noisy contents (derived from student assignments) (Wisniewski et al., 2014) or overabundant efforts (additional human efforts are required on postediting the MT hypothesis) (Popović and Arcan, 2016), making the progress and development of this task challenging.

We believe a corpus annotated with different translation error classes will facilitate the research on translation error detection. Therefore, we construct a high quality annotated corpus (*TransErr*) comprising 15000 Chinese-English translation pairs with inter-annotator agreement at 0.804 measured by Cohen's Kappa (Cohen, 1960). Different from existing error detection works which focus on all error classes, we currently only take care of missing and wrong translation (Specia et al., 2018), the major errors related to adequacy, which is a wide-known issue in neural machine translation (NMT) (Zheng et al., 2019). The errors tags are annotated on source (Chinese) sentences to reflect the loyalty and adequacy with respect to the source. Based on *TransErr*, we discuss the error distribution of dif-

[1]The *wrong translation* is referred to as *incorrect lexical choice* in (Popović and Ney, 2011)

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 942–952, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ferent systems and challenges of unsupervised error annotations using post-edits.

TransErr enables the study task of supervised MT error detection. We benchmark this task by providing a simple yet efficient model called (*AlignDet*). *AlignDet* is based on our observation of the *Alignment Triangle* whose basic idea is that if a word is well translated, the translated word and the corresponding word in reference should be equivalent. We implement such observation by employing both monolingual and bilingual alignment systems as well as various features. We further provide error analyses of *AlignDet* to give more insight to this task.

To study the application of this task, we further conduct a discussion on the impact of different error classes on MT evaluation metrics based on WMT Chinese–English Direct Assessment (DA) corpus (Bojar et al., 2017). We find that embracing the results of our simple *AlignDet* model in existing MTE metrics helps to achieve significantly better correlation with human. Our further analysis on gold standard error annotation suggests that wrong translation tends to produce worse translation. This discovery gives further credence for the usefulness of our proposed adequacy-oriented error detection task.

In short, the paper is towards carrying out the first systematic study of supervised approaches for error detection, with the goal of accelerating the research and development of MT towards human translation quality. Our systematic contribution lies on annotated data, supervised model and discussions of its potential to help existing machine translation evaluation task. Specifically:

- We propose a task of adequacy-oriented error detection for machine translation evaluation and contribute a high-quality corpus *TransErr* annotated by professional annotators for machine translation. The corpus are available[2].
- We propose an *AlignDet* to set the benchmark of this task based on our key observation of *Alignment Triangle*. As far as we know, this is the first model making use of all three alignments from source, MT hypothesis and reference concurrently.
- We conduct various discussions on the challenges of this task and its potential to help existing machine translation evaluation task.

[2]Please contact us to get the *TranErr* corpus and the *AlignDet* source code. Before that, you need to have access to LDC NIST MT evaluation sets {LDC2005T06, NIST02, NIST03, NIST04, NIST05, NIST08}.

2 Related Work

Existing automatic MTE focus on measuring the similarity between MT hypothesis and references. Various dimensions have been considered, such as lexical level (Papineni et al., 2002; Snover et al., 2009; Lo, 2017; Popović, 2017), syntax level (Owczarzak et al., 2007; Duma and Menzel, 2017; Liu and Gildea, 2005), semantic level (Stanojević and Sima'an, 2015; Shimanaka et al., 2018) and discourse level (Guzmán et al., 2014). However, such methods give an overall score to a system or give a relative ranking to a pair of systems, without any detailed insight of MT system output.

To get the fine-grained insights of the MT model performance, Popović and Ney (2011); Popović et al. (2011a) make the first step towards automatic translation error detection using unsupervised approach by performing monolingual alignment between a MT hypothesis and its corresponding reference through WER (Levenshtein, 1966) and PER (Tillmann et al., 1997). Popović (2011b) further develop this algorithm into an open-source tool and demonstrates that the detected errors helps to build better evaluation metrics. However, the edit distance algorithm is not robust (*c. f.* Sec. 3.2). Zeman et al. (2011) improve the monolingual alignment by borrowing ideas from HMM (Vogel et al., 1996) but the error detection performance is still far from real application. To facilitate this task, Wisniewski et al. (2014) derive corpus of 4,854 source sentences from the assignment of master student specializing on translation but the data turns out to be too noisy.

At the same time, edit distance is carried over to another shared task in WMT (Callison-Burch et al., 2012; Specia et al., 2018; Fan et al., 2018; Vaswani et al., 2017) called word-level Quality Estimation (QE) (Luong et al., 2013; Han et al., 2013; Wisniewski et al., 2014; Kim et al., 2017). In QE tasks, the edit distance is calculated between a MT hypothesis and its post-edits. Word needs to be edited is tagged as `BAD` while the unedited words are tagged as `GOOD`. The task requires participants to predict the label for each word. Although similar to our settings, our error detection

task differs from the word-level QE task in the following aspects:

- The QE task is for confidence estimation (Specia et al., 2010) which estimates whether an output is good for an end user. Our error detection task is for fine-grained evaluation and comparison during model development.
- QE only have `GOOD` and `BAD` tag on the MT hypothesis. It cannot make robust distinction on different error classes due to the intrinsic shortcomings of the edit distance algorithm.
- Existing QE data does not have reliable label on the source sentence to indicate which source word cause the errors (*c.f.* Sec. 3.2), which is claimed as "particularly important to translation adequacy" in WMT 18 (Specia et al., 2018) and WMT 19[3].

3 TranErr Corpus and Analysis

TransErr corpus comprises 15000 triples <source, MT hypothesis, reference> with source sentences extracted from LDC NIST MT evaluation sets {LDC2005T06, NIST02, NIST03, NIST04, NIST05, NIST08}. MT hypothesis is obtained through an NMT engine trained on 25 million Chinese-English parallel sentences. To study the correlation between error detection and human evaluation, we also conduct additional annotation on WMT17 Direct Assessment (DA) dataset containing 560 Chinese-English translation pairs.

Annotation is conducted by two professional translators who specialize on Chinese-English translation. All three information <source, MT hypothesis, reference> are given during annotation. Annotators are instructed to mark on the source the two adequacy related errors (*Missing* & *Wrong*) found in the MT hypothesis and to follow the minimum span principle, i.e. identifying the minimum number of words whose content are not (correctly) conveyed in the MT hypothesis regardless of fluency and grammatical correctness. If a span in the source is incorrectly translated in the MT hypothesis, all words in that span will be marked as *Wrong* (`W`); if totally missing, it will be marked as *Missing* (`M`). Due to the intrinsic difference between the two languages, not all words in the source need to be translated in the MT hypothesis. In this case, we do NOT annotate them as missing. We also have more stringent conditions for proper nouns and terminologies since their translations are more specific and domain dependent. They have to be unerringly correct or otherwise, marked as *Wrong Terminology* (`WT`) or *Missing Terminology* (`MT`[4]). All correctly translated words are automatically assigned a label `OK`.

Annotators are first asked to annotate 100 sentence pairs followed by a discussion among the project team to resolve any disagreement. After 5 such iterations, we start the formal annotation. 10% overlapped instances are given to each annotator for monitoring the inter-annotation agreement (IAA). The disagreed instances are discussed every day. We obtain an overall IAA of 0.804 measured by Cohen's Kappa. The speed for both annotators is about 50 sentence pairs per hour.

3.1 Translation Error Analysis

Table 1 shows the error distribution of *TransErr* and WMT 17 corpus. The corpora have different BLEU with *TransErr* having more missing (`M`) errors and WMT17 more wrong (`W`) errors. As WMT17 contains output from multiple MT systems, we further investigate the errors distributions among the different systems, in particular the output from AFRL and NRC. AFRL and NRC have comparable BLEU but different human evaluation. Error distributions for the two corpora vary quite significantly with AFRL having more `W` errors (45% `W` and 19% `WT`) while NRC has more `M` errors (31% `M` and 31% `MT`). This demonstrates the importance of classifying translation errors and the need for the errors to be considered during evaluation.

3.2 Challenges of Automatic Translation Error Annotation

Though MTE and error detection are two different tasks, they are closely related. Popović and Ney (2011) presented the first framework for automatic analysis and classification of translation errors using unsupervised approach for SMT systems. The work has been evolved to word-level QE task in WMT. Instead of directly annotating errors on the source as in our proposed task, we re-implement

[3] http://www.statmt.org/wmt19/

[4] In this paper, we conventionally use the normal font MT to represent *machine translation* while use the typewriter font `MT` to stand for *Missing Terminology*.

	Human	BLEU	Sen	Word	OK	W	WT	M	MT
TransErr	-	19.1	15000	403691	388372	4529 / 0.29	1694 / 0.11	8234 / 0.54	862 / 0.06
WMT17	-	16.2	560	14090	13025	410 / 0.39	206 / 0.19	320 / 0.30	129 / 0.12
AFRL	-0.016	20.6	34	917	820	44 / 0.45	19 / 0.19	17 / 0.18	17 / 0.18
NRC	0.079	20.3	32	786	698	17 / 0.19	17 / 0.19	27 / 0.31	27 / 0.31

Table 1: Corpus Statistics for *TransErr*, WMT17, AFRL and NRC. AFRL and NRC are subsets of WMT17. Human is the corresponding system-level DA score assigned by human in WMT17. All BLEU are calculated using **one reference**. Sen and Word columns list the number of sentences and words while the other four columns present the number of each error class and its proportion.

Label	OK	W	WT	M	MT
F1	0.93	0.33	0.30	0.43	0.35

Table 2: F1 for each class annotated by the unsupervised method using our manual annotation as gold reference

QE and follow (Popović and Ney, 2011) to derive source annotation through two stages of alignments. The first stage is monolingual alignment between post-edits and MT hypotheses through calculating their edit distance to find missing and wrong translations. The second stage is bilingual alignment using Giza++ (Och and Ney, 2000) on post-edits and the sources to propagate the error labels on the post-edits to the corresponding sources. Similar to our manual annotation, we assign `MT` and `WT` label for terminologies.

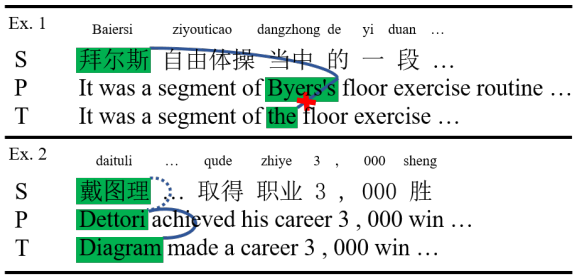

Figure 1: Examples of unsupervised annotation on WMT17. (S), (P) and (T) refer to source, post-edits and MT hypothesis respectively. Solid line indicates correct alignment. Solid line with a red cross refers to wrong alignment while dotted line refers to missing alignment. This convention applies to the whole paper.

To get empirical study, we perform unsupervised annotation on our WMT17 dataset using the above-mentioned method. Table 2 demonstrates its F1 score using the manual annotation as the gold standard. We investigate and summarize the causes in Figure 1:

- The edit distance algorithm is not robust in error class detection since it is purely based on symbolic comparison. (Ex. 1) illustrates a case where *Byers's* is missing. However, TER tool tags it as a substitution of *the* in the MT hypothesis because there is a perfect symbolic alignment before and after the erroneous word. This intrinsic inability to detect missing and wrong translation is also discussed in (Popović and Ney, 2011).

- Giza++ cannot generate reliable alignments for low-frequency words (Riley and Gildea, 2010) and such low-frequency words contribute to a large extent of erroneous words. These misalignments propagate from the post-edits to the source sentence and lead to incorrect error tags. (Ex. 2) gives an example, the *Dettori* should be aligned to *daituli* but was not aligned to any word by GIZA++. This leads to an incorrect `OK` tag in the source sentence.

As such, unsupervised error annotation presents many challenges even leveraging on post-edits. Hence a set of more reliable annotated data will be able to contribute much to the error detection task.

4 AlignDet Model

To revive fine-grained translation error detection, we propose *AlignDet*, a supervised feature-based solution using *TransErr* to set the benchmark for this task. We discuss our *Alignment Triangle* observation and briefly list the features we used. In the subsequent discussions, we denote s_i, t_j and r_k as the ith, jth and kth word in a source sequence S, MT hypothesis T and reference R separately.

4.1 Alignment Triangle Observation

In translation, adequacy can be simply defined as all contents in the source are reproduced correctly

Figure 2: Four samples from *TransErr*. For each example, we show the source (S), MT hypothesis (T), reference (R).

in the MT hypothesis. As long as the MT hypothesis and the reference are semantically equivalent, such reproduction may not require the MT hypothesis and the reference to be exactly identical. This motivates us to analyze the translation t_j in T and r_k in R for the same s_i in S[5], in the following error detection scenarios. We refer t_j and r_k for the same s_i as translation correspondence.

Pattern1: s_i has translation correspondence t_j and r_k. It should be labeled as `OK` if t_j and r_k are semantically equivalent; otherwise, it should be labeled as `W`. For example, in (Ex. 3) from Figure 2, the two words, *swap* and *exchange*, are equivalent in the given context, which should be marked as `OK`. However, compared to (Ex. 6), *students* and *comers* are not equivalent in the given context, although they may be equivalent in higher abstraction, hence it is annotated as `W`.

Pattern2: s_i does not have translation correspondence r_k. Assuming *R* does not have any adequacy issue, this would imply that s_i does not need to be explicitly translated. In this case, the omission of t_j is an `OK` translation. However, if it is explicitly translated in *T* as t_j, we will still accept it as an `OK` translation though it may cause minor redundancy issue and we assume that it will not harm adequacy. For example, either explicitly translation *meiguo* to *USA* or not in (Ex. 4) should be fine.

Pattern3: s_i has translation correspondence r_k but not t_j. This implies that translation of s_i is missing and should be translated. A `M` label will be given in this case. (Ex. 5) shows an example of this. *jinzhu* does not have t_j but it is necessary for it to be translated as the translation correspondence is presence in *R* as r_k.

The same rationale also applies to terminologies, except that they are marked with `MT` or `WT` and have to be unerringly translated for them to be marked as `OK`. For the other cases not illustrated above, we assume that they are either not happening or do not affect the adequacy of the translation.

4.2 Features and Model

To capture the above observation, we build two sets of features, one for finding the corresponding translation t_j and r_k for each s_i, the other for checking the equivalence of t_j and r_k. Here, we only briefly list the features adopted in our model as they are all commonly used standard features. We give detailed description of all features in Appendix A.1.

Giza++ (Och and Ney, 2000) is used to find the corresponding translation t_j and r_k for each s_i. However, as Giza++ generates noisy alignments especially for low-frequency words, we propose a set of features to complement Giza++ results. The same features are applied on T and R, hence we only describe the feature for the alignment between S and T. Suppose that s_i is aligned to t_j[6]. These features are: s_i's POS tag; a binary feature of whether NER tags of s_i and t_j are the same; the corpus frequency and Giza++ translation probability of s_i and t_j; the similarity between t_j and s_i's most frequent translation; the number of aligned-pairs among words linking to s_i and t_j in dependency tree.

We leverage on the state-of-the-art monolingual alignment tool Sultan et al. (2014) to check the equivalence of t_j and r_k. The tool leverages on paraphrase lexicon (Pavlick et al., 2015) and dependency relations to find equivalent expression between two sentences in the same language. The following features are used: a binary feature indicating whether t_j and r_k are aligned by tool proposed by (Sultan et al., 2014); A binary feature indicating whether the NER tag of t_j and r_k are the same.

While this error detection problem can be modeled as sequential labelling task, we choose simple classification model as the benchmark. Therefore,

[5]Generally, t_j, r_k and s_i can be multi-word expression. For the ease of explanation for our feature extraction method, we describe each of them as a single word.

[6]Following Hu et al. (2018), we make adjustment by penalizing the frequency of both words.

we use an Mutilayer Perceptron (MLP) as the detection model which takes all above features in for each source word s_i to choose one of the labels in {OK, W, WT, M, MT} as the prediction.

5 Experiments

We conduct empirical experiments to evaluate the effectiveness of our error detection model, perform error analysis and discuss the challenges of this task. We split our *TransErr* dataset into training and developing sets in a ratio of 9:1 and adopt the whole WMT DA dataset as the testing set. Error detection results are reported in single-class F1. All Chinese sentences are tokenized by THULAC (Li and Sun, 2009).The rest of the pre-processings like POS, NER, parsing for both English and Chinese are performed by Stanford Corenlp (Manning et al., 2014).

5.1 Baselines

We build a naive baseline, random model, to test the worst performance. It randomly assigns a label to each source word according to the distribution of each class in the training set. We then evaluate the performance of our proposed MLP model (*AlignDet*) and two recent models under WMT word-level QE shared-task:

· **CEQE** (Hu et al., 2018) Using a three-part neural network model, which encodes semantic factors, local context and global context successively.

· **SHEF-bRNN** (Ive et al., 2018) Adopting bi-directional recurrent neural network to learn a representation for <source, MT hypothesis> sentence pairs.

We replicate these two models utilizing original implementations but modify them to work in our 5-label setting.[7] We also analyze our proposed model and its variant by ablating or substituting its components

· **Raw alignment** Using only the raw results from the monolingual and bilingual alignment systems and NER on the source to examine the effect of alignment on the model.

· **No reference** We remove all features derived from the reference, for example, bilingual alignment features between S and R, and monolingual alignment features between T and R. This is to test the efficacy of using only source information for translation performance evaluation.

[7]We also tried QEBrain (Fan et al., 2018; Wang et al., 2018) using the released code. However, it did not converge to any meaningful predictions.

5.2 Error Detection Results

Table 3 shows our error detection results on the developing set and test set. Our random baseline (Row (1)) provides a preliminary insight for this error detection problem, with extremely low F1 scores (nearly 0) except for the OK class. It is because errors are scarcely distributed (see Table 1). In addition, the QE models (Row 2, 3) do not perform well in error classification. This is reasonable because they are not designed for error detection in our setting. The overall better performance of our *AlignDet* model supports that our *Alignment Triangle* Observation and its contribution to the error detection task.

However, with raw alignment (Row 4 vs Row 5), the performance of *AlignDet* drops sharply. It is because the alignment model, especially Giza++, generates noisy results. This demonstrates the efficacy of other features in rectifying Giza++ results. The comparison between Row (4) and Row (6) also demonstrates the importance of reference, especially for detecting W label. It is because wrong translation is also likely to get aligned with the source as it can be the translation of the source words in some other contexts. However, reference gives us a pointer to the correct word choice in the given context, hence helping determining W label. Without reference, we may need to rely on more contextual modeling effort to detect a wrong translation.

5.3 Error Analysis

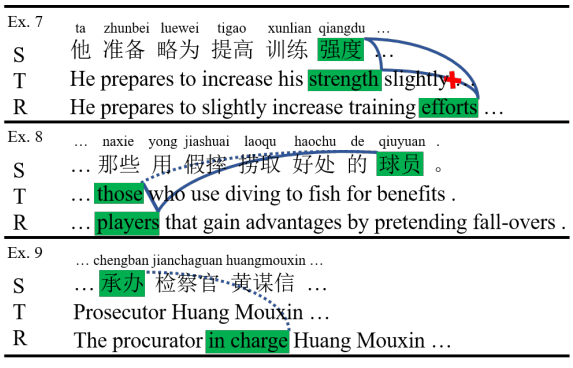

Figure 3: Representative examples of the confusion cases for *AlignDet*.

To get more insight into the difficulty of this task, we perform error analysis on *AlignDet*. We only examine the confusion matrix on test set due to the limitation of space in Table 4. It shows that the significant problems are: (a) Predict W as OK

	Developing					Testing				
	OK	W	WT	M	MT	OK	W	WT	M	MT
(1) Random baseline	0.959	0.009	0.013	0.020	0.027	0.947	0.025	0.029	0.041	0.017
(2) CEQE	0.944	0.134	0.180	0.245	0.161	0.914	0.161	0.147	0.206	0.094
(3) SHEF-bRNN	0.916	0.140	0.212	0.127	0.262	0.884	0.153	0.123	0.098	0.114
(4) AlignDet	**0.973**	**0.275**	**0.480**	**0.416**	**0.365**	**0.964**	**0.212**	**0.293**	**0.400**	**0.429**
(5) Raw alignment	0.762	0.051	0.049	0.168	0.114	0.781	0.131	0.131	0.263	0.328
(6) No reference	0.977	0.040	0.448	0.289	0.289	0.962	0.075	0.213	0.360	0.378

Table 3: F1 score for each class produced by different error detection models.

Gold \ Pred.	OK	W	WT	M	MT
OK	12635	203	68	106	13
W	279	83	3	40	5
WT	109	28	54	9	6
M	121	54	12	122	11
MT	26	12	31	16	44

Table 4: Confusion matrix on test set.

(b) Predict OK as M (c) Predict M as OK. We illustrate the wrong prediction in Figure 3.

(Ex. 7) demonstrates a case for "W as OK". Both *strength* (the wrong translation in T) and *efforts* (the correct translation in R) are aligned to the source word *qiangdu* by Giza++. Though both of them are possible translations for *qiangdu*, they are not semantically equivalent in this context. Unfortunately, monolingual alignment tool aligns them as a pair, hence a more contextual and semantically-sensitive monolingual alignment is required. (Ex. 8) demonstrates a case for "OK as M". In T, *qiuyuan* is translated to *those* and is not detected by our bilingual alignment. This leads the model to treat it as not been translated. This example demonstrates the constraint of bilingual alignment in finding the translation correspondence, which would require contextual-level understanding. (Ex. 9) demonstrates a case for "M as OK". Similar to (Ex. 8), the mis-prediction is caused by the failure of bilingual alignment (between *chengban* in S and *in charge* in R). Our model regards *chengban* as omittable as bilingual alignment fails to align it to *in charge* in R. As a result, though *chengban* is translated in R but not translated in T, we classify it as OK instead of M. This example again demonstrates the important of alignment in error detection task.

Our qualitative error analyses highlight the bottleneck of *AlignDet* model on the proposed alignment features. In a broader context, both bilingual alignment and monolingual alignment are still having open issues in the realm of NLP (Sultan et al., 2014). An intuitive solution is turning to soft alignment (e.g., attention) using neural techniques (Liu and Sun, 2015; Tamura et al., 2014). This raises interesting and challenging questions on how to leverage on such approaches to capture our observations in finding corresponding translations t_j and r_k for each s_i and comparing their equivalence? Neural models usually require large data and how to leverage on limited error annotation data (say, 15000 sentence pairs) and large parallel corpus for such purpose?

6 Discussion: How Does Error Class Affect Existing MT Evaluation Metrics?

This paper proposes an adequacy translation error detection model with the aim to study its contribution to MT. We presume that fine grained MT evaluation is useful for assessing different properties of MT models. Hence, we go one step further to discuss how fine-grained error detection benefits existing MT evaluation metrics using DA as the base for our evaluation.

To explore further, we define a Weight Adequacy Error Rate (WAER) following TER (Snover et al., 2006):

$$\texttt{WAER} = \frac{w_1\#\texttt{W} + w_2\#\texttt{WT} + w_3\#\texttt{M} + w_4\#\texttt{MT}}{\texttt{Len(S)}} \quad (1)$$

where #W, #WT, #M, #MT are the number of wrong words, wrong terminologies, missing words, missing terminologies respectively; w_1, w_2, w_3, w_4 are corresponding weight for each error class, indicating its importance. Len(S) is the source sentence length.

With only missing and wrong error class, WAER is not sufficient to serve as an independent eval-

	Base	+ pred.	+ gold.
BLEU	0.482	0.524	0.541
METEOR	0.638	0.673	0.709
ROUGE-L	0.582	0.645	0.699
BEER	0.582	0.640	0.681
CUNI-TreeAggreg	0.535	0.625	0.670
MEANT_2.0	0.639	0.641	0.680
MEANT_2.0-nosrl	0.630	0.633	0.672
UHH_TSKM	0.477	0.600	0.657

CHRF	0.591	0.641	0.685
CHRF++	0.593	0.644	0.690
NGRAM2VEC	0.520	0.576	0.607
Ave	0.573	0.622	0.662

Table 5: Segment-level Pearson correlation of various metrics and their enhancements with our $WAER$ measure through (Eq. 2). + pred./+gold means $WAER$ is calculated by our error detection model predicted results/gold standard as per se.

uation metric. As a common practice in BLEU and METEOR, we view WAER as a penalty to base metrics, which we refer as Score, and calculate the penalized score as follow:

$$\widetilde{\texttt{Score}} = \texttt{Score} * (1 - \texttt{WAER}) \quad (2)$$

To determine w_1, w_2, w_3, w_4, we build a development set of 300 instances, sampled from our *TransErr*, with overall translation quality scored by multiple judges who are professional at both English and Chinese. To avoid bias, our error annotators of *TransErr* are excluded from this scoring. We adjust w_1, w_2, w_3, w_4 in this development set based on our gold annotation, such that the enhanced metrics achieves highest correlation with the average human score.

We examine three benchmark metrics (BLEU, METEOR, ROUGE) and the recent metrics submitted to WMT17: BEER (Stanojević and Sima'an, 2015), CUNI-TreeAggreg (Mareček et al., 2017), MEANT_2.0, MEANT_2.0-nosrl (Lo, 2017), UHH_TSKM (Duma and Menzel, 2017), NGRAM2VEC, BLEU2VEC_sep (Tättar and Fishel, 2017), CHRF (Popović, 2015), CHRF++ (Popović, 2017). We test their performance on WMT 17 DA dataset. The results are in Table 5. WAER is calculated by both system prediction results and the gold standard. We observe that, with our error prediction, WAER is able to enhance almost all metrics substantially (+0.049 on average). When calculating WAER using the gold standard, the performance is even higher (+0.089 on average). This demonstrates the efficacy of error detection for enhancing existing direct assessment metrics. Note that, we do not conclude that our WAER (Eq. 1) and the way of enhancing existing Score (Eq. 2) is optimal in terms of achieving better correlations with human judgment. We also want to find out which error class affects the overall translation quality more. Therefore, we study how the enhanced metrics correlate to human judgment when the weight of a single class of error changes. The trend is shown in Figure 4 where y-axis is the average correlation of all metrics enhanced by WAER on gold standard. X-axis is the weight of the observed error class. To eliminate the contribution made by other error classes, weights of other error classes are set to 0. From Figure 4, one can observe that wrong related error (W and WT) can help existing metrics achieve higher correlation to human judgment than missing-related error (M and MT). This suggests wrong translation is more severe than missing word. This provides valuable feedback on the advancement of evaluation metric towards human evaluation. Similarly, one can also observe that adequacy issue on terminologies is more severe than normal words and term-related errors need higher weights to achieve highest correlation. Accurate translation of terminology is an issue in neural machine translation if its occurrence is low in the training data. Accurate translation of terminology may be an area that warrens more work.

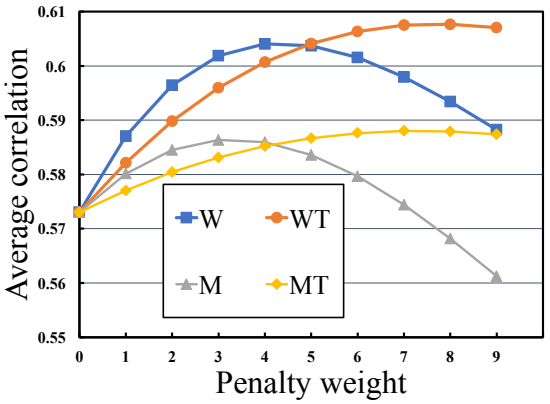

Figure 4: Correlation with respect to each error class.

7 Conclusion

In this paper, we revive the problem of error detection task for fine-grained machine translation

evaluation purpose. We contribute a high-quality dataset *TransErr* with *Missing* and *Wrong* translation manually annotated by professional translators to enable the development of supervised methods. Based on *TransErr*, we benchmark this task by proposing a strong baseline, i.e., *AlignDet* model, based on our *Alignment Triangle* observation. We also conduct various discussions about this task such as the challenges of unsupervised methods for error annotation, the bottleneck of *AlignDet* model and the potential benefits of the error detection task for existing MT evaluation metrics task.

This work represents the preliminary work for more multi-faceted machine translation evaluation, focusing on multiple aspects instead of only a score or ranking, with the goal of push MT techniques to a higher standard. However, there are areas for further exploration. In the future, we will explore more advanced techniques such as neural networks for error detection. We will also investigate how to make better evaluation metrics with the help of error detection. We will also study how to improve machine translation model through error detection. For example, how to improve MT models according to different class of errors.

Abstract

Although neural machine translation (NMT) has advanced the state-of-the-art on various language pairs, the interpretability of NMT remains unsatisfactory. In this work, we propose to address this gap by focusing on understanding the input-output behavior of NMT models. Specifically, we measure the word importance by attributing the NMT output to every input word through a gradient-based method. We validate the approach on a couple of perturbation operations, language pairs, and model architectures, demonstrating its superiority on identifying input words with higher influence on translation performance. Encouragingly, the calculated importance can serve as indicators of input words that are under-translated by NMT models. Furthermore, our analysis reveals that words of certain syntactic categories have higher importance while the categories vary across language pairs, which can inspire better design principles of NMT architectures for multi-lingual translation.

1 Introduction

Neural machine translation (NMT) has achieved the state-of-the-art results on a mass of language pairs with varying structural differences, such as English-French (Bahdanau et al., 2014; Vaswani et al., 2017) and Chinese-English (Hassan et al., 2018). However, so far not much is known about how and why NMT works, which pose great challenges for debugging NMT models and designing optimal architectures.

The understanding of NMT models has been approached primarily from two complementary perspectives. The first thread of work aims to understand the importance of representations by analyzing the linguistic information embedded in representation vectors (Shi et al., 2016; Belinkov et al., 2017) or hidden units (Bau et al., 2019; Ding et al., 2017). Another direction focuses on understanding the importance of input words by interpreting the input-output behavior of NMT models. Previous work (Alvarez-Melis and Jaakkola, 2017) treats NMT models as black-boxes and provides explanations that closely resemble the attention scores in NMT models. However, recent studies reveal that attention does not provide meaningful explanations since the relationship between attention scores and model output is unclear (Jain and Wallace, 2019).

In this paper, we focus on the second thread and try to open the black-box by exploiting the gradients in NMT generation, which aims to estimate the word importance better. Specifically, we employ the *integrated gradients* method (Sundararajan et al., 2017) to attribute the output to the input words with the integration of first-order derivatives. We justify the gradient-based approach via quantitative comparison with black-box methods on a couple of perturbation operations, several language pairs, and two representative model architectures, demonstrating its superiority on estimating word importance.

We analyze the linguistic behaviors of words with the importance and show its potential to improve NMT models. First, we leverage the word importance to identify input words that are under-translated by NMT models. Experimental results show that the gradient-based approach outperforms both the best black-box method and other comparative methods. Second, we analyze the linguistic roles of identified important words, and find that words of certain syntactic categories have higher importance while the categories vary across language. For example, nouns are more important for Chinese⇒English translation, while prepositions are more important for English-French and -Japanese translation. This finding can inspire bet-

ter design principles of NMT architectures for different language pairs. For instance, a better architecture for a given language pair should consider its own language characteristics.

Contributions Our main contributions are:

- Our study demonstrates the necessity and effectiveness of exploiting the intermediate gradients for estimating word importance.
- We find that word importance is useful for understanding NMT by identifying under-translated words.
- We provide empirical support for the design principle of NMT architectures: essential inductive bias (e.g., language characteristics) should be considered for model design.

2 Related Work

Interpreting Seq2Seq Models Interpretability of Seq2Seq models has recently been explored mainly from two perspectives: interpreting internal representations and understanding input-output behaviors. Most of the existing work focus on the former thread, which analyzes the linguistic information embeded in the learned representations (Shi et al., 2016; Belinkov et al., 2017; Yang et al., 2019) or the hidden units (Ding et al., 2017; Bau et al., 2019). Several researchers turn to expose systematic differences between human and NMT translations (Läubli et al., 2018; Schwarzenberg et al., 2019), indicating the linguistic properties worthy of investigating. However, the learned representations may depend on the model implementation, which potentially limit the applicability of these methods to a broader range of model architectures. Accordingly, we focus on understanding the input-output behaviors, and validate on different architectures to demonstrate the universality of our findings.

Concerning interpreting the input-output behavior, previous work generally treats Seq2Seq models as black-boxes (Li et al., 2016; Alvarez-Melis and Jaakkola, 2017). For example, Alvarez-Melis and Jaakkola (2017) measure the relevance between two input-output tokens by perturbing the input sequence. However, they do not exploit any intermediate information such as gradients, and the relevance score only resembles attention scores. Recently, Jain and Wallace (2019) show that attention scores are in weak correlation with the feature importance. Starting from this observation, we exploit the intermediate gradients to better estimate word importance, which consistently outperforms its attention counterpart across model architectures and language pairs.

Exploiting Gradients for Model Interpretation The intermediate gradients have proven to be useful in interpreting deep learning models, such as NLP models (Mudrakarta et al., 2018; Dhamdhere et al., 2019) and computer vision models (Selvaraju et al., 2017; Sundararajan et al., 2017). Among all gradient-based approaches, the integrated gradients (IG, Sundararajan et al., 2017) is appealing since it does not need any instrumentation of the architecture and can be computed easily by calling gradient operations. In this work, we employ the IG method to interpret NMT models and reveal several interesting findings, which can potentially help debug NMT models and design better architectures for specific language pairs.

3 Approach

3.1 Neural Machine Translation

In machine translation task, a NMT model F: $\mathbf{x} \rightarrow \mathbf{y}$ maximizes the probability of a target sequence $\mathbf{y} = \{y_1, ..., y_N\}$ given a source sentence $\mathbf{x} = \{x_1, ..., x_M\}$:

$$P(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta}) = \prod_{n=1}^{N} P(y_n|\mathbf{y}_{<n}, \mathbf{x}; \boldsymbol{\theta})$$

where $\boldsymbol{\theta}$ is the model parameter and $\mathbf{y}_{<n}$ is a partial translation. At each time step n, the model generates an output word of the highest probability based on the source sentence $\mathbf{x}$ and the partial translation $\mathbf{y}_{<n}$. The training objective is to minimize the negative log-likelihood loss on the training corpus. During the inference, beam search is employed to decode a more optimal translation. In this study, we investigate the contribution of each input word x_m to the translated sentence $\mathbf{y}$.

3.2 Word Importance

In this work, the notion of "word importance" is employed to quantify the contribution that a word in the input sentence makes to the NMT generations. We categorize the methods of word importance estimation into two types: *black-box* methods without the knowledge of the model and *white-box* methods that have access to the model

internal information (e.g., parameters and gradients). Previous studies mostly fall into the former type, and in this study, we investigate several representative black-box methods:

- *Content Words*: In linguistics, all words can be categorized as either content or content-free words. Content words consist mostly of nouns, verbs, and adjectives, which carry descriptive meanings of the sentence and thereby are often considered as important.

- *Frequent Words*: We rank the relative importance of input words according to their frequency in the training corpus. We do not consider the top 50 most frequent words since they are mostly punctuation and stop words.

- *Causal Model* (Alvarez-Melis and Jaakkola, 2017): Since the causal model is complicated to implement and its scores closely resemble attention scores in NMT models. In this study, we use *Attention* scores to simulate the causal model.

Our approach belongs to the white-box category by exploiting the intermediate gradients, which will be described in the next section.

3.3 Integrated Gradients

In this work, we resort to a gradient-based method, integrated gradients (Sundararajan et al., 2017) (IG), which was originally proposed to attribute the model predictions to input features. It exploits the handy model gradient information by integrating first-order derivatives. IG is implementation invariant and does not require neural models to be differentiable or smooth, thereby is suitable for complex neural networks like Transformer. In this work, we use IG to estimate the word importance in an input sentence precisely.

Formally, let $\mathbf{x} = (x_1, ..., x_M)$ be the input sentence and $\mathbf{x}'$ be a baseline input. F is a well-trained NMT model, and $F(\mathbf{x})_n$ is the model output (i.e., $P(y_n|\mathbf{y}_{<n}, \mathbf{x})$) at time step n. Integrated gradients is then defined as the integral of gradients along the straightline path from the baseline $\mathbf{x}'$ to the input $\mathbf{x}$. In detail, the contribution of the m^{th} word in $\mathbf{x}$ to the prediction of $F(\mathbf{x})_n$ is defined as follows.

$$IG^n_m(\mathbf{x}) = (\mathbf{x}_m - \mathbf{x}'_m) \int_{\alpha=0}^{1} \frac{\partial F(\mathbf{x}' + \alpha(\mathbf{x} - \mathbf{x}'))_n}{\partial \mathbf{x}_m} \mathrm{d}\alpha$$

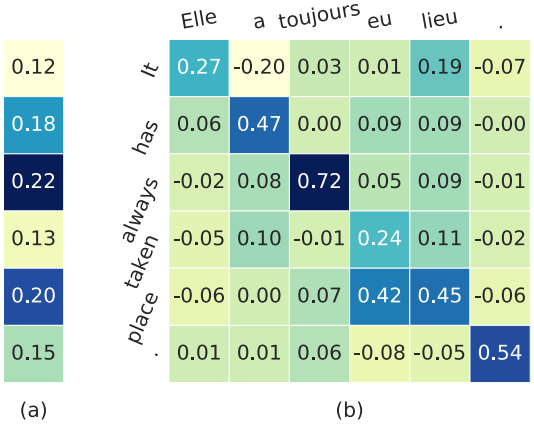

Figure 1: An example of (a) word importance and (b) contribution matrix calculated by *Attribution* (integrated gradients) on English⇒French translation task. Input in English: "It has always taken place ." Output in French: "Elle a toujours eu lieu ."

where $\frac{\partial F(\mathbf{x})_n}{\partial \mathbf{x}_m}$ is the gradient of $F(\mathbf{x})_n$ w.r.t. the embedding of the m^{th} word. In this paper, as suggested, the baseline input $\mathbf{x}'$ is set as a sequence of zero embeddings that has the same sequence length M. In this way, we can compute the contribution of a specific input word to a designated output word. Since the above formula is intractable for deep neural models, we approximate it by summing the gradients along a multi-step path from baseline $\mathbf{x}'$ to the input $\mathbf{x}$.

$$IG^n_m(\mathbf{x}) = \frac{(\mathbf{x}_m - \mathbf{x}'_m)}{S} \sum_{k=0}^{S} \frac{\partial F(\mathbf{x}' + \frac{k}{S}(\mathbf{x} - \mathbf{x}'))_n}{\partial \mathbf{x}_m}$$

where S denotes the number of steps that are uniformly distributed along the path. The IG will be more accurate if a larger S is used. In our preliminary experiments, we varied the steps and found 300 steps yielding fairly good performance.

Following the formula, we can calculate the contribution of every input word makes to every output word, forming a contribution matrix of size $M \times N$, where N is the output sentence length. Given the contribution matrix, we can obtain the *word importance* of each input word to the entire output sentence. To this end, for each input word, we first aggregate its contribution values to all output words by the *sum* operation, and then normalize all sums through the *Softmax* function. Figure 1 illustrates an example of the calculated word importance and the contribution matrix, where an English sentence is translated into a French sentence using the Transformer model. A negative

contribution value indicates that the input word has negative effects on the output word.

4 Experiment

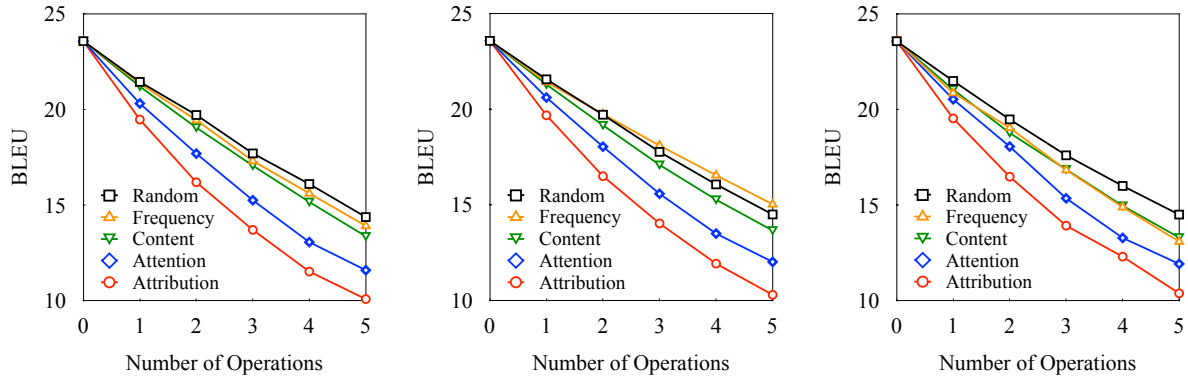
Data To make the conclusion convincing, we first choose two large-scale datasets that are publicly available, i.e., Chinese-English and English-French. Since English, French, and Chinese all belong to the subject-verb-object (SVO) family, we choose another very different subject-object-verb (SOV) language, Japanese, which might bring some interesting linguistic behaviors in English-Japanese translation.

For Chinese-English task, we use WMT17 Chinese-English dataset that consists of 20.6M sentence pairs. For English-French task, we use WMT14 English-French dataset that comprises 35.5M sentence pairs. For English-Japanese task, we follow (Morishita et al., 2017) to use the first two sections of WAT17 English-Japanese dataset that consists of 1.9M sentence pairs. Following the standard NMT procedure, we adopt the standard byte pair encoding (BPE) (Sennrich et al., 2016) with 32K merge operations for all language pairs. We believe that these datasets are large enough to confirm the rationality and validity of our experimental analyses.

Implementation We choose the state-of-the-art Transformer (Vaswani et al., 2017) model and the conventional RNN-Search model (Bahdanau et al., 2014) as our test bed. We implement the *Attribution* method based on the Fairseq-py (Gehring et al., 2017) framework for the above models. All models are trained on the training corpus for 100k steps under the standard settings, which achieve comparable translation results. All the following experiments are conducted on the test dataset, and we estimate the input word importance using the model generated hypotheses.

In the following experiments, we compare IG (*Attribution*) with several black-box methods (i.e., *Content*, *Frequency*, *Attention*) as introduced in Section 3.2. In Section 4.1, to ensure that the translation performance decrease attributes to the selected words instead of the perturbation operations, we randomly select the same number of words to perturb (*Random*), which serves as a baseline. Since there is no ranking for content words, we randomly select a set of content words as important words. To avoid the potential bias introduced by randomness (i.e., *Random* and *Content*), we repeat the experiments for 10 times and report the averaged results. We calculate the *Attention* importance in a similar manner as the *Attribution*, except that the attention scores use a *max* operation due to the better performance.

Evaluation We evaluate the effectiveness of estimating word importance by the translation performance decrease. More specifically, unlike the usual way, we measure the decrease of translation performance when perturbing a set of important words that are of top-most word importance in a sentence. The more translation performance degrades, the more important the word is.



We use the standard BLEU score as the evaluation metric for translation performance. To make the conclusion more convincing, we conduct experiments on different types of synthetic perturbations (Section 4.1), as well as different NMT architectures and language pairs (Section 4.2). In addition, we compare with a supervised erasure method, which requires ground-truth translations for scoring word importance (Section 4.3).

4.1 Results on Different Perturbations

In this experiment, we investigate the effectiveness of word importance estimation methods under different synthetic perturbations. Since the perturbation on text is notoriously hard (Zhang et al., 2019) due to the semantic shifting problem, in this experiment, we investigate three types of perturbations to avoid the potential bias :

- *Deletion* perturbation removes the selected words from the input sentence, and it can be regarded as a specific instantiation of sentence compression (Cohn and Lapata, 2008).
- *Mask* perturbation replaces embedding vectors of the selected words with all-zero vectors (Arras et al., 2016), which is similar to *Deletion* perturbation except that it retains the placeholder.
- *Grammatical Replacement* perturbation replaces a word by another word of the same linguistic role (i.e., POS tags), yielding a sentence that is grammatically correct but semantically nonsensical (Chomsky and Lightfoot, 2002; Gulordava et al., 2018), such as "*colorless green ideas sleep furiously*".

Figure 2 illustrates the experimental results on Chinese⇒English translation with Transformer. It

(a) **Deletion** (b) **Mask** (c) **Grammatical Replacement**

Figure 2: Effect of three types of synthetic perturbations on Chinese⇒English translation using the Transformer.

shows that *Attribution* method consistently outperforms other methods against different perturbations on a various number of operations. Here the operation number denotes the number of perturbed words in a sentence. Specifically, we can make the following observations.

Important words are more influential on translation performance than the others. Under three different perturbations, perturbing words of top-most importance leads to lower BLEU scores than *Random* selected words. It confirms the existence of important words, which have greater impacts on translation performance. Furthermore, perturbing important words identified by *Attribution* outperforms the *Random* method by a large margin (more than 4.0 BLEU under 5 operations).

The gradient-based method is superior to comparative methods (e.g., Attention) in estimating word importance. Figure 2 shows that two *black-box* methods (i.e., *Content*, *Frequency*) perform only slightly better than the *Random* method. Specifically, the *Frequency* method demonstrates even worse performances under the *Mask* perturbation. Therefore, linguistic properties (such as POS tags) and the word frequency can only partially help identify the important words, but it is not as accurate as we thought. In the meanwhile, it is intriguing to explore what exact linguistic characteristics these important words reveal, which will be introduced in Section 5.

We also evaluate the *Attention* method, which bases on the encoder-decoder attention scores at the last layer of Transformer. Note that the *Attention* method is also used to simulate the best *black-box* method SOCRAT, and the results show that it is more effective than *black-box* methods and the *Random* baseline. Given the powerful *Attention* method, *Attribution* method still achieves best performances under all three perturbations. Furthermore, we find that the gap between *Attribution* and *Attention* is notably large (around 1.0+ BLEU difference). *Attention* method does not provide as accurate word importance as the *Attribution*, which exhibits the superiority of gradient-based methods and consists with the conclusion reported in the previous study (Jain and Wallace, 2019).

In addition, as shown in Figure 2, the perturbation effectiveness of *Deletion*, *Mask*, and *Grammatical Replacement* varies from strong to weak. In the following experiments, we choose *Mask* as the representative perturbation operation for its moderate perturbation performance, based on which we compare two most effective methods *Attribution* and *Attention*.

4.2 Results on Different NMT Architecture and Language Pairs

Different NMT Architecture We validate the effectiveness of the proposed approach using a different NMT architecture RNN-Search on the Chinese⇒English translation task. The results are shown in Figure 3(a). We observe that the *Attribution* method still outperforms both *Attention* method and *Random* method by a decent margin. By comparing to Transformer, the results also reveal that the RNN-Search model is less robust to these perturbations. To be specific, under the setting of five operations and *Attribution* method, Transformer shows a relative decrease of 55% on BLEU scores while the decline of RNN-Search model is 64%.

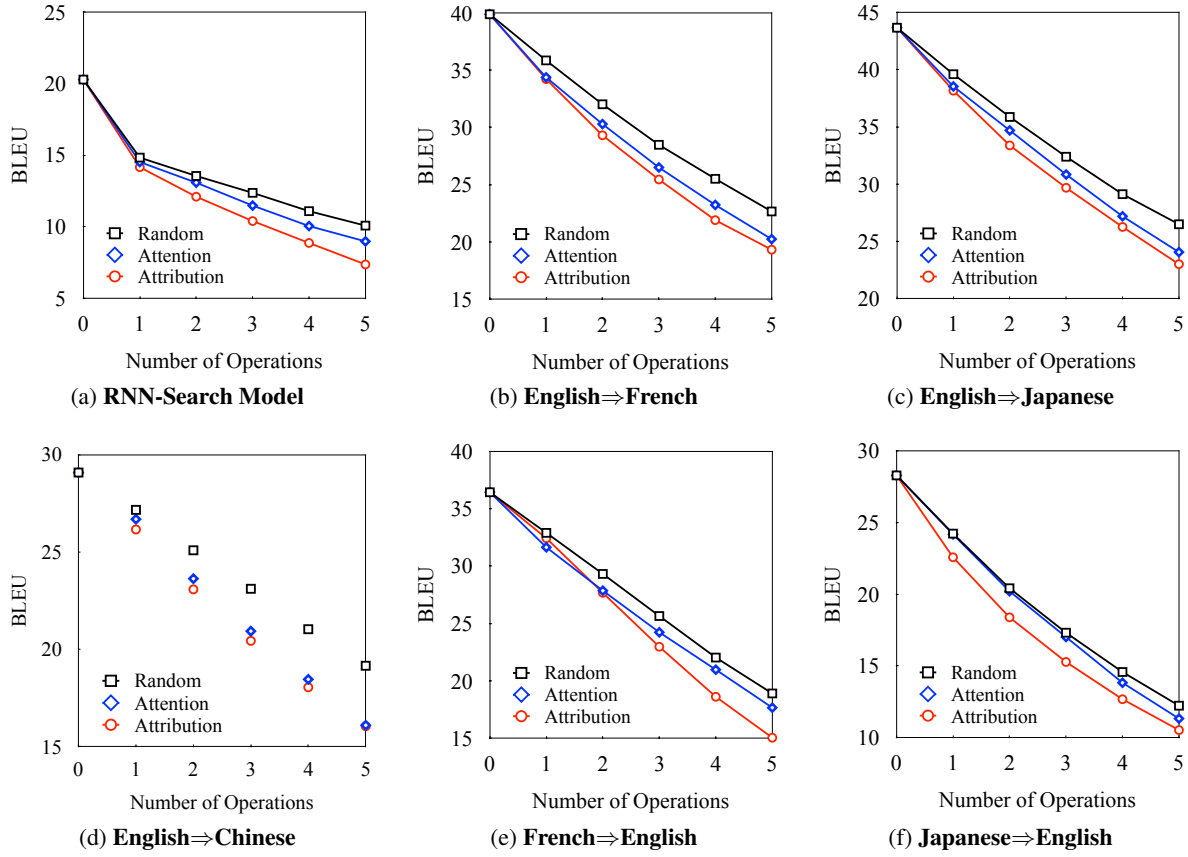


Figure 3: Effect of the *Mask* perturbation on (a) Chinese⇒English translation using the RNN-Search model, (b, c, d, e, f) other language pairs and directions using Transformer model.

Different Language Pairs and Directions We further conduct experiments on another two language pairs (i.e., English⇒French, English⇒Japanese in Figures 3(b, c)) as well as the reverse directions (Figures 3(d, e, f)) using Transformer under the *Mask* perturbation. In all the cases, *Attribution* shows the best performance while *Random* achieves the worst result. More specifically, *Attribution* method shows similar translation quality degradation on all three language-pairs, which declines to around the half of the original BLEU score with five operations.

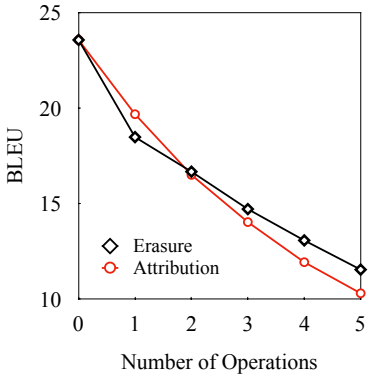

Figure 4: Effect of *Attribution* and *Erasure* methods on Chinese⇒English translation with *Mask* perturbation.

4.3 Comparison with Supervised Erasure

There exists another straightforward method, *Erasure* (Alvarez-Melis and Jaakkola, 2017; Arras et al., 2016; Zintgraf et al., 2017), which directly evaluates the word importance by measuring the translation performance degradation of each word. Specifically, it erases (i.e., *Mask*) one word from the input sentence each time and uses the BLEU score changes to denote the word importance (after normalization).

In Figure 4, we compare *Erasure* method with *Attribution* method under the *Mask* perturbation. The results show that *Attribution* method is less effective than *Erasure* method when only one word is perturbed. But it outperforms the *Erasure* method when perturbing 2 or more words. The results reveal that the importance calculated by erasing only one word cannot be generalized to multiple-words scenarios very well. Besides, the

Method	Top 5%	Top 10%	Top 15%
Attention	0.058	0.077	0.119
Erasure	0.154	0.170	0.192
Attribution	**0.248**	**0.316**	**0.342**

Table 1: F1 accuracy of detecting under-translation errors with the estimated word importance.

Erasure method is a supervised method which requires ground-truth references, and finding a better words combination is computation infeasible when erasing multiple words.

We close this section by pointing out that our gradient-based method consistently outperforms its black-box counterparts in various settings, demonstrating the effectiveness and universality of exploiting gradients for estimating word importance. In addition, our approach is on par with or even outperforms the supervised erasure method (on multiple-word perturbations). This is encouraging since our approach does not require any external resource and is fully unsupervised.

5 Analysis

In this section, we conduct analyses on two potential usages of word importance, which can help debug NMT models (Section 5.1) and design better architectures for specific languages (Section 5.2). Due to the space limitation, we only analyze the results of Chinese⇒English, English⇒French, and English⇒Japanese. We list the results on the reverse directions in Appendix, in which the general conclusions also hold.

5.1 Effect on Detecting Translation Errors

In this experiment, we propose to use the estimated word importance to detect the under-translated words by NMT models. Intuitively, under-translated input words should contribute little to the NMT outputs, yielding much smaller word importance. Given 500 Chinese⇒English sentence pairs translated by the Transformer model (BLEU 23.57), we ask ten human annotators to manually label the under-translated input words, and at least two annotators label each input-hypothesis pair. These annotators have at least six years of English study experience, whose native language is Chinese. Among these sentences, 178 sentences have under-translation errors with 553 under-translated words in total.

Table 1 lists the accuracy of detecting under-translation errors by comparing words of *least* importance and human-annotated under-translated words. As seen, our *Attribution* method consistently and significantly outperforms both *Erasure* and *Attention* approaches. By exploiting the word importance calculated by *Attribution* method, we can identify the under-translation errors automatically without the involvement of human interpreters. Although the accuracy is not high, it is worth noting that our under-translation method is very simple and straightforward. This is potentially useful for debugging NMT models, e.g., automatic post-editing with constraint decoding (Hokamp and Liu, 2017; Post and Vilar, 2018).

Type		Zh⇒En	En⇒Fr	En⇒Ja
POS Tags	Noun	**21.0%**	1.9%	0.7%
	Verb	0.3%	**25.0%**	0.3%
	Adj.	0.4%	9.3%	0.7%
	Prep.	1.3%	4.5%	**26.7%**
	Dete.	3.0%	5.7%	2.1%
	Punc.	3.5%	**18.3%**	**30.5%**

	Middle	0.3%	0.8%	1.4%
	High	0.0%	0.1%	0.1%

Table 2: Correlation between *Attribution* word importance with POS tags, Fertility, and Syntactic Depth. Fertility can be categorized into 4 types: one-to-many ("≥ 2"), one-to-one ("1"), many-to-one ("$(0, 1)$"), and null-aligned ("0"). Syntactic depth shows the depth of a word in the dependency tree. A lower tree depth indicates closer to the root node in the dependency tree, which might indicate a more important word.

5.2 Analysis on Linguistic Properties

In this section, we analyze the linguistic characteristics of important words identified by the attribution-based approach. Specifically, we investigate several representative sets of linguistic properties, including POS tags, and fertility, and depth in a syntactic parse tree. In these analyses, we multiply the word importance with the corresponding sentence length for fair comparison. We use a decision tree based regression model to calculate the correlation between the importance and linguistic properties.

Table 4: Distributions of word fertility and their relative change based on *Attribution* importance and word count.

Table 2 lists the correlations, where a higher value indicates a stronger correlation. We find that the syntactic information is almost independent of the word importance value. Instead, the word importance strongly correlates with the POS tags and fertility features, and these features in total contribute over 95%. Therefore, in the following analyses, we mainly focus on the POS tags (Table 3) and fertility properties (Table 4). For better illustration, we calculate the distribution over the linguistic property based on both the *Attribution* importance ("Attr.") and the word frequency ("Count") inside a sentence. The larger the relative increase between these two values, the more important the linguistic property is.

Certain syntactic categories have higher importance while the categories vary across language pairs. As shown in Table 3, *content* words are more important on Chinese⇒English but *content-free* words are more important on English⇒Japanese. On English⇒French, there is no notable increase or decrease of the distribution since English and French are in essence very similar. We also obtain some specific findings of great interest. For example, we find that noun is more important on Chinese⇒English translation, while preposition is more important on English⇒French translation. More interestingly, English⇒Japanese translation shows a substantial discrepancy in contrast to the other two language pairs. The results reveal that preposition and punctuation are very important in English⇒Japanese translation, which is counter-intuitive.

Punctuation in NMT is understudied since it carries little information and often does not affect the understanding of a sentence. However, we find that punctuation is important on English⇒Japanese translation, whose proportion increases dramatically. We conjecture that it is because the punctuation could affect the sense groups in a sentence, which further benefits the syntactic reordering in Japanese.

Words of high fertility are always important. We further compare the fertility distribution based on word importance and the word frequency on three language pairs. We hypothesize that a source word that corresponds to multiple target words should be more important since it contributes more to both sentence length and BLEU score.

Table 4 lists the results. Overall speaking, one-to-many fertility is consistently more important on all three language pairs, which confirms our hypothesis. On the contrary, null-aligned words receive much less attention, which shows a persis-

tently decrease on three language pairs. It is also reasonable since null-aligned input words contribute almost nothing to the translation outputs.

6 Discussion and Conclusion

We approach understanding NMT by investigating the word importance via a gradient-based method, which bridges the gap between word importance and translation performance. Empirical results show that the gradient-based method is superior to several black-box methods in estimating the word importance. Further analyses show that important words are of distinct syntactic categories on different language pairs, which might support the viewpoint that essential inductive bias should be introduced into the model design (Strubell et al., 2018). Our study also suggests the possibility of detecting the notorious under-translation problem via the gradient-based method.

This paper is an initiating step towards the general understanding of NMT models, which may bring some potential improvements, such as

- *Interactive MT and Constraint Decoding* (Foster et al., 1997; Hokamp and Liu, 2017): The model pays more attention to the detected unimportant words, which are possibly under-translated;
- *Adaptive Input Embedding* (Baevski and Auli, 2019): We can extend the adaptive softmax (Grave et al., 2017) to the input embedding of variable capacity – more important words are assigned with more capacity;
- *NMT Architecture Design*: The language-specific inductive bias (e.g., different behaviors on POS) should be incorporated into the model design.

We can also explore other applications of word importance to improve NMT models, such as more tailored training methods. In general, model interpretability can build trust in model predictions, help error diagnosis and facilitate model refinement. We expect our work could shed light on the NMT model understanding and benefit the model improvement.

There are many possible ways to implement the general idea of exploiting gradients for model interpretation. The aim of this paper is not to explore this whole space but simply to show that some fairly straightforward implementations work well. Our approach can benefit from advanced exploitation of the gradients or other useful intermediate information, which we leave to the future work.

Abstract

Multilingual neural machine translation (NMT), which translates multiple languages using a single model, is of great practical importance due to its advantages in simplifying the training process, reducing online maintenance costs, and enhancing low-resource and zero-shot translation. Given there are thousands of languages in the world and some of them are very different, it is extremely burdensome to handle them all in a single model or use a separate model for each language pair. Therefore, given a fixed resource budget, e.g., the number of models, how to determine which languages should be supported by one model is critical to multilingual NMT, which, unfortunately, has been ignored by previous work. In this work, we develop a framework that clusters languages into different groups and trains one multilingual model for each cluster. We study two methods for language clustering: (1) using prior knowledge, where we cluster languages according to language family, and (2) using language embedding, in which we represent each language by an embedding vector and cluster them in the embedding space. In particular, we obtain the embedding vectors of all the languages by training a universal neural machine translation model. Our experiments on 23 languages show that the first clustering method is simple and easy to understand but leading to suboptimal translation accuracy, while the second method sufficiently captures the relationship among languages well and improves the translation accuracy for almost all the languages over baseline methods.

1 Introduction

Neural machine translation (NMT) (Bahdanau et al., 2015; Luong et al., 2015b; Sutskever et al., 2014; Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017) has witnessed rapid progress in recent years, from novel model structure developments (Gehring et al., 2017; Vaswani et al., 2017) to achieving performance comparable to humans (Hassan et al., 2018).

Although a conventional NMT model can handle a single language translation pair (e.g., German→English, Spanish→French) well, training a separate model for each language pair is unaffordable considering there are thousands of languages in the world. A straightforward solution to reduce computational cost is using one model to handle the translations of multiple languages, i.e., multilingual translation. Johnson et al. (2017); Firat et al. (2016); Ha et al. (2016); Lu et al. (2018) propose to share part of (e.g., attention mechanism) or all models for multiple language pairs and achieve considerable accuracy improvement. While they focus on how to translate multiple language pairs in a single model and improve the performance of the multilingual model, they do not investigate which language pairs should be trained in the same model.

Clearly, it is extremely heavy to translate all language pairs in a single model due to the diverse and large amount of languages; instead we cluster language pairs into multiple clusters and train one model for each cluster, considering that: (1) language pairs that differ a lot (e.g., German→English and Chinese→English) may negatively impact the training process if handling them by one model, and (2) similar language pairs (e.g., German→English and French→English) are likely to boost each other in model training. Then the key challenge is how to cluster language pairs, which is our focus in this paper.

In this paper, we consider the many-to-one settings where there are multiple source languages and one target language (English), and one-to-

[*]Authors contribute equally to this work.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 963–973, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

many settings where there are multiple target languages and one source language (English)[1]. In this way, we only need to consider the languages in the source or target side for the determination of training in the same model, instead of language pairs.

We consider two methods for language clustering. The first one is clustering based on prior knowledge, where we use the knowledge of language family to cluster languages. The second one is a purely learning based method that uses language embeddings for similarity measurement and clustering. We obtain the language embeddings by training all the languages in a universal NMT model, and add each language with a tag to give the universal model a sense of which language it currently processes. The tag of each language (language embedding) is learned end-to-end and used for language clustering. Language clustering based on language family is easy to obtain and understand, while the end-to-end learning method may boost multilingual NMT training, since the language clustering is derived directly from the learning task and will be more useful to the task itself.

Through empirical studies on 23 languages→English and English→23 languages in IWSLT dataset, we have several findings: (1) Language embeddings can capture the similarity between languages, and correlate well with the fine-grained hierarchy (e.g., language branch) in a language family. (2) Similar languages, if clustered together, can indeed boost multilingual performance. (3) Language embeddings based clustering outperforms the language family based clustering on the 23 languages↔English.

2 Background

Neural Machine Translation Given the bilingual translation pair (x, y), an NMT model learns the parameter θ by maximizing the log-likelihood $\log P(y|x, \theta)$. The encoder-decoder framework (Bahdanau et al., 2015; Luong et al., 2015b; Sutskever et al., 2014; Wu et al., 2016; Gehring et al., 2017; Vaswani et al., 2017; Shen et al., 2018; He et al., 2018) is adopted to model the conditional probability $P(y|x, \theta)$, where the encoder maps the input to a set of hidden representations h and the decoder generates each target token y_t using the previous generated tokens $y_{<t}$ and the representations h.

Multilingual NMT NMT has recently been extended from the translation of a language pair to multilingual translation (Dong et al., 2015; Luong et al., 2015a; Firat et al., 2016; Lu et al., 2018; Johnson et al., 2017; He et al., 2019; Ha et al., 2016; Platanios et al., 2018; Tan et al., 2019). Dong et al. (2015) use a single encoder but separate decoders to translate one source language to multiple target languages (i.e., one-to-many translation). Luong et al. (2015a) combine multiple encoders and decoders, one encoder for each source language and one decoder for each target language respectively, to translate multiple source languages to multiple target languages (i.e., many-to-many translation). Firat et al. (2016) use different encoders and decoders but share the attention mechanism for many-to-many translation. Similarly, Lu et al. (2018) propose the neural interlingua, which is an attentional LSTM encoder to link multiple encoders and decoders for different language pairs. Johnson et al. (2017); Ha et al. (2016) use a universal encoder and decoder to handle multiple source and target languages, with a special tag in the encoder to determine which target languages to output.

While all the above works focus on the design of better models for multilingual translation, they implicitly assume that a set of languages are pre-given, and do not consider which languages (language pairs) should be in a set and share one model. In this work we focus on determining which languages (language pairs) should be shared in one model.

3 Multilingual NMT with Language Clustering

Previous work trains a set of language pairs (usually the number is small, e.g., < 10 languages) using a single model and focuses on improving this multilingual model. When facing a large amount of languages (dozens or even hundreds), one single model can hardly handle them all, considering that a single model has limited capacity, some languages are quite diverse and far different, and thus one model will lead to degraded accuracy.

In this paper, we first group the languages into several clusters and then train one multilingual NMT model (Johnson et al., 2017) for the translations in each cluster. By controlling the number of

[1]Many-to-many translation can be bridged through many-to-one and one-to-many translations. Our methods can be also extended to the many-to-many setting with some modifications. We leave this to future work.

clusters, we can balance translation accuracy and computational cost: compared to using one model for each language pair, our approach greatly reduces computational cost, and compared to using one model for all language pairs, our approach delivers better translation accuracy. In this section, we present two methods of language clustering to enhance multilingual NMT.

3.1 Prior Knowledge Based Clustering

Several kinds of prior knowledge can be leveraged to cluster languages (Paul et al., 2009; Comrie, 1989; Bakker et al., 2009; Holman et al., 2008; Liu and Li, 2010; Chen and Gerdes, 2017; Wu et al., 2018; Leng et al., 2019), such as language family, language typology or other language characteristics from the URIEL database (Levin et al., 2017). Here we do not aim to give a comprehensive study of diverse prior knowledge based clusterings. Instead, we choose the commonly used language family taxonomy (Paul et al., 2009) as the prior knowledge for clustering, to provide a comparison with the language embedding based clustering.

Language family is a group of languages related through descent from a common ancestral language or parental language[2]. There are different kinds of taxonomies for language family in the world, among which, Ethnologue (Paul et al., 2009)[3] is one of the most authoritative and commonly accepted taxonomies. The 7,472 known languages in the world fall into 152 families according to Paul et al. (2009). We regard the languages in the same family as similar languages and group them into one cluster.

3.2 Language Embedding Based Clustering

When training a multilingual model, it is common practice to add a tag to the input of encoder to indicate which language the model is currently processing (Johnson et al., 2017; Firat et al., 2016; Malaviya et al., 2017; Tiedemann and Östling, 2017). The embeddings of the tag is learned end-to-end and depicts the characteristics of the corresponding language, which is called language embeddings, analogous to word embeddings (Mikolov et al., 2013).

We first train a universal model to translate all the language pairs. As shown in Figure 1, the encoder of the universal NMT model takes both word embeddings and language embedding as inputs. After model training, we get an embedding vector for each language. We regard the embedding vector as the representation of a language and cluster all languages using the embeddings[4]. There exist many clustering methods. Without loss of generality, we choose hierarchical clustering (Rokach and Maimon, 2005) to cluster the embedding vectors in our experiments.

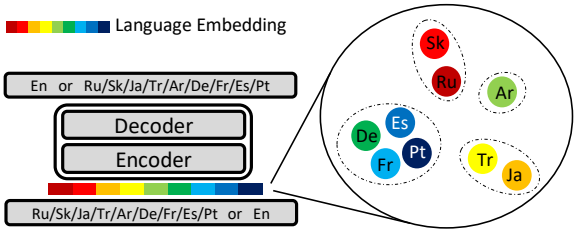

Figure 1: The illustration of learning language embeddings for clustering. For both many-to-one (other languages to English) and one-to-many (English to other languages) setting, we add the language embeddings to the encoder.

3.3 Discussions

We analyze and compare the two clustering methods proposed in this section. Clustering based on prior knowledge (language family) is simple. The taxonomy based on language family is consistent with the human knowledge, easy to understand, and does not change with respect to data/time. This method also has drawbacks. First, the taxonomy built on language family does not cover all the languages in the world since some languages are isolate[5]. Second, there are many language families (152 according to Paul et al. (2009)), which means that we still need a large number of models to handle all the languages in the world. Third, language family cannot characterize all the features of a language to fully capture the similarity between languages.

Since language embeddings are learnt in a universal NMT model, which is consistent with the

[2]https://en.wikipedia.org/wiki/Language_family
[3]https://www.ethnologue.com/browse/families

[4]One may argue that considering training one universal model for all the languages can not ensure the best translation accuracy, how could the learned language embeddings be accurate? We find the learned language embeddings are not that sensitive to translation accuracy and relatively stable during the later training process even when the universal model has not converged to the best translation accuracy. Therefore, the cost to get the language embeddings is much smaller than training a multilingual model to get good accuracy.
[5]https://en.wikipedia.org/wiki/Language_isolate

downstream multilingual NMT task, clustering based on language embeddings is supposed to capture the similarity between different languages well for NMT. As is shown in our experiments, the clustering results implicitly capture and combine multiple aspects of language characteristics and boost the performance of the multilingual model.

4 Experiment Setup

Datasets We evaluate our method on the IWSLT datasets which contain multiple languages from TED talks. We collect datasets from the IWSLT evaluation campaign[6] from years 2011 to 2018, which consist of the translation pairs of 23 languages↔English. The detailed description of the training/validation/test set of the 23 translation pairs can be found in Supplementary Materials (Section 1). All the data has been tokenized and segmented into sub-word symbols using Byte Pair Encoding (BPE) (Sennrich et al., 2016). We learn the BPE operations for all languages together, which results in a shared vocabulary of 90K BPE tokens.

Model Configurations We use Transformer (Vaswani et al., 2017) as the basic NMT model considering that it achieves state-of-the-art performance on multiple NMT benchmark tasks and is a popular choice for recent research on NMT. We use the same model configuration for each cluster with model hidden size $d_{\text{model}} = 256$, feed-forward hidden size $d_{\text{ff}} = 1024$ and the layer number is 2. The size of language embeddings is set to 256.

Training and Inference We up-sample the training data of each language to be roughly the same during training. For the multilingual model training, we concatenate training sentence pairs of all the languages in the same mini-batch. We set the batch size of each language to roughly 4096 tokens, and thus the total batch size is $4096 * |C_k|$, where $|C_k|$ is the number of languages in cluster k. The corresponding language embedding is added on the word embedding of each source token. We train the model with 8 NVIDIA Tesla M40 GPU cards, each GPU card with roughly $512 * |C_k|$ tokens in terms of batch size. We use Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\varepsilon = 10^{-9}$ and follow the learning rate schedule in Vaswani et al. (2017).

[6]https://wit3.fbk.eu/

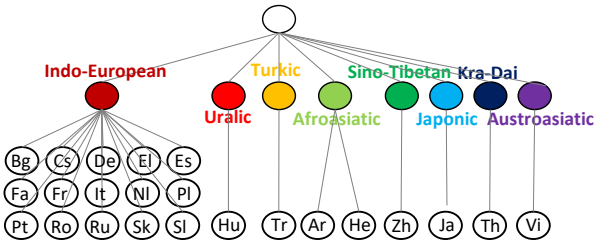

Figure 2: Language clustering of the 23 languages in IWLST dataset according to language family. There are 8 different language families in this dataset, which includes Indo-European, Uralic, Turkic, Afroasiatic, Sino-Tibetan, Japonic, Kra-Dai and Austroasiatic.

During inference, each source token is also added with the corresponding language embedding in order to give the model a sense of the language it is currently processing. We decode with beam search and set beam size to 6 and length penalty $\alpha = 1.1$ for all the languages. We evaluate the translation quality by tokenized case sensitive BLEU (Papineni et al., 2002) with multi-bleu.pl[7].

Our codes are implemented based on tensor2tensor (Vaswani et al., 2018)[8] and we will release the codes once the paper is open to the public.

5 Results

In this section, we mainly show the experiment results and analyses on the many-to-one setting in Section 5.1-5.3. The results on the one-to-many setting are similar and we briefly show the results in Section 5.4 due to space limitations.

5.1 Results of Language Clustering

The language clustering based on language family is shown in Figure 2, which results in 8 groups given our 23 languages. All the language names and their corresponding ISO-639-1 code[9] can be found in Supplementary Materials (Section 2).

We use hierarchical clustering (Rokach and Maimon, 2005)[10] method to group the languages based on language embeddings. We use the elbow method (Thorndike, 1953) to automatically decide the optimal number of clusters K. Note that we have tried to extract the language embeddings from multiple model checkpoints randomly

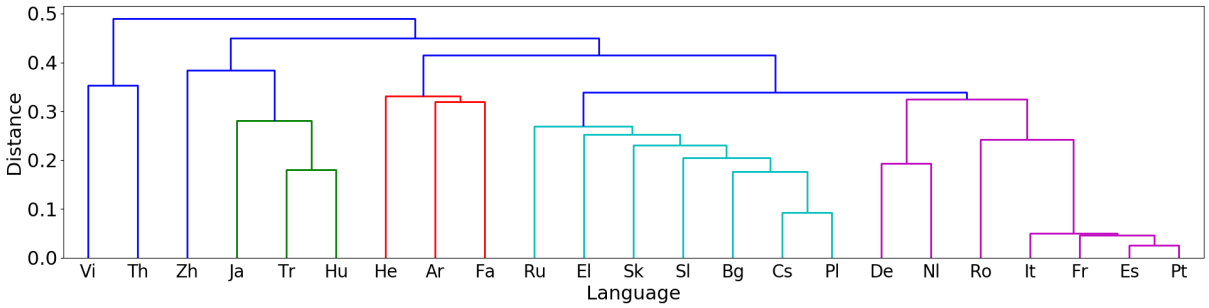

Figure 3: The hierarchical clustering based on language embeddings. The Y-axis represents the distance between two languages or clusters. Languages in the same color are divided into the same cluster, where blue color agglomerates different clusters together. If a language is marked as blue, then it forms a cluster itself. Cluster #1: Vi; Cluster #2: Th; Cluster #3: Zh; Cluster #4: Ja, Tr, Hu; Cluster #5: He, Ar, Fa; Cluster #6: Ru, El, Sk, Sl, Bg, Cs, Pl; Cluster #7: De, Nl, Ro, It, Fr, Es, Pt.

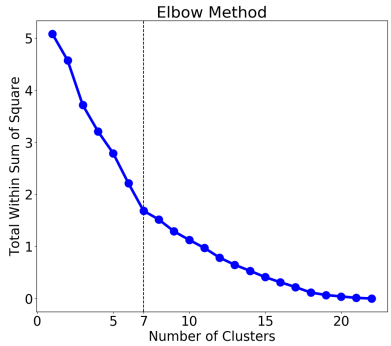

Figure 4: The optimal number of clusters determined by the elbow method for 23 languages→English based on language embeddings. The elbow method plots the curve of clustering performance (which is defined as the intra-cluster variation, i.e., the within-cluster sum of squares) according to different number of clusters, and find the location of a bend (knee) in the curve as the optimal number of clusters (7 as shown in the figure).

chosen in the later training process, and found that the clustering results based on these language embeddings are stable. Figure 3 demonstrates the clustering results based on language embeddings. Each color represents a language cluster and there are 7 clusters according to the elbow method (the details of how this method determines the optimal number of clusters are shown in Figure 7). Figure 3 clearly shows the agglomerative process of the languages and demonstrates the fine-grained relationship between languages.

We have several interesting findings from Figure 2 and 3:

- Language embeddings capture the relationship in the language family well. Cluster #7 in Figure 3 roughly covers the Germanic and Romance languages (De, Nl, Ro, It, Fr, Es, Pt) which are two different language branches in the Indo-European family but both adopt Latin alphabets. It can be further exactly divided into Germanic (De, Nl) and Romance (Ro, It, Fr, Es, Pt) branches. Cluster #6 is very close to Cluster #7 as they all belong to the Indo-European family. The difference is that the languages in Cluster #6 (Ru, El, Sk, Sl, Bg, Cs, Pl) mostly belong to Slavic branch[11].

- Language embeddings can also capture the knowledge of morphological typology (Comrie, 1989). Ja (Japanese), Tr (Turkish), Hu (Hungarian) in Cluster #4 of Figure 3 are all Synthetic-Fusional languages. Language embedding based method can cluster them together by learning their language features end-to-end with the embeddings despite they are in different language families.

- Language embeddings capture the regional, cultural, and historical influences. The languages in Cluster #5 (He, Ar, Fa) of Figure 3 are close to each other in geographical location (West Asia). Ar (Arabic) and He (Hebrew) share the same Semitic language branch in Afroasiatic language family, while Fa (Persian) has been influenced much by Arabic due to history and religion in West Asia[12]. Language embedding can implicitly learn this relationship and cluster them together.

[11]It also contains El (Greek) probably due to that most Slavic languages are influenced by Middle Greek through the Eastern Orthodox Church (Horrocks, 2009).

Table 1: BLEU score of 23 languages→English with multilingual models based on different methods of language clustering: *Random*, *Family* (Language Family) and *Embedding* (Language Embedding).

These findings show that language embeddings can incorporate different prior knowledge such as language family, or some other implicit information like regional, cultural, and historical influence, and can well fuse the information together for clustering. In the next subsection, we show how our language embedding based clustering boosts the performance of multilingual NMT compared with the language family based clustering.

5.2 Translation Accuracy

After dividing the languages into several clusters, we train the models for the languages in each cluster with a multilingual NMT model (Johnson et al., 2017) based on different clustering methods and list the BLEU scores of each language→English in Table 1. We also show the results of random clustering (*Random*) and use the same number of clusters as the language embedding based clustering, and average the BLEU scores on multiple times of random clustering (3 times in our experiments) for comparison. It can be seen that *Random* performs worst, and language embedding (*Embedding*) based clustering outperforms the language family (*Family*) based clustering for most languages[13], demonstrating the superiority of the learning based method over prior knowledge.

We further compare the language embedding based clustering with two extreme settings: 1) Each language trained with a separate model (*Individual*), 2) All languages trained in a universal model (*Universal*), to analyze how language clustering performs on each language. As shown in Table 2, we have several observations:

- First, *Universal* in general performs the worst due to the diverse languages and limited model capacity. *Universal* only performs better on Ja (Japanese) and Sl (slovene) due to their small amount of training data, which will be discussed in the next observation.

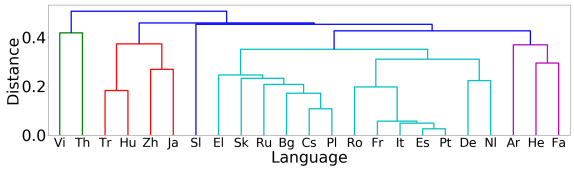
- Second, *Embedding* outperforms *Individual* (mostly by more than 1 BLEU score) on 12 out of 23 languages[14], which demonstrates that clustering can indeed bring performance gains with fewer models, especially for languages with relatively small data size. For these languages, clustering together with similar languages may act as some kind of data augmentation, which will benefit the model training. An extreme case is that Sl (slovene) training together with all the languages gets the best accuracy as shown in Table 2, since Sl is extremely low-resource, which benefits a lot from more training data. This can be also verified by the next observation.

- Third, similar languages can help boost performance. For example, Hu (Hungarian) and Ja (Japanese) are similar as they are typical agglutinative languages in terms of morphological typology (Comrie, 1989). When they are clustered together based on *Embedding*, the performance of both languages improves (Hu: 19.07→21.89, Ja: 9.90→11.57).

5.3 Clustering Results with respect to Training Data Scale

We further study how the clustering results based on language embeddings change with varying training data, in order to study the robustness of

[13] *Embedding* performs worse than *Family* on only 2 languages.



[14] *Embedding* performs slightly worse (mostly within 0.5 BLEU gap) than *Individual* on 8 languages, mainly due to the plenty of training data on these languages. In this case, *Individual* with more number of models will help.

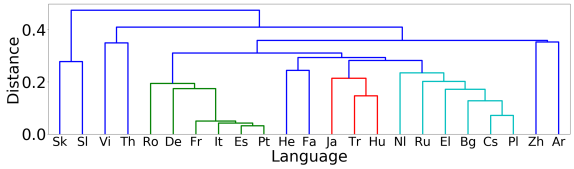
Table 2: BLEU score of 23 languages→English with different number of clusters: *Universal* (all the languages share one model), *Individual* (each language with separate models, totally 23 models)), *Embedding* (Language Embedding with 7 models). *Data size* shows the training data for each language→English.



our language embedding based clustering, which is important in the low-resource multilingual setting. We reduce the training data of each language to 50%, 20% and 5% to check how stable the language embeddings based clustering is, as shown in Figure 5. It can be seen that most languages are clustered stably when training data is relatively large (50% or even 20%), except for Sl (Slovene) which has the least training data (14K) among the 23 languages and thus reducing the training data of Sl to 50% and 20% will influence the learning of language embeddings and further influence clustering results. If further reducing the training data to 5%, more languages are influenced and clustered abnormally as most languages have less than

(a) 50% of training data

(b) 20% of training data

(c) 5% of training data

Figure 5: The results of language embedding based clustering with varying amount of training data.

10K training data. Even so, the similar languages such as Fr (French), It (Italian), Es (Spanish), and Pt (Portuguese) are still clustered together.

5.4 Results of One-to-Many Translation

We finally show experiment results of one-to-many translation, i.e., English→23 languages. We first train a universal model that covers all languages to get the language embeddings, and then perform clustering like in the many-to-one setting. The optimal number of clusters is 5, which is automatically determined by the elbow method (we show the figure of the elbow method in Figure 1 in the Supplementary Materials).

Figure 6 shows the clustering results based on language embeddings, and Table 3 shows the BLEU score of multilingual models clustered by different methods. We also have several findings:

- In one-to-many setting, language embeddings still depict the relationship among language families. Cluster #1 in Figure 6 covers the Romance (Ro, Fr, It, Es, Pt) branch in Indo-European language family while Cluster #2 contains the Germanic (De, Nl) branch in Indo-European language family. The languages in Cluster #3 (Sl, Bg, El, Ru, Sk, Cs, Pl) are mostly from the Slavic branch in Indo-European language family. We find that the cluster results of Indo-European language family is more fine-grained than many-to-one setting, which divides each language into their own branches in a language family.

- Language embedding can capture regional, cultural, and historic influence. For Cluster #4 in Figure 6, Zh (Chinese) and Ja (Japanese) are in different language families

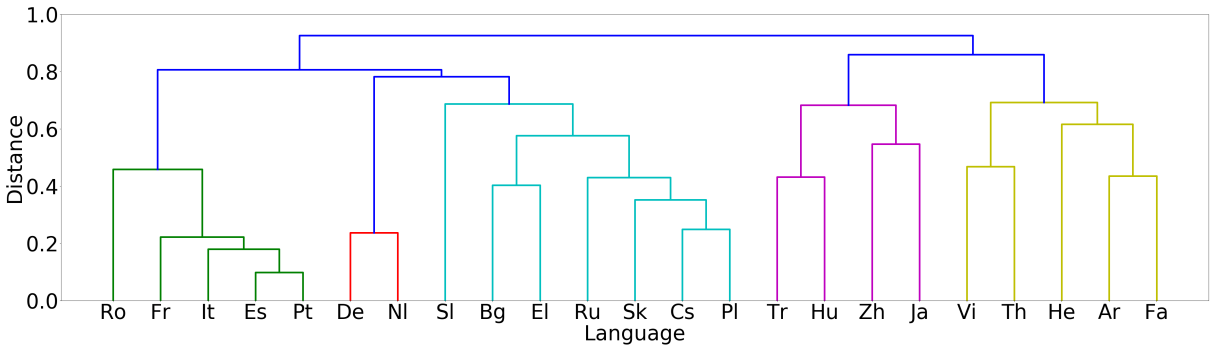


Figure 6: The hierarchical clustering based on language embedding in one-to-many setting. The Y-axis represents the distance between two languages or clusters. Languages in the same color are divided into the same cluster. Cluster #1: Ro, Fr, It, Es, Pt; Cluster #2: De, Nl; Cluster #3: Sl, Bg, El, Ru, Sk, Cs, Pl; Cluster #4: Tr, Hu, Zh, Ja; Cluster #5: Vi, Th, He, Ar, Fa.

but influence each other through the history and culture. Th (Thai) and Vi (Vietnamese) in Cluster #5 that are close to each other in geographical location can be captured by their language embeddings.

These findings show that language embeddings can stably characterize relationships among languages no matter in one-to-many setting or in many-to-one setting. Although there exist some differences in the clustering results between one-to-many setting and many-to-one setting due to the nature of the learning based clustering method, most of the clustering results are reasonable. Our experiment results shown in Table 3 demonstrate that the language embedding can provide more reasonable clustering than prior knowledge, and thus result in higher BLEU score for most of the languages.

We also find from Table 3 that each language with separate model (*Individual*) perform best on nearly 10 languages, due to the abundant model capacity. However, there are still several languages on which our clustering methods (*Family* or *Embedding*) largely outperform *Individual*. The reason is similar as the many-to-one setting that some languages are of smaller data sizes. In this situation, similar languages clustered together will boost the accuracy compared with separate model.

6 Conclusion

In this work, we have studied language clustering for multilingual neural machine translation. Experiments on 23 languages→English and English→23 languages show that language embeddings can sufficiently characterize the similarity between languages and outperform prior knowledge (language family) for language clustering in terms of the BLEU scores.

For future work, we will test our methods for many-to-many translation. We will consider more languages (hundreds or thousands) to study our methods in larger scale setting. We will also study

how to obtain language embeddings from monolingual data, which will make our method scalable to cover those languages with little or without bilingual data. On the other hand, we will also consider other pre-training methods (Song et al., 2019) for multilingual and low-resource NMT.

A Dataset Description

We evaluate our experiments on IWSLT datasets. We collect 23 languages↔English translation pairs form IWSLT evaluation campaign from year 2011 to 2018. The training data sizes of each languages are shown in Table 4 and we use the default validation and test set for each language pairs. For Bg (Bulgarian), El (Greek), Hu (Hungarian) and Ja (Japanese), there are no available validation and test data in IWSLT, we randomly split 1K sentence pairs from the corresponding training set as the validation and test data respectively.

B Language Name and Code

The language names and their corresponding language codes according to ISO 639-1 standard are listed in Table 5.

C The Elbow Method for One-to-Many Setting

The optimal number of clusters is 5 in one-to-many setting, which is automatically determined by the elbow method as shown in Figure 7.

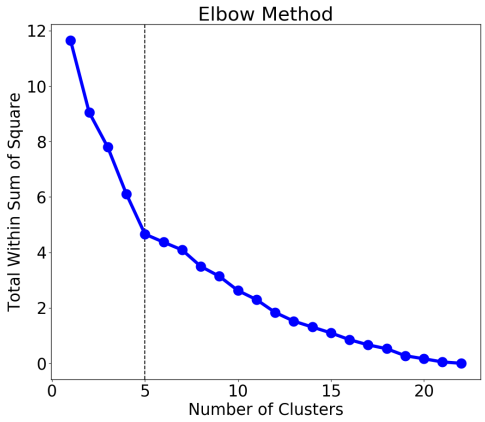

Figure 7: The optimal number of clusters determined by the elbow method for English→23 languages based on language embeddings. The detailed description of the elbow method can be seen in Figure 4 in the main paper.

Abstract

Human translators routinely have to translate rare inflections of words—due to the Zipfian distribution of words in a language. When translating from Spanish, a good translator would have no problem identifying the proper translation of a statistically rare inflection such as *hablarámos*. Note the lexeme itself, *hablar*, is relatively common. In this work, we investigate whether state-of-the-art bilingual lexicon inducers are capable of learning this kind of generalization. We introduce 40 *morphologically complete* dictionaries in 10 languages[1] and evaluate three of the state-of-the-art models on the task of translation of less frequent morphological forms. We demonstrate that the performance of state-of-the-art models drops considerably when evaluated on infrequent morphological inflections and then show that adding a simple morphological constraint at training time improves the performance, proving that the bilingual lexicon inducers can benefit from better encoding of morphology.

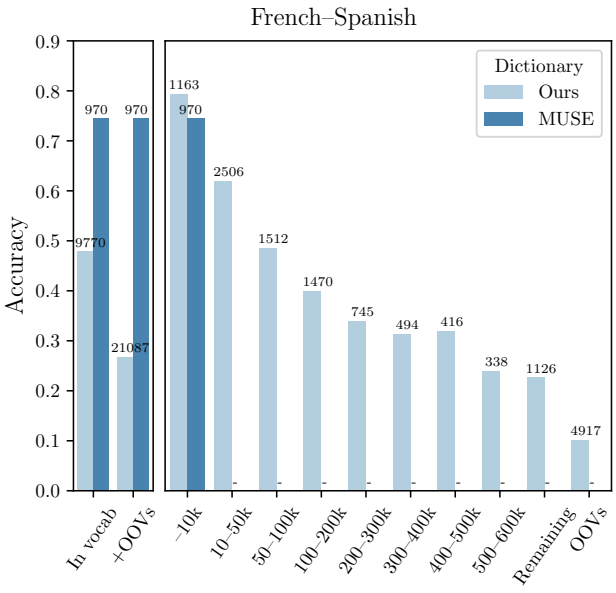

Figure 1: The relation between the BLI performance and the frequency of source words in the test dictionary. The graph presents results for the model of Ruder et al. (2018) evaluated on both the MUSE dictionary (Conneau et al., 2018) and our morphologically complete dictionary, which contains many rare morphological variants of words. The numbers above the bars correspond to the number of translated source words (a hyphen represents an empty dictionary).

1 Introduction

Human translators exhibit remarkable generalization capabilities and are able to translate even rare inflections they may have never seen before. Indeed, this skill is necessary for translation since language follows a Zipfian distribution (Zipf, 1949): a large number of the tokens in a translated text will come from rare types, including rare inflections of common lexemes. For instance, a Spanish translator will most certainly know the verb *hablar* "to speak", but they will only have seen the less frequent, first-person plural future form *hablarámos* a few times. Nevertheless, they would have no problem translating the latter. In this paper we ask whether current methods for bilingual lexicon induction (BLI) generalize morphologically as humans do. Generalization to rare and novel words is arguably the main point of BLI as a task—most frequent translation pairs are already contained in digital dictionaries. Modern word embeddings encode character-level knowledge (Bojanowski et al., 2017), which should—in principle—enable the models to learn this behaviour; but morphological generalization has never been directly tested.

Most existing dictionaries used for BLI evaluation do not account for the full spectrum of linguistic properties of language. Specifically, as we demonstrate in §2, they omit *most morphological inflections* of even common lexemes. To enable a more thorough evaluation we introduce a new resource: 40 **morphologically complete** dictionar-

ies for 5 Slavic and 5 Romance languages, which contain the inflectional paradigm of every word they hold. Much like with a human translator, we expect a BLI model to competently translate full paradigms of lexical items. Throughout this work we place our focus on genetically-related language pairs. This not only allows us to cleanly map one morphological inflection onto another, but also provides an upper bound for the performance on the generalization task; if the models are not able to generalize for closely related languages they would most certainly be unable to generalize when translating between unrelated languages.

We use our dictionaries to train and evaluate three of the best performing BLI models (Artetxe et al., 2016, 2017; Ruder et al., 2018) on all 40 language pairs. To paint a complete picture of the models' generalization ability we propose a new experimental paradigm in which we independently control for four different variables: the word form's frequency, morphology, the lexeme frequency and the lexeme (a total of 480 experiments). Our comprehensive analysis reveals that BLI models can generalize for frequent morphosyntactic categories, even of infrequent lexemes, but fail to generalize for the more rare categories. This yields a more nuanced picture of the known deficiency of word embeddings to underperform on infrequent words (Gong et al., 2018). Our findings also contradict the strong empirical claims made elsewhere in the literature (Artetxe et al., 2017; Conneau et al., 2018; Ruder et al., 2018; Grave et al., 2018b), as we observe that performance severely degrades when the evaluation includes rare morphological variants of a word and infrequent lexemes. We picture this general trend in Figure 1, which also highlights the skew of existing dictionaries towards more frequent words.[2] As our final contribution, we demonstrate that better encoding of morphology is indeed beneficial: enforcing a simple morphological constraint yields consistent performance improvements for all Romance language pairs and many of the Slavic language pairs.

2 Morphological Dictionaries

2.1 Existing Dictionaries

Frequent word forms can often be found in human-curated dictionaries. Thus, the practical purpose of training a BLI model should be to create translations of new and less common forms, not present in the existing resources. In spite of this, most ground truth lexica used for BLI evaluation contain mainly frequent word forms. Many available resources are restricted to the top 200k most frequent words; this applies to the English–Italian dictionary of Dinu et al. (2015), the English–German and English–Finnish dictionaries of Artetxe et al. (2017), and Artetxe et al. (2018a)'s English–Spanish resource. The dictionaries of Irvine and Callison-Burch (2017) contain only the top most frequent 10k words for each language. Zhang et al. (2017) extracted their Spanish–English and Italian–English lexica from Open Multilingual WordNet (Bond and Paik, 2012), a resource which only yields high frequency, lemma level mappings. Another example is the recent MUSE dataset (Conneau et al., 2018), which was generated using an "internal translation tool", and in which the majority of word pairs consist of forms ranked in the top 10k of the vocabularies of their respective languages.

Source Word	Target Word	Source Lemma	Target Lemma	Tag
morza	moře	morze	moře	N;NOM;PL
morzu	moři	morze	moře	N;DAT;SG
morze	moře	morze	moře	N;NOM;SG
morzami	moři	morze	moře	N;INS;PL
mórz	moř	morze	moře	N;GEN;PL
morzu	moři	morze	moře	N;ESS;SG
morzom	mořím	morze	moře	N;DAT;PL

Table 1: An example extract from our morphologically complete Polish–Czech dictionary.

Another problem associated with existing resources is 'semantic leakage' between train and evaluation sets. As we demonstrate in §2.3, it is common for a single lexeme to appear in both train and test dictionary—in the form of different word inflections. This circumstance is undesirable in evaluation settings as it can lead to performance overstatements—a model can 'memorize' the corresponding target lemma, which ultimately reduces the translation task to a much easier task of finding the most appropriate inflection. Finally, most of the available BLI resources include English in each language pair and, given how morphologically impoverished English is, those resources are unsuitable for analysis of morphological generalization.

2.2 Our Dictionaries

To address the shortcomings of the existing evaluation, we built 40 new **morphologically complete**

[2]For MUSE, we only evaluate on forms that are not present in our training dictionary (970 out of 1500 source words).

Slavic	Czech	Russian	Slovak	Ukrainian	**Romance**	Spanish	Catalan	Portuguese	Italian
Polish	53,353	128,638	14,517	12,361	French	686,139	381,825	486,575	705,800
Czech	-	65,123	10,817	8,194	Spanish	-	343,780	476,543	619,174
Russian		-	128,638	10,554	Catalan		-	261,016	351,609
Slovak			-	3,434	Portuguese			-	468,945

Table 2: The sizes of our morphologically complete dictionaries for Slavic and Romance language families. We present the sizes for 20 *base* dictionaries. We further split those to obtain 40 train, development and test dictionaries—one for each mapping direction to ensure the correct source language lemma separation.

dictionaries, which contain most of the inflectional paradigm of every word they contain. This enables a more thorough evaluation and makes the task much more challenging than traditional evaluation sets. In contrast to the existing resources our dictionaries consist of many rare forms, some of which are out-of-vocabulary for large-scale word embeddings such as FASTTEXT. Notably, this makes them the only resource of this kind that enables evaluating *open-vocabulary* BLI.

We focus on pairs of genetically-related languages for which we can cleanly map one morphological inflection onto another.[3] We selected 5 languages from the Slavic family: Polish, Czech, Russian, Slovak and Ukrainian, and 5 Romance languages: French, Spanish, Italian, Portuguese and Catalan. Table 1 presents an example extract from our resource; every source–target pair is followed by their corresponding lemmata and a shared tag.

We generated our dictionaries automatically based on openly available resources: Open Multilingual WordNet (Bond and Paik, 2012) and Extended Open Multilingual WordNet[4] (Bond and Foster, 2013), both of which are collections of lexical databases which group words into sets of synonyms (synsets), and UniMorph[5] (Kirov et al., 2016)—a resource comprised of inflectional word paradigms for 107 languages, extracted from Wiktionary[6] and annotated according to the UniMorph schema (Sylak-Glassman, 2016). For each language pair $(L1, L2)$ we first generated lemma translation pairs by mapping all $L1$ lemmata to all $L2$ lemmata for each synset that appeared in both $L1$ and $L2$ WordNets.[7] We then filtered out the pairs which contained lemmata not present in UniMorph and generated inflected entries from the remaining pairs: one entry for each tag that appears in the UniMorph paradigms of both lemmata.[8] The sizes of dictionaries vary across different language pairs and so does the POS distribution. In particular, while Slavic dictionaries are dominated by nouns and adjectives, verbs constitute the majority of pairs in Romance dictionaries. We report the sizes of the dictionaries in Table 2. In order to prevent semantic leakage, discussed in §2.1, for each language pair we split the initial dictionary into train, development and test splits so that each sub-dictionary has its own, independent set of lemmata. In our split, the train dictionary contains 60% of all lemmata, while the development and test dictionaries each have 20% of the lemmata.

2.3 Comparison with MUSE

In this section we briefly outline important differences between our resource and the MUSE dictionaries (Conneau et al., 2018) for Portuguese, Italian, Spanish, and French (12 dictionaries in total). We focus on MUSE as it is one of the few openly available resources that covers genetically-related language pairs.

Word Frequency The first and most prominent difference lies in the skew towards frequent word forms in MUSE evaluation. While our test dictionaries contain a representative sample of forms in

[3] One may translate *talked*, the past tense of *talk*, into many different Spanish forms, but the Portuguese *falavam* has, arguably, only one best Spanish translation: *hablaban*.

[4] We used the union of the extended and the original version of the multilingual WordNet since the latter included entries that were not present in the extended version.

[5] https://unimorph.github.io/

[6] Wiktionary (https://en.wiktionary.org/wiki/Wiktionary:Main_Page) is a large-scale, free content multilingual dictionary.

[7] Note that with this many-to-many mapping we allow for many translations of a single word.

[8] As UniMorph annotations are not consistent across different languages (e.g. in Czech and Polish resources verbs are marked for animacy, while for other Slavic resources they lack such markings) we performed minor tag processing in order to make the tags more compatible. We also discovered that for some languages, the UniMorph resource was either incomplete (resources for Romance languages do not contain adjectives or nouns) or incorrect (Czech verb inflections), in which cases we personally scraped lemma inflections directly from Wiktionary.

lower frequency bins, the majority of forms present in MUSE are ranked in the top 10k in their respective language vocabularies. This is clearly presented in Figure 1 for the French–Spanish resource and also holds for the remaining 11 dictionaries.

Morphological Diversity Another difference lies in the morphological diversity of both dictionaries. The average proportion of paradigm covered for lemmata present in MUSE test dictionaries is 53% for nouns, 37% for adjectives and only 3% for verbs. We generally observe that for most lemmata the dictionaries contain *only one* inflection. In contrast, for our test dictionaries we get 97% coverage for nouns, 98% for adjectives and 67% for verbs. Note that we do not get 100% coverage as we are limited by the compatibility of source language and target language UniMorph resources.

Train–test Paradigm Leakage Finally, we carefully analyze the magnitude of the train–test paradigm leakage. We found that, on average 20% (299 out of 1500) of source words in MUSE test dictionaries share their lemma with a word in the corresponding train dictionary. E.g. the French–Spanish test set includes the form *perdent*—a third-person plural present indicative of *perdre* (to lose) which is present in the train set. Note that the splits we provide for our dictionaries do not suffer from any leakage as we ensure that each dictionary contains the full paradigm of every lemma.

3 Bilingual Lexicon Induction

The task of bilingual lexicon induction is well established in the community (Vulić and Moens, 2013; Gouws et al., 2015) and is the current standard choice for evaluation of cross-lingual word embedding models. Given a list of N source language word forms $x_1, \ldots, x_N$, the goal is to determine the most appropriate translation t_i, for each query form x_i. In the context of cross-lingual embeddings, this is commonly accomplished by finding a target language word that is most similar to x_i in the shared semantic space, where words' similarity is usually computed using a cosine between their embeddings. The resulting set of (x_i, t_i) pairs is then compared to the gold standard and evaluated using the precision at k (P@k) metric, where k is typically set to 1, 5 or 10.[9] Throughout our evaluation we use P@1, which is equivalent to accuracy.

In our work, we focus on the supervised and semi-supervised settings in which the goal is to automatically generate a dictionary given only monolingual word embeddings and some initial, seed translations. For our experiments we selected the models of Artetxe et al. (2016), Artetxe et al. (2017) and Ruder et al. (2018)—three of the best performing BLI models, which induce a shared cross-lingual embedding space by learning an orthogonal transformation from one monolingual space to another (model descriptions are given in the supplementary material).[10] In particular, the last two employ a self-learning method in which they alternate between a mapping step and a word alignment (dictionary induction) step in an iterative manner. As we observed the same general trends across all models, in the body of the paper we only report the results for the best performing model of Ruder et al. (2018). We present the complete set of results in the supplementary material.

Experimental Setup We trained and evaluated all models using the Wikipedia FASTTEXT embeddings (Grave et al., 2018a). Following the existing work, for training we only used the most frequent 200k words in both source and target vocabularies. To allow for evaluation on less frequent words, in all our experiments the models search through the whole target embedding matrix at evaluation (not just the top 200k words, as is common in the literature). This makes the task more challenging, but also gives a more accurate picture of performance. To enable evaluation on the unseen word forms we generated a FASTTEXT embedding for every out-of-vocabulary (OOV) inflection of every word in WordNet that also appears in UniMorph. We built those embeddings by summing the vectors of all n-grams that constitute an OOV form.[11] In the OOV evaluation we append the resulting vectors to the original embedding matrices.

4 Morphological Generalization

We propose a novel **quadripartite analysis** of the BLI models, in which we independently control for four different variables: (i) word form frequency, (ii) morphology, (iii) lexeme frequency and (iv)

[9] Precision at k represents how many times the correct translation of a source word is returned as one of its k nearest neighbours in the target language.

[10] We also used our dictionaries to train and test the more recent model of Artetxe et al. (2018b) on a handful of languages and observed the same general trends.

[11] We did this within the FASTTEXT framework, using the trained *.bin* models for each of our 10 languages.

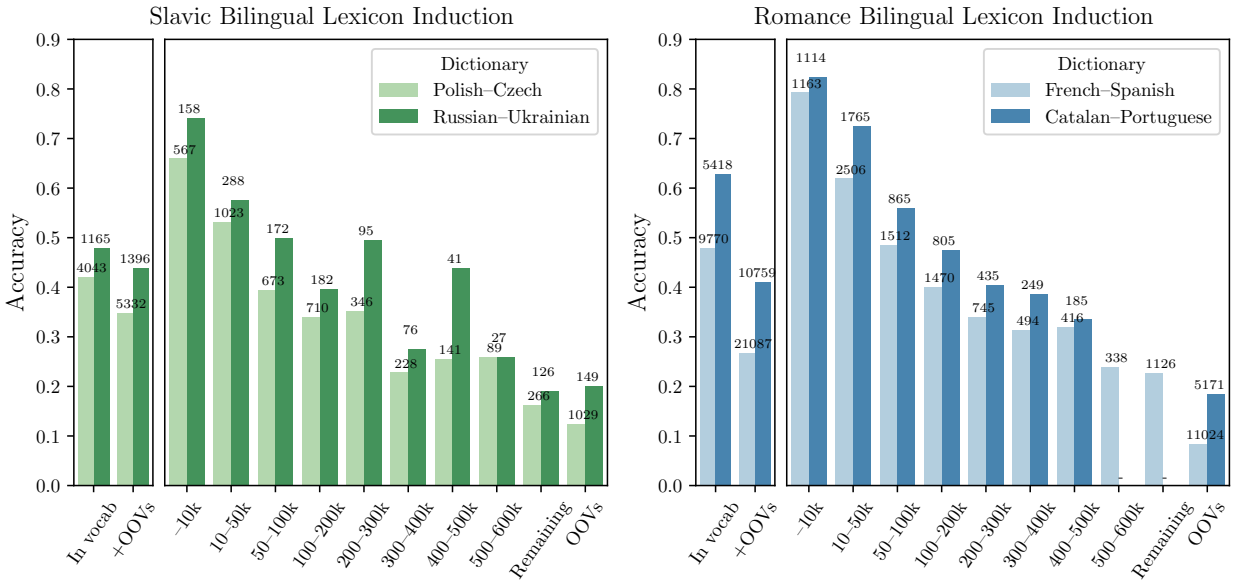

Figure 2: The relation between performance and the frequency of source words in the test dictionary for four example language pairs on the standard BLI task. The numbers above the bars correspond to the dictionary sizes.

lexeme. We provide detailed descriptions for each of those conditions in the following sections. For each condition, we analyzed all 40 language pairs for each of our selected models—a total of 480 experiments. In the body of the paper we only present *a small representative subset* of our results.

4.1 Controlling for Word Frequency

For highly inflectional languages, many of the infrequent types are rare forms of otherwise common lexemes and, given the morphological regularity of less frequent forms, a model that generalizes well should be able to translate those capably. Thus, to gain insight into the models' generalization ability we first examine the relation between their performance and the frequency of words in the test set.

We split each test dictionary into 9 frequency bins, based on the relative frequencies of words in the original training corpus for the word embeddings (Wikipedia in the case of FASTTEXT). More specifically, a pair appears in a frequency bin if its source word belongs to that bin, according to its rank in the respective vocabulary. We also considered unseen words that appear in the test portion of our dictionaries, but do not occur in the training corpus for the embeddings. This is a fair experimental setting since most of those OOV words are associated with known lemmata. Note that it bears a resemblance to the classic Wug Test (Berko, 1958) in which a child is introduced to a single instance of a fictitious object—'a wug'—and is asked to name two instances of the same object—'wugs'. However, in contrast to the original setup, we are interested in making sure the unseen inflection of a known lexeme is properly translated.

Figure 2 presents the results on the BLI task for four example language pairs: two from the Slavic and two from the Romance language family. The left-hand side of the plots shows the performance for the full dictionaries (with and without OOVs), while the right-hand side demonstrates how the performance changes as the words in the evaluation set become less frequent. The general trend we observe across all language pairs is an acute drop in accuracy for infrequent word forms—e.g. for Catalan–Portuguese the performance falls from 83% for pairs containing only the top 10k most frequent words to 40% for pairs, which contain source words ranked between 200k and 300k.

4.2 Controlling for Morphology

From the results of the previous section, it is not clear whether the models perform badly on inflections of generally *infrequent lemmata* or whether they fail on *infrequent morphosyntactic categories*, independently of the lexeme frequency. Indeed, the frequency of different morphosyntactic categories is far from uniform. To shed more light on the underlying cause of the performance drop in §4.1, we first analyze the differences in the models' performance as they translate forms belonging to different categories and, next, look at the dis-

Tag	Accuracy		Distribution Across Frequency Bins									
	In vocab	All	10k	50k	100k	200k	300k	400k	500k	600k	Tail	OOVs

Table 3: BLI results for word pairs that have a specific morphosyntactic category (left) and a distribution of those forms across different frequency bins (right).

tribution of these categories across the frequency bins.

In Table 3 we present our findings for a representative sample of morphosyntactic categories for one Slavic and one Romance language pair (we present the results for all models and all language pairs in the supplementary material).[12] It illustrates the great variability across different paradigm slots—both in terms of their frequency and the difficulty of their translation.

As expected, the performance is best for the slots belonging to the highest frequency bins and forms residing in the rarer slots prove to be more challenging. For example, for French–Spanish the performance on 2;IMP;PL;POS;V, 3;FUT;PL;V and 3;COND;SG;V[13] is notably lower than that for the remaining categories. For both language pairs, the accuracy for the second-person plural present imperative (2;IMP;PL;V) is particularly low: 1.5% accuracy for French–Spanish and 11.1% for Polish–Czech in the in-vocabulary setting. Note that it is unsurprising for an imperative form, expressing an order or command, to be infrequent in the Wikipedia corpora (the resource our monolingual embeddings were trained on). The complex distribution of the French 2;IMP;PL;POS;V across the frequency bins is likely due to syncretism—the 2;IMP;PL;POS;V paradigm slot shares a form with 2nd person present plural slot, 2;PL;PRS;V. Our hypothesis is that syncretism may have an effect on the quality of the monolingual embeddings. To our knowledge, the effect of syncretism on embeddings has not yet been systematically investigated.

4.3 Controlling for Lexeme Frequency

To get an even more complete picture, we inspect how the performance on translating inflections of *common lemmata* differs to translating forms coming from *less frequent paradigms* by controlling for the frequency of the lexeme. We separated our dictionaries into two bins based on the relative frequency of the source lexeme. We approximated frequency of the lexemes by using ranks of their most common inflections: our first bin contained lexemes whose most common inflection is ranked in the top 20k forms in its respective vocabulary, while the second bin consisted of lexemes with most common inflection ranked lower than 60k.[14] We present the results for the same morphosyntactic categories as in §4.2 on the left side of the graphs in Figure 3. As anticipated, in the case of less frequent lexemes the performance is generally worse than for frequent ones. However, perhaps more surprisingly, we discover that some morphosyntactic categories prove to be problematic even for the most frequent lexemes. Some

[12] We selected the morphosyntactic categories independently for each language family based on how well the models translate words of such morphology–'the good, the bad and the ugly'.

[13] 2nd person imperative plural form of a verb, 3rd person future plural form of a verb and 2nd person conditional singular form of a verb.

[14] Future work could operate on actual word counts rather than relative frequencies of words.

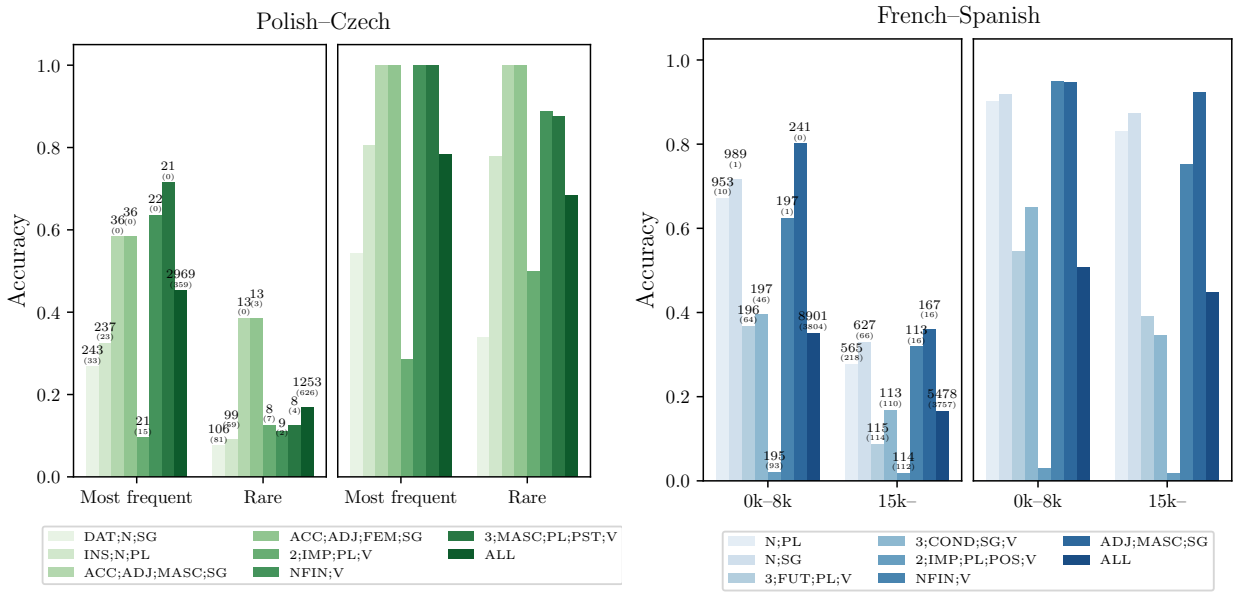

Figure 3: The performance on the standard BLI task (left side of the graphs) and the controlled for lexeme BLI (right side) for words pairs belonging to the most frequent paradigms and the infrequent paradigms. The numbers above the bars are dictionary sizes and the number of out-of-vocabulary forms in each dictionary (bracketed).

examples include the previously mentioned imperative verb form or, for Slavic languages, singular dative nouns (DAT;N;SG).

4.4 Controlling for Lexeme

We are, in principle, interested in the ability of the models to generalize *morphologically*. In the preceding sections we focused on the standard BLI evaluation, which given our objective is somewhat unfair to the models—they are additionally punished for not capturing lexical semantics. To gain more direct insight into the models' generalization abilities we develop a novel experiment in which the lexeme is controlled for. At test time, the BLI model is given a set of candidate translations, all of which belong to the same paradigm, and is asked to select the most suitable form. Note that the model only requires morphological knowledge to successfully complete the task—no lexical semantics is required. When mapping between closely related languages this task is particularly straightforward, and especially so in the case of FASTTEXT where a single n-gram, e.g. the suffix *-ing* in English as in the noun *running*, can be highly indicative of the inflectional morphology of the word.

We present results on 8 representative language pairs in Table 4 (column Lexeme). We report the accuracy on the in-vocabulary pairs as well as all the pairs in the dictionary, including OOVs. As expected, compared to standard BLI this task is much easier for the models—the performance is generally high. For Slavic languages numbers remain high even in the open-vocabulary setup, which suggests that the models can generalize morphologically. On the other hand, for Romance languages we observe a visible drop in performance. We hypothesize that this difference is due to the large quantities of verbs in Romance dictionaries; in both Slavic and Romance languages verbs have substantial paradigms, often of more than 60 forms, which makes identifying the correct form more difficult. In contrast, most words in our Slavic dictionaries are nouns and adjectives with much smaller paradigms.

Following our analysis in §4.3, we also examine how the performance on this new task differs for less and more frequent paradigms, as well as across different morphosyntactic categories. Here, we exhibit an unexpected result, which we present in the two right-hand side graphs of Figure 3: the state-of-the-art BLI models *do* generalize morphologically for frequent slots, but *do not* generalize for infrequent slots. For instance, for the Polish–Czech pair, the models achieve 100% accuracy on identifying the correct inflection when this inflection is ACC;ADJ;MASC;SG, ACC;ADJ;FEM;SG, 3;MASC;PL;PST;V or NFIN;V[15] for frequent and, for the first two categories, also the *infrequent* lex-

[15]Masculine accusative singular form of an adjective, feminine accusative singular form of an adjective, 3rd person masculine plural past form of a verb and a verbal infinitive.

emes; all of which are common morphosyntactic categories (see Table 3). The results from Figure 3 also demonstrate that the worst performing forms for the French–Spanish language pair are indeed the infrequent verbal inflections.

4.5 Experiments on an Unrelated Language Pair

So far, in our evaluation we have focused on pairs of genetically-related languages, which provided an upper bound for morphological generalization in BLI. But our experimental paradigm is not limited to related language pairs. We demonstrate this by experimenting on two example pairs of one Slavic and one Romance language: Polish–Spanish and Spanish–Polish. To construct the dictionaries we followed the procedure discussed in §2, but matched the tags based only on the features exhibited in both languages (e.g. Polish DAT;N;SG can be mapped to N;SG in Spanish, as Spanish nouns are not declined for case). Note that mapping between morphosyntactic categories of two unrelated languages is a challenging task (Haspelmath, 2010), but we did our best to address the issues specific to translation between Polish and Spanish. E.g. we ensured that Spanish imperfective/perfective verb forms can only be translated to Polish forms of imperfective/perfective verbs.

The results of our experiments are presented in the last two rows of Table 4 and, for Polish–Spanish, also in Figure 4. As expected, the BLI results on unrelated languages are generally, but not uniformly, worse than those on related language pairs. The accuracy for Spanish–Polish is particularly low, at 28% (for in vocabulary pairs). We see large variation in performance across morphosyntactic categories and more and less frequent lexemes, similar to that observed for related language pairs. In particular, we observe that 2;IMP;PL;V—the category difficult for Polish–Czech BLI is also among the most challenging for Polish–Spanish. However, one of the highest performing categories for Polish–Czech, 3;MASC;PL;PST;V, yields much worse accuracy for Polish–Spanish.

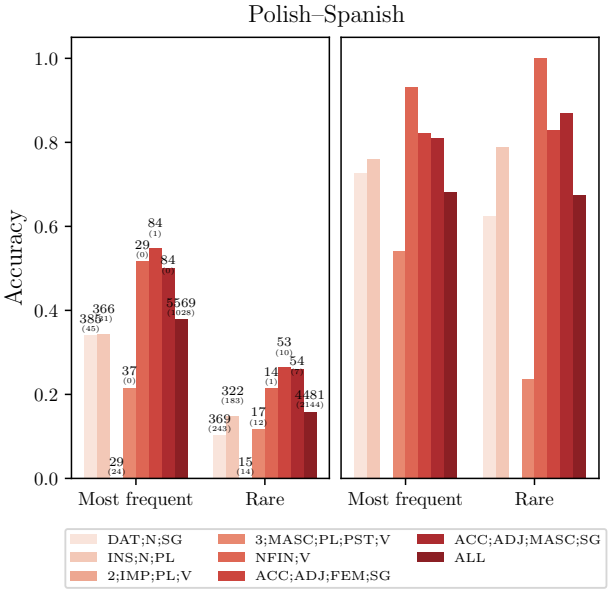

Figure 4: The results of the experiments on a pair of unrelated languages—Polish and Spanish—on the standard BLI task (left side) and the controlled for lexeme BLI (right side) for word pairs belonging to the most frequent and the infrequent paradigms.

4.6 Adding a Morphological Constraint

In our final experiment we demonstrate that improving morphological generalization has the potential to improve BLI results. We show that enforcing a

simple, hard morphological constraint *at training time* can lead to performance improvements at test time—both on the standard BLI task and the controlled for lexeme BLI. We adapt the self-learning models of Artetxe et al. (2017) and Ruder et al. (2018) so that at each iteration they can align two words only if they share the same morphosyntactic category. Note that this limits the training data only to word forms present in UniMorph, as those are the only ones for which we have a gold tag.[16] The results, a subset of which we present in Table 4, show that the constraint, despite its simplicity and being trained on less data, leads to performance improvements for *every* Romance language pair and many of the Slavic language pairs. We take this as evidence that properly modelling morphology will have a role to play in BLI.

5 Discussion and Conclusion

We conducted a large-scale evaluation of the generalization ability of the state-of-the-art bilingual lexicon inducers. To enable our analysis we created 40 morphologically complete dictionaries for 5 Slavic and 5 Romance languages and proposed a novel experimental paradigm in which we independently control for four different variables.

Our study is the first to examine morphological generalization in BLI and it reveals a nuanced picture of the interplay between performance, the word's frequency and morphology. We observe that the performance degrades when models are evaluated on less common words—even for the infrequent forms of common lexemes. Our results from the controlled for lexeme experiments suggest that models are able to generalize well for more frequent morphosyntactic categories and for part-of-speech with smaller paradigms. However, their ability to generalize decreases as the slots get less frequent and/or the paradigms get larger. Finally, we proposed a simple method to inject morphological knowledge and demonstrated that making models more morphologically aware can lead to general performance improvements.

Pushing the Limits of Low-Resource Morphological Inflection

Antonios Anastasopoulos and Graham Neubig
Language Technologies Institute, Carnegie Mellon University
{aanastas,gneubig}@cs.cmu.edu

Abstract

Recent years have seen exceptional strides in the task of automatic morphological inflection generation. However, for a long tail of languages the necessary resources are hard to come by, and state-of-the-art neural methods that work well under higher resource settings perform poorly in the face of a paucity of data. In response, we propose a battery of improvements that greatly improve performance under such low-resource conditions. First, we present a novel two-step attention architecture for the inflection decoder. In addition, we investigate the effects of cross-lingual transfer from single and multiple languages, as well as monolingual data hallucination. The macro-averaged accuracy of our models outperforms the state-of-the-art by 15 percentage points.[1] Also, we identify the crucial factors for success with cross-lingual transfer for morphological inflection: typological similarity and a common representation across languages.

1 Introduction

The majority of the world's languages are categorized as synthetic, meaning that they have rich morphology, be it fusional, agglutinative, polysynthetic, or a mixture thereof. As Natural Language Processing (NLP) keeps expanding its frontiers to encompass more and more languages, modeling of the grammatical functions that guide language generation is of utmost importance.

In the case of morphologically-rich languages, explicit modeling of the inflection processes has significant potential to alleviate issues created by data scarcity and the resulting lack of vocabulary coverage. Especially on low-resource, under-represented languages and dialects, the potential for *impact* is much higher. For example, speech recognition (Foley et al., 2018) and predictive keyboards (Breiner et al., 2019) for under-represented languages, if they exist, largely still rely on unigram lexicons with performance inferior to the sophisticated language models used in high-resource ones. Good inflection models would be invaluable for predictive text technology in morphologically-rich languages as they could effectively enable proper handling of the huge vocabulary.

Additionally, they could be very useful for building educational applications for languages of under-represented communities (along with their inverse, morphological analyzers). Encouraging examples are the Yupik morphological analyzer (Schwartz et al., 2019) and the Inuktitut educational tools from the respective Native Peoples communities.[2] The social impact of such applications can be enormous, effectively raising the status of the languages slightly closer to the level of

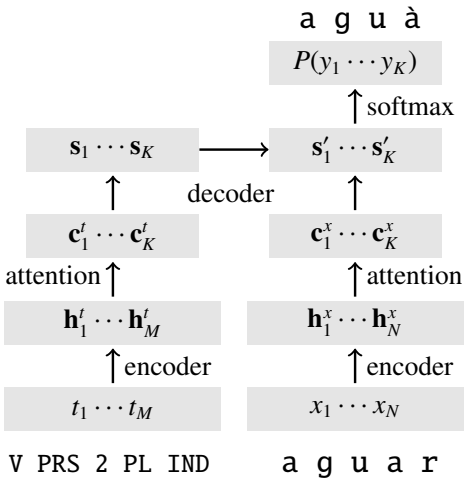

Figure 1: Visualization of our proposed two-step attention architecture. The decoder first attends over the tag sequence **T** and then uses the updated decoder state $\mathbf{s}'$ to attend over the character sequence **X** in order to produce the inflected form **Y**. (Example from Asturian.)

the dominant regional language.

Morphological inflection has been thoroughly studied in monolingual high resource settings, especially through the recent SIGMORPHON challenges (Cotterell et al., 2016, 2017, 2018). Low-resource settings, in contrast, are relatively underexplored. One promising direction and the main focus of the SIGMORPHON 2019 challenge (McCarthy et al., 2019b) is cross-lingual training, which has been successfully applied in other low-resource tasks such as Machine Translation (MT) or parsing.

In this work we focus in this cross-lingual setting for low-resource morphological inflection and propose several simple, yet effective approaches to mitigating problems caused by extreme lack of data which, put together, *improve accuracy by 15 percentage points over a state-of-the-art baseline*. This is achieved through the combination of a novel decoder architecture, a training regime that alleviates the need for costly structural biases that force attention monotonicity, and a data hallucination technique. We also present thorough ablations and identify the crucial factors for success with our approach.

Our system was the best performing system in the 2019 SIGMORPHON shared task on morphological inflection when evaluated on accuracy, while it ranked third when evaluated with average Levenshtein distance.

2 Task Definition and Approach

Morphological inflection is the process that creates grammatical forms (typically guided by sentence structure) of a lexeme/lemma. As a computational task it is framed as mapping from the lemma and a set of morphological tags to the desired form, which simplifies the task by removing the necessity to infer the form from context. For an example from Asturian, given the lemma `aguar` and tags `V;PRS;2;PL;IND`, the task is to create the indicative voice, present tense, 2nd person plural form aguà.

Let $\mathbf{X} = x_1 \dots x_N$ be a character sequence of the lemma, $\mathbf{T} = t_1 \dots t_M$ a set of morphological tags, and $\mathbf{Y} = y_1 \dots y_K$ be an inflection target character sequence. The goal is to model $P(\mathbf{Y} \mid \mathbf{X}, \mathbf{T})$.

Our approach consists of three major components. First, we propose a novel two-step attention decoder architecture (§2.1). Second, we augment the low-resource datasets with a data hallucination technique (§2.2). Third, we devise a training schedule (§2.3) that substitutes structural biases for attention monotonicity.

2.1 Model Architecture

Our models are based on a sequence-to-sequence model with attention (Bahdanau et al., 2015). In broad terms, the model is composed of three parts: an encoder, the attention, and a recurrent decoder. In the setting of the inflection task, there is an additional input provided (the set of morphological tags) which requires an additional encoder.

A visualization of our model is shown in Figure 1. First, an encoder transforms the input character sequence $x_1 \dots x_N$ into a sequence of intermediate representations $\mathbf{h}^x_1 \dots \mathbf{h}^x_N$. A second encoder transforms the set of morphological tags $t_1 \dots t_M$ into another sequence of states $\mathbf{h}^t_1 \dots \mathbf{h}^t_M$:

$$\mathbf{h}^x_n = \text{enc}^{\text{x}}(\mathbf{h}^x_{n-1}, x_n) \quad \text{and} \quad \mathbf{h}^t_m = \text{enc}^{\text{t}}(\mathbf{T}).$$

In our implementation, we use a single layer bidirectional recurrent encoder for the lemma, and a self-attention encoder (Vaswani et al., 2017) for encoding the tags as there is no inherent order (e.g. left-to-right) in their presentation. In preliminary experiments, a self-attention lemma encoder proved hard to train, while a recurrent tag encoder yielded quite competitive results.

Next, we have attention mechanisms that transform the two sequences of input states into two sequences of *context vectors* via two matrices of *attention weights* (k is the current decoder time step):

$$\mathbf{c}^x_k = \left[\textstyle\sum_n \alpha^x_{kn} \mathbf{h}^x_n\right] \qquad \mathbf{c}^t_k = \left[\textstyle\sum_m \alpha^t_{km} \mathbf{h}^t_m\right].$$

Finally, the recurrent decoder computes a sequence of *output states* in a two-step process, from which a probability distribution over output characters can be computed:

$$\begin{aligned} \mathbf{s}_k &= \mathbf{s}'_{k-1} + \mathbf{c}^t_k \\ \mathbf{s}'_k &= \text{dec}(\mathbf{s}'_{k-1}, \mathbf{c}^x_k, y_{k-1}) \\ P(y_k) &= \text{softmax}(\mathbf{s}'_k). \end{aligned}$$

The attention mechanisms produce their weights as in Luong et al. (2015), with $\mathbf{v}^x$, $\mathbf{v}^t$, $\mathbf{W}^{s'}_{\alpha^x}$, $\mathbf{W}^{s}_{\alpha^t}$, $\mathbf{W}^{h}_{\alpha^x}$, and $\mathbf{W}^{h}_{\alpha^t}$ being parameters to be learned:

$$\alpha^t_{km} = \text{softmax}(\mathbf{v}^t \tanh(\left[\mathbf{W}^{s}_{\alpha^t} \mathbf{s}'_{k-1}; \mathbf{W}^{h}_{\alpha^t} \mathbf{h}^t_m\right]))$$

$$\alpha^x_{kn} = \text{softmax}(\mathbf{v}^x \tanh(\left[\mathbf{W}^{s'}_{\alpha^x} \mathbf{s}_k; \mathbf{W}^{h}_{\alpha^x} \mathbf{h}^x_n\right])).$$

The two-step attention process essentially first uses the decoder's previous state $\mathbf{s}'_{k-1}$ as the query for attending over the tags. Then, it creates a tag-

informed state $\mathbf{s}'_k$ by adding the tag context $\mathbf{c}^t_k$ to the previous state. The tag-informed state is then used as the query for attending over the source characters and produce the context $\mathbf{c}^x_k$. The last step is then to update the recurrent state and produce the output character. Ultimately, we desire that the provided tag set guides the generation, which also means influencing the attention over the characters of the lemma.

Additional Structural Biases for Attention Incorporating structural biases in the model's architecture or in the training objective can lead to improvements in performance, especially for tasks where the attention mechanism is expected to behave similarly to an alignment model, like MT. This idea has been successfully applied to the inflection task and is at the core of the state-of-the-art model (Wu and Cotterell, 2019).

One bias we deem important is *coverage* of all input characters and tags from the attentions. Intuitively, this entails encouraging the model to "look at" the whole input. We take the approach of Cohn et al. (2016) and add two regularizers over the final attention matrices, encouraging them to also sum to one column-wise:

$$-\lambda \parallel \Sigma_j a^t_{jm} - \mathbb{I} \parallel_2 \qquad -\lambda \parallel \Sigma_j a^x_{jn} - \mathbb{I} \parallel_2$$

Another bias that we incorporate encourages the Markov assumption over attention/alignments. Briefly, this means that if the i-th source character/word is aligned to the j-th target one ($i \leftarrow j$), then alignments $i{+}1 \leftarrow j{+}1$ or $i \leftarrow j{+}1$ are also quite likely. In a neural architecture this can be approximated by providing the attention weight vector from the previous timestep as input to the function that computes the attention weights. We refer the reader to Cohn et al. (2016) for exact details.

Adversarial Language Discriminator When training multilingual systems, encouraging the encoder to learn language-invariant representations can often lead to improvements (Xie et al., 2017; Chen et al., 2018), as it forces the model to truly work in a multilingual setting. We achieve that by introducing a language discriminator (Ganin et al., 2016). This additional component receives the last output of the (bi-directional) intermediate lemma representations $\mathbf{h}^x_N$ and outputs a prediction y_l of the source language such that y_l=softmax(MLP($\mathbf{h}^x_N$)).

The discriminator is trained to predict the language by minimizing a standard cross-entropy loss $\mathcal{L}_l$ similar to Lample et al. (2018). However, in order to encourage the encoder to learn language-invariant representations, we reverse the gradients flowing from that component into the encoder during back-propagation.

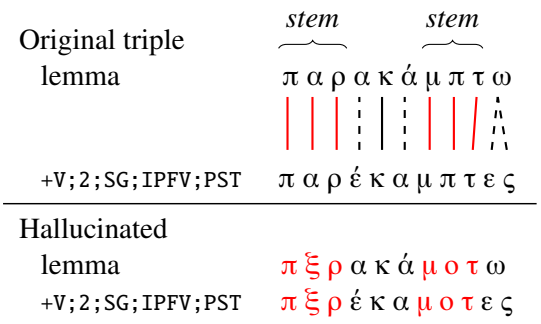

Figure 2: Example of our hallucination process (Greek). The lemma and inflected forms are aligned at the character level. The inside of *stem*-considered parts (highlighted) are substituted with random characters, creating hallucinated triples (bottom).

2.2 Data Hallucination

Low-resource language datasets are usually too small to allow for proper learning with neural networks. A major issue in our case is *label bias*. Put simply, the character decoder will overly prefer outputting common character sequences. However, with just 50 examples to learn from, the output character n-gram distribution will hardly match the real one, because the majority of the n-grams will have zero probability. In order to mitigate this issue, we augment our training sets with hallucinated data.

In most languages morphological reinflection is realized by adding, deleting, or modifying prefixes or suffixes over a stem that is mainly unchanged. Though we do not have prior information regarding the stem or affixes of our data we can use character alignment to approximately compute them. We use the alignment method from the SIGMORPHON 2016 baseline (Cotterell et al., 2016) to align the lemmata and the inflected forms. For each example, we consider as part of the stem *any* sequence of three or more[3] consecutive lemma characters that are aligned to the exact same characters in the inflected form.

Now, for each such region considered as a "stem", we randomly substitute its inside (not start or end) characters with other characters from the language's alphabet. Note that we do not change

[3]This heuristic number is largely arbitrary and could potentially be tuned to different values for each language.

the length of the region, though allowing for such variation could possibly lead to further improvement. The substitution characters are sampled uniformly for the alphabet, rather than attempting to sample from a more informed distribution, which has potential for further improvements. Overall, we hallucinated 10,000 examples for each low-resource language, creating an additional hallucinated dataset $\mathcal{H}$.

A visualized example of our hallucination process is outlined in Figure 2. Out of the three regions with matching aligned characters (thick lines), we identify two with length equal to three or more. In the hallucinated example (bottom of the figure), we sample random characters for the inside of such regions.

Silfverberg et al. (2017) have proposed a data hallucination method conceptually quite similar to ours, which treats the *single* longest common continuous substring between lemma and form as the stem. Their approach would be effectively similar to ours for languages with affixal stem-invariant morphology, but it would likely fail in more complicated morphological phenomena like apophony, stem alternation (conceptually similar to infix morphology) or in the root-and-pattern morphology of semitic languages. Consider the apophony example from the past participle form `gschwommen` of the lemma `schwimmen` in Swiss German: our approach would treat both the `schw` and the `mmen` regions as a stem, as opposed to only considering one.[4] Note that neither of the two approaches are suitable for phenomena such as suppletion (e.g. the inflection of the Spanish verb `ir` 'to go' into `fue` 'went') or phenomena like the reduplication pattern of Indonesian noun plurals as in `kuda` 'horse', `kuda-kuda` 'horses' (Sneddon et al., 2012).

2.3 Training Schedule

Our training schedule attempts to balance two desires: helping the model to (1) learn to copy, and (2) learn cross-lingually with a particular focus on the low-resource language. To achieve this, we split training into three phases: warm-up, cross-lingual training, and low-resource fine-tuning.

Phase 1: Warm-Up As several previous works have noted, learning to copy is crucial. Unlike other proposed models, though, our model does not include any structural biases that encourage copying. Instead, we rely on an additional copying task in a warm up period.

We transform each training triple $[\mathbf{X}, \mathbf{T}, \mathbf{Y}]$ into two additional triples that encourage copying: $[\mathbf{X}, \texttt{COPY}, \mathbf{X}]$ and $[\mathbf{Y}, \mathbf{T}, \mathbf{Y}]$. Using both the input and output sequences for the copying task allows the use of slightly more diverse data. Note that we only use the correct tags when copying the inflected form. For copying the lemma we use a specialized tag (`COPY`). Additional improvements could be achieved if one knew the exact tags that match the lemmata. But this could vary by language: an English verb's lemma is its infinitive and has a `V;NFIN` tag, while a verb lemma in Modern Greek is its `V;1;SG;IPFV;PRS` form.

In this stage we use a relatively large batch size (10) in order to encourage more coarse updates. In most cases, the model achieves extremely high copying accuracy after a couple of warm-up epochs, so we stop the warm up stage when copying accuracy exceeds 75%. At this point the attention mechanism over the source characters has learned to be monotonic. In contrast, the model of Wu and Cotterell (2019) requires a dynamic programming method that forces strict monotonicity, with an additional (non-parallelizable) computational cost $O(|x|^2)$ throughout training.

Model	Accuracy	Median
Wu and Cotterell (2019)	48.5	45.5
this work	48.8	67.0
+$\mathcal{H}$	60.1	66.6
+$\mathcal{H}$ + $\mathcal{L}_l$	60.8	66.0
+multi-language transfer	**63.8**	64.0
oracle	68.2	74.0

Table 1: Macro-averaged accuracy over 100 language test pairs. Our best model outperforms the baseline by 15 percentage points.

Phase 2: Cross-lingual training In the main training phase we use both high- and low-resource language data (including any hallucinated data). If not using hallucinated data, we up-sample the low-resource data in order to match the size of the high-resource ones. Furthermore, with probability 0.30 we also sample copying tasks to intersperse throughout the training epoch. This ensures the source-character attention keeps being monotonic.

Phase 3: Fine-tuning The last phase is inspired by fine-tuning, or continued training, as applied to

[4] Most likely, the desired parts are `schw` and `mm`.

Model	Dev Accuracy (macro-averaged)
Wu and Cotterell (2019):	
0^{th}-order soft attention	37.1
0^{st}-order hard attention	43.5
0^{th}-order monotonic attention	45.5
1^{st}-order monotonic attention	51.3
two-step attention (this work)	
– warm-up, copy task	31.2
+ warm-up, copy task	48.0
+ structural biases	48.7
+ scheduled sampling	49.1
+ minibatch schedule	49.4
with hallucinated data:	
$+\mathcal{H}$	$82.6^{\dagger}$
$+\mathcal{H} + \mathcal{L}_l$	$85.4^{\dagger}$
+ensemble (three models)	$85.6^{\dagger}$

Table 2: Our proposed two-step attention architecture outperforms almost all baselines on the development set (but with higher gains on the test set). Additional biases and scheduled sampling contribute improvements. †: results with hallucinated data are not directly comparable, as dev data were used for hallucination.

cross-lingual MT e.g. by Neubig and Hu (2018) or to domain adaptation for MT e.g. by Luong and Manning (2015). The setting is nearly identical to the second phase, except we only use the low-resource language data for training and do not use the copying task. Furthermore, we substitute teacher forcing for scheduled sampling (Bengio et al., 2015), where with probability 50% the input to the next step of the decoder is not the gold one, but its previous prediction. This technique allows the model to become more robust to its own mistakes, effectively limiting the effect of exposure bias. It is worth noting that at this point, the learning rate is typically quite small, so we reduce the batch size to a single instance. In most cases, though, the improvements on development set accuracy are marginal (1 to 2%).

2.4 Inference and Implementation Details

The performance of inflection systems is typically evaluated with exact-match token-level accuracy, as well as character-level Levenshtein distance.[5] Hence, during training we continuously evaluate the model's performance on the development set with both metrics. Consequently we store three checkpoints: the one that achieved the highest accuracy, the one that reached the lowest Levenshtein distance, and the one that improved on both metrics over previous dev evaluations. In a few cases these three checkpoints coincide, but this is rather rare. We ensemble these three models with equal weights for producing our final predictions.

All our models are implemented in DyNet (Neubig et al., 2017). Each model is trained on a single CPU, as each training run requires less than 1GB of RAM and typically concludes within 3 to 4 hours. We provide additional hyperparameter details in the Appendix.

3 Empirical Results

Our experiments are conducted on the SIGMORPHON 2019 challenge datasets (McCarthy et al., 2019a). The dataset consists of 100 pairs between (mostly related) high-resource transfer languages and 43 low-resource test languages with examples taken from the Unimorph database (Kirov et al., 2018). The low-resource languages typically have about 100 training examples, plus 50–100 (or in very few cases, 1000) examples in the development set. In contrast, most high-resource language training sets include 10,000 instances.

Test Accuracy Our main results are summarized in Table 1. Our models significantly outperform the baseline, evaluated with macro-averaged accuracy over the 100 language pairs. Our novel architecture performs slightly better than the baseline without any additional data. Importantly, including the hallucinated datasets boosts total accuracy by 10 percentage points, while transfer from multiple languages further improves to a state-of-the-art accuracy of 63.8% – higher than any system submitted to the shared task.

It is worth noting that all of these improvements are not uniform across languages/pairs: without hallucinated training data, our model's median is notably larger than its average, implying that for a few language pairs our model is under-trained and under-performs (in particular, pairs with Yiddish, Votic, and Ingrian as test languages). Nonetheless, if one had access to an oracle that would allow them to select the best performing model out of all the different settings, they would achieve an oracle accuracy of 68.2%.

[5] Due to space constraints, we do not provide Levenshtein distance results. They generally inversely correlate with token-level accuracy.

Table 3: Results with a single transfer language. Monolingual data hallucination is crucial due to the distance of the languages. In some cases cross lingual transfer should be avoided in favor of a purely monolingual setting ($\mathcal{H}$).

Architecture Ablations We focus on the architecture of the model and the structural biases we introduced, using the development set for evaluation. Table 2 presents the macro-averaged accuracy for the baseline (Wu and Cotterell, 2019) and the different versions of our model.[6]

The first thing to note is the importance of the warm-up period in our training schedule and the use of the copying task. Our model neither handles copying in any explicit way nor encourages the attention to be monotonic. Without the warm-up period and the additional copying tasks, our model's dev accuracy is worse than any of the baselines.

On the other hand, our two-step attention trained with the additional copying task already improves over most baselines without any of the additional biases, with a dev accuracy of 48. The best baseline model, with an average dev accuracy of 51.3, is better than our models, but this difference is not reflected on the test set (see Table 1) where our model performs slightly better. This discrepancy could be due to optimizer or early stopping decisions, but we leave a more thorough investigation for future work.

We attribute the success of our model to two factors, the first being our novel architecture. Compared to a single attention over the concatenated tag and lemma sequences, our two-step attention has the advantage of two distinct attention mechanisms, which capture the inherently different properties of the tag and the lemma character sequences. Another advantage is the two-step process that guides the lemma attention with the tags. Disentangling the two attentions *and* ordering them in an intuitive way makes it easier for them to learn their respective tasks.

The second factor is, we suspect, a slightly better choice of hyperparameters: our models are smaller than the baseline ones. Although we did not tune our hyperparameters extensively, a few experiments on a couple of language pairs showed that increasing the model size hurt performance under these extremely data-scarce conditions.

Each of the additional techniques we tested further contributed a few accuracy points. The attention biases add 0.7% points and scheduled sampling in the third training phase further adds 0.4% points. The different batching schedule with large batch sizes in the beginning but smaller towards the end of training helps a little more in terms of accuracy, but most importantly it speeds up training. Table 2 also reports the development set accuracy when using hallucinated data. Although the large improvements are also proportionally reflected in the test set, these numbers are not directly comparable to the rest, as the development set data were used in the hallucination process.

4 Analysis

We analyze the results over various groupings of languages to elucidate the properties of our models over the 100 quite diverse language pairs. We use typological information from the URIEL database (Littell et al., 2017) in this analysis.

Single Language Transfer We first focus on the test languages for which a *single* transfer language

[6]Table 2 includes unpublished results kindly shared by Wu and Cotterell, the authors of the baseline.

Table 4: Results with multiple transfer languages (sample). The best performing system per target (L2) language is **highlighted**. We repeated the hallucinated-data-only experiments as many times as potential transfer (L1) languages, hence the $\mathcal{H}$ column reports average accuracy ± standard deviation.

was provided, with detailed results presented in Table 3. Generally, the average genetic distance between the transfer and the task language is quite high (0.75) for these pairs. It is easy to observe that the larger the typological distance, the larger the improvement from adding hallucinated data. In fact, excluding the languages with no typological information available, there is strong correlation (ρ=0.6) between genetic distance and improvement from hallucinated data.

For cross-lingual transfer to be useful, the languages need to be at least somewhat related and share similar characteristics. A prime example is transfer from Italian for Neapolitan, which achieves a 70% accuracy without any additional synthesized data. In the same vein, the same condition is necessary for the adversarial language discriminator to have impact, as using it on extremely distant language pairs leads to worse performance (e.g. Russian-Portuguese, Bengali-Greek, or Urdu-Old English). This is expected, as forcing language invariant representations across vastly different languages is analogous to representing a bimodal distribution with its mean.

The results on Kurmanji-Sorani (Northern Kurdish-Central Kurdish) seem to be a valid counter-example to the above statement, i.e. the two languages are related,[7] but cross-lingual transfer without hallucinated data performs poorly, achieving a mere 16.2 accuracy. The reason for this discrepancy lies in the characters: Kurmanji is written in the Latin alphabet, while Sorani uses the Arabic one.[8] The lack of any similar representations across the languages is too hard to overcome even with the adversarial language discriminator.[9]

Multiple Transfer Languages For most low-resource languages and especially dialects, there exist several possible candidate transfer languages that can be related enough to satisfy the similarity constraint. We present extensive ablations on such cases in Table 4 with results on the rest of the SIGMORPHON language pairs.[10]

We again observe positive correlations between the language genetic proximity and the performance of cross-lingual transfer, even with all the transfer and test languages being related. For example, transfer from (distant) Basque to Kashubian performs about 10 percentage points worse than transfer from (related) Slovak or Czech, which in turn perform worse than transfer from Polish (more closely related to Kashubian than the

[7] A reviewer pointed out that Kurmanji and Sorani might actually be more distant than the politically-motivated term "Kurdish dialects" might imply.

[8] Kurmanji is also sometimes written with the Cyrillic or the Nashk Arabic scripts, but our data are Latin-only.

[9] We did not attempt to address this issue, by e.g. increasing the loss weight, but we leave this for future work.

[10] We present a sample due to space constraints. The discussion pertains to all language pairs. The full table is available in the Appendix.

others). Transfer for North Frisian using Danish is also 10 percentage points worse than transfer from the more closely related Dutch. It is worth noting that using the hallucinated data reduces the effect of the genetic distance between languages, with the standard deviation across the results within the same test language becoming much smaller.

A very interesting case of cross-lingual transfer is Maltese, which is a semitic language and hence genetically close to Hebrew and Arabic. Surprisingly, we obtain better results when transferring from Italian. Again, a script discrepancy could be the main reason, also considering that the root and pattern morphology is only partially expressed in the scripts of Hebrew and Arabic, whereas it is fully expressed (by writing all the vowels) in Maltese. We should also point out that genetic similarity might not be enlightening enough. As Hoberman and Aronoff (2003) point out, the productive verbal morphology in Maltese has become affixal due to borrowings from Romance languages. To further exacerbate the situation, all provided train, dev, and test examples are verbs (no nouns or adjectives), providing an explanation to this seemingly counter-intuitive result.

Another interesting case is that of cross-lingual transfer for Bengali, with the potential languages varying from very related (Sanskrit, Hindi) to even only distantly related (Greek). Nevertheless, there is notably little variance in the performance of the systems. We believe that again the culprit is the difference in writing systems between all selected transfer and test language, which does not allow our system to leverage cross-lingual information: our Bengali data use the Bengali script, the Urdu dataset is in the Arabic one, Hindi and Sanskrit use Devanagari, and Greek uses the Greek alphabet.

We also present analytic results with cross-lingual transfer from all transfer languages from the suggested SIGMORPHON pairs.[11] In 14 out of the 29 test languages, our best-performing model is trained on multiple transfer languages. For instance, using Turkish, Persian, Bashkir, and Uzbek data for transfer to Azeri leads to a 6 point improvement over any single-language-transfer result. A potential explanation is that a dialect/language has indeed been influenced by multiple languages. Another reason could lie in the increased amount of data and potential regularization effects. We suspect the truth lies in the union of those factors, but nonetheless we conclude that **whenever available, transfer from multiple related languages can further improve accuracy**.

In our experiments we used all transfer languages that the SIGMORPHON organizers proposed in the 2019 challenge. On the one hand, a more sophisticated data selection process could likely yield improvements. For example, Yiddish is primarily based in High German and it has elements from Hebrew, Aramaic, as well as Slavic languages, but we did not test how transfer from these languages might perform. Moreover, in order to remain faithful to the SIGMORPHON challenge, we used some distant languages that probably worsen the results (e.g. Greek for Bengali).

Also, alphabet divergence issues still need to be addressed. For instance, we suspect that our accuracy in Yiddish (which uses the Hebrew alphabet with Yiddish orthography) could be greatly improved by finding some type of mapping between its orthography and the Latin script that most of its related languages use. The same could hold for transfer for the central Asian languages (Tatar, Turkmen, Azeri among others) which use a variety of the Latin, Cyrillic, or Arabic scripts.

Lastly, we experimented with a completely monolingual setting, using just the low-resource and hallucinated language data (columns $\mathcal{H}$ in Tables 3 and 4). For fairer comparison to cross-lingual transfer, we repeated the hallucination process as many times as candidate transfer languages and we report the mean and standard deviation of the test set accuracy. This baseline is extremely competitive, lagging only a few points behind the $\mathcal{L} + \mathcal{H}$ combination. Encouragingly, this entails that hallucination is a viable option for entire language families without a single high-resource representative or low-resource isolates.

Interpretability We find that the attention matrices can help understand our model's predictions. A visualization of two examples is shown in Figure 3, showcasing the interpretability advantage of the disentangled two-step attentions. In the Kazakh example the tag attention clearly identifies the suffixes да (that marks plural) and рды (that marks the accusative case). The Greek example is a great one of how the two-step process allows the tags to guide the lemma attention. Due to the SBJV tag, the model does not use the lemma until the necessary particle να has been generated. Conse-

[11] We do not use *all* languages for transfer in a test language. For instance, when testing on Occitan 'all' stands for training on Asturian, Spanish, and French.

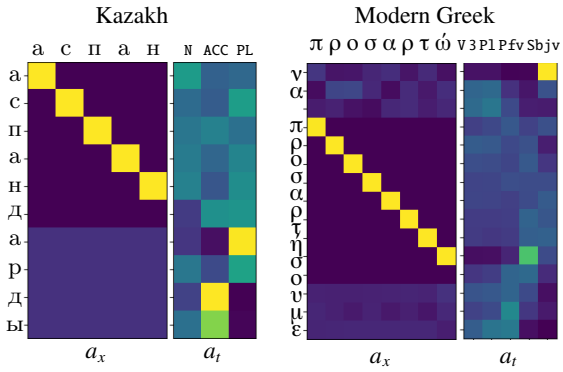

Figure 3: Attention visualization examples. The inflected form is generated from top to bottom.

quently, the lemma attention properly copies the stem, and then the tag attention attends first over PFV and then over PL and 3 in order to construct the correct suffix for perfective and 3rd person plural.

5 Related Work

The inflection task in high-resource settings has been extensively studied through the SIGMORPHON shared tasks. Notably, the best models explicitly model copying and hard monotonic attention (Aharoni et al., 2016; Aharoni and Goldberg, 2017) with the previous state-of-the-art forcing strict monotonicity (Wu and Cotterell, 2019). We instead achieve state-of-the-art with a cheaper approach that simply intermixes a copying task which also encourages monotonicity.

Data augmentation for inflection has been explored by Bergmanis et al. (2017) and Zhou and Neubig (2017) among others. The work of Silfverberg et al. (2017) is the most similar to ours, but as we already discussed, it has a few shortcomings that our approach addresses.

Kann et al. (2017) have identified typology as playing a role for cross-lingual transfer, but they measure language similarity using lexical overlap. We attest that this data-based measure is less informative and more suspect to variation, so we instead use the genetic typological information to quantify correlations between performance improvements and language distance.

Our novel two-step process decoder architecture bares similarities with multi-source models (Anastasopoulos and Chiang, 2018; Zoph and Knight, 2016) which provide two contexts from two encoded sources to the decoder. A similar disentangled encoding was also used by Ács (2018) for their SIGMORPHON 2018 submission. We in fact experimented with this architecture but preliminary results on the development sets showed that our two-step architecture achieved better performance. Interestingly, the second-best performing system (Peters and Martins, 2019) at SIGMORPHON 2019, which also ranked first in terms of Levenshtein distance, also uses decoupled encoders to separately encode the lemma and the tags; this further cosolidates our belief that such an approach is superior to using a single encoder for the concatentated sequence of the tags and lemma. The main difference to our model is that they do not use our two-step decoder process, while they substitute all softmax operations with sparsemax (Martins and Astudillo, 2016), yielding interpretable attention matrices very similar to ours. The use of sparsemax in conjunction with our two-step decoder process, as well as along our data hallucination technique, presents a promising direction towards even better results in the future.

6 Conclusion

With this work we advance the state-of-the-art for morphological inflection on low-resource languages by 15 points, through a novel architecture, data hallucination, and a variety of training techniques. Our two-step attention decoder follows an intuitive order, also enhancing interpretability. We also suggest that complicated methods for copying and forcing monotonicity are unnecessary. We identify language genetic similarity as a major success factor for cross-lingual training, and show that using many related languages leads to even better performance. Despite this significant stride, the problem is far from solved. Language-specific or language-family-specific improvements (i.e. proper dealing with different alphabets, or using an adversarial language discriminator) could potentially further boost performance.

Acknowledgements

The authors are grateful to the anonymous reviewers for their exceptionally constructive and insightful comments, to Arya McCarthy for discussions on morphological inflection, to Shruti Rijhwani for her comments on Bengali, to Shijie Wu and Ryan Cotterell for sharing the dev performance of their model, as well as to Gabriela Weigel for her invaluable help with editing and proofreading the paper. A Hyperparameters

Here we list all the hyperparameters of our models:

- Encoder/Decoder number of layers: 1
- Character/Tag Embedding size: 32
- Recurrent State Size: 100
- LSTM Type: CoupledLSTM
- Attention Size: 100
- Target and Source Character Embeddings are Tied
- Tag Self-Attention size: 100
- Tag Self-Attention heads: 1

Here we list the optimizer settings:

- Optimizer: SimpleSGD
- Starting learning rate: 0.1
- Learning Rate Decay: 0.5
- Learning Rate Decay Patience: 6 epochs
- Maximum number of epochs: 20, 40, 40 (for each training phase)
- Minibatch Size: 10, 10, 2 (for each training phase).

Abstract

Treebank translation is a promising method for cross-lingual transfer of syntactic dependency knowledge. The basic idea is to map dependency arcs from a source treebank to its target translation according to word alignments. This method, however, can suffer from imperfect alignment between source and target words. To address this problem, we investigate syntactic transfer by code mixing, translating only confident words in a source treebank. Cross-lingual word embeddings are leveraged for transferring syntactic knowledge to the target from the resulting code-mixed treebank. Experiments on University Dependency Treebanks show that code-mixed treebanks are more effective than translated treebanks, giving highly competitive performances among cross-lingual parsing methods.

1 Introduction

Treebank translation (Tiedemann et al., 2014; Tiedemann, 2015; Tiedemann and Agić, 2016) has been considered as a method for cross-lingual syntactic transfer. Take dependency grammar for instance. Given a source treebank, machine translation is used to find target translations of its sentences. Then word alignment is used to find mappings between source and target words, so that source syntactic dependencies can be projected to the target translations. Following, a post-processing step is applied by removing unaligned target words, in order to ensure that the resulting target syntax forms a valid dependency tree, The method has shown promising performance for unsupervised cross-lingual dependency parsing among transfer methods (McDonald et al., 2011; Täckström et al., 2012; Rasooli and Collins, 2015; Guo et al., 2016b).

(a) full-scale translation.

(b) this method, partial translation.

Figure 1: An example to illustrate our method, where the source and target languages are English (en) and Swedish (sv), respectively.

The treebank translation method, however, suffers from various sources of noise. For example, machine translation errors directly affect the resulting treebank, by introducing ungrammatical word sequences. In addition, the alignments between source and target words may not be isomorphic due to inherent differences between languages or paraphrasing during translation. For example, in the case of Figure 1, the English words "are" and "being", and the Swedish word "med", do not have corresponding word-level translation. In addition, it can be perfect to express "as soon as they can" using "very quickly" in a translation, which looses word alignment information because of the longer span. Finally, errors in automatic word alignments can also bring noise. Such alignment errors can directly affect grammaticality of the resulting target treebank due to deletion of unaligned words during post-processing, or cause

lost or mistaken dependency arcs.

We consider a different approach for translation-based syntactic knowledge transfer, which aims at making the best use of source syntax with the minimum noise being introduced. To this end, we leverage recent advances in cross-lingual word representations, such as cross-lingual word clusters (Täckström et al., 2012) and cross-lingual word embeddings (Guo et al., 2015), which allow words from different languages to reside within a consistent feature vector space according to structural similarities between words. Thus, they offer a bridge on the lexical level between different languages (Ammar et al., 2016).

A cross-lingual model can be trained by directly using cross-lingual word representations on a source treebank (Guo et al., 2015). Using this method, knowledge transfer can be achieved on the level of token correspondences. We take this approach as a naive baseline. To further introduce structural feature transfer, we transform a source treebank into a code-mixed treebank by considering word alignments between a source sentence and its machine translation. In particular, source words with highly confident target alignments are translated into target words by consulting the machine translation output, so that target word vectors can be directly used for learning target syntax. In addition, continuous spans of target words of the code-mixed treebank are reordered according to the translation, so that target grammaticality can be exploited to the maximum potent.

We conduct experiments on Universal Dependency Treebanks (v2.0) (McDonald et al., 2013; Nivre et al., 2016). The results show that a code-mixed treebank can bring significantly better performance compared to a fully translated treebank, resulting in averaged improvements of 4.30 points on LAS. The code and related data will be released publicly available under Apache License 2.0.[1]

2 Related Work

Existing work on cross-lingual transfer can be classified into two categories. The first aims to train a dependency parsing model on source treebanks (McDonald et al., 2011; Guo et al., 2016a,b), or their adapted versions (Zhao et al., 2009; Tiedemann et al., 2014; Wang et al., 2017) in the target language. The second category, namely annotation projection, aims to produce a set of large-scale training instances full of automatic dependencies by parsing parallel sentences (Hwa et al., 2005; Rasooli and Collins, 2015). The two broad methods are orthogonal to each other, and can both make use of the lexicalized dependency models trained with cross-lingual word representations (Rasooli and Collins, 2017, 2019).

Source Treebank Adaption. There has been much work on unsupervised cross-lingual dependency parsing by direct source treebank transferring. Several researchers investigate delexicalized models where only non-lexical features are used in the models (Zeman and Resnik, 2008; Cohen et al., 2011; McDonald et al., 2011; Naseem et al., 2012; Täckström et al., 2013; Rosa and Zabokrtsky, 2015). All the features in these models are language independent, and are consistent across languages and treebanks. Thus they can be applied into target languages directly.

Subsequent research proposes to exploit lexicalized features to enhance the parsing models, by resorting to cross-lingual word representations (Täckström et al., 2012; Guo et al., 2015; Duong et al., 2015b,a; Zhang and Barzilay, 2015; Guo et al., 2016b; Ammar et al., 2016; Wick et al., 2016; de Lhoneux et al., 2018). Cross-lingual word clusters and cross-lingual word embeddings are two main sources of features for transferring knowledge between source and target language sentences. These studies enable us to train lexicalized models on code-mixed treebanks as well. Thus here we integrate the cross-lingual word representations as well, which gives more direct interaction between source and target words.

Our work follows another mainstream method of this line of work, namely treebank translation (Tiedemann et al., 2014; Tiedemann, 2015; Tiedemann and Agić, 2016), which aims to adapt an annotated source treebank into the target language by machine translation. In addition, the target-side sentences are produced by machine translation. Previous work aims to build a well-formed tree (Tiedemann and Agić, 2016) from source dependencies, solving word alignment conflicts by heuristic rules. In contrast, we use partial translation instead to avoid unnecessary noise.

Annotation Projection. The annotation projection approach relies on a set of parallel sentences between the source and target languages (Hwa et al., 2005; Ganchev et al., 2009). In par-

[1] https://github.com/zhangmeishan/CodeMixedTreebank

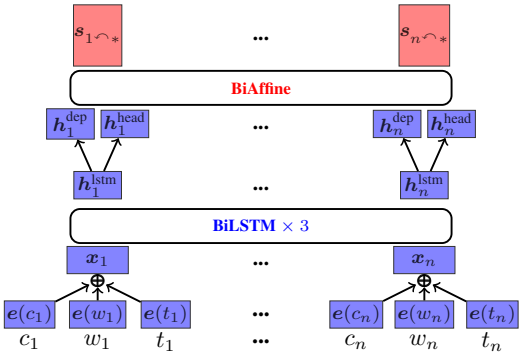

Figure 2: The overall architecture of the BiAffine parser.

ticular, a source parser trained on the source treebank is used to parse the source-side sentences of the parallel corpus. The source dependencies are then projected onto the target sentences according to word alignments. Different strategies can be applied for the dependency projection task (Ma and Xia, 2014; Rasooli and Collins, 2015; Xiao and Guo, 2015; Agić et al., 2016; Schlichtkrull and Søgaard, 2017). For example, one can project only dependency arcs whose words are aligned to target-side words with high confidence (Lacroix et al., 2016). The resulting treebank can be highly noisy due to the auto-parsed source dependency trees. Recently Lacroix et al. (2016) and Rasooli and Collins (2017) propose to filter the results from the large-scale parallel corpus. Our work is different in that the source dependencies are from gold-standard treebanks.

3 Dependency Parsing

We adopt a state-of-the-art neural BiAffine parser (Dozat and Manning, 2016) as the baseline, which has achieved competitive performances for dependency parsing. The overall architecture is shown in Figure 2. Given an input sentence $w_1 \cdots w_n$, the model finds its embedding representations of each word $\boldsymbol{x}_1 \cdots \boldsymbol{x}_n$, where

$$\boldsymbol{x}_i = \boldsymbol{e}(w_i) \oplus \boldsymbol{e}(c_i) \oplus \boldsymbol{e}(t_i) \quad (1)$$

Here c_i denotes the word cluster of w_i, and t_i denotes the POS tag. We exploit cross-lingual word embeddings, clusters and also universal POS tags, respectively, which are consistent across language and treebanks.

A three-layer deep bidirectional long short term memory (LSTM) neural structure is applied on $\boldsymbol{x}_1 \cdots \boldsymbol{x}_n$ to obtain hidden vectors $\boldsymbol{h}_1^{\text{LSTM}} \cdots \boldsymbol{h}_n^{\text{LSTM}}$. For head finding, two non-linear feed-forward neural layers are used on $\boldsymbol{h}_1^{\text{LSTM}} \cdots \boldsymbol{h}_n^{\text{LSTM}}$ to obtain $\boldsymbol{h}_1^{\text{dep}} \cdots \boldsymbol{h}_n^{\text{dep}}$ and $\boldsymbol{h}_1^{\text{head}} \cdots \boldsymbol{h}_n^{\text{head}}$. We compute the score for each dependency $i \curvearrowleft j$ by:

$$\boldsymbol{s}_{i \curvearrowleft j} = \text{BiAffine}(\boldsymbol{h}_i^{\text{dep}}, \boldsymbol{h}_j^{\text{head}}) \quad (2)$$

The above process is also used for scoring a labeled dependency $i \overset{l}{\curvearrowleft} j$, by extending the 1-dim vector $\boldsymbol{s}$ into L dims, where L is the total number of dependency labels.

When all scores are ready, a softmax function is used at each position for all candidate heads and labels, and then the normalized scores are used for decoding and training. For decoding, we exploit the MST algorithm to ensure tree-structural outputs. For training, we accumulate the cross-entropy loss at the word-level by treating the normalized scores as prediction probabilities. The reader is referred to Dozat and Manning (2016) for more details.

4 Code-Mixed Treebank Translation

We derive code-mixed trees from source dependency trees by partial translation, projecting words and the corresponding dependencies having high-confidence alignments with machine-translated target sentences. Our approach assumes that sentence level translations and alignment probabilities are available. The motivation is to reduce noise induced by problematic word alignments.

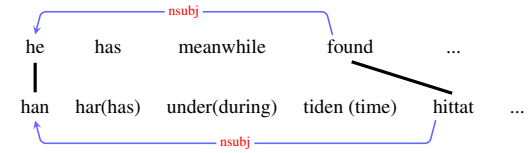
We adopt the word-level alignment strategy, which has been demonstrated as effective as phrase-level alignment yet much simpler (Tiedemann et al., 2014; Tiedemann, 2015; Tiedemann and Agić, 2016). Give a source sentence $e_1 \cdots e_n$ and its target language translation $f_1 \cdots f_m$, $p(e_i|f_j)$ denotes the probability of word f_j being aligned with e_i ($0 \leq i \leq n$ and $0 < j \leq m$), where e_0 denotes a null word, indicating the no alignment probability for one target word.

The translation process can be conducted by three steps:

(1) word substitution, which incrementally substitutes the source words with the target translations;

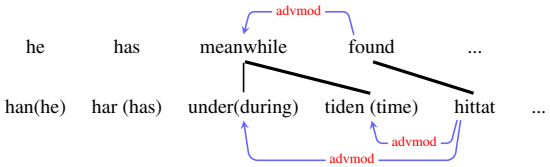
(2) word deletion, which removes several unaligned source words;

Algorithm 1 The process of tree translation.



Input: $e_1 \cdots e_n$, $f_1 \cdots f_m$, T_e, $\{p(e|f)\}$, λ
Output: T_{mix}

1: Let $\mathrm{T}_{\text{mix}} = \mathrm{T}_e$.
2: **for** $j \in [1, m]$ **do**
3: $\quad a_j, p_j \leftarrow \text{argmax}_i\, p(e_i|f_j), \max_i p(e_i|f_j)$
4: **end for**
5: $S_{\text{sub}} \leftarrow \textsc{Select}(\{\langle f_j, a_j, \boldsymbol{v}{=}p_j\rangle\}, \lambda)$
6: **for** $f_j, a_j \in S_{\text{sub}}$ **do**
7: $\quad \mathrm{T}_{\text{mix}} \leftarrow \textsc{Substitute}(f_j, a_j, \mathrm{T}_{\text{mix}})$
8: **end for**
9: $D = [1, n] - \{a_j\}|_{j\in[1,m]}$
10: **for** $i \in D$ **do**
11: $\quad r_i = \sum_j p(e_i|f_j)$
12: **end for**
13: $S_{\text{del}} \leftarrow \textsc{Select}(\{\langle e_i, \boldsymbol{v}{=}\text{-}r_i\rangle\}, \lambda)$
14: **for** $e_i \in S_{\text{del}}$ **do**
15: $\quad \mathrm{T}_{\text{mix}} \leftarrow \textsc{Delete}(e_i, \mathrm{T}_{\text{mix}})$
16: **end for**
17: $\mathrm{T}_{\text{mix}} \leftarrow \textsc{Reorder}(\mathrm{T}_{\text{mix}}, f_1 \cdots f_m)$



(3) sentence reordering, which reorders the partially translated sentence, ensuring local target language word order.

Algorithm 1 shows pseudocode for code-mixing tree translation, where line 1-8 denotes the first step, line 9-16 denotes the second and line 17 denotes the last step.

There is a hyper-parameter λ to control the overall ratio of translation. The function $\textsc{Select}(S, \lambda)$ is to obtain a subset of S by ratio λ with top element values as indicated by $\boldsymbol{v}$ inside S. If $\lambda = 0$, it is still the source language dependence tree, since no source word is substituted or deleted. In this condition, our method is equal to Guo et al. (2015) by bridging source and target dependency parsing with universal word representations. If $\lambda = 1$, the resulting tree is a fully translated target dependency tree, as all words are target language produced by translation. In this setting, our method is equal to Tiedemann and Agić (2016) where the only difference the our baseline parsing model. Thus our method can be regarded as a generalization of both source-side training (Guo et al., 2015) and fully translated target training (Tiedemann and Agić, 2016) with fine-grained control over translation confidence.

(a) one-to-one.

(b) many-to-one.

Figure 3: Examples of word substitution, where the thicker lines indicates more confident alignments.

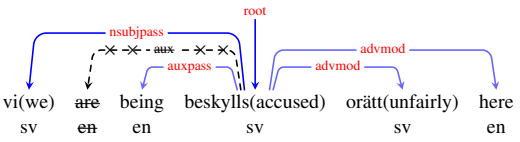
4.1 Word Substitution

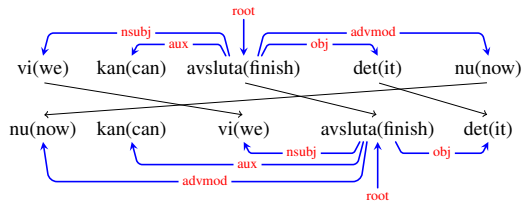
Word substitution is the key step for producing a target treebank. We first obtain the most confidently aligned source word e_{a_j} for each target word f_j as well as their alignment probability $p_j = p(e_{a_j}|f_j)$, as shown by line 3 in Algorithm 1. Then we sort the target words by these alignment probabilities, choosing the top $\lceil m\lambda \rceil$ words with highest alignment probabilities for substitution. The sorting and choosing is reflected in line line 5 of Algorithm 1. Finally for each chosen word f_j and its aligned source word e_{a_j} , we replace the source word e_{a_j} by f_j, as shown by line 7 in Algorithm 1.

One key of the substitution is to maintain the corresponding dependency structures. If e_{a_j} and f_j bares a one-one mapping, with no other target word being aligned with e_{a_j}, the source dependencies are kept unchanged, as shown by Figure 3(a). While if two or more words (i.e., $f_{j_1}, \cdots, f_{j_k}(j_1 < \cdots < j_k)$) are aligned to e_{a_j}, we simply link all words to e_{a_j}, with the same dependency label as the original dependency arc. Figure 3(b) illustrates this condition. Both the Swedish words "under" and "tiden" are headed to "hittat" (the Swedish translation of English word "found") by the dependency label "advmod" inherited from the source English side . Note that the POS tags of the substituted words are the same as the corresponding source words.

4.2 Word Deletion

There can be source words to which no target word is aligned. These words are typically functional words belonging to source language only, such as





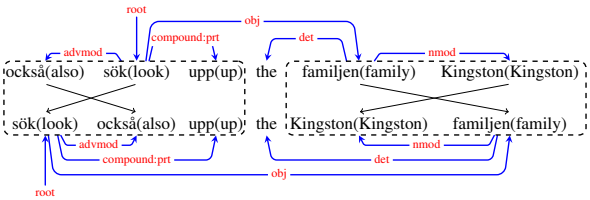


Figure 4: An example of word deletion.

(a) full sentence

(b) two spans

Figure 5: Two examples of sentence reorder.

"the", "are" and "have". We remove such words to produce dependency trees that are close in syntax to the target language.

In particular, we accumulate the probabilities of $p(e_i|f_j)$ for the source word e_i who has no aligned target word:

$$r_i = \sum_j p(e_i|f_j) \quad \text{(line 11 in Algorithm 1)},$$

where we traverse all target words to sum their alignment probabilities with e_i. The value of r_i can be interpreted as the confidence score of retention. The words with lower retention scores should be more preferred to be deleted, as these words have lower probabilities aligning with some word of the target language sentence. Concretely, we collect all source words with no aligned target words, computing their retention values, and the selecting a subset of these words with the lowest retention values by the hyper-parameter λ (line 13 in Algorithm 1). Finally we delete all the selected words (line 15 in Algorithm 1).

Figure 4 shows an example of word deletion. The two words "are" and "being" both have no aligned words in the other side, and meanwhile "are" has a lower retention score compared with "being".[2] Thus the source word "are" is prefer to be deleted. In most cases, the deleted words are leaf nodes, which can be unattached to the resulted dependency tree and deleted them directly. In case of exceptions, we simply reset the corresponding heads of its child nodes by the head of e_i (i.e., h_{e_i}) instead. For example, a dependency $w_i^{\curvearrowleft} e_i$ is changed into $w_i^{\curvearrowleft} \mathrm{h}_{e_i}$.

4.3 Sentence Reordering

Continuous target spans are reordered to make the final code-mixed sentence contain grammatical phrases in the target language. Figure 5(a) shows one example of full sentence reordering. We can see that the word order by word-level substitutions on the source words is different with the order of the machine-translated sentence. Thus we adjust the leaf nodes, letting the word order strictly follow the machine-translated sentence order For example, the word "vi" is moved from the first position into the third position, and similarly the word "mu" is moved from the last position into the first position.

Concretely, we perform the word reorder by the span level, extracting all the continuous spans of target words, because the target language words may be interrupted by source language words. Then we reorder the words in each span according to their order in the machine translation outputs. Figure 5(b) shows another example, where there are two spans separated by the English word "the". Each span is reordered individually. We do not consider the inconsistent orders inter the spans in this work. Note that this step does not change any dependency arc between words.

5 Experiments

We conduct experiments to verify the effectiveness of our proposed models in this section.

5.1 Settings

Our experiments are conducted on the Google Universal Dependency Treebanks (v2.0) (McDonald et al., 2013; Nivre et al., 2016), using English as the source language, and choosing six languages, including Spanish (ES), German (DE), French (FR), Italian (IT), Portuguese (PT) and Swedish (sv), as the target languages. Google

[2] Both the two words are only related to the Swedish word "med", but p(are|med) is slightly lower.

Translate[3] is used to translate the sentences in the English training set into other languages. In order to generate high-quality word-level alignments, we merge the translated sentence pairs and the parallel data of EuroParl (Koehn, 2005) to obtain word alignments. We use the fastAlign tool (Dyer et al., 2013) to obtain word alignments.

We use the cross-lingual word embeddings and clusters by Guo et al. (2016b) for the baseline system. The dimension size of word embeddings is 50 and the word cluster number across of all languages is 256.

For network building and training, we use the same setting as Dozat and Manning (2016), including the dimensional sizes, the dropout ratio, as well as the parameter optimization method. We assume that no labeled corpus is available for the target language. Thus training is performed for 50 iterations over the whole training data without early-stopping.

To evaluate dependency parsing performances, we adopt UAS and LAS as the major metrics, which indicate the accuracies of unlabeled dependencies and labeled dependencies, respectively. We ignore the punctuation words during evaluation following previous work. We run each experiment 10 times and report the averaged results.

5.2 Models

We compare performances on the following models:

- `Delex` (McDonald et al., 2013): The delexicalized BiAffine model without cross-lingual word embeddings and clusters.
- `Src` (Guo et al., 2015): The BiAffine model trained on the source English treebank only.
- `PartProj` (Lacroix et al., 2016): The BiAffine model trained on the corpus by projecting only the source dependencies involving high-confidence alignments into target sentences. Note that the baseline only draws the idea from Lacroix et al. (2016), and the two models are significant different in fact.
- `Tgt` (Tiedemann and Agić, 2016): The BiAffine model trained on the fully translated target treebank only.

[3]https://translate.google.com/ at Oct, 2018

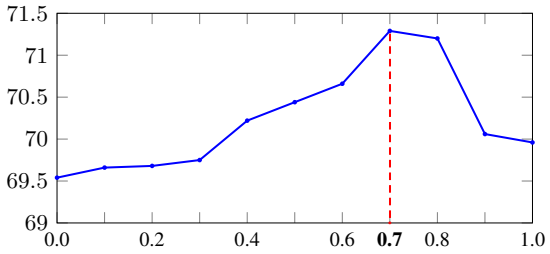

Figure 6: The LAS relative to the translation ratio λ.

Model	UAS	LAS
`Src`	79.52	69.54
`Tgt`	79.34	69.96
`Mix`	**80.33**	**71.29**
`Src + Tgt`	80.12	71.16
`Src + Mix`	**80.91**	**71.73**

Table 1: Experiments of corpus mixing.

- `Src+Tgt`: The BiAffine model trained on the combination dataset of the source and fully translated target treebanks.
- `Mix`: The BiAffine model trained on the code-mixed treebank only.
- `Src+Mix`: The BiAffine model trained on the combination dataset of the source and code-mixed treebanks.

The `Src` and `Tgt` methods have been discussed in Section 4. The `PartProj` model is another way to leverage imperfect word alignments (Lacroix et al., 2016). The training corpus of `PartProj` may be incomplete dependency trees with a number of words missing heads, because no word is deleted from machine translation outputs. The POS tags of words in `PartProj` with low-confidence alignments are obtained by a supervised POS tagger (Yang et al., 2018) trained on the corresponding universal treebank.

5.3 Development Results

We conduct several developmental experiments on the Swedish dataset to examine important factors to our model.

5.3.1 Influence of The Translation Ratio λ

Our model has an important hyper-parameter λ to control the percentage of translation. Figure 6 shows the influence of this factor, where the percentages increase from 0 to 1 by intervals of 0.1. A

Model	UAS	LAS
Mix	**80.33**	**71.29**
−Sentence Reordering	79.79	70.47
−Word Deletion	79.82	70.64
−Both	79.46	69.59

Table 2: Ablation experiments.

λ of 0 gives our baseline by using the source treebank only. As the λ grows, more source words are translated into the target. We can see that the performance improves after translating some source dependencies into the target, demonstrating the effectiveness of syntactic transferring. The performance reaches the peak when $\lambda = 0.7$, but there is a significant drop when λ grows from 0.8 to 0.9. This can be because the newly added dependency arc projections are mostly noisy. This sharp decrease indicates that noise from low-confidence word alignments can have strong impact on the performance. According to the results, we adopt $\lambda = 0.7$ for code-mixed treebanking.

5.3.2 Mixing with Source TreeBank

We investigate the effectiveness of the source treebank by merging it into the translated treebanks. First, we show the model performances of `Src`, `Tgt` and `Mix`, which are trained on the individual treebanks, respectively. Then we merge the source treebank with the two translated treebanks, and show the results trained on the merging corpora. Table 1 shows the results. According to the results, we can find that the source treebank is complementary with the translated treebanks. Noticeably, although `Src + Mix` gives the best performance, its improvement over `Mix` is relatively smaller than that of `Src + Tgt` over `Tgt`. This is reasonable as the code-mixed treebank contains relatively more source treebank content than the fully translated target treebank.

5.3.3 Ablation Studies

The overall translation is conducted by three steps as mentioned in Section 4, where the first word substitution is compulsory, and the remaining two steps aim to build better mixed dependency trees. Here we conduct ablation studies to test the effectiveness of word deletion and sentence reordering. Table 2 shows the experimental results. We can see both steps are important for dependency tree translation. Without word deletion and sentence reordering, the `mix` model shows decreases of 0.82 and 0.65 on LAS, respectively. If both are removed, the performance is only comparable with the baseline `src` model (see Table 1).

5.4 Final Results

We show the final results of our proposed models in Table 3. As shown, the model `Tgt` gives better averaged performance compared to `Src`. However, its results on French and Italian are slightly worse, which indicates that noise from translation impacts the quality of the projected treebank. The model `Mix` gives much better performance compared with `Src`, demonstrating the effectiveness of structural transfer. `Mix` also outperforms `Tgt` significantly, obtaining average increases of $80.93 - 76.37 = 4.56$ points on UAS and $72.87 - 68.28 = 4.59$ points on LAS, respectively. The best setting is the model `Src + Mix`, trained on the combined corpus of the source and code-mixed treebanks, which gives better performance than solely code-mixed treebanks.

By comparing with the delexicalized model `Delex`, we can see that lexicalized features are highly useful for cross-lingual transfer. For the `PartProj` model, we conduct preliminary experiments on Swedish to tune the ratio of the projected dependencies. The results show that the difference is very small ($\delta = 0.24$ for UAS) between 0.9 to 1.0, and the performance degrades significantly as the ratio decreases below 0.9. The observation indicates that this method is probably not effective for filtering low-confidence word alignments. The final results confirm our hypothesis. As shown in Table 3, the `PartProj` model gives only comparable performance with `Src`. One possible reason may be the unremoved target words (if the words are removed, the `PartProj` model with ratio 1.0 will be identical to `Tgt`), which have been demonstrated noisy previously (Tiedemann and Agić, 2016).

5.5 Comparison with Previous Work

We compare our method with previous work in the literature. Table 4 shows the results, where the UAS values are reported. Our model denoted by **`This`** refers to the model of `Src + Mix`. Note that these models are not directly comparable due to the setting and baseline parser differences. The first block shows several models by directly transferring gold-standard source treebank knowledge into the target side, including the models of

Guo15 (Guo et al., 2015), Guo16 (Guo et al., 2016b) and TA16 (Tiedemann and Agić, 2016). Our model gives the best performance with one exception on the German language. One possible reason may be that TA16 has exploited multiple sources of treebanks besides English.

The second block shows representative annotation projection models, including MX14 (Ma and Xia, 2014), RC15 (Rasooli and Collins, 2015), LA16. The models of annotation projection can be complementary with our work, since they build target training corpus from raw parallel texts. The best-performed results of the RC17 model (Rasooli and Collins, 2017) have demonstrated this point, which can be regarded as a combination of the dictionary-based treebank translation[4] (Zhao et al., 2009) and RC15.

5.6 Analysis

We conduct experimental analysis on the Spanish (ES) dataset to show the differences between the models of Src, Tgt and Mix.

[4]The method has been demonstrated worse than TA16 in Tiedemann and Agić (2016).

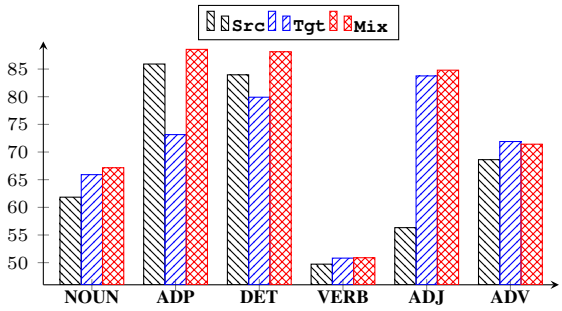

Figure 7: Performance relative to POS tags (F-score).

5.6.1 Performance Relative to POS Tags

Figure 7 show the F-scores of labeled dependencies on different POS tags. We list the six most representative POS tags. The Mix model achieves the best F-scores on 5 of 6 POS tags, with the only exception on tag ADV which has no significant difference with the Tgt model. The Mix and Tgt models are much better than the Src model as a whole, especially on the POS tag ADJ where an increase of over 20% has been achieved. In addition, we find that the Src model can significantly outperform the Tgt model on ADP and DET. For Spanish, ADP words are typically "de", "en", "con" and etc., which behave similarly to the English words such as "'s", "to" and "of". The Spanish words of DET include "el", "la", "su" and etc., which are similar to the English words such as "the" and "a". These words are highly ambiguous for automatic word alignment. The results indicate that our Mix model can better handle these word alignment noise, mitigating their negative influence of treebank translation, while the Tgt model suffers from such noise.

5.6.2 Performance Relative to Arc Distances

Figure 8 show the F-scores of labeled dependencies by different arc distances. Particularly we treat the root type as one special case. According

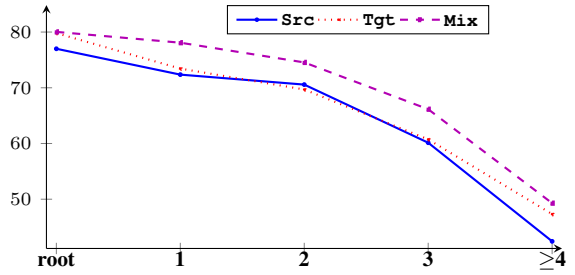

Figure 8: Performance relative to arc distances (F-score).

to the results, the `Mix` model performs the best over all distances, indicating its effectiveness on treebank transferring. The `Tgt` model achieves better performance than the `Src` model with one exception on distance 2. We look into the dependency patterns of distance 2 arcs further, finding that the dependency arc **ADP↶*** accounts for over 30%, and it is the major source of errors. The finding is consistent with that on POS tags, denoting the effectiveness of the code-mixed treebank in handling noise. In addition, as the distance increases the performance drops gradually. The F-score of root dependency is the highest.

6 Conclusion

We proposed a new treebank translation method for unsupervised cross-lingual dependency parsing. Unlike previous work, which adopts full-scale translation for source dependency trees, we investigated partial translation instead, producing synthetic code-mixed treebanks. The method can better leverage imperfect word alignments between source and target sentence pairs, translating only high-confidence source sentential words, thus generating dependencies in high-quality. Experimental results on Universal Dependency Treebak v2.0 showed that partial translation is highly effective, and code-mixed treebanks can give significantly better results than full-scale translation.

Our method is complementary with several other methods for cross-lingual transfer, such as annotation projection, and thus can be further integrated with these methods.

Acknowledgments

We thank all anonymous reviewers for their valuable comments. Several suggestions are not integrated in this version, i.e., more experiments on really low-resource languages, and detailed analysis on more languages. We will supplement later on the webpages of the authors. This work is supported by National Natural Science Foundation of China (NSFC) grants 61602160, U1836222 and 61672211.

Abstract

Transition-based top-down parsing with pointer networks has achieved state-of-the-art results in multiple parsing tasks, while having a linear time complexity. However, the decoder of these parsers has a sequential structure, which does not yield the most appropriate inductive bias for deriving tree structures. In this paper, we propose hierarchical pointer network parsers, and apply them to dependency and sentence-level discourse parsing tasks. Our results on standard benchmark datasets demonstrate the effectiveness of our approach, outperforming existing methods and setting a new state-of-the-art.

1 Introduction

Parsing of sentences is a core natural language understanding task, where the goal is to construct a tree structure that best describes the relationships between the tree constituents (*e.g.,* words, phrases). For example, Figure 1 shows examples of a **dependency tree** and a sentence-level **discourse tree** that respectively represent how the words and clauses are related in a sentence. Such parse trees are directly useful in numerous NLP applications, and also serve as intermediate representations for further language processing tasks such as semantic and discourse processing.

Existing approaches to parsing can be distinguished based on whether they employ a greedy **transition-based** algorithm (Marcu, 1999; Zhang and Nivre, 2011; Wang et al., 2017) or a globally optimized algorithm such as **graph-based** methods for dependency parsing (Eisner, 1996) or **chart parsing** for discourse (Soricut and Marcu, 2003; Joty et al., 2015). Transition-based parsers build the tree incrementally by making a series of shift-reduce decisions. The advantage of this method is that the parsing time is linear with respect to the sequence length. The limitation, however, is that the decisions made at each step are based on local information, disallowing the model to capture long distance dependencies and also causing error propagation to subsequent steps. Recent methods attempt to address this issue using neural networks capable of remembering long range relationships such as Stacked LSTMs (Dyer et al., 2015; Ballesteros et al., 2015) or using globally normalized models (Andor et al., 2016).

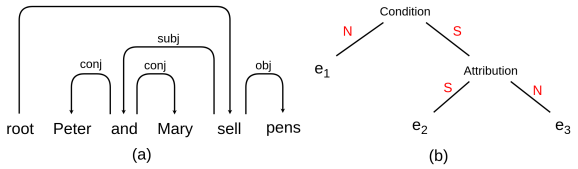

Figure 1: (a) A dependency tree for a sentence; (b) a discourse tree for the sentence "[Now that's name-dropping,]$_{e_1}$ [if you know]$_{e_2}$ [what I mean.]$_{e_3}$", where 'S' denotes Satellite and 'N' denotes Nucleus.

The globally optimized methods, on the other hand, learn scoring functions for subtrees and perform search over all possible trees to find the most probable tree for a text. Recent graph-based methods use neural models as scoring functions (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017). Despite being more accurate than greedy parsers, these methods are generally slow having a polynomial time complexity ($O(n^3)$ or higher).

Recently, transition-based **top-down** parsing with Pointer Networks (Vinyals et al., 2015) has attained state-of-the-art results in both dependency and discourse parsing tasks with the same computational efficiency (Ma et al., 2018; Lin et al., 2019); thanks to the **encoder-decoder** architecture that makes it possible to capture information from the whole text and the previously derived subtrees,

while limiting the number of parsing steps to linear. However, the decoder of these parsers has a sequential structure, which may not yield the most appropriate **inductive bias** for deriving a hierarchical structure. For example, when decoding *"pens"* in Figure 1 in a top-down depth-first manner, the decoder state is directly conditioned on *"and"* as opposed to the states representing its parent *"sell"*. This on one hand may induce irrelevant information in the current state, on the other, as the text length gets longer, the decoder state at later steps tends to forget more relevant information due to long distance. Having an explicit hierarchical inductive bias should allow the model to receive more relevant information and help with the long-term dependency problem by providing shortcuts for gradient back-propagation.

In this paper, we propose a **Hierarchical Pointer Network (H-PtrNet)** parser to address the above mentioned limitations. In addition to the sequential dependencies, our parser also directly models the parent-child and sibling relationships in the decoding process. We apply our proposed method to both dependency and discourse parsing tasks. To verify the effectiveness of our approach, we conduct extensive experiments and analysis on both tasks. Our results demonstrate that in dependency parsing, our model outperforms in most of the languages. In discourse parsing, we push forward the state-of-the-art in all evaluation metrics. Furthermore, our results on the hardest task of relation labeling have touched human agreement scores on this task. We have released our code at https://ntunlpsg.github.io/project/parser/ptrnet-depparser/ for research purposes.

2 Background

2.1 Dependency Parsing

Dependency parsing is the task of predicting the existence and type of linguistic dependency relations between words in a sentence (Figure 1a). Given an input sentence, the output is a tree that shows relationships (*e.g.,* NOMINAL SUBJECT (NSUBJ), DETERMINER (DET)) between *head* words and words that modify those heads, called *dependents* or *modifiers*.

Approaches to dependency parsing can be divided into two main categories: greedy transition-based parsing and graph-based parsing. In both paradigms, neural models have proven to be more effective than feature-based models where selecting the composition of features is a major challenge. Kiperwasser and Goldberg (2016) proposed graph-based and transition-based dependency parsers with a Bi-LSTM feature representation. Since then much work has been done to improve these two parsers. Dozat and Manning (2017) proposed a **bi-affine** classifier for the prediction of arcs and labels based on graph-based model, and achieved state-of-the-art performance. Nguyen and Verspoor (2018) adopted a joint modeling approach by adding a Bi-LSTM POS tagger to generate POS tags for the graph-based dependency parser. Though transition-based methods are superior in terms of time complexity, they fail in capturing the global dependency information when making decisions. To address this issue, Andor et al. (2016) proposed a globally optimized transition-based model. Recently, by incorporating a stack within a pointer network, Ma et al. (2018) proposed a transition-based model and achieved state-of-the-art performance across many languages .

2.2 Discourse Parsing

Rhetorical Structure Theory or RST (Mann and Thompson, 1988) is one of the most influential theories of discourse, which posits a tree structure (called discourse tree) to represent a text (Fig. 1b). The leaves of a discourse tree represent contiguous text spans called Elementary Discourse Units (EDUs). The adjacent EDUs and larger units are recursively connected by coherence relations (*e.g.,* CONDITION, ATTRIBUTION). Furthermore, the discourse units connected by a relation are distinguished based on their relative importance — NUCLEUS refers to the core part(s) while SATELLITE refers to the peripheral one. Coherence analysis in RST consists of two subtasks: (*a*) identifying the EDUs in a text, referred to as **Discourse Segmentation**, and (*b*) building a discourse tree by linking the EDUs hierarchically, referred to as **Discourse Parsing**. This work focuses on the more challenging task of discourse parsing assuming that EDUs have already been identified. In fact, state-of-the-art segmenter (Lin et al., 2019) has already achieved 95.6 F_1 on RST discourse treebank, where the human agreement is 98.3 F_1.

Earlier methods have mostly utilized handcrafted lexical and syntactic features (Soricut and Marcu, 2003; Feng and Hirst, 2014; Joty et al., 2015; Wang et al., 2017). Recent approaches have

shown competitive results with neural models that are able to automatically learn the feature representations in an end-to-end fashion (Ji and Eisenstein, 2014; Li et al., 2014). Very recently, Lin et al. (2019) propose a parser based on pointer networks and achieve state-of-the-art performance.

Remark. Although related, the dependency and RST tree structures (hence the parsing tasks) are different. RST structure is similar to constituency structure. Therefore, the differences between constituency and dependency structures also hold here.[1] First, while dependency relations can only be between words, discourse relations can be between elementary units, between larger units or both. Second, in dependency parsing, any two words can be linked, whereas RST allows connections only between two adjacent units. Third, in dependency parsing, a head word can have multiple modifier words, whereas in discourse parsing, a discourse unit can be associated with only one connection. The parsing algorithm needs to be adapted to account for these differences.

2.3 Pointer Networks.

Pointer networks (Vinyals et al., 2015) are a class of encoder-decoder models that can tackle problems where the output vocabulary depends on the input sequence. They use attentions as pointers to the input elements. An encoder network first converts the input sequence $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ into a sequence of hidden states $\boldsymbol{H} = (\boldsymbol{h}_1, \ldots, \boldsymbol{h}_n)$. At each time step t, the decoder takes the input from previous step, generates a decoder state $\boldsymbol{d}_t$, and uses it to attend over the input elements. The attention gives a $\mathrm{softmax}$ distribution over the input elements.

$$s_{t,i} = \sigma(\boldsymbol{d}_t, \boldsymbol{h}_i); \quad \boldsymbol{a}_t = \mathrm{softmax}(\boldsymbol{s}_t) \quad (1)$$

where $\sigma(.,.)$ is a scoring function for attention, which can be a neural network or an explicit formula like dot product. The model uses $\boldsymbol{a}_t$ to infer the output: $\hat{\mathrm{y}}_t = \arg\max(\boldsymbol{a}_t) = \arg\max p(\mathrm{y}_t|\mathrm{y}_{<t}, \boldsymbol{X}, \theta)$ where θ is the set of parameters. To condition on y_{t-1}, the corresponding input $\boldsymbol{x}_{\mathrm{y}_{t-1}}$ is copied as the input to the decoder.

[1] There are also studies that use dependency structure to directly represent the relations between the EDUs; see (Muller et al., 2012; Li et al., 2014; Morey et al., 2018).

3 Hierarchical Pointer Networks

Before presenting our proposed hierarchical pointer networks, we first revisit how pointer networks have been used for parsing tasks.

3.1 Pointer Networks for Parsing.

Ma et al. (2018) and Lin et al. (2019) both use a pointer network as the backbone of their parsing models and achieve state-of-the-art performance in dependency and discourse parsing tasks, respectively. As shown in Figures 2(a) and 3, in both cases, the parsing algorithm is implemented in a top-down depth-first order. They share the same encoder-decoder structure. A bi-directional Recurrent Neural Network (RNN) encodes a sequence of word embeddings $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$ into a sequence of hidden states $\boldsymbol{H} = (\boldsymbol{h}_1, \ldots, \boldsymbol{h}_n)$. The decoder implements a unidirectional RNN to greedily generate the corresponding tree. It maintains a stack to keep track of the units that yet need to be parsed, *i.e.,* head words for dependency parsing and larger units for discourse parsing. At each step t, the decoder takes out an element from the stack and generates a decoder state $\boldsymbol{d}_t$, which is in turn used in the pointer layer to compute the attention over the relevant input elements. In the case of dependency parsing, the representation of the head word is used to find its dependent. For discourse parsing, it uses the representation of the span to identify the break position that splits the text span into two subspans.

In addition to the tree structure, the parser also deals with the corresponding labelling tasks. Whenever the pointer network yields a newly created pair (*i.e.,* head-dependent in dependency parsing, two sub-spans in discourse parsing), a separate classifier is applied to predict the corresponding relation between them.

3.2 Limitations of Existing Methods

One crucial limitation of the existing models is that the decoder has a linear structure, although the task is to construct a hierarchical structure. This can be noticed in the Figures 2 and 3, where the current decoder state $\boldsymbol{d}_t$ is conditioned on the previous state $\boldsymbol{d}_{t-1}$ (see horizontal blue lines), but not on its parent's decoder state or siblings' decoder state, when it was pointed from its head. This can induce irrelevant information if the previous decoding state corresponds to an element that is not

relevant to the current element. For example, in Figure 2, the decoder state for pointing to "pens" is conditioned on the state used for pointing to "and", but not the one used for pointing to "sell", which is more relevant according to the dependency structure. Also, the decoder state for "sell" is far apart from the one for "pens". Therefore, more relevant information could be diminished in a sequential decoder, especially for long range dependencies.

3.3 Hierarchical Decoder

To address the above issues, we propose hierarchical pointer network (H-PtrNet), which poses a hierarchical decoder that reflects the underlying tree structure. H-PtrNet has the same encoder-decoder architecture as the original pointer network except that each decoding state $\boldsymbol{d}_t$ is conditioned directly on its parent's decoder state $\boldsymbol{d}_{p(t)}$ and its immediate sibling's decoder state $\boldsymbol{d}_{s(t)}$ in addition to the previous decoder state $\boldsymbol{d}_{t-1}$ and parent's encoder state $\boldsymbol{h}_{p(t)}$ (from input). Formally, the pointing mechanism in H-PtrNet can be defined as:

$$\boldsymbol{d}_t = f(\boldsymbol{d}_{p(t)}, \boldsymbol{d}_{s(t)}, \boldsymbol{d}_{t-1}, \boldsymbol{h}_{p(t)}) \quad (2)$$

$$s_{t,i} = \sigma(\boldsymbol{d}_t, \boldsymbol{h}_i) \quad (3)$$

$$p(\mathrm{y}_t|\mathrm{y}_{<t}, \boldsymbol{X}, \theta) = \mathrm{softmax}(\boldsymbol{s}_t) = \frac{\exp(s_{t,i})}{\sum_i \exp(s_{t,i})} \quad (4)$$

where $f(.)$ is a fusion function to combine the four components into a decoder state, and other terms are similarly defined as before for Eq. 1. Figure 2(b) shows an example of H-PtrNet decoder connections for dependency parsing.

The fusion function $f(.)$ can be implemented in multiple ways and may depend on the specific parsing task. More variants of the fusion function will be discussed in Section 4.

Decoder Time Complexity. Given a sentence of length n, the number of decoding steps to build a parse tree is linear. The attention mechanism at each decoding step computes an attention vector of length n. The overall decoding complexity is $O(n^2)$, which is same as the StackPointer Parser (Ma et al., 2018).

Remark. If we look at the decoding steps of the StackPointer Parser (Ma et al., 2018) more closely, we notice that it also takes the decoder state of the immediate sibling (when it points to itself). This decoder state represents the state after all its children are generated. Thus it contains information about its children. In contrast, in our model we consider the decoder state when the sibling was first generated from its parent. Therefore this state contains the sibling's parent information, which helps with capturing long term dependencies.

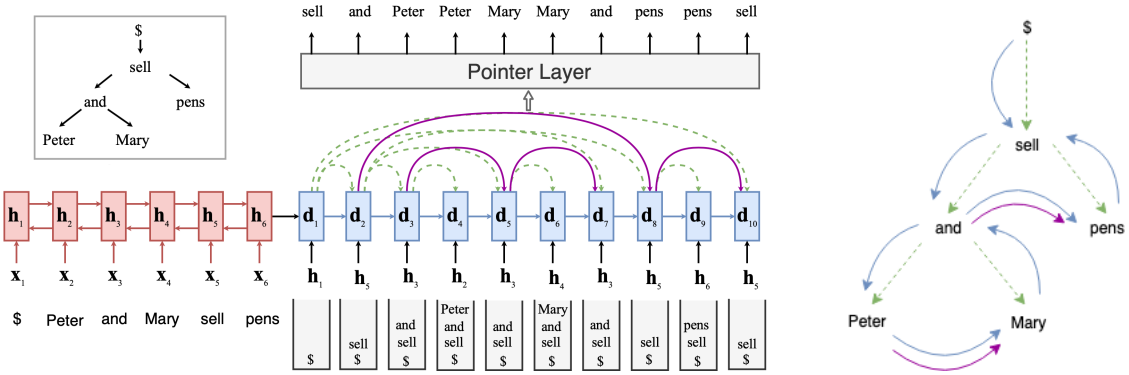
3.4 Model Specifics for Dependency Parsing

Figure 2(a) shows the encoding and decoding steps of H-PtrNet for dependency parsing. We use the same encoder as Ma et al. (2018) (red color).[2] Given a sentence, a convolutional neural network (CNN) is used to encode character-level representation of each word, which is then concatenated with word embedding and POS embedding vectors to generate the input sequence $\boldsymbol{X} = (\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$. Then a three-layer bi-directional LSTM encodes $\boldsymbol{X}$ into a sequence of hidden states $\boldsymbol{H} = (\boldsymbol{h}_1, \ldots, \boldsymbol{h}_n)$. The decoder (blue color) is a single layer uni-directional LSTM, and also maintains a stack to track of the decoding status. At each decoding step t, the decoder receives the *encoder state* of the parent from the stack. In addition, it gets *decoder states* from three different sources: previous decoding step $\boldsymbol{d}_{t-1}$, parent $\boldsymbol{d}_{p(t)}$ and immediate sibling $\boldsymbol{d}_{s(t)}$.

Instead of simply feeding these three components to the decoder, we incorporate a gating mechanism to generalize the ability of our model to extract the most useful information. Eventually, the **fusion function** $f(\boldsymbol{d}_{p(t)}, \boldsymbol{d}_{s(t)}, \boldsymbol{d}_{t-1}, \boldsymbol{h}_{p(t)})$ in Eq. 2 is defined with a *gating mechanism*. We experimented with two different gating functions:

$$\boldsymbol{g}_t = \mathrm{sigmoid}(\boldsymbol{W}_{gd}\boldsymbol{d}_{t-1} + \boldsymbol{W}_{gp}\boldsymbol{d}_{p(t)} + \boldsymbol{W}_{gs}\boldsymbol{d}_{s(t)} + \boldsymbol{b}_g) \quad (5)$$

$$\boldsymbol{g}_t = \mathrm{sigmoid}(\boldsymbol{W}_{gp}(\boldsymbol{d}_{t-1} \odot \boldsymbol{d}_{p(t)}) + \boldsymbol{W}_{gs}(\boldsymbol{d}_{t-1} \odot \boldsymbol{d}_{s(t)}) + \boldsymbol{b}_g) \quad (6)$$



where $\boldsymbol{W}_{gp}$, $\boldsymbol{W}_{gs}$, $\boldsymbol{W}_{gd}$ and $\boldsymbol{b}_g$ are the gating weights. The fusion function is then defined as

$$\boldsymbol{h}'_t = \tanh(\boldsymbol{W}_d\boldsymbol{d}_{t-1} + \boldsymbol{W}_p\boldsymbol{d}_{p(t)} + \boldsymbol{W}_s\boldsymbol{d}_{s(t)}) \quad (7)$$

$$\boldsymbol{h}''_t = \boldsymbol{g}_t \odot \boldsymbol{h}'_t \quad (8)$$

$$\boldsymbol{d}_t = \mathrm{LSTM}(\boldsymbol{h}''_t, \boldsymbol{h}_{p(t)}) \quad (9)$$

[2] https://github.com/XuezheMax/NeuroNLP2

(a) Model Structure (b) Decoder Connections

Figure 2: (a) H-PtrNet for dependency parsing. To reduce visual clutter, we do not show the attention scores over all the input elements at each pointing step, rather show only the pointed element. Figure (b) shows the decoder connections in our H-PtrNet model. The StackPointer network of Ma et al. (2018) has a sequential decoder (shown as blue straight lines). The Green dash lines indicate parent connections and purple solid lines denote the immediate sibling connections in our model.

where $\boldsymbol{W}_d$, $\boldsymbol{W}_p$, $\boldsymbol{W}_s$ are the weights to get the intermediate hidden state $\boldsymbol{h}'_t$, and $\boldsymbol{g}_t$ is a gate to control the information flow from the three decoder states LSTM is the LSTM layer that accepts $\boldsymbol{h}''_t$ as the the hidden state and $\boldsymbol{h}_{p(t)}$ as its input. The LSTM decoder state $\boldsymbol{d}_t$ is then used to compute the attention distribution over the encoder states in pointer layer.

Pointer and Classifier. Same as Ma et al. (2018), the pointer and the label classifier are implemented as **bi-affine** layers. Formally, the scoring function $\sigma(\boldsymbol{d}_t, \boldsymbol{h}_i)$ in Eq. 3 is defined as:

$$s_{t,i} = g_1(\boldsymbol{d}_t)^T \boldsymbol{W} g_2(\boldsymbol{h}_i) + \boldsymbol{U} g_1(\boldsymbol{d}_t) + \boldsymbol{V} g_2(\boldsymbol{h}_i) + \boldsymbol{b} \quad (10)$$

where $\boldsymbol{W}$, $\boldsymbol{U}$ and $\boldsymbol{V}$ are the weights, and $g_1(.)$ and $g_2(.)$ are two single layer MLPs with ELU activations. The dependency label classifier has the same structure as the pointer. More specifically,

$$p(\mathrm{y}_l|\boldsymbol{X}) = \mathrm{softmax}(g'_1(\boldsymbol{d}_t)^T \boldsymbol{W}_c g'_2(\boldsymbol{h}_k) + \boldsymbol{U}_c g'_1(\boldsymbol{d}_t) + \boldsymbol{V}_c g'_2(\boldsymbol{h}_k) + \boldsymbol{b}_c) \quad (11)$$

where $\boldsymbol{h}_k$ is the encoder state of the dependent word, $\boldsymbol{d}_t$ is the decoder state of the head word, $\boldsymbol{W}_c$, $\boldsymbol{U}_c$ and $\boldsymbol{V}_c$ are the weights, and $g'_1(.)$ and $g'_2(.)$ are two single layer MLPs with ELU activations.

Partial Tree Information. Similar to Ma et al. (2018), we provide the decoder at each step with higher order information about the parent and the sibling of the current node.

3.5 Model Specifics for Discourse Parsing.

For discourse parsing, our model uses the same structure as Lin et al. (2019).[3] The encoder is a 5-layer bidirectional RNN based on Gated Recurrent Units (BiGRU) (Cho et al., 2014). As shown in Figure 3, after obtaining a sequence of encoder hidden states representing the words, the last hidden states of the EDUs (*e.g.*, $\boldsymbol{h}_2$, $\boldsymbol{h}_3$, $\boldsymbol{h}_5$, $\boldsymbol{h}_6$, $\boldsymbol{h}_8$ and $\boldsymbol{h}_{10}$) are taken as the EDU representations, generating a sequence of EDU representations $\boldsymbol{E} = (\boldsymbol{e}_1, \ldots, \boldsymbol{e}_m)$ for the input sentence.

Our hierarchical decoder is based on a 5-layer unidirectional GRU. The decoder maintains a **stack** to keep track of the spans that need to be parsed further. At time step t, the decoder takes the text span (*e.g.*, $\boldsymbol{e}_{i:j}$) representation from the top of the stack and receives the corresponding parent decoder state $\boldsymbol{d}_{p(t)}$, sibling decoder state $\boldsymbol{d}_{s(t)}$ and previous decoder state $\boldsymbol{d}_{t-1}$ as the input to generate a current decoder state $\boldsymbol{d}_t$. For discourse parsing, we apply Eq. 7 and 9 (with GRU) to implement the fusion function $f(.)$ and to get the decoder state $\boldsymbol{d}_t$.[4] The decoder state is then used in the pointer layer to compute the attention score over the current text span (*e.g.*, $\boldsymbol{e}_{i:j}$) in order to find the position k to generate a new split $(\boldsymbol{e}_{i:k}, \boldsymbol{e}_{k+1:j})$. The parser then applies a relation classifier $\Phi(\boldsymbol{e}_{i:k}, \boldsymbol{e}_{k+1:j})$ to predict the relation and the nuclearity labels for the the new split.

[3] https://ntunlpsg.github.io/project/parser/pointer-net-parser

[4] Adding gating mechanism did not give any gain, rather increased the number of parameters.

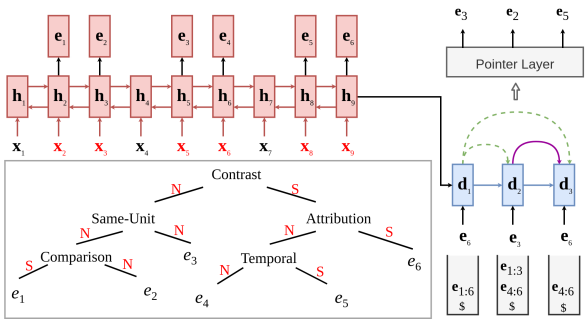


Figure 3: H-PtrNet for discourse parsing. The input symbols in red ($\mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_5, \mathbf{x}_6, \mathbf{x}_8, \mathbf{x}_9$) represent last words of the respective EDUs. To avoid visual clutter, we do not show the attention distributions over the EDUs, rather only show the decisions. Green dash lines indicate parent connections and purple solid lines denote the immediate sibling connections.

For pointing, the parser uses a simple **dot product** attention. For labeling, it uses a **bi-affine classifier** similar to the one in Eq. 11. It takes the representations of two spans (*i.e.,* $\boldsymbol{e}_k$ for $\boldsymbol{e}_{i:k}$, $\boldsymbol{e}_j$ for $\boldsymbol{e}_{k+1:j}$) as input and predicts the corresponding relation between them. Whenever the length of any of the newly created span ($\boldsymbol{e}_{i:k}$ and $\boldsymbol{e}_{k+1:j}$) is larger than two, the parser pushes it onto the stack for further processing. Similar to dependency parsing, the decoder is also provided with **partial tree information** – the representations of the **parent** and the immediate **sibling**.

3.6 Objective Function

Same as Ma et al. (2018) and Lin et al. (2019), our parsers are trained to minimize the total log loss (cross entropy) for building the right tree **structure** for a given sentence $\boldsymbol{X}$. The structure loss $\mathcal{L}$ is the pointing loss for the pointer network:

$$\mathcal{L}(\theta) = -\sum_{t=1}^{T} \log P_\theta(\mathrm{y}_t | \mathrm{y}_{<t}, \boldsymbol{X}) \qquad (12)$$

where θ denotes the model parameters, $y_{<t}$ represents the subtrees that have been generated by our parser at previous steps, and T is the number needed for parsing the whole sentence (*i.e.,* number of words in dependency parsing and spans containing more than two EDUs in discourse parsing). The label classifiers are trained simultaneously, so the final loss function is the sum of structure loss (Eq. 12) and the loss for label classifier.

4 Experiments

In this section, we describe the experimental details about dependency parsing and discourse parsing, as well as the analysis on both tasks.

Apart from the two gating-based fusion functions described in Section 3 (Eq. 5-6), we experimented with three different versions of our model depending on which connections are considered in the decoder. We append suffixes **P** for *parent*, **S** for *sibling* and **T** for *temporal* to the model name (H-PtrNet) to denote different versions.

- **H-PtrNet-P**: The H-PtrNet model with fusion function $\boldsymbol{d}_t = f(\boldsymbol{d}_{p(t)}, \boldsymbol{h}_{p(t)})$, where the decoder receives hidden (decoder) state only from the parent ($\boldsymbol{d}_{p(t)}$) in each decoding step. Note that $\boldsymbol{h}_{p(t)}$ is the encoder state of the parent.

- **H-PtrNet-PS**: The H-PtrNet model with fusion function $\boldsymbol{d}_t = f(\boldsymbol{d}_{p(t)}, \boldsymbol{d}_{s(t)}, \boldsymbol{h}_{p(t)})$, where the decoder receives the hidden states from both the parent and sibling in each decoding step.

- **H-PtrNet-PST**: This is the full model with fusion function $\boldsymbol{d}_t = f(\boldsymbol{d}_{p(t)}, \boldsymbol{d}_{s(t)}, \boldsymbol{d}_{t-1}, \boldsymbol{h}_{p(t)})$ (Eq. 2). In this model, the decoder receives the hidden states from its parent, sibling and previous step in each decoding step.

4.1 Dependency Parsing

Dataset. We evaluate our model on the English Penn Treebank (PTB v3.0) (Marcus et al., 1994), which is converted to Stanford Dependencies format with Stanford Dependency Converter 3.3.0 (Schuster and Manning, 2016). To make a thorough empirical comparison with previous studies, we also evaluate our system on seven (7) languages from the Universal Dependency (UD) Treebanks[5] (version 2.3).

Metrics. We evaluate the performance of our models with unlabeled attachment score (UAS) and labeled attachment score (LAS). We ignore punctuations in the evaluation for English.

Experimental Settings. We use the same setup as Ma et al. (2018) in the experiments for English Penn Treebank and UD Treebanks. For a fair comparison, we rerun their model with the hyperparameters provided by the authors on the same machine as our experiments. For all the languages,

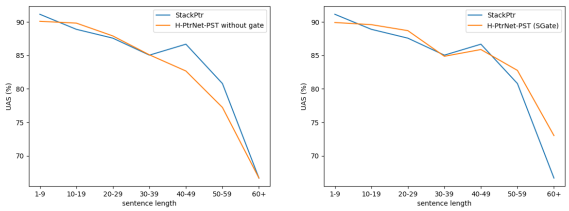
Table 1: Dependency parsing results on 7 UD Treebanks. **StackPtr (code)** denotes the experiments we rerun on our machine. **H-PtrNet-PST (Gate)** and **H-PtrNet-PST (SGate)** are H-PtrNet models with gating mechanism.

we follow the standard split for training, validation and testing. It should be noted that Ma et al. (2018) used UD Treebanks 2.1, which is not the most up-to-date version. Therefore, during experiments, we rerun their codes with UD Treebanks 2.3 to match our experiments. To be specific, we use structured-skipgram (Ling et al., 2015) for English and German, while Polyglot embedding (Al-Rfou et al., 2013) for the other languages. Adam optimizer (Kingma and Ba, 2015) is used as the optimization algorithm. We apply 0.33 dropout rate between layers of encoder and to word embeddings as well as Eq. 8. We use beam size of 10 for English Penn Treebank, and beam size of 1 for UD Treebanks. The gold-standard POS tags is used for English Penn Treebank. We also use the universal POS tags (Petrov et al., 2011) provided in the dataset for UD Treebanks. See Appendix for a complete list of hyperparameters.

Results on UD Treebanks. We evaluate on 7 different languages from the UD Treebanks: 4 major ones: English (en), German (de), French (fr), and Italian (it), and 3 relatively minor ones: Bulgarian (bg), Catalan (ca), and Romanian (ro). Table 1 shows the results. We refer to the results of our run of the code released by Ma et al. (2018) as StackPtr (code).[6] StackPtr (code) and our models are trained in identical settings making them comparable. H-PtrNet-PST (Gate) (Eq. 5) and H-PtrNet-PST (SGate) (Eq. 6) are H-PtrNet models with gating mechanism. Element wise product in Eq. 6 has the effect of similarity comparison, so we denote it as **SGATE**. With gating mechanism, our model shows consistent improvements against the baseline on bg, en, de, fr, it and ro. We also tested H-PtrNet-PS on these 7 languages, but the performances are worse than StackPtr.



[6] We do not directly report the results from their paper because we use a different version of the UD Treebanks.

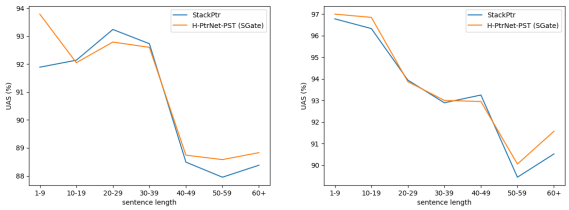
Table 2: Dependency parsing results on English Penn Treebank v3.0.



Results on English Penn Treebank. Table 2 presents the results on English Penn Treebank. StackPtr (paper) refer to the results reported by Ma et al. (2018), and StackPtr (code) is our run of their code in identical settings as ours. Our model H-PtrNet-PST (Gate) outperforms the baseline by 0.09 and 0.08 in terms of UAS and LAS, respectively. Performance of H-PtrNet-PST (SGate) is close to that of H-PtrNet-PST (Gate), though we see slight improvement. We also test H-PtrNet-PS (Gate), the model with parent and sibling connections only, which further improves the performance to 96.09 and 95.03 in UAS and LAS.

Performance Analysis. To make a thorough analysis of our model, we breakdown UAS in terms of sentence lengths to compare the performance of our model and StackPtr. We first take the performance on UD German as an example,

(a) H-PtrNet-PST (no gating) (b) H-PtrNet-PST (SGate)

Figure 4: UD German parsing performance in terms of sentence length.

(a) UD French (b) UD Italian

Figure 5: Performance analysis on French and Italian based on H-PtrNet-PST (SGate).

which is shown in Figure 4. The blue line shows the performance of StackPtr, and the orange line shows the performance of our model. From Figure 4(a) we can see that our model without gate performs better on relatively short sentences (10 to 29 words), however, the accuracy drops on longer sentences. The reason could be that adding parent and sibling hidden states to decoder may amplify error accumulation from early parsing mistakes.

Figure 4(b) shows the performance of our model with SGATE (Eq. 6), where we can see that the performance on long sentences has been improved significantly. In the meanwhile, it still maintains higher accuracy than StackPtr on the short sentences (10 to 29 words). Figure 5 shows two more examples, again, from which we can see that our model with SGATE tends to outperform StackPtr on longer sentences.

4.2 Discourse Parsing

Dataset. We use the standard RST Discourse Treebank (RST-DT) (Carlson et al., 2002), which contains discourse annotations for 385 news articles from Penn Treebank (Marcus et al., 1994). We evaluate our model in sentence-level parsing, for which we extract all the well-formed sentence-level discourse trees from document-level trees.

Table 3: Discourse parsing results with gold segmentation. † denotes the models selected based on Span. § denotes the models selected based on Relation. We run all the experiments for three times and report the averages and the standard deviations.

In all, the training data contains 7321 sentences, and the testing data contains 951 sentences. These numbers match the statistics reported by Lin et al. (2019). We follow the same settings as in their experiments and randomly choose 10% of the training data for hyperparameter tuning.

Metric and Relation Labels. Following the standard in RST parsing, we use the unlabeled (Span) and labeled (Nuclearity, Relation) metrics proposed by Marcu (2000). We only present F_1-score for space limitations. Following the previous work, we attach the nuclearity labels (NS, SN, NN) to 18 discourse relations, together giving 39 distinctive relation labels.

Experimental Settings. Since our goal is to evaluate our parsing method, we conduct the experiments based on gold EDU segmentations. We compare our results with the recently proposed pointer network based parser of Lin et al. (2019) (Pointer Net). However, unlike their paper, we report results for both cases: (i) when the model was selected based on the best performance on Span identification; and (ii) when it was selected based on the relation labeling performance on the development set. We retrain their model for both settings. We also apply Adam optimizer as optimization algorithm and ELMo (Peters et al., 2018) with 0.5 dropout rate as word embeddings.

Results. We present the results in Table 3. In discourse parsing, the number of EDUs in a sentence is relatively small compared to the sentence lengths (in words) in dependency parsing. Based on the observation in dependency parsing that the performance of H-PtrNet may drop for longer sentences due to parent error accumulation, we expect that in discourse parsing, this should not be the case since the the number of parsing steps is much smaller compared to that of dependency parsing.

We first consider the models that were selected based on Span performance (models with † superscript). H-PtrNet-P, with only parent connection, outperforms the baseline in all three tasks. It achieves an absolute improvement of 0.29 F_1 in span identification compared to the baseline. Considering the performance has already exceeded the human agreement of 95.7 F_1, this gain is remarkable. Thanks to the higher accuracy on finding the right spans, we also achieve 0.85 and 0.74 absolute improvements in Nuclearity and Relation tasks, respectively. By adding the sibing and temporal connections, we test the performance of our full model, H-PtrNet-PST. The performance on Span is 0.17 F_1 higher than the baseline. However, it is not on par with our H-PtrNet-P. But, it is not surprising since we adopt binary tree structures in discourse parsing, which means the sibling information could be redundant in most cases. This also accords with our previous assumption that parent connections may bring enough information to decode RST trees.

Now we consider the models that were selected based on Relation labeling performance (models with § superscript). We achieve significant improvement in Relation compared to the baseline. Eventually the parser yields an F_1 of 82.77, which is very close to the human agreement (83.0 F_1). We observe that the performance in H-PtrNet-PS and H-PtrNet-PST is better than the H-PtrNet-P. As the relation classifier and the pointer network share the same encoder information (Sec. 3), we believe that richer decoder information leads the model to learn better representations of the text spans (encoder states) and further leads to a better performance in relation labeling.

We further analyze the performance of our proposed model in terms of number of EDUs. We present the F_1 score in Span of H-PtrNet-P and H-PtrNet-PST as well as the baseline in Figure 6. It can be observed that both H-PtrNet-P and H-PtrNet-PST outperform the baseline with respect to almost every number of EDUs. Moreover, we can see that the H-PtrNet-P performs better in most of the cases, which once again conforms to our assumption that parent information is enough to decode RST trees. However, as discussed in our dependency parsing experiments, when the number of words (EDUs for discourse parsing) increases, the model may suffer from error accumulation from early parsing. Hence, H-PtrNet-PST tends to perform better when EDU number becomes large.

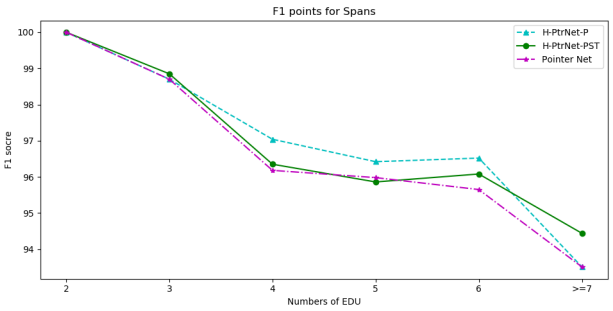

Figure 6: F_1 score in Span for different EDU numbers.

5 Conclusions

In this paper, we propose hierarchical pointer network parsers and apply them to dependency and discourse parsing tasks. Our parsers address the limitation of previous methods, where the decoder has a sequential structure while it is decoding a hierarchical tree structure, by allowing more flexible information flow to help the decoder receive the most relevant information. For both tasks, our parsers outperform existing methods and set new state-of-the-arts of the two tasks. The broken-down analysis clearly illustrates that our parsers perform better for long sequences, complying with the motivation of our model.

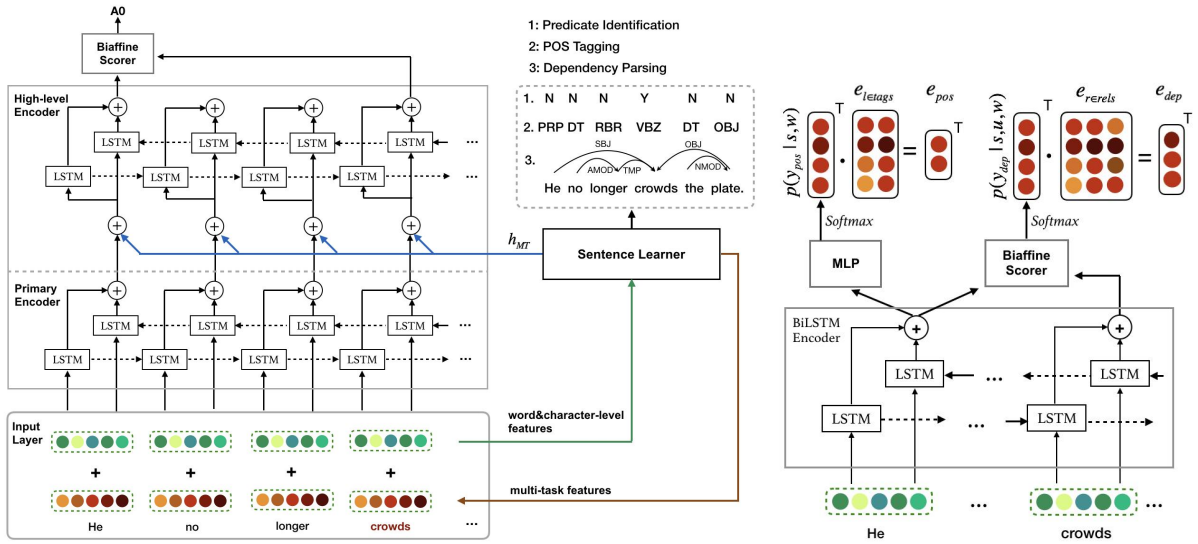
Abstract

The successful application of neural networks to a variety of NLP tasks has provided strong impetus to develop end-to-end models for semantic role labeling which forego the need for extensive feature engineering. Recent approaches rely on high-quality annotations which are costly to obtain, and mostly unavailable in low resource scenarios (e.g., rare languages or domains). Our work aims to reduce the annotation effort involved via semi-supervised learning. We propose an end-to-end SRL model and demonstrate it can effectively leverage unlabeled data under the cross-view training modeling paradigm. Our LSTM-based semantic role labeler is jointly trained with a sentence learner, which performs POS tagging, dependency parsing, and predicate identification which we argue are critical to learning directly from unlabeled data without recourse to external pre-processing tools. Experimental results on the CoNLL-2009 benchmark dataset show that our model outperforms the state of the art in English, and consistently improves performance in other languages, including Chinese, German, and Spanish.



1 Introduction

Semantic role labeling — the task of automatically identifying and labeling the semantic roles conveyed by sentential constituents — has enjoyed renewed interest in the last few years thanks to the popularity of neural network models and their ability to learn continuous representations which forego the need for extensive feature engineering. Recent modeling developments aside, semantic role labeling (SRL) has been generally recognized as a core task in NLP with relevance for applications ranging from machine translation (Aziz et al., 2011; Marcheggiani et al., 2018), to information extraction (Christensen et al., 2011), and summarization (Khan et al., 2015).

State-of-the art semantic role labelers (He et al., 2018b; Cai et al., 2018) rely on high-quality annotations (of semantic predicates and their arguments) for use in training. These annotations are costly to obtain, and mostly unavailable in low resource scenarios (e.g., rare languages or domains) motivating the need for effective semi-supervised methods that leverage unlabeled examples. Cross-View Training (CVT; Clark et al. 2018) is a recently proposed semi-supervised learning algorithm that improves representation learning using a mix of labeled and unlabeled data. The main idea behind CVT is to train a model to produce consistent predictions across different restricted views of the input with the aid of auxiliary prediction tasks. Clark et al. (2018) demonstrate performance gains when applying CVT to sequence tagging tasks, machine translation, and dependency parsing.

Unfortunately, application of CVT to semantic role labeling is fraught with difficulty. This is partly due to the nature of the task which relies on various syntactic features, even when conceptualized as a sequence labeling task (Marcheggiani et al., 2017; He et al., 2018b; Cai et al., 2018). The reliance on syntactic features is problematic for semi-supervised training, since these would have to be extracted from large amounts of unlabeled data. In addition, any semantic role labeler would need to identify (and disambiguate) predicates prior to labeling their augments which might be given during training (e.g., as in the CoNLL 2009 dataset), but would still have to be detected on unlabeled data. Resorting to various pre-processing tools for semi-supervised training almost defeats the purpose of using unlabeled data which would have to be annotated, albeit automatically, with pre-trained models which require labeled data on their own, and might not be portable across languages and domains. Moreover, the usage of external tools often leads to pipeline-style

(a) Semantic role labeler (left) and sequence learner (right)

(b) Sentence learner.

Figure 1: Overview of end-to-end SRL model.

architectures where errors propagate to later processing stages, affecting model performance.

In this paper we aim to render semi-supervised learning for semantic role labeling as simple as possible, by eliminating the reliance on multiple external pre-processing tools. We develop a sentence learner which is able to perform all tasks subsidiary to semantic role labeling (i.e., POS tagging, dependency parsing, and predicate detection) on labeled and unlabeled data. The sentence learner is jointly trained with a semantic role labeler, and its outputs are fed to the semantic role labeler during supervised and semi-supervised learning. Aside from building a self-sufficient semantic role labeler which can be directly applied on plain text, an added benefit of the proposed approach is that the sentence learner naturally provides multiple hidden layers (for the various subtasks) from which "multi-task hidden features" (Peters et al., 2018) can be extracted.

In addition to overcoming the difficulty of utilizing plain text for semi-supervised SRL, we show that application of CVT to SRL requires special attention over and above the sequence tagging and dependency parsing tasks discussed in Clark et al. (2018). We investigate how to best formulate different views for CVT focusing on semantic predicates which have been proven to be very useful in recent SRL models (Marcheggiani et al., 2017; Marcheggiani and Titov, 2017; Cai et al., 2018). Experimental results on the CONLL-2009 benchmark datasets show that our model is able to outperform the state of the art in English, and to improve SRL performance in other languages, including Chinese, German, and Spanish.

2 Model Description

Figure 1 provides a schematic overview of our model which has two main components, namely a sentence learner and a semantic role labeler. The sentence learner consists of:

- look-ups of word embeddings and character embeddings;
- a bidirectional LSTM (BiLSTM) encoder which takes as input the representation of each word in a sentence and produces context-dependent representations;
- a multi-task prediction module to perform POS tagging, dependency parsing, and predicate identification.

While the semantic role labeler consists of:

- an input layer which combines multi-source representations of the input sentence;
- a primary bidirectional LSTM (BiLSTM) encoder which takes as input the representation of each word in a sentence and produces context-dependent embeddings;
- a high-level BiLSTM encoder which takes as input the hidden states of the primary BiLSTM and multi-task hidden features;
- a biaffine classifier for calculating the score of each semantic role for each word.

2.1 Sentence Learner

The sentence learner (see Figure 1b) operates over sentences to perform the intermediate tasks of POS tagging, dependency parsing, and predicate identification, which are subsequently used to inform the decisions of the semantic role labeler.

Sentence Encoder As we expect the sentence encoder to be applied directly to plain text, we represent words as the concatenation of character- and word-level features. We learn character-level representations x_{cr} by feeding character embeddings to a convolutional neural network module. We represent words with randomly initialized word embeddings $x_{re} \in R^{d_w}$, pre-trained word embeddings $x_{pe} \in R^{d_w}$ estimated on an external text collection, and pre-trained ELMo embeddings x_{elmo} (Peters et al., 2018). The final word representation is given by $x = x_{re} \circ x_{pe} \circ x_{cr} \circ x_{elmo}$, where $\circ$ represents concatenation.

Following Marcheggiani et al. (2017), sentences are represented using a two-layer bi-directional LSTM (Hochreiter and Schmidhuber, 1997); the BiLSTM receives at time step t a representation x for each word and recursively computes two hidden states, one for the forward pass ($\overrightarrow{h}^t$), and another one for the backward pass ($\overleftarrow{h}^t$). Each word is the concatenation of its forward and backward LSTM state vectors $h^t = \overrightarrow{h}^t \circ \overleftarrow{h}^t$.

Multi-task Learning After obtaining word representations with the sentence encoder, the input is POS tagged, dependency parsed, and predicates are identified. Given sentence s, the probability distribution of POS tags for word w is obtained using a one hidden-layer neural network applied to the corresponding encoder output h_2^w:

$$p(y_{pos}|s,w) = \text{softmax}(U \cdot \text{ReLU}(W h_2^w) + b) \quad (1)$$

For dependency parsing, words in a sentence are treated as nodes in a graph. In particular, each word w in sentence s receives exactly one in-going edge (u, w, r) from head word u to its dependent w with relation r. We use a graph-based dependency parser similar to the one presented in Clark et al. (2018), which treats dependency parsing as a classification task and its goal is to predict which in-going edge (u, w, r) connects to each word w. Mathematically, the probability of an edge is:

$$p((u,w,r)|s) = \propto \exp(\text{score}(h_2^u, h_2^w, r)) \quad (2)$$

where "score" is the scoring function:

$$\begin{aligned} \text{score}(z_1, z_2, r) = &\text{ReLU}(W_{head} z_1 + b_{head}) \\ &(W_r + W)\,\text{ReLU}(W_{dep} z_2 + b_{dep}) \end{aligned} \quad (3)$$

The bilinear classifier uses a weight matrix W_r specific to the candidate relation and a weight matrix W shared across all dependency relations.

With regard to predicate identification, we introduce a virtual root following Cai et al. (2018) who model the entire SRL task as word pair classification. Similarly to the dependency parsing module described above, representations produced by the encoder for the virtual root and words are passed through separate hidden layers and a biaffine classifier is applied to produce a score for each word.

2.2 Semantic Role Labeler

Word Representation For our SRL model, words are represented by a vector x which is the concatenation of four types of features: predicate-specific, character-level, word-level, and multi-task features. Following previous work (Marcheggiani et al., 2017), we leverage a predicate specific indicator embedding x_{ie} rather than directly using a binary flag. Character- and word-level features are shared with the sentence learner.

With regard to multi-task features, for each word w in input sentence s, we employ a probability-weighted POS tag embedding e_{pos} and dependency relation embedding e_{dep}:

$$\begin{aligned} e_{pos} &= \sum_{l \in tags} p(y_{pos} = l|s,w)[l] * e_l \\ e_{dep} &= \sum_{r \in rels} p(y_{dep} = r|s,u,w)[r] * e_r \end{aligned} \quad (4)$$

where e_l and e_r and the embeddings of POS tags and dependency relations respectively, and $p(y_{dep} = r|s,u)$ is the probability of relation r given its predicted dependency head u.

In order to incorporate more syntactic information, we adopt as an additional feature the probability of linking a word to candidate predicate x_{pr} which we obtain from the sentence learner. x_{pr} is made of two scalar values, p_{head} and p_{dep}, which represent the probability of a word being the syntactic head or dependent of the current predicate, respectively.

Multi-task Hidden Features Drawing inspiration from ELMo (Peters et al., 2018), a recently

proposed model for generating word representations based on bidirectional LSTMs trained with a coupled language modeling objective, we extract various hidden features via multi-task learning. ELMo representations are deep, essentially a linear combination of representations learnt at all layers of an LSTM instead of just the final layer. Compared with unsupervised ELMo representations, our sentence learner takes advantage of labeled data — it attempts to learn representations towards multiple SRL-related tasks rather than generally effective ones.

In order to utilize all hidden layers in the sentence learner, we collapse them into a single vector. Although we could simply concatenate these or select the top layer, we compute multi-task hidden features h_{MT} as a weighting of the BiLSTM layers, followed by a non-linear projection:

$$h_{MT} = \mathrm{ReLU}(W_{hidden}(\gamma \sum_{j=1}^{j=L} \beta_j h_j)) \quad (5)$$

where L is the depth of sentence learner, β are softmax-normalized weights for h_j, and the scalar parameter γ is of practical importance to aid optimization (Peters et al., 2018).

Biaffine Role Scorer After the high-level BiLSTM encoder produces representations h for each word, we perform two distinct non-linear transformations for the currently considered predicate and its candidate arguments, respectively:

$$\begin{aligned} h_{pred} &= \mathrm{ReLU}(W_{pred} h + b_{pred}) \\ h_{arg} &= \mathrm{ReLU}(W_{arg} h + b_{arg}) \end{aligned} \quad (6)$$

where h_{pred} and h_{arg} are hidden representations for the predicate and candidate arguments. The score s_{role} of a semantic role between a predicate and its arguments is calculated as:

$$\begin{aligned} s_{role} = & h_{arg}^{\top} W_{role} h_{pred} \\ & + U_{role}(h_{arg} \circ h_{pred}) \\ & + b_{role} \end{aligned} \quad (7)$$

where W_{role}, U_{role}, and b_{role} are parameters updated during training.

2.3 Cross-view Training for SRL

CVT works by improving representation learning for a model. Let $D_{ul} = \{x_1, x_2, .., x_N\}$ represent an unlabeled dataset. We use $p_\theta(y|x_i)$ to denote the output distribution over classes produced by the model with parameters θ. CVT adds multiple different auxiliary prediction modules to a model, which are used when learning on unlabeled examples. Each prediction module takes as input an intermediate representation $h^j(x_i)$ produced by a primary BiLSTM encoder and outputs a distribution over all possible classes $p_\theta^j(y|x_i)$. Each h^j is chosen such that it can only see parts of the input.

Given an unlabeled example, the model first produces soft targets $p_\theta(y|x_i)$ by performing inference. CVT then trains auxiliary prediction modules to match the teacher prediction module on the unlabeled data by minimizing:

$$\mathcal{L}_{\mathrm{CVT}}(\theta) = \frac{1}{D_{ul}} \sum_{x_i \in D_{ul}} \sum_{j=1}^{k} D(p_\theta(y|x_i), p_\theta^j(y|x_i)) \quad (8)$$

where D is a distance function between probability distributions (we use KL divergence). During training, we keep predictions $p_\theta(y|x_i)$ from the teacher module fixed so that the auxiliary modules learn to imitate the teacher, but not vice versa. As auxiliary modules train, the representations they use as input improve so they are useful for making predictions even when some of the models' inputs are not available. This in turn improves the primary prediction module, which is built on top of the same shared representations.

We applied CVT on the primary Bi-LSTM encoder of our semantic role labeler, while utilizing the output of the sentence learner on the unlabeled data. Given unlabeled sentence $s = w^1, ..., w^T$, the primary Bi-LSTM encoder produces hidden representations h_{pri} for each word, while the semantic role labeler produces the teacher prediction. The sentence learner may recognize more than one words as predicates in sentence s, and we just randomly choose one as the target predicate w^p.

The auxiliary prediction modules take $\overrightarrow{h}^t_{pri}$ and $\overleftarrow{h}^t_{pri}$ as input. Specifically, we add the following four auxiliary prediction modules to the model:

$$\begin{aligned} p_\theta^{\mathrm{fwd}}(r^t|w^t, w^p, s) &= \mathrm{NN}^{\mathrm{fwd}}(\overrightarrow{h}^t_{pri}(s)) \\ p_\theta^{\mathrm{bwd}}(r^t|w^t, w^p, s) &= \mathrm{NN}^{\mathrm{bwd}}(\overleftarrow{h}^t_{pri}(s)) \\ p_\theta^{\mathrm{future}}(r^t|w^t, w^p, s) &= \mathrm{NN}^{\mathrm{future}}(\overrightarrow{h}^{t-1}_{pri}(s)) \\ p_\theta^{\mathrm{past}}(r^t|w^t, w^p, s) &= \mathrm{NN}^{\mathrm{past}}(\overleftarrow{h}^{t+1}_{pri}(s)) \end{aligned} \quad (9)$$

The "forward" module makes predictions without seeing the right context of the current word.

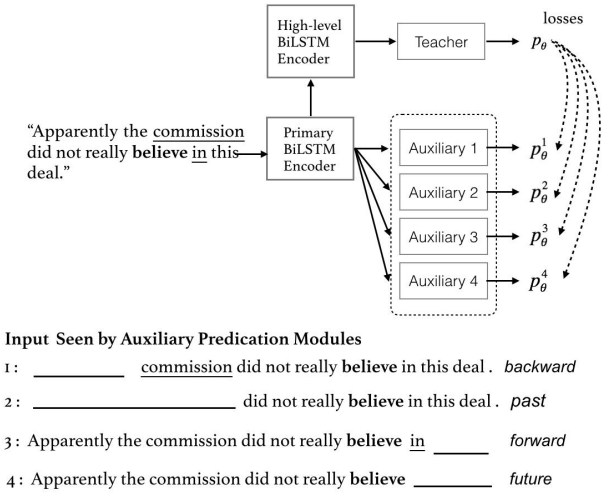

Figure 2: CVT on a sentence from the CoNLL 2009 training set. The current predicate is "*believe*", while "*commission*" and "*in*" are two candidate arguments.

The "future" module makes predictions without seeing the right context *and* the current word itself. The "backward" and "past" modules are defined analogously for left contexts. Figure 2 illustrates the auxiliary modules and the types of context they see. Unlike the biaffine role scorer, the auxiliary modules do not explicitly use the hidden state of the target predicate, so as to encourage the primary Bi-LSTM encoder to capture long-distance relations between the predicate and its context.

We empirically observed (see Section 3) that applying CVT on representations which do not "see" the target predicate is not ideal for SRL. We therefore devised a strategy which applies different auxiliary modules to each word depending on its relative position to the target predicate. We only apply "backward" and "past" modules to words preceding the predicate, while "forward" and "future" modules apply to words following the predicate. This way, we ensure that each word is aware of the current predicate when performing CVT. In the example in Figure 2, "backward" and "past" views would be applied to *commission* and "forward" and "future" views to *in*.

We also apply CVT on the first hidden layer of the sentence learner to further improve the performances of auxiliary tasks, utilizing the views introduced in Clark et al. (2018) for sequence tagging and dependency parsing.

2.4 Training Objectives

For both supervised learning and cross-view training our model makes predictions on labeled and unlabeled examples across all tasks (SRL and auxiliary tasks). During supervised learning, the model is trained on labeled data and its objective is the sum of cross-entropy losses for all tasks. With respect to multi-task CVT, the model takes unlabeled examples as input and calculates the CVT loss given in Equation (8). The semi-supervised objective is the sum of the CVT loss for all auxiliary modules across all tasks.

3 Experiments

We implemented our model[1] in PyTorch and evaluated it on the English CoNLL-2009 benchmark following the standard training, testing, and development set splits. To evaluate whether our model generalizes to other languages, we also report experiments on Chinese, German, and Spanish, again using standard CoNLL-2009 splits. This subset of languages has been commonly used in previous work (Björkelund et al., 2010; Roth and Lapata, 2016; Lei et al., 2015) and allows us to compare our model against a wide range of alternative approaches. The benchmarks contain gold-standard dependency annotations, and also gold lemmas, part-of-speech tags, and morphological features. With regard to unlabeled datasets, we used the 1 Billion Word Language Model Benchmark (Chelba et al., 2013) for English, the Sougou News Data[2] for Chinese, the NEGRA corpus [3] for

German, and the Spanish Language News Corpus[4] for Spanish.

For experiments on English, we used the embeddings of Dyer et al. (2015) which were learned using the structured skip n-gram approach of Ling et al. (2015). We also used a convolutional neural network (Chiu and Nichols, 2016; Ma and Hovy, 2016) to learn character-level representations. For Chinese, Spanish, and German word embeddings were pre-trained on Wikipedia using `fastText` (Bojanowski et al., 2017).

The Bi-LSTM encoders in our model, used recurrent dropout (Gal and Ghahramani, 2016) with an 80% keep probability between time-steps and layers during supervised training; keep probability was set to 90% when applying the model to unlabeled data. We used the Adam optimizer (Kingma and Ba, 2014) and performed hyperparameter tuning and model selection on the English development set; optimal hyperparameter values (for all languages) are shown in Table 1.

3.1 Results

Our results on the English (in-domain) test set are summarized in Table 2. We compared our system against previous models which employ external tools to obtain required features. We also report the results of various ensemble SRL models (second block). Most comparisons involve neural systems which are based on BiLSTMs (Marcheggiani et al., 2017; He et al., 2018b; Marcheggiani and Titov, 2017; Cai et al., 2018) or use neural networks for learning SLR-specific embeddings (FitzGerald et al., 2015; Roth and Lapata, 2016). We also report the results of two strong symbolic models based on tensor factorization (Lei et al., 2015) and a pipeline of modules that carry out tokenization, lemmatization, part-of-speech tagging, dependency parsing, and semantic role labeling (Björkelund et al., 2010). As can be seen in Table 2, our supervised model outperforms previously published single and ensemble models. With cross-view training, our model achieves 91.2% F_1 (the difference over the supervised model is statistically significant at $p < 0.05$), which is an absolute improvement of 1.4% over the state of the art (Li et al., 2018).

Results on the out-of-domain English test set are presented in Table 3. We include comparisons with the same models as in the in-domain case. Again, our end-to-end model significantly outperforms previously published single and ensemble models, even without taking unlabeled data into account. We achieve a relatively higher improvement with CVT on out-of-domain data (F_1 increases from 81.6% to 82.5%, and the difference is significant at $p < 0.05$). This suggests that semi-

Roth and Lapata (2016)	81.8	78.5	80.1
Ours (supervised training)	84.5	82.1	83.3
Ours (with CVT)	84.9	82.7	**83.8**
Spanish	P	R	F
Björkelund et al. (2010)	78.9	74.3	76.5
Roth and Lapata (2016)	83.2	77.4	80.2
Marcheggiani et al. (2017)	81.4	79.3	80.3
Ours (supervised training)	83.0	81.3	82.1
Ours(with CVT)	83.6	82.2	**82.9**

Table 4: CoNLL-2009 results on Chinese, German, and Spanish (test sets). Differences in F_1 between our models and previous systems are statistically significant ($p < 0.05$) using stratified shuffling (Noreen, 1989).

supervised training indeed increases the robustness of our model, leading to more accurate predictions for both SRL and auxiliary tasks.

Table 4 presents the results of our experiments (without ELMo) on Chinese, German, and Spanish. Although we have not performed detailed parameter selection in these languages (i.e., we used the same parameters as in English), our model achieves state-of-the-art performance across all three languages.

3.2 Ablation Studies

To investigate the contribution of the sentence learner and cross-view training, we conducted a series of ablation studies on the English development set without predicate disambiguation.

Our experiments are summarized in Table 5. The first block shows the performance of the full model. In the second block, we assess the effect of different kinds of representations used in our model. Interestingly, the impact of ELMo (about 0.6 in F_1) is slightly less compared to multi-task hidden features (about 0.7 in F_1). This suggests that multi-task hidden features provide as useful information for SRL as pre-trained representations. We next eliminate the sentence learner model and have the semantic role labeler use the predicted POS tags and dependency labels provided in CoNLL-2009 dataset. As can be seen, this leads to a substantial drop in performance over the full model (1.4% in F_1).

Model	P	R	F_1
Ours	88.6	86.8	87.7
w/o ELMo	87.9	86.4	87.1
w/o multi-task hidden features	88.0	86.1	87.0
w/o sentence learner	87.2	85.5	86.3
w/o cross-view training	88.0	85.8	86.9
w/o splitting sentence	87.4	85.7	86.6

Table 5: Ablation results on the CoNLL-2009 English development set.

Preceding	Following	F_1	ΔF_1
Backward	*Forward*	87.3	0.4
Past	*Future*	87.4	0.5

Table 6: CVT with different auxiliary modules for SRL (CoNLL-2009 English development set). Δ denotes difference from model trained without CVT.

In the third block, we remove cross-view training from our model, and observe a 0.8% drop in F_1 over the full model. Finally, we apply the auxiliary modules on the full sentence instead of treating the words preceding and following the target predicate differently, and observe a 0.3% drop in F_1 over the supervised model. This is not surprising as the predicate indicator plays an important role in improving the performance of semantic role labeler.

3.3 CVT Analysis

In Table 6, we briefly explore which auxiliary prediction modules are more important for CVT when applied to SRL. We apply two types of auxiliary modules both of which take care not to "see" the target predicate directly. The "forward/backward" module does not see the right/left context of the current word, while the "future/past" module does not see the right/left context and the current token itself. Both kinds of modules improve performance (over a supervised model without CVT, see second row in Table 5); future and past modules are slightly better corroborating the results of Clark et al. (2018) on sequence tagging. Overall, the results in Table 6 suggest that more restricted views of the input are beneficial.

Strategy	F_1	ΔF_1
Randomly chosen word	87.0	0.1
Randomly chosen predicate	87.7	0.8
Most confident predicate	86.4	-0.5

Table 7: CVT with different predicate selection strategies for SRL (CoNLL-2009 English development set). Δ denotes difference from model trained without CVT.

We further explore how the strategy of selecting the target predicate (in sentences containing multiple candidates) influences performance. For each unlabeled sentence, we adopt the strategy of randomly selecting a predicate amongst those words identified as predicate candidates by the sentence learner. We could also select the predicate with the highest predicted score or a random word from the sentence. The experiments in Table 7 confirm that the adopted strategy works best delivering a 0.8 improvement in F_1 over a supervised model without CVT (second row in Table 5). Selecting the most confident predicate is the worst possible strategy, decreasing F_1 performance by 0.6 over a supervised model without CVT (see Table 5); the model concentrates on a few predicates with very high scores (these tend to be common verbs such as *say*, *is*, and *have*), while ignoring nominal predicates and less frequent verbs. The strategy of randomly selecting a word from the sentence performs better, precisely because it pays attention to a wider range of predicates.

4 Related Work

Our model resonates the recent trend of developing neural network models for semantic role labeling using relatively simple architectures based on bidirectional LSTMs (Marcheggiani et al., 2017; Cai et al., 2018; Strubell et al., 2018). It also agrees with previous work in adopting multi-task learning as a means to improve a main task by jointly learning one or more related auxiliary tasks (Collobert et al., 2011; Søgaard and Goldberg, 2016; Swayamdipta et al., 2017; Peng et al., 2017; Strubell et al., 2018).

The idea of resorting to semi-supervised learning as a means of reducing the annotation effort involved in creating labeled data for SRL is by no means new. Fürstenau and Lapata (2012) propose to augment a labeled dataset with unlabeled examples whose roles are inferred automatically via annotation projection. Other work uses a language model to learn word similarities from unlabeled texts (Croce et al., 2010; Deschacht and Moens, 2009) or constructs an informed prior from labeled data in order to learn a generative model from unlabeled data (Titov and Klementiev, 2012).

More recently, Mehta et al. (2018) have proposed a semi-supervised method for constituency-based SRL. Their work builds upon a state-of-the-art neural model (He et al., 2018b; Peters et al., 2018) whose training objective they augment with a syntactic inconsistency loss component. Their hypothesis is that by leveraging syntactic structure during training, the SRL model may become more robust in low resource scenarios. This method is very much geared towards improving constituent-based SRL, where syntactic constraints are widely used during decoding (He et al., 2017, 2018a). And requires a robust syntactic parser to analyze (out-of-domain) unlabeled sentences for consistency. Our model does not rely on external tools, and is generally applicable across semantic role representations based on dependencies or constituents (i.e., phrases or spans). However, we leave experiments on the latter for future work.

Although the focus of this work has been on semi-supervised learning, we have developed a competitive SRL system which could be used on its own, after being trained on labeled data. Following previous work (Strubell et al., 2018; Cai et al., 2018) we proposed an end-to-end model, which is able to distinguish predicates and label their arguments while learning a POS-tagger and a dependency parser. Importantly, our model can be simultaneously used for supervised and semi-supervised learning without modification. Cai et al. (2018) do not use any syntactic information which is critical when dealing with unlabeled data. Strubell et al. (2018) directly predict POS tags and predicates on top of the lower layers of their model; while this information is fed to the final SRL classifier, it is not propagated through the network, and is not shared with their multi-head self-attention layers.

5 Conclusions

In this paper we developed an end-to-end SRL model and demonstrated it can effectively leverage unlabeled data under the crossview training modeling paradigm. Experiments on the CONLL-2009 benchmark datasets show that our model delivers state of the art performance in English, Chi-

nese, German, and Spanish. Directions for future work are many and varied. We would like to apply the proposed model in low-resource settings, e.g., to transfer roles from English to another language via annotation projection or to learn an SRL model from weak supervision where only annotations for dependency labels are available.

Abstract

Previous work on cross-lingual sequence labeling tasks either requires parallel data or bridges the two languages through word-by-word matching. Such requirements and assumptions are infeasible for most languages, especially for languages with large linguistic distances, e.g., English and Chinese. In this work, we propose a Multilingual Language Model with deep semantic Alignment (MLMA) to generate language-independent representations for cross-lingual sequence labeling. Our methods require only monolingual corpora with no bilingual resources at all and take advantage of deep contextualized representations. Experimental results show that our approach achieves new state-of-the-art NER and POS performance across European languages, and is also effective on distant language pairs such as English and Chinese.[1]

1 Introduction

Sequence labeling tasks such as named entity recognition (NER) and part-of-speech (POS) tagging are fundamental problems in natural language processing (NLP). Recent sequence labeling models achieve state-of-the-art performance by combining both character-level and word-level information (Chiu and Nichols, 2016; Ma and Hovy, 2016; Lample et al., 2016). However, these models heavily rely on large-scale annotated training data, which may not be available in most languages. Cross-lingual transfer learning is proposed to address the label scarcity problem by transferring annotations from high-resource languages (source languages) to low-resource languages (target languages). In this scenario, a major challenge is how to bridge interlingual gaps with modest resource requirements.

There is a large body of work exploring cross-lingual transfer through language-independent features, such as morphological features and universal POS tags for cross-lingual NER (Tsai et al., 2016) and dependency parsers (McDonald et al., 2011). However, these approaches require linguistic knowledge for language-independent feature engineering, which is expensive in low-resource settings. Other work relies on bilingual resources to transfer knowledge from source languages to target languages. Parallel corpora are widely used to project annotations from the source to the target side (Yarowsky et al., 2001; Ehrmann et al., 2011; Kim et al., 2012; Wang and Manning, 2014). These methods could achieve strong performance with a large amount of bilingual data, which is scarce in low-resource settings.

Recent research leverages cross-lingual word embeddings (CLWEs) to establish inter-lingual connections and reduce the requirements of parallel data to a small lexicon or even no bilingual resource (Ni et al., 2017; Fang and Cohn, 2017; Xie et al., 2018). However, word embedding spaces may not be completely isomorphic due to language-specific linguistic properties, and therefore cannot be perfectly aligned. For example, different from English, Chinese nouns do not distinguish singular and plural forms, while Spanish nouns distinguish masculine and feminine.

On the other hand, NER tags such as person names, organizations, and locations are shared across different languages. Language-independent frameworks such as universal conceptual cognitive annotation (Abend and Rappoport, 2013), universal POS (Petrov et al., 2011a), and universal dependencies (Nivre et al., 2016) are defined to represent different languages in a unified formation. These work serves as our motivation to assume

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1028–1039, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

that the semantic meanings of words from different languages can be roughly aligned at a conceptual level and it is more reasonable to align deep semantic representations instead of shallow word embeddings. Meanwhile, monolingual contextualized embeddings derived from language models have shown to be effective for extracting semantic information and have achieved significant improvement on several NLP tasks (Peters et al., 2018).

In this paper, we propose a Multilingual Language Model with deep semantic Alignment (MLMA). We train MLMA on monolingual corpora from each language and align its internal states across different languages. Then MLMA is utilized to generate language-independent representations and to bridge the gaps between high-resource and low-resource languages. For evaluation, we conduct extensive experiments on the NER and POS benchmark datasets under cross-lingual settings. The experiment results show that our methods achieve substantial improvements comparing to previous state-of-the-art methods in European languages. We also validate our approaches on a distant language pair, English-Chinese, and the results are competitive with previous methods which use large-scale parallel corpora. Our contributions are as follows:

1. Instead of word-level alignment, we propose MLMA that uses contextualized representations to bridge the inter-lingual gaps.
2. We propose three methods to align contextualized representations without any bilingual resource.
3. Our methods achieve new state-of-the-art performance on cross-lingual NER and POS tasks in European languages, and very competitive results for English-Chinese NER, where previous work uses large parallel data.

2 Approach

Our approach belongs to the model transfer (Section 5.2) and mainly consists of three steps:

1. Training a multilingual language model with alignment (MLMA) using monolingual corpora of the source and the target languages. (Section 2.1, 2.2 and 2.3)
2. Building a cross-lingual sequence labeling model based on the language-independent representations from the MLMA. (Section 2.4 and 2.5)
3. Learning the cross-lingual sequence labeling model (with MLMA fixed) on the annotated data of source languages and directly applying it to the target languages.

The architecture of MLMA is shown in Figure 1. In the following sections, we focus on introducing the Step 1 and 2. We first present the architecture of MLMA and describe how to build the unsupervised multilingual alignment. Next, we propose effective methods for collapsing the multi-layer hidden states from MLMA into a single representation. Finally, we introduce the sequence labeling model used in the experiments.

2.1 Language Model Architecture

MLMA is a language model with multi-head self-attention mechanism (Vaswani et al., 2017). The architecture is similar to Radford et al. (2018), except that we combine both a forward and a backward Transformer decoder to build a bidirectional language model. Take the forward direction as an example, given a sentence with N tokens $W = [w_1, w_2, \cdots, w_N]^T$ as input, we first map the sequence of tokens W to token embeddings $\overrightarrow{H}_0 \in \mathbb{R}^{N \times d}$:

$$\overrightarrow{H}_0 = W E_e + E_p \tag{1}$$

where E_e and E_p are the embedding matrix and the positional encoding matrix, and d is the dimension of embeddings and hidden states.

Then n blocks of transformer layers are stacked above the token embeddings. Each block contains a masked multi-head self-attention and a position-wise feedforward layer. The detailed implementation is the same as Vaswani et al. (2017).

$$\overrightarrow{H}_l = \text{TransformerLayer}(\overrightarrow{H}_{l-1}) \tag{2}$$

where $\overrightarrow{H}_l$ refers to the output of the l-th transformer block. Finally, the output distribution over the next tokens is calculated through a softmax function with tied embedding matrix.

$$\overrightarrow{P} = \text{softmax}(\overrightarrow{H}_n E_e^T) \tag{3}$$

For the backward direction, we calculate $\overleftarrow{H}_l$ and $\overleftarrow{P}$ in an analogous way. Finally, we jointly minimize the negative log likelihood of the forward and backward directions:

$$\begin{aligned} NLL = -\sum_{t=1}^{N} (& \log p(w_t | w_1, \ldots, w_{t-1}) \\ & + \log p(w_t | w_{t+1}, \ldots, w_N)) \end{aligned} \tag{4}$$

In a multilingual setting, we share all param-

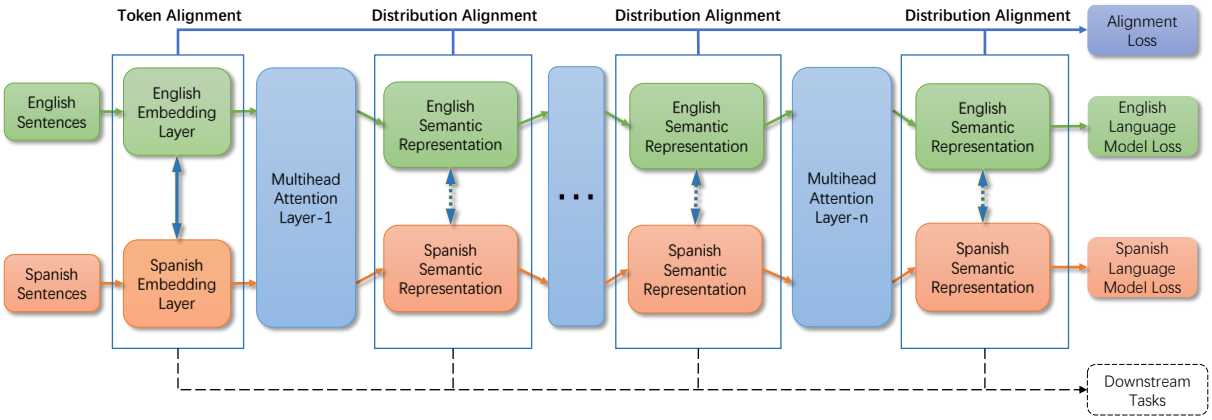

Figure 1: The architecture of MLMA consists of language-specific embedding layers and language-agnostic Transformer layers. MLMA is jointly learned through language modeling loss and alignment loss, and its internal representations are utilized to bridge the gap between source and target languages.

eters in Transformer layers across different languages to facilitate language-agnostic representations, except that we adopt an individual embedding matrix E_e for each language.

2.2 Unsupervised Distribution Alignment

We find that only sharing Transformer layers is not enough for forcing hidden representations from different languages into a common space, as suggested in experiments (Section 3.4). Therefore, we propose three methods to build cross-lingual representations based on identical strings, mean/variance, and average linkage.

To simplify the description, we take the alignment between two languages s and t as an example, but our methods can be directly extended to a scenario with multiple languages by adding the alignment between each pair of languages.

Notation

For the language model, given a sentence with N tokens, the forward internal representation $\overrightarrow{H}_l$ in Eq (2) can be expanded as $\overrightarrow{H}_l = [\overrightarrow{h}_{l,1}, \cdots, \overrightarrow{h}_{l,k}, \cdots, \overrightarrow{h}_{l,N}]^T$, where $\overrightarrow{h}_{l,k}$ refers to the forward hidden representation of the k-th token in the sentence. Then we concatenate the forward and backward hidden representations for each token, $h_{l,k} = \overrightarrow{h}_{l,k} \oplus \overleftarrow{h}_{l,k}$.

We denote the collection of the token representations $h_{l,k}$ at layer l from the whole corpora of language s as C_l^s, which can be regarded as a sampling from the deep semantic space of language s. Similarly, C_l^t is used for language t.

Identical Strings

Similar language pairs such as English and Spanish have a large number of identical strings shared between their vocabularies, which are utilized as the seed dictionary for embedding alignment in previous work (Smith et al., 2017). Similarly, we treat identical strings as explicit supervision signals and align the embeddings of identical strings between different languages. The matching of the embeddings from different languages will lead to an implicit alignment of internal representations. In the experiments, we directly minimize the Euclidean distance between the embeddings of each identical string across different languages:

$$L_{iden} = \frac{\lambda^{iden}}{|W_{iden}^{(s,t)}|} \sum_{w \in W_{iden}^{(s,t)}} ||e_w^s - e_w^t||$$

where $W_{iden}^{(s,t)}$ is the set of identical strings between the vocabulary of language s and language t, and $|W_{iden}^{(s,t)}|$ refers to the number of members in $W_{iden}^{(s,t)}$. λ^{id} is a scaling weight, and e_w^s (e_w^t) is the embedding of word w from embedding matrix E_e^s (E_e^t) of language s (t).

Mean and Variance

In this section, we propose another approach to directly align the distributions of internal representations between different languages. In particular, we leverage the mean and variance of internal distributions for alignment. We denote the mean and variance of C_l^s as m_l^s and v_l^s. Similarly, m_l^t and v_l^t refer to the mean and variance of C_l^t. We minimize the Euclidean distance between the mean and variance of language s and language t for all layers:

$$L_{mv} = \sum_{l=0}^{n} (\lambda_l^m \cdot \frac{||m_l^s - m_l^t||}{|m_l^s| + |m_l^t|} + \lambda_l^v \cdot \frac{||v_l^s - v_l^t||}{|v_l^s| + |v_l^t|})$$

where λ_l is a scaling weight, and $|\cdot|$ is the L1 norm of a vector. Without the denominators, the

model could escape this regularization by learning a mean and variance with low absolute values.

In practice, rather than calculating the mean and variance over the whole source and target corpora, we use the mean and variance of the source and target inner states $h_{l,k}$ in the current mini-batch as an approximation.

Average Linkage

In this method, we employ another metric, average linkage, to perform a more precise point-wise matching. The average linkage is a widely used metric for calculating the similarity of clusters and networks (Yim and Ramdeen, 2015; Seifoddini, 1989; Newman, 2012; Moseley and Wang, 2017). It is sensitive to the shape, thus serves as a better choice than mean and variance. The average linkage measures the similarity of two sets X and Y by calculating the averaged distance between all members of each set:

$$avl(X, Y) = \frac{1}{n_X \cdot n_Y} \sum_{x \in X} \sum_{y \in Y} f(x, y)$$

where n_X (n_Y) is the number of members in X (Y), and f is a distance function. We take Euclidean distance as the distance function f and minimize the average linkage between C_l^s and C_l^t:

$$L_{avl} = \sum_{l=0}^{n} \lambda_l^{avl} \cdot [2 \cdot avl(C_l^s, C_l^t) - avl(C_l^s, C_l^s) - avl(C_l^t, C_l^t)]$$

Similarly, the terms $avl(C_l^s, C_l^s)$ and $avl(C_l^t, C_l^t)$ are used to prevent the model from escaping this regularization. In practice, we calculate L_{avl} between the source and target inner states $h_{l,k}$ inside the mini-batch as an approximation.

The regularization L_{avl} is similar to the maximum mean discrepancy (MMD), which is often employed in domain adaptation (Tzeng et al., 2014; Long et al., 2015) and style transfer (Li et al., 2017) for images. However, different from MMD, our method directly uses Euclidean distance instead of the kernel function.

2.3 Training of MLMA

During the training stage of MLMA, we sample equivalent number of sentences from the monolingual corpora of each language for each mini-batch. Then MLMA is optimized through a combination of the language modeling loss L_{lm} and the alignment regularization loss L_{reg}. For each alignment method, we use its corresponding alignment loss:

$$\begin{aligned} L =& L_{lm} + L_{reg} \\ \text{where } L_{lm} =& \sum_{i \in \{s,t\}} \lambda_i^{lm} \cdot NLL_i, \\ & L_{reg} \in \{L_{id}, L_{mv}, L_{avl}\} \end{aligned}$$

where λ_i^{lm} is used for balancing the convergence speed of different languages. NLL_i is the negative log likelihood of language i in Eq (4).

2.4 Cross-lingual Representations

After the MLMA is trained, we fix its parameters and extract the hidden states as cross-lingual contextualized representations (CLCRs). In this section, we propose two effective strategies for integrating these multi-layer high-dimensional representations into downstream models.

Self-Weighted Sum For each token, we concatenate all layers of hidden states and feed them into a multi-layer perceptron (MLP) to calculate a $(n+1)$-dimensional weight vector, $s = \text{softmax}(\text{MLP}(h_{0,k} \oplus \cdots \oplus h_{n,k}))$. Then we calculate a weighted sum of these layers according to the weight vector, $\mathbf{CLCR}_k = \sum_{l=0}^{n} s_l \cdot h_{l,k}$.

Fully-Weighted Sum We introduce a weight matrix, $F \in \mathbb{R}^{(n+1) \times 2d}$, with separate weights for each hidden dimension. The weight matrix F is softmaxed by column and used to calculate a weighted sum of all layers for each hidden dimension, $\mathbf{CLCR}_k = \sum_{l=0}^{n} F_l \odot h_{l,k}$, where $\odot$ is the element-wise product.

The parameters of the MLP and F are trained during the learning of sequence labeling model.

2.5 Sequence Labeling Model

The sequence labeling model is then built on the CLCRs. For both NER and POS tasks, we use an LSTM-CRF model following Lample et al. (2016), which consists of a character-level LSTM, a word-level LSTM, and a linear-chain CRF.

More specifically, given a sequence of words as $[w_1, w_2, \ldots, w_N]$, where w_k is composed of a sequence of characters $[c_{k,1}, c_{k,2}, \ldots, c_{k,m}]$. First, for each word w_k, the character-level LSTM takes its character sequence $[c_{k,1}, c_{k,2}, \ldots, c_{k,m}]$ as input and outputs a vector e_k to represent this word. Then the pre-trained $\mathbf{CLCR}_k$ is concatenated with e_k to form a word-level embedding x_k. Finally, the sequence of word-level embeddings $[x_1, x_2, \ldots, x_N]$ are fed into the word-level LSTM, and the linear-chain CRF are employed to

predict the probability distribution for all possible output label sequences.

3 Experiments

We first introduce the datasets used in the experiment and then the implementation details of our models, before presenting the results on NER and POS tasks.

3.1 Datasets

For cross-lingual NER, we evaluate the proposed approaches on CoNLL 2002/2003 datasets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003), which contain four European languages, English (en), Spanish (es), Dutch (nl), German (de) and four entity types (person, location, organization, and MISC). We also evaluate a distant language pair, English-Chinese, on OntoNotes(v4.0) dataset (Hovy et al., 2006). We adopt the same dataset split and four valid entity types (person, location, organization, and GPE) as described in (Wang and Manning, 2014).

For cross-lingual POS, we use the Danish (da), Dutch (nl), German (de), Greek (el), Italian (it), Portuguese (pt), Spanish (es) and Swedish (sv) portion from CoNLL 2006/2007 dataset (Buchholz and Marsi, 2006; Nivre et al., 2007). Following previous work (Fang and Cohn, 2017), we train the sequence labeling model on Penn Treebank data and adopt the universal POS tagset (Petrov et al., 2011b).

In all cases, the sequence labeling model is trained on the source language (English) training data and is tested on the target language test data.

3.2 Details of MLMA

We adopt a 6-layer bi-directional Transformer decoder with 8 attention heads. The dimension size of hidden states and inner states are 512 and 2048, respectively. The dropout rates after attention and residual connection are both 0.1. We use the Adam optimization scheme (Kingma and Ba, 2014) with a learning rate of 0.0001 and a gradient clip norm of 5.0. The vocabulary size of each language is 200,000, and we train the model with a sampled softmax (Jean et al., 2015) of 8192 samples. We only keep the sentences containing less than 200 tokens for training and group them into batches by length. Each batch contains around 4096 tokens for each language. The language modeling weight λ_i^{lm} is set to be 1.0 for each language. For alignment, λ_l^m, λ_l^v, λ_l^{al} are set to be 0.1, 0.01 and 1.0 for every layer l, and λ^{iden} is set to be 100.

For languages except English, the latest dump of Wikipedia is used as monolingual corpora. For English, we use 1B Word Benchmark (Chelba et al., 2013) to reduce the effects of potential internal alignment in Wikipedia (Zirikly and Hagiwara, 2015; Tsai et al., 2016).

All characters are preprocessed to lowercase, and Chinese text are converted into the simplified version through OpenCC[2]. The corpora of European languages are tokenized by nltk (Loper and Bird, 2002) and Chinese text is segmented using Ltp[3].

3.3 Details of Sequence Labeling Model

In our experiments, we set the hidden size of word-level LSTM and character-level LSTM to be 300 and 100, respectively. The character embedding size is set to be 100. We apply dropout at both the input and the output of word-level LSTM to prevent overfitting. The dropout rate is set to be 0.5. We train the sequence labeling model for 20 epochs using Adam optimizer with a batch size of 20 and perform an early stopping when there is no improvement for 3 epochs. We set the initial learning rate to be 0.001 and decay the learning rate by 0.1 for each epoch. We do not update the pre-trained cross-lingual deep representations from MLMA during training. For each model, we run it five times and report the mean and standard deviation. We disable the character-level LSTM in English-German and English-Chinese NER as they have a different character pattern from English. For POS, we disable the character-level LSTM following Fang and Cohn (2017).

3.4 Results for NER

We first train a multilingual language model without alignment (MLM) and report its performance of cross-lingual NER in Table 1. The poor performance demonstrates that only sharing part of the parameters in a language model is far from enough for cross-lingual transfer.

As shown in Table 1, the mean/variance alignment strategy (MLMA-Mv) is competitive with previous work which utilizes extra bilingual resources (Section 5.1). The average linkage strategy (MLMA-Avl) performs a more precise align-

Table 1: NER F1 scores on test sets of European languages. For previous work which reports multiple results, we only list their best performance on each language. Results of methods with mark * are obtained by running their released source code or models. The results of MUSE embeddings are produced by using them for direct model transfer. "MLM" denotes our multilingual language model without alignment. The three alignment methods, **Iden** = identical strings, **Mv** = mean and variance, **Avl** = average linkage, respectively. "s.w.s" and "f.w.s." are self-weighted sum and fully-weighted sum. "init" represents using MUSE to initialize the embedding matrices in the MLMA. "multi" refer to the multi-source transfer.

ment and gains a further improvement. We conducted experiments of using all three alignments together, and results show no significant improvement over average linkage alone. These results agree with our statements that average linkage performs a more precise matching, and thus, carries the benefits brought by the other methods.

To demonstrate the strengths of the proposed cross-lingual contextualized representations (CLCRs) over cross-lingual word embeddings (CLWEs), we also report the results of using CLWEs for direct model transfer in Table 1. Specifically, we compare with the unsupervised method MUSE from Conneau et al. (2017). The experiment results demonstrate its effectiveness for cross-lingual sequence labeling. The alignment method using identical strings (MLMA-Iden) outperforms MUSE, suggesting that the contextual-level representations are more effective than the word-level ones. The other proposed methods (MLMA-Mv and MLMA-Avl) achieve significant improvement over MUSE and MLMA-Iden, which shows the benefit of directly aligning the contextualized representations.

Combination with CLWEs We further demonstrate that CLWEs are compatible with our methods by using MUSE embeddings to initialize the embedding layer of our multilingual language model. The results of MLMA-Avl (init) shown in Table 1 indicate that the CLWEs lead to a better initialization and improved performance.

Multi-source Transfer We conduct experiments of multi-source transfer based on method MLMA-Avl and report the performance as MLMA-Avl (multi) in Table 1. The experiment settings largely follow the previous work (Mayhew et al., 2017). They employ two source languages for each target language and use syntactic features to choose the related source languages. For Spanish and German, we use English and Dutch as source languages. English and Spanish are adopted for

Table 3: POS accuracy on test sets of European languages. The notations are consistent with Table 1. Fang and Cohn (2017) report different results according to different resource requirements. We only list their best results in each setting. Methods with mark ◇, †, ‡ require parallel corpora, bilingual lexicons, and training data respectively.

Dutch. The multi-source transfer leads to a significant improvement for Spanish and German, but a slight decline for Dutch. In the follow-up experiment, we find that the Spanish training set achieves a poor cross-lingual performance on Dutch. Similar results are observed in the experiments of Spanish to English and Dutch to English. These results suggest that the cross-lingual transfer may be directional, and we leave this issue for future work.

Comparison with BERT We also compare the performance of our MLMA with the released multilingual BERT (Devlin et al., 2018). As shown in Table 1, our MLMA-Avl achieves a better performance on Spanish and Dutch. For German, BERT achieves a high performance as it employs effective subword information through BPE. The architecture of BERT also performs better than LSTM.

It is worth mentioning that, in previous work and this work, the corpora used in the experiments are limited to the source and the target language. In contrast, the multilingual BERT is jointly learned on Wikipedia of 102 languages and may benefit from a multi-hop transfer. BERT employs a shared BPE vocabulary for different languages, which implicitly performs a subword alignment similar to MLMA-Iden. Meanwhile, the proposed MLMA-Mv and MLMA-Avl methods are compatible with BERT and can be used to align the inner states of BERT.

3.5 A Case Study of Chinese NER

We conduct experiments and evaluate our approaches on a distant language pair, English-Chinese. The experiment results are shown in Table 2. Wang and Manning (2014) utilize 80K parallel sentences for annotation projection and report a strong performance. As Chinese and English do not share the alphabet, the number of identical strings is significantly smaller than similar languages pairs such as English-Spanish. Therefore, the MLMA-Iden achieves a lower result comparing to MUSE which uses adversarial training. The MLMA-Avl method performs a direct alignment of internal representations and achieves a significant improvement over the word-level methods. The initialization from CLWEs also proves its effectiveness for distant language pairs by gaining further improvement and reaching a comparable result with Wang and Manning (2014). This experiment suggests that cross-lingual transfer is still challenging between distant language pairs.

3.6 Results for POS

We evaluate our methods on another sequence labeling task POS, and the results are shown in Table 3. We compare with previous studies using unsupervised cross-lingual clustering (Fang and Cohn, 2017) and large-scale parallel corpora (Das and Petrov, 2011). As shown in Table 3, our models with deep semantic alignment outperform previous lexicon-based cross-lingual clustering by a large margin. When comparing to the previous method with a small amount of training data, the MLMA-Avl method obtains an improved accuracy without training data in the target languages. For further comparison, We also list the performance of applying the method from Xie et al. (2018) and

Table 4: English words and their nearest Spanish words according to MUSE and MLMA-Avl.

multilingual BERT to the POS task.[4]

POS mainly relies on the information of each single word, and parallel corpora providing word alignment are effective for cross-lingual POS. Thus, previous annotation projection methods through parallel corpora are strong approaches for cross-lingual POS and often achieve a significantly better performance against previous unsupervised methods. The experimental results show that the proposed CLCRs are competitive and even achieve better average accuracy.

3.7 Self-Weighted v.s. Fully-Weighted Sum

As shown in Table 1, 2 and 3, we observe that Self-Weighted Sum (SWS) generally outperforms Fully-Weighted Sum (FWS) in NER tasks, while the opposite is true for POS tasks. SWS allows weights to vary at each position in a sequence, while FWS imposes adaptive weights for each hidden dimension. We hypothesize that NER is more context-sensitive and requires models to adapt to different context information, which makes SWS a better option. On the other hand, the POS of words is more independent across different context, but certain feature dimensions in contextualized representations may be critical for making a judgment. Therefore, FWS has the edge over SWS for its ability to select out these dimensions.

4 What is Connected during Alignment?

In this section, we dive into the MLMA and investigate the question of what is connected between different languages during the alignment. From English 1B and Spanish Wikipedia, we randomly select 1,000 sentences for each language and extract their cross-lingual contextual representations using our MLMA-Avl model. We calculate the nearest neighbors in cosine distance for each word, and some of them are listed in Table 4.

In these cases, the MLMA can disambiguate word senses according to context information. For example, for the word *brown* in English, the MLMA groups color *brown* with *verde* (green), and name *Brown* with *Neira* (a person name in Spanish) in the Spanish corpus. The proposed method is different from unsupervised translation in that, instead of learning a precise matching between English and Spanish words, the CLCRs establishes a high-level semantic connection between the source and the target language. The next example demonstrates that the MLMA is able to distinguish the part-of-speech of words. It connects an English verb *chair* with a Spanish verb *presidir* (preside), while a noun *chair* with a noun *asiento* (seat) in Spanish. To compare with unsupervised cross-lingual word embeddings, we list the top 5 similar words calculated using MUSE. As shown in Table 4, MUSE successfully groups the English word *brown* with Spanish words that are related to colors. However, without the help of contextual information, its ability of word sense disambiguation is limited.

5 Related Work

Previous work in cross-lingual transfer learning can be roughly divided into two main branches: annotation projection and model transfer.

5.1 Annotation Projection

In annotation projection approaches, parallel or comparable corpora are commonly used (Yarowsky et al., 2001; Ehrmann et al., 2011; Das and Petrov, 2011; Li et al., 2012; Täckström et al.,

[4]The poor performance of Xie et al. (2018) on en-da is due to the low quality of word translation pairs generated by their method.

2013; Wang and Manning, 2014; Ni et al., 2017). The source language sentences of parallel corpora are first annotated either manually or by a pre-trained tagger. Then, annotations on the source side are projected to the target side through word alignment to generate distantly supervised training data. Finally, a model of the target language is trained on the generated data. Wikipedia contains multilingual articles for various topics and can thus be used to generate parallel/comparable corpora or even weakly annotated target language sentences (Kim et al., 2012).

However, parallel corpora and Wikipedia can be rare for true low-resource languages. Mayhew et al. (2017) reduce the resource requirement by proposing a cheap translation method, which "translates" the training data from the source to the target language word by word through a bilingual lexicon. While Xie et al. (2018) reduce the requirement of bilingual lexicons by an unsupervised word-by-word translation through CLWEs.

5.2 Model Transfer

Model transfer methods train a model on the source language with language-independent features. Thus, the trained model can be directly applied to the target language.

McDonald et al. (2011) design a cross-lingual parser based on delexicalized features like universal POS tags. Täckström et al. (2012) reveal that cross-lingual word cluster features induced using large parallel corpora are useful. Lexicon and Wikipedia also demonstrate effectiveness for language-independent feature engineering. Zirikly and Hagiwara (2015) generate multilingual gazetteers from the source language gazetteers and comparable corpus. Page categories and linkage information to entries from Wikipedia are extracted as strong language-independent features (wikifier features) (Tsai et al., 2016). Bharadwaj et al. (2016) facilitate the cross-lingual transfer through phonetic features, which work well between languages like Turkish, Uzbek, and Uyghur, but are not strictly language independent. Recently, CLWEs are used as language-invariant representations for direct model transfer in NER (Ni et al., 2017) and POS (Fang and Cohn, 2017).

Some of the previous work also proposes sequence labeling models with shared parameters between languages for performing cross-lingual knowledge transfer (Lin et al., 2018; Cotterell and Duh, 2017; Yang et al., 2017; Ammar et al., 2016; Kim et al., 2017). However, these models are usually obtained through joint learning and require annotated data from the target language.

6 Conclusion

In this paper, we focused on a low-resources cross-lingual setting and proposed transfer learning methods based on the alignment of deep semantic spaces between different languages. The proposed multilingual language model bridges different languages by automatically learning cross-lingual disambiguated representations. Abundant NER and POS experiments are conducted on the benchmark datasets. Experimental results show that our approaches using only monolingual corpora achieve improved performance comparing to previous strong cross-lingual studies with extra resources.

Abstract

Recurrent neural networks (RNN) used for Chinese named entity recognition (NER) that sequentially track character and word information have achieved great success. However, the characteristic of chain structure and the lack of global semantics determine that RNN-based models are vulnerable to word ambiguities. In this work, we try to alleviate this problem by introducing a lexicon-based graph neural network with global semantics, in which lexicon knowledge is used to connect characters to capture the local composition, while a global relay node can capture global sentence semantics and long-range dependency. Based on the multiple graph-based interactions among characters, potential words, and the whole-sentence semantics, word ambiguities can be effectively tackled. Experiments on four NER datasets show that the proposed model achieves significant improvements against other baseline models.

1 Introduction

The task of named entity recognition (NER) involves determining entity boundaries and recognizing categories of named entities, which is a fundamental task in the field of natural language processing (NLP). NER plays an important role in many downstream NLP tasks, including information retrieval (Chen et al., 2015b), relation extraction (Bunescu and Mooney, 2005), question answering systems (Diefenbach et al., 2018), and other applications. Compared with English NER, Chinese named entities are more difficult to identify due to their uncertain boundaries, complex composition, and NE definitions within the nest (Duan and Zheng, 2011).

One intuitive way to alleviate word boundary problems is to first perform word segmentation and then apply word sequence labeling (Yang et al., 2016; He and Sun, 2017). However, the rare gold-standard segmentation in NER datasets and incorrectly segmented entity boundaries both negatively impact the identification of named entities (Peng and Dredze, 2015; He and Sun, 2016). Hence, character-level Chinese NER using lexicon features to better leverage word information has attracted research attention (Passos et al., 2014; Zhang and Yang, 2018). In particular, Zhang and Yang (2018) introduced a variant of a long short-term memory network (lattice-structured LSTM) that encodes all potential words matching a sentence to exploit explicit word information, achieving state-of-the-art results.

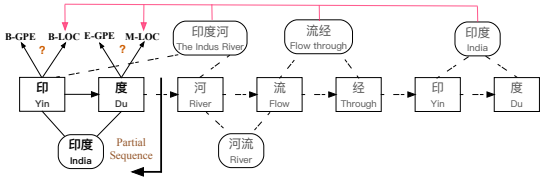

Figure 1: Example of word character lattice with partial input. Because of the characteristic of chain structure, RNN-based methods must predict the label "度" using only previous partial sequences "印度 (India)", which may suffer from word ambiguities without global sentence semantics.

However, these methods are usually based on RNN or CRF to sequentially encode a sentence, while the underlying structure of language is not strictly sequential (Shen et al., 2019). As a result, these models would encounter serious word ambiguity problems (Mich et al., 2000). Especially in Chinese texts, the recognition of named entities with overlapping ambiguous strings is even more challenging. As shown in Figure 1, the middle character of an overlapping ambiguous string can constitute words with the characters to both their left and their right (Yen et al., 2012), such as "河

*Equal contribution.

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

流 (River)" and "流经 (Flow through)", which share a common character "流". However, RNN-based models process characters in a strictly serial order, which is similar to reading Chinese, and a character has priority in being assigned to the word on the left (Perfetti and Tan, 1999). More seriously, RNN-based models must give the label of "度" using only previous partial sequences "印度 (India)", which is problematic without seeing the remaining characters. Hence, Ma et al. (2014) suggested that the overlapping ambiguity must be settled using sentence context and high-level information.

In this work, we introduce a lexicon-based graph neural network (LGN) that achieves Chinese NER as a node classification task. The proposed model breaks the serialization processing structure of RNNs with better interaction results between characters and words through careful connections. The lexicon knowledge connects related characters to capture the local composition. Meanwhile, a global relay node is designed to capture long-range dependency and high-level features. LGN follows a neighborhood aggregation scheme wherein the node representation is computed by recursively aggregating its incoming edges and the global relay node. Because of multiple iterations of aggregation, the model can use global context information to repeatedly compare ambiguous words for better prediction. Experimental results show that the proposed method can achieve state-of-the-art performance on four NER datasets.

The main contributions of this paper can be summarized as follows: 1) we propose the use of a lexicon to construct a graph neural network and achieve Chinese NER as a graph node classification task; 2) the proposed model can capture global context information and local compositions to tackle Chinese word ambiguity problems through recursively aggregating mechanism; 3) several experimental results demonstrate the effectiveness of the proposed method in different aspects.

2 Related Work

2.1 Chinese NER with Lexicon.

Some previous Chinese NER researches have compared word-based and character-based methods (Li et al., 2014) and show that due to the limited performance of the current Chinese word segmentation, character-based name taggers can outperform their word-based counterparts (He and Wang, 2008; Liu et al., 2010). Lexicon features have been widely used to better leverage word information for Chinese NER (Huang et al., 2015; Luo et al., 2015; Gui et al., 2019). Especially, Zhang and Yang (2018) proposed a lattice LSTM to model characters and potential words simultaneously. However, their lattice LSTM used a concatenation of independently trained left-to-right and right-to-left LSTM to represent features, which was also limited (Devlin et al., 2018). In this work, we propose a novel character-based method that treats the named entities as a node classification task. The proposed method can utilize global information (both the left and the right context) (Dong et al., 2019) to tackle word ambiguities.

2.2 Graph Neural Networks on Texts

Graph neural networks have been successfully applied to several text classification tasks (Veličković et al., 2017; Yao et al., 2018; Zhang et al., 2018b). Peng et al. (2018) proposed a GCN-based deep learning model for text classification. Zhang et al. (2018c) proposed using the dependency parse trees to construct a graph for relation extraction. Recently, multi-head attention mechanisms (Vaswani et al., 2017) have been widely used by graph neural networks during the fusion process (Zhang et al., 2018a; Lee et al., 2018), which can aggregate graph information by assigning different weights to neighboring nodes or associated edges. Given a set of vectors $\mathbf{H} \in \mathbb{R}^{n\times d}$, a query vector $\hat{\mathbf{q}} \in \mathbb{R}^{1\times d}$, and a set of trainable parameters $\mathbf{W}$, this mechanism can be formulated as:

$$\begin{aligned}
&\text{Attention}(\mathbf{q},\mathbf{K},\mathbf{V}) = softmax(\frac{\mathbf{q}\mathbf{K}^\top}{\sqrt{d_k}})\mathbf{V} \\
&\text{head}_i = \text{Attention}(\hat{\mathbf{q}}\mathbf{W}_i^Q, \mathbf{H}\mathbf{W}_i^K, \mathbf{H}\mathbf{W}_i^V) \\
&\text{MultiAtt}(\hat{\mathbf{q}},\mathbf{H}) = [\text{head}_1;\ldots;\text{head}_k]\mathbf{W}^O. \quad (1)
\end{aligned}$$

However, very little work has explored how to use the relationship among characters to construct graphs in raw Chinese texts. The few previous studies on morphological processing in Chinese proposed a decomposed lexical structure (Zhang and Peng, 1992; Zhou and Marslen-Wilson, 1994) in which Chinese words are represented in terms of their constituent characters. Inspired by these

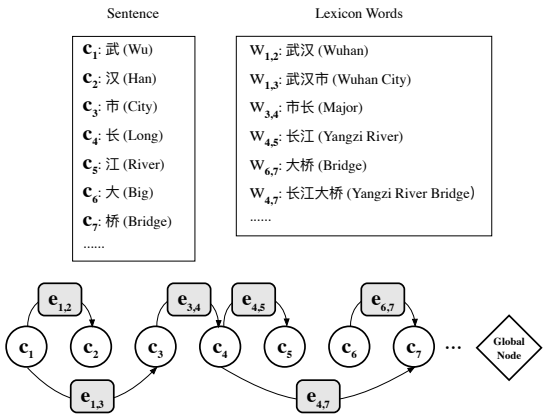

Figure 2: Illustration of graph construction.

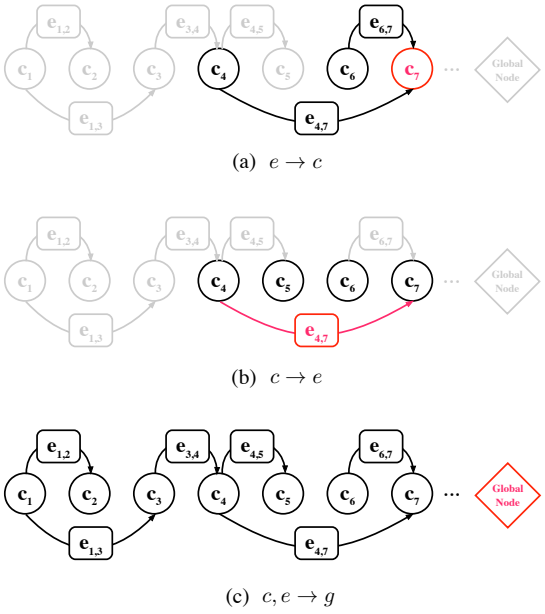
theoretical basis, we propose the use of graph neural networks to construct the relationship between constituent characters and words.

3 Lexicon-Based Graph Neural Network



In this work, we propose the use of lexicon information to construct graph neural networks, and achieve Chinese NER as a node classification task. The proposed model obtains better interaction among characters, words, and sentences through, **aggregation** $\rightarrow$ **update** $\rightarrow$ **aggregation** $\rightarrow$ ..., an efficient graph message passing architecture (Gilmer et al., 2017).

3.1 Graph Construction and Aggregation

We use the lexicon knowledge to connect characters to capture the local composition and potential word boundaries. In addition, we propose a global relay node to capture long-range dependency and high-level features. The implementation of the aggregation module for nodes and edges is similar to the multi-head attention mechanism in Transformer (Vaswani et al., 2017).

Graph Construction The whole sentence is converted into a directed graph, as shown in Figure 2, where each node represents a character and the connection between the first and last characters in a word can be treated as an edge. The state of the i-th node represents the features of the i-th token in a text sequence. The state of each edge represents the features of a corresponding potential word. The global relay node is used as a virtual hub to gather the information from all the nodes and edges, and then utilizes the global information to help the node remove ambiguity.

Formally, let $s = c_1, c_2, ..., c_n$ denote a sentence, where c_i denotes the i-th character. The

(a) $e \rightarrow c$

(b) $c \rightarrow e$

(c) $c, e \rightarrow g$

Figure 3: Aggregation in LGN. Red indicates the element that is being updated, and black indicates other elements involved in the aggregation. The aggregation results are then used in update modules.

potential words in the lexicon that match a character subsequence can be formulated as $w_{b,e} = c_b, c_{b+1}, ..., c_{e-1}, c_e$, where the index of the first and last letters are b and e, respectively. In this work, we propose the use of a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ to model a sentence, where each character $c_i \in \mathcal{V}$ is a graph node and $\mathcal{E}$ is the set of edges. Once a character subsequence matches a potential word $w_{b,e}$, we construct one edge $e_{b,e} \in \mathcal{E}$, pointing from the beginning character c_b to the ending character c_e.

To capture global information, we add a global relay node to connect each character node and word edge. For a graph with n character nodes and m edges, there are $n + m$ global connections linking each node and edge to the shared relay node. With the global connections, every two non-adjacent nodes are two-hop neighbors and receive non-local information with a two-step update.

In addition, we consider the transpose of the constructed graph[1]. It is another directed graph on the same set of nodes with all of the edges reversed compared to the orientation of the corresponding edges in $\mathcal{G}$. We denote the transpose graph as $\mathcal{G}^\top$. Similar to the bidirectional LSTM, we compose $\mathcal{G}$ and $\mathcal{G}^\top$ as a bidirectional graph and concatenate the node states of $\mathcal{G}$ and $\mathcal{G}^\top$ as final outputs.

Local Aggregation Given the node features $\mathbf{c}_i^t$

[1] https://en.wikipedia.org/wiki/Transpose_graph

and the incoming edge features $\mathbf{E}^t_{c_i} = \{\forall_k \mathbf{e}^t_{k,i}\}$, we use multi-head attention to aggregate $\mathbf{e}_{k,i}$ and the corresponding predecessor nodes $\mathbf{c}_k$ for each node $\mathbf{c}_i$, where intuition is that the incoming edges and predecessor nodes can effectively indicate potential word boundary information, as shown in Figure 3 (a). Formally, the node aggregation function can be formulated as follows:

$$e \rightarrow c : \hat{\mathbf{c}}^t_i = \text{MultiAtt}(\mathbf{c}^t_i, \{\forall_k [\mathbf{c}^t_k; \mathbf{e}^t_{k,i}]\}), \quad (2)$$

where t refers to the aggregation at the t-th step and $[\cdot;\cdot]$ represents concatenation operation.

For edge aggregation, all the forces or potential energies acting on the edges should be considered (Battaglia et al., 2018). To exploit the word orthographic information, lexicons used to construct edges should consider all the character composition, as shown in Figure 3 (b). Hence, different from the classic graph neural networks that use the features of terminal vertices to aggregate edges, we use the whole matching character subsequence $\mathbf{C}^t_{b,e} = \{\mathbf{c}^t_b, \ldots, \mathbf{c}^t_e\}$ for the edge aggregation function, as follows:

$$c \rightarrow e : \quad \hat{\mathbf{e}}^t_{b,e} = \text{MultiAtt}(\mathbf{e}^t_{b,e}, \mathbf{C}^t_{b,e}). \quad (3)$$

Given the character sequence embeddings $\mathbf{C} \in \mathbb{R}^{n \times d}$ and potential word embeddings $\mathbf{E} \in \mathbb{R}^{m \times d}$, we first fed $\mathbf{C}$ into an LSTM network to generate contextualized representations as the initial node states $\mathbf{C}^0$ (Zhang et al., 2018c), and we used the word embeddings as the initial edge states $\mathbf{E}^0$.

Global Aggregation The underlying structure of language is not strictly sequential (Shen et al., 2019). To capture long-range dependency and high-level features, as shown in Figure 3 (c), we utilized a global relay node to aggregate each character node and edge, as follows:

$$\begin{aligned} \mathbf{g}^t_c &= \text{MultiAtt}(\mathbf{g}^t, \mathbf{C}^t_{1,n}) \\ \mathbf{g}^t_e &= \text{MultiAtt}(\mathbf{g}^t, \{\forall \mathbf{e}^t \in \mathcal{E}\}) \\ c, e \rightarrow g : \quad \hat{\mathbf{g}}^t &= [\mathbf{g}^t_c; \mathbf{g}^t_e]. \end{aligned} \quad (4)$$

After multiple exchanges of information (§ 3.2), $\hat{\mathbf{g}}_t$ aggregates node vectors and edge vectors to summarize the global information, and $\hat{\mathbf{e}}^t_{b,e}$ captures the compositional character information to form the local composition. As a result, the proposed model, with a thorough knowledge of both local and non-local composition, would contribute character nodes to distinguish ambiguous words (Ma et al., 2014).

3.2 Recurrent-based Update Module

Node Update The effective use of sentence context to tackle the ambiguity among the potential words is still a key issue (Ma et al., 2014). For a general graph, it is common practice to apply recurrent-based modules to update hidden representations of nodes (Scarselli et al., 2009; Li et al., 2015). Hence, we fused the global feature $\hat{\mathbf{g}}$ into a character nodes update module, as follows:

$$\begin{aligned} \boldsymbol{\xi}^t_i &= [\mathbf{c}^{t-1}_{i-1}; \mathbf{c}^{t-1}_i], \quad \boldsymbol{\chi}^t_i = [\hat{\mathbf{c}}^{t-1}_i; \hat{\mathbf{g}}^{t-1}] \\ \hat{\boldsymbol{a}}^t_i &= \sigma(\mathbf{W}^a_i \boldsymbol{\xi}^t_i + \mathbf{V}^a_i \boldsymbol{\chi}^t_i + \mathbf{b}^a_i), \quad \boldsymbol{a} = \{\boldsymbol{i}, \boldsymbol{f}, \boldsymbol{l}\} \\ \boldsymbol{u}^t_i &= tanh(\mathbf{W}_{cu} \boldsymbol{\xi}^t_i + \mathbf{V}_{cu} \boldsymbol{\chi}^t_i + \mathbf{b}_{cu}) \\ \boldsymbol{i}^t_i, \boldsymbol{f}^t_i, \boldsymbol{l}^t_i &= softmax(\hat{\boldsymbol{i}}^t_i, \hat{\boldsymbol{f}}^t_i, \hat{\boldsymbol{l}}^t_i) \\ \mathbf{c}^t_i &= \boldsymbol{l}^t_i \odot \mathbf{c}^{t-1}_{i-1} + \boldsymbol{f}^t_i \odot \mathbf{c}^{t-1}_i + \boldsymbol{i}^t_i \odot \boldsymbol{u}^t_i, \end{aligned} \quad (5)$$

where $\mathbf{W}$, $\mathbf{V}$, and $\mathbf{b}$ are trainable parameters. $\boldsymbol{\xi}^t_i$ is the concatenation of adjacent vectors of a context window. The window size in our model is 2 and actually plays a role as a character bigram, which has been shown to be useful for representing characters in sequence labeling tasks (Chen et al., 2015a; Zhang and Yang, 2018). $\boldsymbol{\chi}^t_i$ is the concatenation of the global information vector $\hat{\mathbf{g}}^t$ and the $e \rightarrow c$ aggregation result $\hat{\mathbf{c}}^t_i$. The gates $\boldsymbol{i}^t_i$, $\boldsymbol{f}^t_i$ and $\boldsymbol{l}^t_i$ control information flow from global features to $\mathbf{c}^t_i$, which can make further readjustment of the weights of the lexicon attention ($e \rightarrow c$) to tackle the ambiguities at the subsequent aggregation step.

Edge Update To better leverage the interaction among characters, words, and whole sentences, we not only designed a recurrent module for nodes but also for edges and the global relay node (Battaglia et al., 2018). We update the edges as follows:

$$\begin{aligned} \boldsymbol{\chi}^t_{b,e} &= [\hat{\mathbf{e}}^{t-1}_{b,e}; \hat{\mathbf{g}}^{t-1}], \quad \boldsymbol{a} = \{\boldsymbol{i}, \boldsymbol{f}\} \\ \hat{\boldsymbol{a}}^t_{b,e} &= \sigma(\mathbf{W}^a_i \mathbf{e}^{t-1}_{b,e} + \mathbf{V}^a_i \boldsymbol{\chi}^t_{b,e} + \mathbf{b}^a_i) \\ \boldsymbol{u}^t_{b,e} &= tanh(\mathbf{W}_{eu} \mathbf{e}^{t-1}_{b,e} + \mathbf{V}_{eu} \boldsymbol{\chi}^t_{b,e} + \mathbf{b}_{eu}) \\ \boldsymbol{i}^t_{b,e}, \boldsymbol{f}^t_{b,e} &= softmax(\hat{\boldsymbol{i}}^t_{b,e}, \hat{\boldsymbol{f}}^t_{b,e}) \\ \mathbf{e}^t_{b,e} &= \boldsymbol{f}^t_{b,e} \odot \mathbf{e}^{t-1}_{b,e} + \boldsymbol{i}^t_{b,e} \odot \boldsymbol{u}^t_{b,e}, \end{aligned} \quad (6)$$

where $\boldsymbol{\chi}^t_{b,e}$ is the concatenation of $\hat{\mathbf{g}}^t$ and the $c \rightarrow e$ aggregation result $\hat{\mathbf{e}}^t_{b,e}$. Similar to the node update function, $\boldsymbol{i}^t_{b,e}$ and $\boldsymbol{f}^t_{b,e}$ are gates that control information flow from $\mathbf{e}^{t-1}_{b,e}$ and $\hat{\mathbf{g}}^t$ to $\mathbf{e}^t_{b,e}$.

Global Relay Node Update In terms of the global state $\mathbf{g}$, recent works (Zhang et al., 2018b; Guo

et al., 2019) have shown the effectiveness of sharing useful messages across contexts. Thus, we also designed an update function for $\mathbf{g}$, with the initialization $\mathbf{g}^0 = \text{average}(\mathbf{C}, \mathbf{E})$. More formally:

$$\begin{aligned}\hat{\boldsymbol{a}}^t &= \sigma(\mathbf{W}_i^a \mathbf{g}^{t-1} + \mathbf{V}_i^a \hat{\mathbf{g}}^{t-1} + \mathbf{b}_i^a),\ \boldsymbol{a} = \{\boldsymbol{i}, \boldsymbol{f}\} \\ \boldsymbol{u}^t &= tanh(\mathbf{W}_{gu} \mathbf{g}^{t-1} + \mathbf{V}_{gu} \hat{\mathbf{g}}^{t-1} + \mathbf{b}_{gu}) \\ \boldsymbol{i}^t, \boldsymbol{f}^t &= softmax(\hat{\boldsymbol{i}}^t, \hat{\boldsymbol{f}}^t) \\ \mathbf{g}^t &= \boldsymbol{f}^t \odot \mathbf{g}^{t-1} + \boldsymbol{i}^t \odot \boldsymbol{u}^t. \end{aligned} \tag{7}$$

3.3 Decoding and Training

A standard conditional random field (CRF) is used in the graph message passing process. Given the sequence of final node states $\mathbf{c}_1^T, \mathbf{c}_2^T, \ldots, \mathbf{c}_n^T$, the probability of a label sequence $\hat{y} = \hat{l}_1, \hat{l}_2, \ldots, \hat{l}_n$ can be defined as follows:

$$p(\hat{y}|s) = \frac{exp(\sum_{i=1}^{n} \phi(\hat{l}_{i-1}, \hat{l}_i, \mathbf{c}_i^T))}{\sum_{y' \in \mathrm{Y}(s)} exp(\sum_{i=1}^{n} \phi(l'_{i-1}, l'_i, \mathbf{c}_i^T))}, \tag{8}$$

where, $\mathrm{Y}(s)$ is the set of all arbitrary label sequences. $\phi(l_{i-1}, l_i, \mathbf{c}_i^T) = \mathbf{W}_{(l_{i-1}, l_i)} \mathbf{c}_i^T + \mathbf{b}_{(l_{i-1}, l_i)}$, where $\mathbf{W}_{(l_{i-1}, l_i)}$ and $\mathbf{b}_{(l_{i-1}, l_i)}$ are the weight and bias parameters specific to the labels l_{i-1} and l_i.

For training, we minimize the sentence-level negative log-likelihood loss as follows:

$$L = -\sum_{i=1}^{N} log(p(y_i|s_i)). \tag{9}$$

For testing and decoding, we maximized the likelihood to find the optimal sequence y^*:

$$y^* = \underset{y \in \mathrm{Y}(s)}{\text{argmax}}\, p(y|s). \tag{10}$$

We used the Viterbi algorithm to calculate the above equations, which can reduce the computational complexity efficiently.

4 Experimental Setup

In this section, we describe the datasets across different domains and the baseline methods applied for comparison. We also detail the hyper-parameter configuration of the proposed model. Our codes and datasets can be found at https://github.com/RowitZou/LGN.

Dataset	Type	Train	Dev.	Test
OntoNotes	Sent.	15.7k	4.3k	4.3k
	Char.	491.9k	200.5k	208.1k
MSRA	Sent.	46.4k	-	4.4k
	Char.	2169.9k	-	172.6k
Weibo	Sent.	1.4k	0.27k	0.27k
	Char.	73.8k	14.5k	14.8k
Resume	Sent.	3.8k	0.46k	0.48k
	Char.	124.1k	13.9k	15.1k

Table 1: Statistics of datasets.

4.1 Data

We conducted experiments on four Chinese NER datasets. (1) **OntoNotes 4.0** (Weischedel et al., 2011): OntoNotes is a manually annotated multilingual corpus in the news domain that contains various text annotations, including Chinese named entity labels. Gold-standard segmentation is available. We only use Chinese documents (about 16k sentences) and process the data in the same way as Che et al. (2013). (2) **MSRA** (Levow, 2006): MSRA is also a dataset in the news domain and contains three types of named entities: LOC, PER, and ORG. Chinese word segmentation is available in the training set but not in the test set. (3) **Weibo NER** (Peng and Dredze, 2015): It consists of annotated NER messages drawn from the social media Sina Weibo[2]. The corpus contains PER, ORG, GPE, and LOC for both named entity and nominal mention. (4) **Resume NER** (Zhang and Yang, 2018): It is composed of resumes collected from Sina Finance[3] and is annotated with 8 types of named entities. Both Weibo and Resume datasets do not contain the gold-standard Chinese segmentation. Statistics of the above datasets are detailed in Table 1.

4.2 Lexicon

We used the lexicon over automatically segmented Chinese Giga-Word [4], obtaining 704.4k words in the final lexicon. The embeddings of lexicon words were pre-trained using word2vec (Mikolov et al., 2013) and fine-tuned during training. According to the lexicon statistics, the number of single-character, two-character and three-character words are 5.7k, 291.5k, 278.1k, respectively. It covers 31.2% of the named entities in the four data sets, which means most of the lexicon words are not named entities. For a

[2]https://www.weibo.com
[3]https://finance.sina.com.cn/stock/
[4]https://catalog.ldc.upenn.edu/LDC2011T13

fair comparison, we used such a general lexicon instead of a professional named entity lexicon in our experiments and we still obtained competitive results. Empirically, a high-quality lexicon could lead to further performance improvements.

Character embeddings are pre-trained on Chinese Giga-Word using word2vec and fine-tuned at model training. Both the pre-trained character and lexicon word embeddings are released by Zhang and Yang (2018)[5].

4.3 Comparison Methods

We applied the character-level and word-level methods as baselines for comparison, which incorporate the bichar, softword, and lexicon features. We also compared several state-of-the-art methods on the four datasets to verify the effectiveness of our method. We used the BMES tagging scheme for both character-level and word-level NER tagging.

Character-level methods: These methods are based on character sequences. We applied the bi-directional LSTM (Hochreiter and Schmidhuber, 1997) and CNN (Kim, 2014) as classic baseline methods.

Character-level methods + bichar + softword: Character bigrams are useful for capturing adjacent features and representing characters. We concatenated bigram embeddings with character embeddings to better leverage the bigram information. In addition, we added the segmentation information by incorporating segmentation label embeddings into the character representation. The BMES scheme is used for representing the word segmentation (Xue and Shen, 2003).

Word-level methods: For the datasets with gold segmentation, we directly employed word-level NER methods to evaluate the performance, which are denoted as **Gold seg**. Otherwise, we first used open source segmentation toolkit[6] to automatically segment the datasets. Then word-level NER methods are applied, which are denoted as **Auto seg**. The bi-directional LSTM and CNN are also applied as baselines.

Word-level methods + char + bichar: For characters in the subsequence $w_{b,e}$, we first used a bi-directional LSTM to learn their hidden states and bigram states. We then augmented the word-level methods with the character-level features.

Table 2: Main results on OntoNotes.

Lattice LSTM: Lattice LSTM (Zhang and Yang, 2018) incorporates word information into character-level recurrent units, which can avoid segmentation errors. This method achieved state-of-the-art performance on the four datasets.

4.4 Hyper-parameter Settings

We used the Adam (Kingma and Ba, 2014) as the optimizer, with a learning rate of 2e-5 for large datasets like Ontonotes and MSRA, while a rate of 2e-4 for small datasets Weibo and Resume. A densely connected structure (Huang et al., 2017) was applied, which composites all hidden states from previous update steps as final inputs for aggregation modules at step t. To further reduce overfitting, we employed the Dropout (Srivastava et al., 2014) with a rate of 0.5 for embeddings and a rate of 0.2 for aggregation module outputs. The embedding size and state size were both set to 50. The head number of multi-head attention was 10. The head dimension was set to 10 for small datasets like Weibo and Resume, while the head dimension was 20 for Ontonotes and MSRA. Step number T was selected among $\{1, 2, 3, 4, 5, 6\}$, which is detailed analyzed in § 5.2. The standard Precision (P), Recall (R), and F1-score (F1) were used as evaluation metrics.

5 Results and Discussion

In this section, we demonstrate the main results of LGN for the Chinese NER task across different domains. The model achieving best results on the development set was chosen for the final evaluation on the test set. We also probe the

effectiveness and interpretability of LGN by explanatory experiments.

5.1 Main Results

OntoNotes Table 2[7] shows the results of word-level and character-level methods on OntoNotes with various settings. In the gold or automatic segmentation settings, the char and bichar features boost the performance of word-level methods. In particular, with the gold-standard segmentation, these methods are able to achieve competitive state-of-the-art results on the dataset (Che et al., 2013; Wang et al., 2013). However, the gold-standard segmentation is not always available. On the other hand, the automatic segmentation may induce word segmentation errors and result in a loss of performance for the downstream NER task. A feasible solution is applying character-level methods to avoid the need for word segmentation. Our proposed LGN is a character-level model based on graphic structure. It outperforms lattice LSTM by 1.01% in F1 score and leads to a 3.00% increment of F1 score over the LSTM with bichar and softword features. The LGN also significantly outperforms the word-level models with automatic segmentation.

MSRA/Weibo/Resume Results on the MSRA, Weibo, and Resume datasets are shown in Table 3, 4, and 5, respectively. Gold-standard segmentation is not available for the Weibo and Resume datasets and the test set of MSRA. The best classic methods leverage rich handcrafted features (Chen et al., 2006; Zhang et al., 2006; Zhou et al., 2013), embedding features (Lu et al., 2016; Peng and Dredze, 2015), radical features (Dong et al., 2016), cross-domain, and semi-supervised data (He and Sun, 2017) for Chinese NER. Compared with the existing methods and the word-level and character-level methods, our LGN model gives the best results by a large margin. Moreover, different from the lattice LSTM, which also leverages lexicon features, our LGN model integrates lexicon information into the graph neural network in a more effective fashion. As a result, it outperforms the lattice LSTM on all three datasets.

5.2 Steps of Message Passing

To investigate the influence of step number T during the update process, we analyzed the performance of LGN under different step numbers. Figure 4 illustrates the variation of F1 score on the development sets[8] as the step number increases. We used **D-F1** to represent the F1 scores at different steps minus the best results.

The results indicate that the number of update steps is crucial to the performance of LGN, which peaks when $T \geq 3$ on all four datasets. The F1 score decreases 1.20% on average against the best results when the step number is less than 3. In particular, the F1 score of the OntoNotes and Weibo datasets even suffered a serious reduction around 1.5% and 1.8%, respectively. After several rounds of updates, the model gives steady and competitive results and reveals that LGN benefits from the update process. Empirically, at each

[7] In Table 2, 3, 4 and 5, the models with * use external labeled data for semi-supervised learning. Those with † also use discrete features.

[8] Since the MSRA dataset does not have the development set, we used the test set instead.

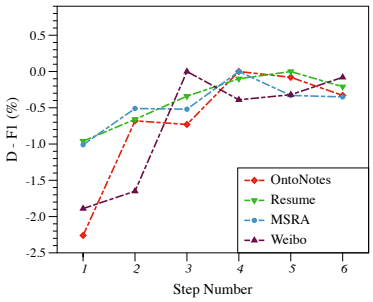

Figure 4: F1 variation under different update steps on the development sets. D-F1 represents the F1 scores at different steps minus the best results.

Models	Onto-Notes	MSRA	Weibo	Resume
LGN	71.96	93.46	62.42	94.43
-global	71.26	92.99	62.30	94.31

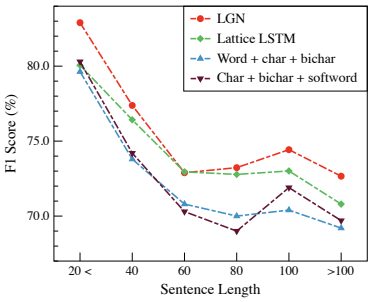

Figure 5: F1 score against sentence length on the OntoNotes dateset.

update step, graph nodes aggregate information from their neighbors and incrementally gain more information from further reaches of the graph as the process iterates (Hamilton et al., 2017). In the LGN model, more valuable information can be captured through the recursive aggregation.

5.3 Ablation Experiments

To study the contribution of each component in LGN, we conducted ablation experiments on the four datasets and display the results in Table 6. The results show that the model's performance is degraded if the global relay node is removed, indicating that global connections are useful in the graph structure. We also find that lexicons play an important role in character-level NER. In particular, the performance of the OntoNotes, MSRA and Weibo datasets are seriously hurt by over 3.0% without lexicons. Moreover, missing both edges and the global node will cause a further performance loss.

To better illustrate the advantage of our model, we remove the CRF decoding layer and simplify the structure to a non-bidirectional version on both LGN and the lattice LSTM model. The results show that, with a single direction structure, the LGN achieves a higher F1 score by 0.77% on average than the lattice LSTM. In addition, the two models have an obvious performance gap when they get rid of the CRF layer. The F1 score of LGN decreases by 3.59% on average on the four datasets without CRF. In contrast, the lattice LSTM decreases by 6.24%. It manifests the LGN has stronger ability to model sentences.

5.4 Performance Against Sentence Length

Figure 5 shows the performance of LGN and several baseline models on the OntoNotes dataset. We split the dataset into six parts according to the sentence length. The lattice is a strong baseline that outperforms the word+char+bichar and char+bichar+softword models over different sentence lengths. However, the lattice accuracy decreases significantly as the sentence length increases. In contrast, the LGN not only gives higher results over short sentences, but also shows its effectiveness and robustness when the sentence length is more than 80 characters. It gives a higher F1 score in most cases compared to the baselines, which indicates that global sentence semantics and long-range dependency can be better captured under the graph structure.

5.5 Case Study

Table 7 illustrates an example that probes the ability of LGN to tackle the word ambiguity problems. The lattice LSTM ignores the sentence context and wrongly identifies "印 度(India)". Removing the global relay node, LGN also makes the same mistake, which indicates that global connections are indispensable and can capture high-level information to help LGN better understand the sentence context. In contrast, with the global relay node, the LGN can correctly identify the entity boundary, even though the

Sentence	印度河流经巴基斯坦 The Indus River flows through Pakistan.
Gold seg	印度河 流经 巴基斯坦 The Indus River, flow through, Pakistan
Lexicon words	印度 河流 印度河 流经 巴基斯坦 India, river, The Indus River, flow through, Pakistan
Lattice LSTM	B E (GPE) O O O B M M E (GPE) 印度 (GPE) 河流经 巴基斯坦 (GPE) India (GPE) ... Pakistan (GPE).
LGN -global	B E (GPE) O O O B M M E (GPE) 印度 (GPE) 河流经 巴基斯坦 (GPE) India (GPE) ... Pakistan (GPE).
LGN (one step)	B M E (GPE) O O B M M E (GPE) 印度河 (GPE) 流经 巴基斯坦 (GPE) The Indus River (GPE) flows through Pakistan (GPE).
LGN	B M E (LOC) O O B M M E (GPE) 印度河 (LOC) 流经 巴基斯坦 (GPE) The Indus River (LOC) flows through Pakistan (GPE).

Table 7: An example with overlapping ambiguity. Contents with red and blue colors represent incorrect and correct entities, respectively.

graph composition states are updated for only one step. However, it gives an incorrect class of the entity "印度河(The Indus River)", which is a location entity but not a GPE (Geo-Political Entity). Because of the multi-step graph message passing process, the LGN is able to fuse the context information and finally detects the correct location entity in success.

6 Conclusion

In this work, we investigated a GNN-based approach to alleviate the word ambiguity in Chinese NER. Lexicons are used to construct the graph and provide word-level features. The LGN enables interactions among different sentence compositions and can capture non-sequential dependencies between characters based on the global sentence semantics. As a result, it shows improved performance significantly on multiple datasets in different domains. The explanatory experiments also illustrate the effectiveness and interpretability of our proposed model.

Abstract

Spoken Language Understanding (SLU) mainly involves two tasks, intent detection and slot filling, which are generally modeled jointly in existing works. However, most existing models fail to fully utilize co-occurrence relations between slots and intents, which restricts their potential performance. To address this issue, in this paper we propose a novel Collaborative Memory Network (CM-Net) based on the well-designed block, named CM-block. The CM-block firstly captures slot-specific and intent-specific features from memories in a collaborative manner, and then uses these enriched features to enhance local context representations, based on which the sequential information flow leads to more specific (slot and intent) global utterance representations. Through stacking multiple CM-blocks, our CM-Net is able to alternately perform information exchange among specific memories, local contexts and the global utterance, and thus incrementally enriches each other. We evaluate the CM-Net on two standard benchmarks (ATIS and SNIPS) and a self-collected corpus (CAIS). Experimental results show that the CM-Net achieves the state-of-the-art results on the ATIS and SNIPS in most of criteria, and significantly outperforms the baseline models on the CAIS. Additionally, we make the CAIS dataset publicly available for the research community [1].

1 Introduction

Spoken Language Understanding (SLU) is a core component in dialogue systems. It typically aims to identify the intent and semantic constituents for a given utterance, which are referred as intent detection and slot filling, respectively. Past years have witnessed rapid developments in diverse deep learning models (Haffner et al., 2003; Sarikaya et al., 2011) for SLU. To take full advantage of supervised signals of slots and intents, and share knowledge between them, most of existing works apply joint models that mainly based on CNNs (Xu and Sarikaya, 2013; Gupta et al., 2019), RNNs (Guo et al., 2014a; Liu and Lane, 2016), and asynchronous bi-model (Wang et al., 2018). Generally, these joint models encode words convolutionally or sequentially, and then aggregate hidden states into a utterance-level representation for the intent prediction, without interactions between representations of slots and intents.

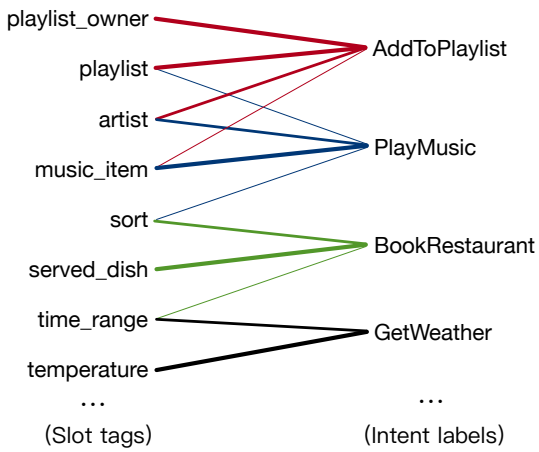

Figure 1: Statistical association of slot tags (on the left) and intent labels (on the right) in the SNIPS, where colors indicate different intents and thicknesses of lines indicate proportions.

Intuitively, slots and intents from similar fields tend to occur simultaneously, which can be observed from Figure 1 and Table 1. Therefore, it is beneficial to generate the representations of slots and intents with the guidance from each other. Some works explore enhancing the slot filling task

unidirectionally with the guidance from intent representations via gating mechanisms (Goo et al., 2018; Li et al., 2018), while the predictions of intents lack the guidance from slots. Moreover, the capsule network with dynamic routing algorithms (Zhang et al., 2018a) is proposed to perform interactions in both directions. However, there are still two limitations in this model. The one is that the information flows from words to slots, slots to intents and intents to words in a pipeline manner, which is to some extent limited in capturing complicated correlations among words, slots and intents. The other is that the local context information which has been shown highly useful for the slot filling (Mesnil et al., 2014), is not explicitly modeled.

In this paper, we try to address these issues, and thus propose a novel **C**ollaborative **M**emory **N**etwork, named CM-Net. The main idea is to directly capture semantic relationships among words, slots and intents, which is conducted simultaneously at each word position in a collaborative manner. Specifically, we alternately perform information exchange among the task-specific features referred from memories, local context representations and global sequential information via the well-designed block, named CM-block, which consists of three computational components:

- **Deliberate Attention**: Obtaining slot-specific and intent-specific representations from memories in a collaborative manner.
- **Local Calculation**: Updating local context representations with the guidances of the referred slot and intent representations in the previous *Deliberate Attention*.
- **Global Recurrence**: Generating specific (slot and intent) global sequential representations based on local context representations from the previous *Local Calculation*.

Above components in each CM-block are conducted consecutively, which are responsible for encoding information from different perspectives. Finally, multiple CM-blocks are stacked together, and construct our CM-Net.

We firstly conduct experiments on two popular benchmarks, SNIPS (Coucke et al., 2018) and ATIS (Hemphill et al., 1990; Tur et al., 2010). Experimental results show that the CM-Net achieves the state-of-the-art results in 3 of 4 criteria (*e.g.,* intent detection accuracy on ATIS) on both benchmarks. Additionally, trials on our self-collected dataset, named CAIS, demonstrate the effectiveness and generalizability of the CM-Net.

Our main contributions are as follows:

- We propose a novel CM-Net for SLU, which explicitly captures semantic correlations among words, slots and intents in a collaborative manner, and incrementally enriches the specific features, local context representations and global sequential representations through stacked CM-blocks.
- Our CM-Net achieves the state-of-the-art results on two major SLU benchmarks (ATIS and SNIPS) in most of criteria.
- We contribute a new corpus CAIS with manual annotations of slot tags and intent labels to the research community.

2 Background

In principle, the slot filling is treated as a sequence labeling task, and the intent detection is a classification problem. Formally, given an utterance $X = \{x_1, x_2, \cdots, x_N\}$ with N words and its corresponding slot tags $Y^{slot} = \{y_1, y_2, \cdots, y_N\}$, the slot filling task aims to learn a parameterized mapping function $f_\theta : X \rightarrow Y$ from input words to slot tags. For the intent detection, it is designed to predict the intent label $\hat{y}^{int}$ for the entire utterance X from the predefined label set S^{int}.

Typically, the input utterance is firstly encoded into a sequence of distributed representations $\mathbf{X} =$

$\{\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_N\}$ by character-aware and pre-trained word embeddings. Afterwards, the following bidirectional RNNs are applied to encode the embeddings $\mathbf{X}$ into context-sensitive representations $\mathbf{H} = \{\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_N\}$. An external CRF (Lafferty et al., 2001) layer is widely utilized to calculate conditional probabilities of slot tags:

$$p(\mathbf{y}^{slot}|\mathbf{H}) = \frac{e^{F(\mathbf{H}, \mathbf{y}^{slot})}}{\sum_{\widetilde{\mathbf{y}}^{slot} \in \mathbf{Y}_x} e^{F(\mathbf{H}, \widetilde{\mathbf{y}}^{slot})}} \quad (1)$$

Here $\mathbf{Y}_x$ is the set of all possible sequences of tags, and $F(\cdot)$ is the score function calculated by:

$$F(\mathbf{h}, \mathbf{y}) = \sum_{i=1}^{N} \mathbf{A}_{y_i, y_{i+1}} + \sum_{i=1}^{N} \mathbf{P}_{i, y_i} \quad (2)$$

where $\mathbf{A}$ is the transition matrix that $\mathbf{A}_{i,j}$ indicates the score of a transition from i to j, and $\mathbf{P}$ is the score matrix output by RNNs. $P_{i,j}$ indicates the score of the j^{th} tag of the i^{th} word in a sentence (Lample et al., 2016).

When testing, the Viterbi algorithm (Forney, 1973) is used to search the sequence of slot tags with maximum score:

$$\hat{\mathbf{y}}^{slot} = \arg\max_{\widetilde{\mathbf{y}}^{slot} \in \mathbf{Y}_x} F(\mathbf{H}, \widetilde{\mathbf{y}}^{slot}) \quad (3)$$

As to the prediction of intent, the word-level hidden states $\mathbf{H}$ are firstly summarized into a utterance-level representation $\mathbf{v}^{int}$ via mean pooling (or max pooling or self-attention, *etc.*):

$$\mathbf{v}^{int} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{h}_t \quad (4)$$

The most probable intent label $\hat{y}^{int}$ is predicted by softmax normalization over the intent label set:

$$\begin{aligned} \hat{y}^{int} &= \arg\max_{\widetilde{y} \in S^{int}} P(\widetilde{y}|\mathbf{v}^{int}) \\ P(\widetilde{y} = j|\mathbf{v}^{int}) &= softmax(\mathbf{v}^{int})[j] \end{aligned} \quad (5)$$

Generally, both tasks are trained jointly to minimize the sum of cross entropy from each individual task. Formally, the loss function of the join model is computed as follows:

$$\begin{aligned} L &= (1-\lambda) \cdot L^{slot} + \lambda \cdot L^{int} \\ L^{int} &= -\sum_{i=1}^{|S^{int}|} \hat{y}_i^{int} log(y_i^{int}) \\ L^{slot} &= -\sum_{j=1}^{N} \sum_{i=1}^{|S^{slot}|} \hat{y}_{i,j}^{slot} log(y_{i,j}^{slot}) \end{aligned} \quad (6)$$

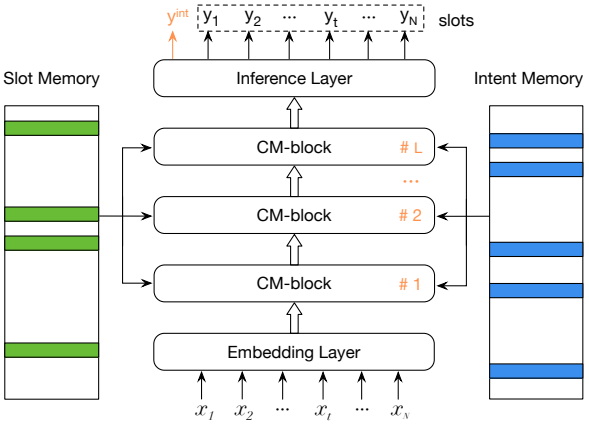

Figure 2: Overview of our proposed CM-Net. The input utterance is firstly encoded with the Embedding Layer (bottom), and then is transformed by multiple CM-blocks with the assistance of both slot and intent memories (on both sides). Finally we make predictions of slots and the intent in the Inference Layer (top).

where y_i^{int} and $y_{i,j}^{slot}$ are golden labels, and λ is hyperparameter, and $|S^{int}|$ is the size of intent label set, and similarly for $|S^{slot}|$.

3 CM-Net

3.1 Overview

In this section, we start with a brief overview of our CM-Net and then proceed to introduce each module. As shown in Figure 2, the input utterance is firstly encoded with the Embedding Layer, and then is transformed by multiple CM-blocks with the assistance of slot and intent memories, and finally make predictions in the Inference Layer.

3.2 Embedding Layers

Pre-trained Word Embedding The pre-trained word embeddings has been indicated as a de-facto standard of neural network architectures for various NLP tasks. We adapt the cased, 300d Glove[2] (Pennington et al., 2014) to initialize word embeddings, and keep them frozen.

Character-aware Word Embedding It has been demonstrated that character level information (*e.g.* capitalization and prefix) (Collobert et al., 2011) is crucial for sequence labeling. We use one layer of CNN followed by max pooling to generate character-aware word embeddings.

3.3 CM-block

The CM-block is the core module of our CM-Net, which is designed with three computational com-

[2]https://nlp.stanford.edu/projects/glove/

ponents: *Deliberate Attention*, *Local Calculation* and *Global Recurrence* respectively.

Deliberate Attention

To fully model semantic relations between slots and intents, we build the slot memory $\mathbf{M^{slot}}$ and intent memory $\mathbf{M^{int}}$, and further devise a collaborative retrieval approach. For the slot memory, it keeps $|S^{slot}|$ slot cells which are randomly initialized and updated as model parameters. Similarly for the intent memory. At each word position, we take the hidden state $\mathbf{h}_t$ as query, and obtain slot feature $\mathbf{h}_t^{slot}$ and intent feature $\mathbf{h}_t^{int}$ from both memories by the deliberate attention mechanism, which will be illustrated in the following.

Specifically for the slot feature $\mathbf{h}_t^{slot}$, we firstly get a rough intent representation $\widetilde{\mathbf{h}}_t^{int}$ by the word-aware attention with hidden state $\mathbf{h}_t$ over the intent memory $\mathbf{M^{int}}$, and then obtain the final slot feature $\mathbf{h}_t^{slot}$ by the intent-aware attention over the slot memory $\mathbf{M^{slot}}$ with the intent-enhanced representation $[\mathbf{h}_t; \widetilde{\mathbf{h}}_t^{int}]$. Formally, the above-mentioned procedures are computed as follows:

$$\begin{aligned} \widetilde{\mathbf{h}}_t^{int} &= ATT(\mathbf{h_t}, \mathbf{M^{int}}) \\ \mathbf{h}_t^{slot} &= ATT([\mathbf{h_t}; \widetilde{\mathbf{h}}_t^{int}], \mathbf{M^{slot}}) \end{aligned} \tag{7}$$

where $ATT(\cdot)$ is the query function calculated by the weighted sum of all cells $\mathbf{m}_i^x$ in memory $\mathbf{M}^x$ $(x \in \{slot, int\})$:

$$\begin{aligned} ATT(\mathbf{h_t}, \mathbf{M}^x) &= \sum_i \alpha_i \mathbf{m_i^x} \\ \alpha_i &= \frac{\exp(\mathbf{u}^\top s_i)}{\sum_j \exp(\mathbf{u}^\top s_j)} \\ s_i &= \mathbf{h}_t^\top \mathbf{W} \mathbf{m_i^x} \end{aligned} \tag{8}$$

Here $\mathbf{u}$ and $\mathbf{W}$ are model parameters. We name the above calculations of two-round attentions (Equation 7) as "deliberate attention".

The intent representation $\mathbf{h}_t^{int}$ is computed by the deliberate attention as well:

$$\begin{aligned} \widetilde{\mathbf{h}}_t^{slot} &= ATT(\mathbf{h_t}, \mathbf{M^{slot}}) \\ \mathbf{h}_t^{int} &= ATT([\mathbf{h_t}; \widetilde{\mathbf{h}}_t^{slot}], \mathbf{M^{int}}) \end{aligned} \tag{9}$$

These two deliberate attentions are conducted simultaneously at each word position in such collaborative manner, which guarantees adequate knowledge diffusions between slots and intents. The retrieved slot features $\mathbf{H}_t^{slot}$ and intent features $\mathbf{H}_t^{int}$ are utilized to provide guidances for the next local calculation layer.

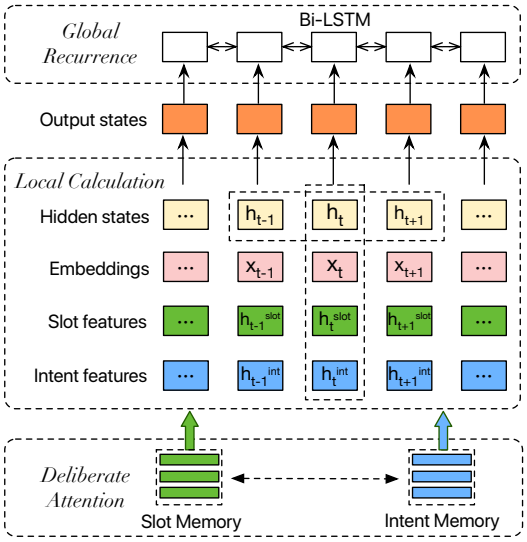

Figure 3: The internal structure of our CM-Block, which is composed of *deliberate attention*, *local calculation* and *global recurrent* respectively.

Local Calculation

Local context information is highly useful for sequence modeling (Kurata et al., 2016; Wang et al., 2016b). Zhang et al. (2018b) propose the S-LSTM to encode both local and sentence-level information simultaneously, and it has been shown more powerful for text representation when compared with the conventional BiLSTMs. We extend the S-LSTM with slot-specific features $\mathbf{H}_t^{slot}$ and intent-specific features $\mathbf{H}_t^{slot}$ retrieved from memories.

Specifically, at each input position t, we take the local window context ξ_t, word embedding $\mathbf{x}_t$, slot feature $\mathbf{h}_t^{slot}$ and intent feature $\mathbf{h}_t^{int}$ as inputs to conduct combinatorial calculation simultaneously. Formally, in the l^{th} layer, the hidden state $\mathbf{h_t}$ is updated as follows:

$$\begin{aligned} \xi_t^{l-1} &= [\mathbf{h}_{t-1}^{l-1}, \mathbf{h}_t^{l-1}, \mathbf{h}_{t+1}^{l-1}] \\ \hat{\mathbf{i}}_t^l &= \sigma(\mathbf{W}_1^i \xi_t^{l-1} + \mathbf{W}_2^i \mathbf{x}_t + \mathbf{W}_3^i \mathbf{h}_t^{slot} + \mathbf{W}_4^i \mathbf{h}_t^{int}) \\ \hat{\mathbf{o}}_t^l &= \sigma(\mathbf{W}_1^o \xi_t^{l-1} + \mathbf{W}_2^o \mathbf{x}_t + \mathbf{W}_3^o \mathbf{h}_t^{slot} + \mathbf{W}_4^o \mathbf{h}_t^{int}) \\ \hat{\mathbf{f}}_t^l &= \sigma(\mathbf{W}_1^f \xi_t^{l-1} + \mathbf{W}_2^f \mathbf{x}_t + \mathbf{W}_3^f \mathbf{h}_t^{slot} + \mathbf{W}_4^f \mathbf{h}_t^{int}) \\ \hat{\mathbf{l}}_t^l &= \sigma(\mathbf{W}_1^l \xi_t^{l-1} + \mathbf{W}_2^l \mathbf{x}_t + \mathbf{W}_3^l \mathbf{h}_t^{slot} + \mathbf{W}_4^l \mathbf{h}_t^{int}) \\ \hat{\mathbf{r}}_t^l &= \sigma(\mathbf{W}_1^r \xi_t^{l-1} + \mathbf{W}_2^r \mathbf{x}_t + \mathbf{W}_3^r \mathbf{h}_t^{slot} + \mathbf{W}_4^r \mathbf{h}_t^{int}) \\ \mathbf{u}_t^l &= \tanh(\mathbf{W}_1^u \xi_t^{l-1} + \mathbf{W}_2^u \mathbf{x}_t + \mathbf{W}_3^u \mathbf{h}_t^{slot} \\ &\qquad + \mathbf{W}_4^u \mathbf{h}_t^{int}) \\ \mathbf{i}_t^l, \mathbf{f}_t^l, \mathbf{l}_t^l, \mathbf{r}_t^l &= softmax(\hat{\mathbf{i}}_t^l, \hat{\mathbf{f}}_t^l, \hat{\mathbf{l}}_t^l, \hat{\mathbf{r}}_t^l) \\ \mathbf{c}_t^l &= \mathbf{f}_t^l \odot \mathbf{c}_t^{l-1} + \mathbf{l}_t^l \odot \mathbf{c}_{t-1}^{l-1} + \mathbf{r}_t^l \odot \mathbf{c}_{t+1}^{l-1} \\ &\qquad + \mathbf{i}_t^l \odot \mathbf{u}_t^{l-1} \\ \mathbf{h}_t^l &= \mathbf{o}_t^l \odot \tanh \mathbf{c}_t^l \end{aligned} \tag{10}$$

where ξ_t^l is the concatenation of hidden states in a local window, and $\mathbf{i}_t^l$, $\mathbf{f}_t^l$, $\mathbf{o}_t^l$, $\mathbf{l}_t^l$ and $\mathbf{r}_t^l$ are gates to control information flows, and $\mathbf{W}_n^x$ $(x \in \{i, o, f, l, r, u\}, n \in \{1, 2, 3, 4\})$ are model parameters. More details about the state transition can be referred in (Zhang et al., 2018b). In the first CM-block, the hidden state $\mathbf{h}_t$ is initialized with the corresponding word embedding. In other CM-blocks, the $\mathbf{h}_t$ is inherited from the output of the adjacent lower CM-block.

At each word position of above procedures, the hidden state is updated with abundant information from different perspectives, namely word embeddings, local contexts, slots and intents representations. The local calculation layer in each CM-block has been shown highly useful for both tasks, and especially for the slot filling task, which will be validated in our experiments in Section 5.2.

Global Recurrence

Bi-directional RNNs, especially the BiLSTMs (Hochreiter and Schmidhuber, 1997) are regarded to encode both past and future information of a sentence, which have become a dominant method in various sequence modeling tasks (Hammerton, 2003; Sundermeyer et al., 2012). The inherent nature of BiLSTMs is able to supplement global sequential information, which is insufficiently modeled in the previous local calculation layer. Thus we apply an additional BiLSTMs layer upon the local calculation layer in each CM-block. By taking the slot- and intent-specific local context representations as inputs, we can obtain more specific global sequential representations. Formally, it takes the hidden state $\mathbf{h}_t^{l-1}$ inherited from the local calculation layer as input, and conduct recurrent steps as follows:

$$\begin{aligned} \mathbf{h}_t^l &= [\overrightarrow{\mathbf{h}_t^l}; \overleftarrow{\mathbf{h}_t^l}] \\ \overrightarrow{\mathbf{h}_t^l} &= \overrightarrow{\mathbf{LSTM}}(\mathbf{h}_t^{l-1}, \overrightarrow{\mathbf{h}}_{t-1}^l; \overrightarrow{\theta}) \\ \overleftarrow{\mathbf{h}_t^l} &= \overleftarrow{\mathbf{LSTM}}(\mathbf{h}_t^{l-1}, \overleftarrow{\mathbf{h}}_{t+1}^l; \overleftarrow{\theta}) \end{aligned} \tag{11}$$

The output "states" of the BiLSTMs are taken as "states" input of the local calculation in next CM-block. The global sequential information encoded by the BiLSTMs is shown necessary and effective for both tasks in our experiments in Section 5.2.

3.4 Inference Layer

After multiple rounds of interactions among local context representations, global sequential information, slot and intent features, we conduct predictions upon the final CM-block. For the predictions of slots, we take the hidden states $\mathbf{H}$ along with the retrieved slot $\mathbf{H}^{slot}$ representations (both are from the final CM-block) as input features, and then conduct predictions of slots similarly with the Equation (3) in Section 2:

$$\hat{\mathbf{y}}^{slot} = \underset{\widetilde{\mathbf{y}}^{slot} \in \mathbf{Y}_x}{\arg\max} F([\mathbf{H}; \mathbf{H}^{slot}], \widetilde{\mathbf{y}}^{slot}) \tag{12}$$

For the prediction of intent label, we firstly aggregate the hidden state $\mathbf{h}_t$ and the retrieved intent representation $\mathbf{h}_t^{int}$ at each word position (from the final CM-block as well) via mean pooling:

$$\mathbf{v}^{int} = \frac{1}{N} \sum_t^N [\mathbf{h_t}; \mathbf{h}_t^{int}] \tag{13}$$

and then take the summarized vector $\mathbf{v}^{int}$ as input feature to conduct prediction of intent consistently with the Equation (5) in Section 2.

4.1 Datasets and Metrics

We evaluate our proposed CM-Net on three real-word datasets, and statistics are listed in Table 2.

ATIS The Airline Travel Information Systems (ATIS) corpus (Hemphill et al., 1990) is the most widely used benchmark for the SLU research. Please note that, there are extra named entity features in the ATIS, which almost determine slot tags. These hand-crafted features are not generally available in open domains (Zhang and Wang, 2016; Guo et al., 2014b), therefore we train our model purely on the training set without additional hand-crafted features.

SNIPS SNIPS Natural Language Understanding benchmark [3] (Coucke et al., 2018) is collected in a crowsourced fashion by Snips. The intents of this

Table 3: Results on test sets of the SNIPS and ATIS, where our CM-Net achieves state-of-the-art performances in most cases. "*" indicates that results are retrieved from Slot-Gated (Goo et al., 2018), and "†" indicates our implementation.

dataset are more balanced when compared with the ATIS. We split another 700 utterances for validation set following previous works (Goo et al., 2018; Zhang et al., 2018a).

CAIS We collect utterances from the **C**hinese **A**rtificial **I**ntelligence **S**peakers (CAIS), and annotate them with slot tags and intent labels. The training, validation and test sets are split by the distribution of intents, where detailed statistics are provided in the supplementary material. Since the utterances are collected from speaker systems in the real world, intent labels are partial to the *PlayMusic* option. We adopt the BIOES tagging scheme for slots instead of the BIO2 used in the ATIS, since previous studies have highlighted meaningful improvements with this scheme (Ratinov and Roth, 2009) in the sequence labeling field.

Metrics Slot filling is typically treated as a sequence labeling problem, and thus we take the conlleval [4] as the token-level F_1 metric. The intent detection is evaluated with the classification accuracy. Specially, several utterances in the ATIS are tagged with more than one labels. Following previous works (Tur et al., 2010; Zhang and Wang, 2016), we count an utterrance as a correct classification if any ground truth label is predicted.

4.2 Implementation Details

All trainable parameters in our model are initialized by the method described in Glorot and Bengio (2010). We apply dropout (Srivastava et al., 2014) to the embedding layer and hidden states with a rate of 0.5. All models are optimized by the Adam optimizer (Kingma and Ba, 2014) with gradient clipping of 3 (Pascanu et al., 2013). The initial learning rate α is set to 0.001, and decrease with the growth of training steps. We monitor the training process on the validation set and report the final result on the test set. One layer CNN with a filter of size 3 and max pooling are utilized to generate 100d word embeddings. The cased 300d Glove is adapted to initialize word embeddings, and kept fixed when training. In auxiliary experiments, the output hidden states of BERT are taken as additional word embeddings and kept fixed as well. We share parameters of both memories with the parameter matrices in the corresponding softmax layers, which can be taken as introducing supervised signals into the memories to some extent. We conduct hyper-parameters tuning for layer size (finally set to 3) and loss weight λ (finally set to 0.5), and empirically set other parameters to the values listed in the supplementary material.

4.3 Main Results

Main results of our CM-Net on the SNIPS and ATIS are shown in Table 3. Our CM-Net achieves the state-of-the-art results on both datasets in terms of slot filling F_1 score and intent detection

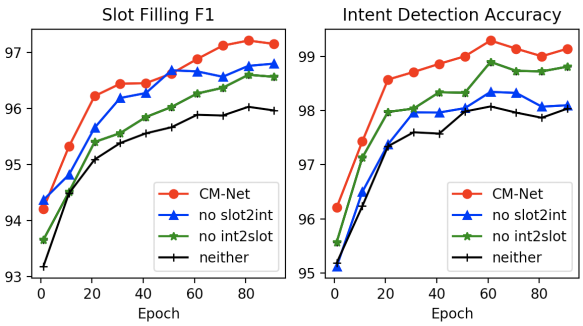

Figure 4: Investigations of the collaborative retrieval approach on slot filling (on the left) and intent detection (on the right), where "no slot2int" indicates removing slow-aware attention for the intent representation, and similarly for "no int2slot" and "neither".

#	Models	SNIPS	
		Slot (F_1)	Intent (Acc)
0	CM-Net	**97.15**	**99.29**
1	– slot memory	96.64	99.14
2	– intent memory	96.95	98.84
3	– local calculation	96.73	99.00
4	– global recurrence	96.80	98.57

Table 4: Ablation experiments on the SNIPS to investigate the impacts of various components, where "- slot memory" indicates removing the slot memory and its interactions with other components correspondingly. Similarly for the other options.

accuracy, except for the F_1 score on the ATIS. We conjecture that the named entity feature in the ATIS has a great impact on the slot filling result as illustrated in Section 4.1. Since the SNIPS is collected from multiple domains with more balanced labels when compared with the ATIS, the slot filling F_1 score on the SNIPS is able to demonstrate the superiority of our CM-Net.

It is noteworthy that the CM-Net achieves comparable results when compared with models that exploit additional language models (Siddhant et al., 2018; Chen et al., 2019). We conduct auxiliary experiments by leveraging the well-known BERT (Devlin et al., 2018) as an external resource for a relatively fair comparison with those models, and report details in Section 5.3.

5 Analysis

Since the SNIPS corpus is collected from multiple domains and its label distributions are more balanced when compared with the ATIS, we choose the SNIPS to elucidate properties of our CM-Net and conduct several additional experiments.

5.1 Whether Memories Promote Each Other?

In the CM-Net, the deliberate attention mechanism is proposed in a collaborative manner to perform information exchange between slots and intents. We conduct experiments to verify whether such kind of knowledge diffusion in both memories can promote each other. More specifically, we remove one unidirectional diffusion (*e.g.* from slot to intent) or both in each experimental setup. The results are illustrated in Figure 4.

We can observe obvious drops on both tasks when both directional knowledge diffusions are removed (CM-Net *vs.* neither). For the slot filling task (left part in Figure 4), the F_1 scores decrease slightly when the knowledge from slot to intent is blocked (CM-Net *vs.* "no slot2int"), and a more evident drop occurs when the knowledge from intent to slot is blocked (CM-Net *vs.* "no int2slot"). Similar observations can be found for the intent detection task (right part in Figure 4).

In conclusion, the bidirectional knowledge diffusion between slots and intents are necessary and effective to promote each other.

5.2 Ablation Experiments

We conduct ablation experiments to investigate the impacts of various components in our CM-Net. In particular, we remove one component among slot memory, intent memory, local calculation and global recurrence. Results of different combinations are presented in Table 4.

Once the slot memory and its corresponding interactions with other components are removed, scores on both tasks decrease to some extent, and a more obvious decline occurs for the slot filling (row 1 *vs.* row 0), which is consistent with the conclusion of Section 5.1. Similar observations can be found for the intent memory (row 2). The local calculation layer is designed to capture better local context representations, which has an evident impact on the slot filling and slighter effect on the intent detection (row 3 *vs.* row 0). Opposite observations occur in term of global recurrence, which is supposed to model global sequential information and thus has larger effect on the intent detection (row 4 *vs.* row 0).

5.3 Effects of Pre-trained Language Models

Recently, there has been a growing body of works exploring neural language models that trained on

Models	SNIPS	
	Slot (F_1)	Intent (Acc)
BiLSTMs + EMLoL	93.29	98.83
BiLSTMs + EMLo	93.90	99.29
Joint BERT	97.00	98.60
CM-Net + BERT	**97.31**	**99.32**

Table 5: Results on the SNIPS benchmark with the assistance of pre-trained language model, where we establish new state-of-the-art results on the SNIPS.

Models	CAIS	
	Slot (F_1)	Intent (Acc)
BiLSTMs + CRF	85.32	93.25
S-LSTM + CRF †	85.74	94.36
CM-Net	**86.16**	**94.56**

Table 6: Results on our CAIS dataset, where "†" indicates our implementation of the S-LSTM.

massive corpora to learn contextual representations (*e.g.* BERT (2018) and EMLo (2018)). Inspired by the effectiveness of language model embeddings, we conduct experiments by leveraging the BERT as an additional feature. The results emerged in Table 5 show that we establish new state-of-the-art results on both tasks of the SNIPS.

5.4 Evaluation on the CAIS

We conduct experiments on our self-collected CAIS to evaluate the generalizability in different language. We apply two baseline models for comparison, one is the popular *BiLSTMs + CRF* architecture (Huang et al., 2015) for sequence labeling task, and the other one is the more powerful sententce-state LSTM (Zhang et al., 2018b). The results listed in Table 6 demonstrate the generalizability and effectiveness of our CM-Net when handling various domains and different languages.

6 Related Work

Memory Network Memory network is a general machine learning framework introduced by Weston et al. (2014), which have been shown effective in question answering (Weston et al., 2014; Sukhbaatar et al., 2015), machine translation (Wang et al., 2016a; Feng et al., 2017), aspect level sentiment classification (Tang et al., 2016), *etc.* For spoken language understanding, Chen et al. (2016) introduce memory mechanisms to encode historical utterances. In this paper, we propose two memories to explicitly capture the semantic correlations between slots and the intent in a given utterance, and devise a novel collaborative retrieval approach.

Interactions between slots and intents Considering the semantic proximity between slots and intents, some works propose to enhance the slot filling task unidirectionally with the guidance of intent representations via gating mechanisms (Goo et al., 2018; Li et al., 2018). Intuitively, the slot representations are also instructive to the intent detection task and thus bidirectional interactions between slots and intents are benefical for each other. Zhang et al. (2018a) propose a hierarchical capsule network to perform interactions from words to slots, slots to intents and intents to words in a pipeline manner, which is relatively limited in capturing the complicated correlations among them. In our CM-Net, information exchanges are performed simultaneously with knowledge diffusions in both directions. The experiments demonstrate the superiority of our CM-Net in capturing the semantic correlations between slots and intents.

Sentence-State LSTM Zhang et al. 2018b propose a novel graph RNN named S-LSTM, which models sentence between words simultaneously. Inspired by the new perspective of state transition in the S-LSTM, we further extend it with task-specific (*i.e.,* slots and intents) representations via our collaborative memories. In addition, the global information in S-LSTM is modeled by aggregating the local features with gating mechanisms, which may lose sight of sequential information of the whole sentence. Therefore, We apply external BiLSTMs to supply global sequential features, which is shown highly necessary for both tasks in our experiments.

7 Conclusion

We propose a novel Collaborative Memory Network (CM-Net) for jointly modeling slot filling and intent detection. The CM-Net is able to explicitly capture the semantic correlations among words, slots and intents in a collaborative manner, and incrementally enrich the information flows with local context and global sequential information. Experiments on two standard benchmarks and our CAIS corpus demonstrate the effectiveness and generalizability of our proposed CM-Net. In addition, we contribute the new corpus (CAIS) to the research community.

Tree Transformer: Integrating Tree Structures into Self-Attention

Yau-Shian Wang Hung-Yi Lee Yun-Nung Chen

king6101@gmail.com hungyilee@ntu.edu.tw y.v.chen@ieee.org

Abstract

Pre-training Transformer from large-scale raw texts and fine-tuning on the desired task have achieved state-of-the-art results on diverse NLP tasks. However, it is unclear what the learned attention captures. The attention computed by attention heads seems not to match human intuitions about hierarchical structures. This paper proposes Tree Transformer, which adds an extra constraint to attention heads of the bidirectional Transformer encoder in order to encourage the attention heads to follow tree structures. The tree structures can be automatically induced from raw texts by our proposed "*Constituent Attention*" module, which is simply implemented by self-attention between two adjacent words. With the same training procedure identical to BERT, the experiments demonstrate the effectiveness of Tree Transformer in terms of inducing tree structures, better language modeling, and further learning more explainable attention scores[1].

1 Introduction

Human languages exhibit a rich hierarchical structure which is currently not exploited nor mirrored by the self-attention mechanism that is the core of the now popular Transformer architecture. Prior work that integrated hierarchical structure into neural networks either used recursive neural networks (Tree-RNNs) (C.Goller and A.Kuchler, 1996; Socher et al., 2011; Tai et al., 2015) or simultaneously generated a syntax tree and language in RNN (Dyer et al., 2016), which have shown beneficial for many downstream tasks (Aharoni and Goldberg, 2017; Eriguchi et al., 2017; Strubell et al., 2018; Zaremoodi and Haffari, 2018). Considering the requirement of the annotated parse trees and the costly annotation effort, most prior work relied on the supervised syntactic parser. However, a supervised parser may be unavailable when the language is low-resourced or the target data has different distribution from the source domain.

Therefore, the task of learning latent tree structures without human-annotated data, called *grammar induction* (Carroll and Charniak, 1992; Klein and Manning, 2002; Smith and Eisner, 2005), has become an important problem and attractd more attention from researchers recently. Prior work mainly focused on inducing tree structures from recurrent neural networks (Shen et al., 2018a,b) or recursive neural networks (Yogatama et al., 2017; Drozdov et al., 2019), while integrating tree structures into Transformer remains an unexplored direction.

Pre-training Transformer from large-scale raw texts successfully learns high-quality language representations. By further fine-tuning pre-trained Transformer on desired tasks, wide range of NLP tasks obtain the state-of-the-art results (Radford et al., 2019; Devlin et al., 2018; Dong et al., 2019). However, what pre-trained Transformer self-attention heads capture remains unknown. Although an attention can be easily explained by observing how words attend to each other, only some distinct patterns such as attending previous words or named entities can be found informative (Vig, 2019). The attention matrices do not match our intuitions about hierarchical structures.

In order to make the attention learned by Transformer more interpretable and allow Transformer to comprehend language hierarchically, we propose Tree Transformer, which integrates tree structures into bidirectional Transformer encoder. At each layer, words are constrained to attend to other words in the same constituents. This constraint has been proven to be effective in prior work (Wu et al., 2018). Different from the prior

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1061–1070, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

work that required a supervised parser, in Tree Transformer, the constituency tree structures is automatically induced from raw texts by our proposed "*Constituent Attention*" module, which is simply implemented by self-attention. Motivated by Tree-RNNs, which compose each phrase and the sentence representation from its constituent sub-phrases, Tree Transformer gradually attaches several smaller constituents into larger ones from lower layers to higher layers.

The contributions of this paper are 3-fold:

- Our proposed Tree Transformer is easy to implement, which simply inserts an additional "Constituent Attention" module implemented by self-attention to the original Transformer encoder, and achieves good performance on the unsupervised parsing task.
- As the induced tree structures guide words to compose the meaning of longer phrases hierarchically, Tree Transformer improves the perplexity on masked language modeling compared to the original Transformer.
- The behavior of attention heads learned by Tree Transformer expresses better interpretability, because they are constrained to follow the induced tree structures. By visualizing the self-attention matrices, our model provides the information that better matchs the human intuition about hierarchical structures than the original Transformer.

2 Related Work

This section reviews the recent progress about grammar induction. Grammar induction is the task of inducing latent tree structures from raw texts without human-annotated data. The models for grammar induction are usually trained on other target tasks such as language modeling. To obtain better performance on the target tasks, the models have to induce reasonable tree structures and utilize the induced tree structures to guide text encoding in a hierarchical order. One prior attempt formulated this problem as a reinforcement learning (RL) problem (Yogatama et al., 2017), where the unsupervised parser is an actor in RL and the parsing operations are regarded as its actions. The actor manages to maximize total rewards, which are the performance of downstream tasks.

PRPN (Shen et al., 2018a) and On-LSTM (Shen et al., 2018b) induce tree structures by introducing a bias to recurrent neural networks. PRPN proposes a parsing network to compute the syntactic distance of all word pairs, and a reading network utilizes the syntactic structure to attend relevant memories. On-LSTM allows hidden neurons to learn long-term or short-term information by the proposed new gating mechanism and new activation function. In URNNG (Kim et al., 2019b), they applied amortized variational inference between a recurrent neural network grammar (RNNG) (Dyer et al., 2016) decoder and a tree structures inference network, which encourages the decoder to generate reasonable tree structures. DIORA (Drozdov et al., 2019) proposed using inside-outside dynamic programming to compose latent representations from all possible binary trees. The representations of inside and outside passes from same sentences are optimized to be close to each other. Compound PCFG (Kim et al., 2019a) achieves grammar induction by maximizing the marginal likelihood of the sentences which are generated by a probabilistic context-free grammar (PCFG) in a corpus.

3 Tree Transformer

Given a sentence as input, Tree Transformer induces a tree structure. A 3-layer Tree Transformer is illustrated in Figure 1(A). The building blocks of Tree Transformer is shown in Figure 1(B), which is the same as those used in bidirectional Transformer encoder, except the proposed Constituent Attention module. The blocks in Figure 1(A) are constituents induced from the input sentence. The red arrows indicate the self-attention. The words in different constituents are constrained to not attend to each other. In the 0-th layer, some neighboring words are merged into constituents; for example, given the sentence "*the cute dog is wagging its tail*", the tree Transformer automatically determines that "*cute*" and "*dog*" form a constituent, while "*its*" and "*tail*" also form one. The two neighboring constituents may merge together in the next layer, so the sizes of constituents gradually grow from layer to layer. In the top layer, the layer 2, all words are grouped into the same constituent. Because all words are into the same constituent, the attention heads freely attend to any other words, in this layer, Tree Transformer behaves the same as the typical Transformer encoder. Tree Transformer can be trained in an end-to-end fashion by using "masked LM",

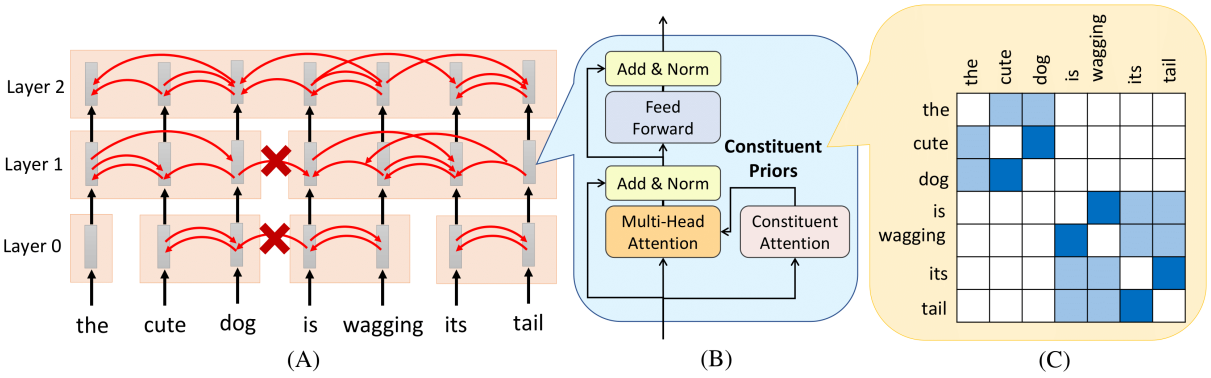

Figure 1: (A) A 3-layer Tree Transformer, where the blocks are constituents induced from the input sentence. The two neighboring constituents may merge together in the next layer, so the sizes of constituents gradually grow from layer to layer. The red arrows indicate the self-attention. (B) The building blocks of Tree Transformer. (C) Constituent prior C for the layer 1.

which is one of the unsupervised training task used for BERT training.

Whether two words belonging to the same constituent is determined by "*Constituent Prior*" that guides the self-attention. Constituent Prior is detailed in Section 4, which is computed by the proposed Constituent Attention module in Section 5. By using BERT masked language model as training, latent tree structures emerge from Constituent Prior and unsupervised parsing is thereby achieved. The method for extracting the constituency parse trees from Tree Transformer is described in Section 6.

4 Constituent Prior

In each layer of Transformer, there are a query matrix Q consisting of query vectors with dimension d_k and a key matrix K consisting of key vectors with dimension d_k. The attention probability matrix is denoted as E, which is an N by N matrix, where N is the number of words in an input sentence. $E_{i,j}$ is the probability that the position i attends to the position j. The Scaled Dot-Product Attention computes the E as:

$$E = \text{softmax}(\frac{QK^T}{d}), \tag{1}$$

where the dot-product is scaled by $1/d$. In Transformer, the scaling factor d is set to be $\sqrt{d_k}$.

In Tree Transformer, the E is not only determined by the query matrix Q and key matrix K, but also guided by Constituent Prior C generating from Constituent Attention module. Same as E, the constituent prior C is also a N by N matrix, where $C_{i,j}$ is the probability that word w_i and word w_j belong to the same constituency. This matrix is symmetric that $C_{i,j}$ is same as $C_{j,i}$. Each layer has its own Constituent Prior C. An example of Constituent Prior C is illustrated in Figure 1 (C), which indicates that in layer 1, "the cute dog" and "is wagging its tail" are two constituents.

To make each position not attend to the position in different constituents, Tree Transformer constrains the attention probability matrix E by constituent prior C as below,

$$E = C \odot \text{softmax}(\frac{QK^T}{d}), \tag{2}$$

where $\odot$ is the element-wise multiplication. Therefore, if $C_{i,j}$ has small value, it indicates that the positions i and j belong to different constituents, where the attention weight $E_{i,j}$ would be small. As Transformer uses multi-head attention with h different heads, there are h different query matrices Q and key matrices K at each position, but here in the same layer, all attention heads in multi-head attention share the same C. The multi-head attention module produces the output of dimension $d_{model} = h \times d_k$.

5 Constituent Attention

The proposed Constituent Attention module is to generate the constituent prior C. Instead of directly generating C, we decompose the problem into estimating the breakpoints between constituents, or the probability that two adjacent words belong to the same constituent. In each layer, the Constituent Attention module generates a sequence $a = \{a_1, ..., a_i, ..., a_N\}$, where a_i is the probability that the word w_i and its neighbor

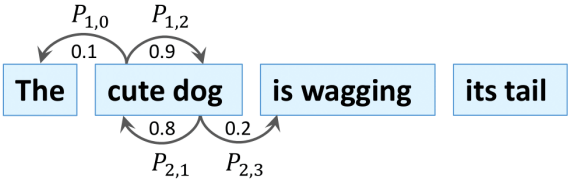

Figure 2: The example illustration about how neighboring attention works.

word w_{i+1} are in the same constituent. The small value of a_i implies that there is a breakpoint between w_i and w_{i+1}, so the constituent prior C is obtained from the sequence a as follows. $C_{i,j}$ is the multiplication of all $a_{i \leqslant k<j}$ between word w_i and word w_j:

$$C_{i,j} = \prod_{k=i}^{j-1} a_k. \tag{3}$$

In (3), we choose to use multiplication instead of summation, because if one of $a_{i \leqslant k<j}$ between two words w_i and w_j is small, the value of $C_{i,j}$ with multiplication also becomes small. In implementation, to avoid probability vanishing, we use log-sum instead of directly multiplying all a:

$$C_{i,j} = e^{\sum_{k=i}^{j-1} \log(a_k)}. \tag{4}$$

The sequence a is obtained based on the following two mechanisms: *Neighboring Attention* and *Hierarchical Constraint*.

5.1 Neighboring Attention

We compute the score $s_{i,i+1}$ indicating that w_i links to w_{i+1} by scaled dot-product attention:

$$s_{i,i+1} = \frac{q_i \cdot k_{i+1}}{d}, \tag{5}$$

where q_i is a link query vector of w_i with d_{model} dimensions, and k_{i+1} is a link key vector of w_{i+1} with d_{model} dimensions. We use $q_i \cdot k_{i+1}$ to represent the tendency that w_i and w_{i+1} belong to the same constituent. Here, we set the scaling factor d to be $\frac{d_{model}}{2}$. The query and key vectors in (5) are different from (1). They are computed by the same network architecture, but with different sets of network parameters.

For each word, we constrain it to either link to its *right neighbor* or *left neighbor* as illustrated in Figure 2. This constraint is implemented by applying a softmax function to two attention links of w_i:

$$p_{i,i+1}, p_{i,i-1} = \text{softmax}(s_{i,i+1}, s_{i,i-1}), \tag{6}$$

where $p_{i,i+1}$ is the probability that w_i attends to w_{i+1}, and $(p_{i,i+1} + p_{i,i-1}) = 1$. We find that without the constraint of the softmax operation in (6) the model prefers to link all words together and assign all words to the same constituency. That is, giving both $s_{i,i+1}$ and $s_{i,i-1}$ large values, so the attention head freely attends to any position without restriction of constituent prior, which is the same as the original Transformer. Therefore, the softmax function is to constraint the attention to be sparse.

As $p_{i,i+1}$ and $p_{i+1,i}$ may have different values, we average its two attention links:

$$\hat{a}_i = \sqrt{p_{i,i+1} \times p_{i+1,i}}. \tag{7}$$

The $\hat{a}_i$ links two adjacent words only if two words attend to each other. $\hat{a}_i$ is used in the next subsection to obtain a_i.

5.2 Hierarchical Constraint

As mentioned in Section 3, constituents in the lower layer merge into larger one in the higher layer. That is, once two words belong to the same constituent in the lower layer, they would still belong to the same constituent in the higher layer. To apply the hierarchical constraint to the tree Transformer, we restrict a_k^l to be always larger than a_k^{l-1} for the layer l and word index k. Hence, at the layer l, the link probability a_k^l is set as:

$$a_k^l = a_k^{l-1} + (1 - a_k^{l-1})\hat{a}_k^l, \tag{8}$$

where a_k^{l-1} is the link probability from the previous layer $l-1$, and $\hat{a}_k^l$ is obtained from Neighboring Attention (Section 5.1) of the current layer l. Finally, at the layer l, we apply (4) for computing C^l from a^l. Initially, different words are regarded as different constituents, and thus we initialize a_k^{-1} as zero.

6 Unsupervised Parsing from Tree Transformer

After training, the neighbor link probability a can be used for unsupervised parsing. The small value of a suggests this link be the breakpoint of two constituents. By top-down greedy parsing (Shen et al., 2018a), which recursively splits the sentence into two constituents with minimum a, a parse tree can be formed.

However, because each layer has a set of a^l, we have to decide to use which layer for parsing. Instead of using a from a specific layer for parsing

Algorithm 1 Unsupervised Parsing with Multiple Layers

$a \leftarrow$ link probabilities
$m \leftarrow minimum\ layer\ id$ ▷ Discard the a from layers below minimum layer
$thres \leftarrow 0.8$ ▷ Threshold of breakpoint
procedure BUILDTREE(l, s, e) ▷ l: layer index, s: start index, e: end index
  if $e - s < 2$ **then** ▷ The constituent cannot be split
    return (s, e)
  $span \leftarrow a^l_{s \le i < e}$
  $b \leftarrow$ **argmin**$(span)$ ▷ Get breakpoint
  $last \leftarrow$ **max**$(l-1, m)$ ▷ Get index of last layer
  if $a^l_b > thres$ **then**
    if $l = m$ **then**
      return (s, e)
    return BuildTree$(last, s, e)$
  $tree1 \leftarrow$ **BuildTree**$(last, s, b)$
  $tree2 \leftarrow$ **BuildTree**$(last, b+1, e)$
  return $(tree1, tree2)$ ▷ Return tree

(Shen et al., 2018b), we propose a new parsing algorithm, which utilizes a from all layers for unsupervised parsing. As mentioned in Section 5.2, the values of a are strictly increasing, which indicates that a directly learns the hierarchical structures from layer to layer. Algorithm 1 details how we utilize hierarchical information of a for unsupervised parsing.

The unsupervised parsing starts from the top layer, and recursively moves down to the last layer after finding a breakpoint until reaching the bottom layer m. The bottom layer m is a hyperparameter needed to be tuned, and is usually set to 2 or 3. We discard a from layers below m, because we find the lowest few layers do not learn good representations (Liu et al., 2019) and thus the parsing results are poor (Shen et al., 2018b). All values of a on top few layers are very close to 1, suggesting that those are not good breakpoints. Therefore, we set a threshold for deciding a breakpoint, where a minimum a will be viewed as a valid breakpoint only if its value is below the threshold. As we find that our model is not very sensitive to the threshold value, we set it to be 0.8 for all experiments.

7 Experiments

In order to evaluate the performance of our proposed model, we conduct the experiments detailed below.

7.1 Model Architecture

Our model is built upon a bidirectional Transformer encoder. The implementation of our Transformer encoder is identical to the original Transformer encoder. For all experiments, we set the hidden size d_{model} of Constituent Attention and Transformer as 512, the number of self-attention heads h as 8, the feed-forward size as 2048 and the dropout rate as 0.1. We analyze and discuss the sensitivity of the number of layers, denoted as L, in the following experiments.

7.2 Grammar Induction

In this section, we evaluate the performance of our model on unsupervised constituency parsing. Our model is trained on WSJ training set and WSJ-all (i.e. including testing and validation sets) by using BERT Masked LM (Devlin et al., 2018) as unsupervised training task. We use WordPiece (Wu et al., 2016) tokenizer from BERT to tokenize words with a 16k token vocabulary. Our best result is optimized by `adam` with a learning rate of 0.0001, $\beta_1 = 0.9$ and $\beta_2 = 0.98$. Following the evaluation settings of prior work (Htut et al., 2018; Shen et al., 2018b)[2], we evaluate F1 scores of our model on WSJ-test and WSJ-10 of Penn Treebank (PTB) (Marcus et al., 1993). The WSJ-10 has 7422 sentences from whole PTB with sentence length restricted to 10 after punctuation removal, while WSJ-test has 2416 sentences from the PTB testing set with unrestricted sentence length.

The results on WSJ-test are in Table 1. We mainly compare our model to PRPN (Shen et al., 2018a), On-lstm (Shen et al., 2018b) and Compound PCFG(C-PCFG) (Kim et al., 2019a), in which the evaluation settings and the training data are identical to our model. DIORA (Drozdov et al., 2019) and URNNG (Kim et al., 2019b) use a relative larger training data and the evaluation settings are slightly different from our model. Our model performs much better than trivial trees (i.e. right and left-branching trees) and random trees, which suggests that our proposed model successfully learns meaningful trees. We also find that

C-PCFG	WSJ-train	**55.2**	**60.1**
Tree-T,L=12	WSJ-train	48.4	50.2
Tree-T,L=10	WSJ-train	49.5	51.1
Tree-T,L=8	WSJ-train	48.3	49.6
Tree-T,L=6	WSJ-train	47.4	48.8
DIORA	NLI	**55.7**	**56.2**
URNNG	Billion	-	52.4
Tree-T,L=10	WSJ-all	50.5	52.0
Random	-	21.6	21.8
LB	-	9.0	9.0
RB	-	39.8	39.8

Table 1: **The F1 scores on WSJ-test.** Tree Transformer is abbreviated as Tree-T, and L is the number of layers(blocks). DIORA is trained on multi-NLI dataset (Williams et al., 2018). URNNG is trained on the subset of one billion words (Chelba et al., 2013) with 1M training data. LB and RB are the left and right-brancing baselines.

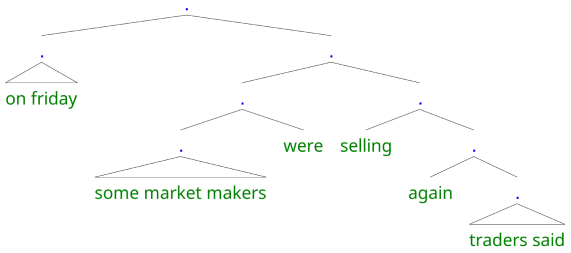

Figure 3: A parse tree induced by Tree Transformer. As shown in the figure, because we set a threshold in Algorithm 1, the leaf nodes are not strictly binary.

increasing the layer number results in better performance, because it allows the Tree Transformer to model deeper trees. However, the performance stops growing when the depth is above 10. The words in the layers above the certain layer are all grouped into the same constituent, and therefore increasing the layer number will no longer help model discover useful tree structures. In Table 2, we report the results on WSJ-10. Some of the baselines including CCM (Klein and Manning, 2002), DMV+CCM (Klein and Manning, 2005) and UML-DOP (Bod, 2006) are not directly comparable to our model, because they are trained using POS tags our model does not consider.

In addition, we further investigate what kinds of trees are induced by our model. Following URNNG, we evaluate the performance of constituents by its label in Table 3. The trees induced by different methods are quite different. Our model is inclined to discover noun phrases (NP) and adverb phrases (ADVP), but not easy to discover verb phrases (VP) or adjective phrases (ADJP). We show an induced parse tree in Figure 3 and more induced parse trees can be found in Appendix.

7.3 Analysis of Induced Structures

In this section, we study whether Tree Transformer learns hierarchical structures from layers to layers. First, we analyze the influence of the hyperparameter minimum layer m in Algorithm. 1 given the model trained on WSJ-all in Table 1. As illustrated in Figure 4(a), setting m to be 3 yields the best performance. Prior work discovered that the representations from the lower layers of Transformer are not informative (Liu et al., 2019). Therefore, using syntactic structures from lower layers decreases the quality of parse trees. On the other hand, most syntactic information is

(a) F1 in terms of different minimum layers.

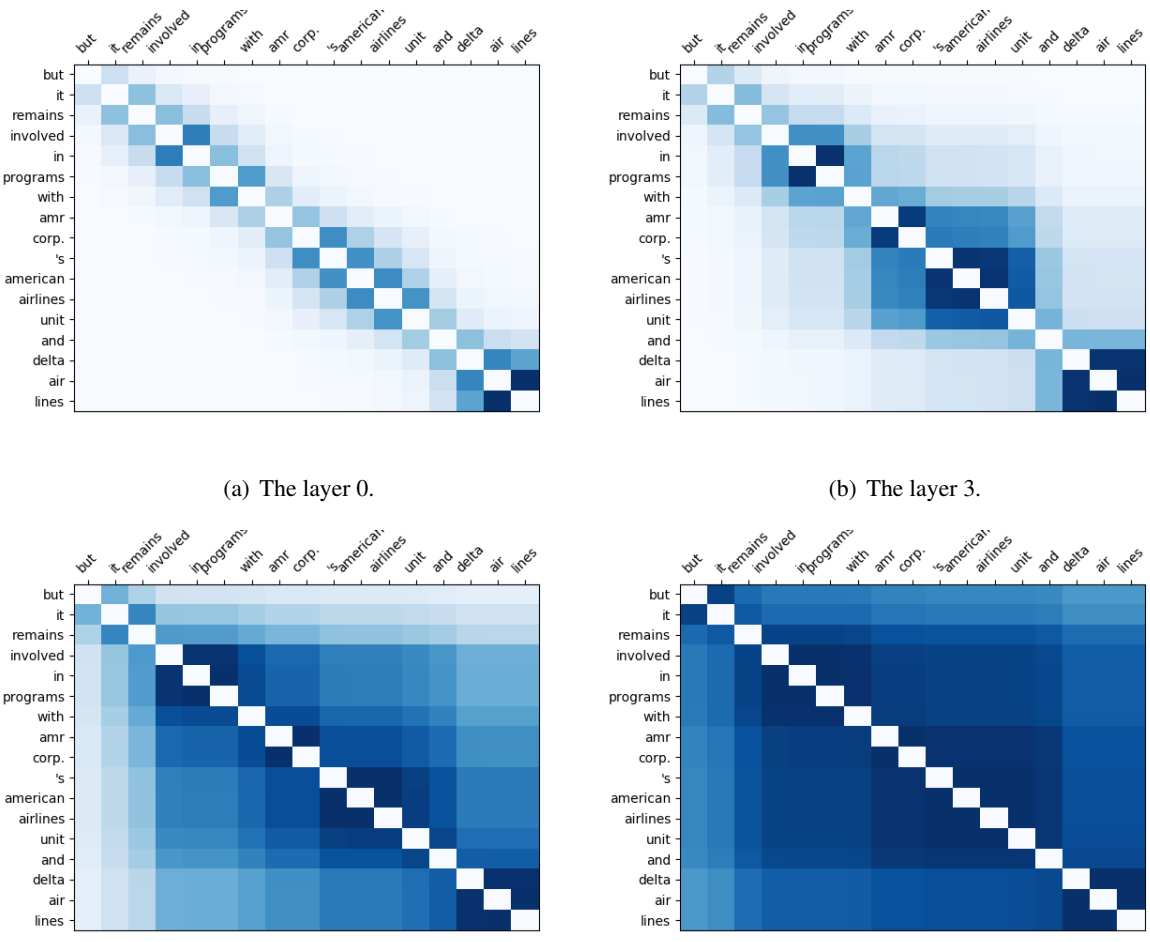
(b) F1 of parsing via a specific layer.

Figure 4: Performance of unsupervised parsing.

missing when a from top few layers are close to 1, so too large m also decreases the performance.

To further analyze which layer contains richer information of syntactic structures, we evaluate the performance on obtaining parse trees from a specific layer. We use a^l from the layer l for parsing with the top-down greedy parsing algorithm (Shen et al., 2018a). As shown in Figure 4(b), using a^3 from the layer 3 for parsing yields the best F1 score, which is 49.07. The result is consistent to the best value of m. However, compared to our best result (52.0) obtained by Algorithm 1, the F1-score decreases by 3 ($52.0 \rightarrow 49.07$). This demonstrates the effectiveness of Tree Transformer in terms of learning hierarchical structures. The higher layers indeed capture the higher-level syntactic structures such as clause patterns.

7.4 Interpretable Self-Attention



This section discusses whether the attention heads in Tree Transformer learn hierarchical structures. Considering that the most straightforward way of interpreting what attention heads learn is to visualize the attention scores, we plot the heat maps of Constituent Attention prior C from each layer in Figure 5.

In the heat map of constituent prior from first layer (Figure 5(a)), as the size of constituent is small, the words only attend to its adjacent words. We can observe that the model captures some subphrase structures, such as the noun phrase "*delta air line*" or "*american airlines unit*". In Figure 5(b)-(d), the constituents attach to each other and become larger. In the layer 6, the words from "*involved*" to last word "*lines*" form a high-level adjective phrase (ADJP). In the layer 9, all words are grouped into a large constituent except the first word "*but*". By visualizing the heat maps of the constituent prior from each layer, we can easily know what types of syntactic structures are learned in each layer. The parse tree of this example can be found in Figure 3 of Appendix. We also visualize the heat maps of self-attention from the original Transformer layers and one from the Tree Transformer layers in Appendix A. As the self-attention heads from our model are constrained by the constituent prior, compared to the original Transformer, we can discover hierarchical structures more easily.

Those attention heat maps demonstrate that: (1) the size of constituents gradually grows from layer to layer, and (2) at each layer, the attention heads tend to attend to other words within constituents posited in that layer. Those two evidences support the success of the proposed Tree Transformer in terms of learning tree-like structures.

Model	L	Params	Perplexity
Transformer	8	40M	48.8
Transformer	10	46M	48.5
Transformer	10-B	67M	49.2
Transformer	12	52M	48.1
Tree-T	8	44M	46.1
Tree-T	10	51M	45.7
Tree-T	12	58M	45.6

Table 4: **The perplexity of masked words.** Params is the number of parameters. We denote the number of layers as L. In Transformer $L = 10 - B$, the increased hidden size results in more parameters.

7.5 Masked Language Modeling

To investigate the capability of Tree Transformer in terms of capturing abstract concepts and syntactic knowledge, we evaluate the performance on language modeling. As our model is a bidirectional encoder, in which the model can see its subsequent words, we cannot evaluate the language model in a left-to-right manner. We evaluate the performance on masked language modeling by measuring the perplexity on masked words[3]. To perform the inference without randomness, for each sentence in the testing set, we mask all words in the sentence, but not at once. In each masked testing data, only one word is replaced with a "[MASK]" token. Therefore, each sentence creates the number of testing samples equal to its length.

In Table 4, the models are trained on WSJ-train with BERT masked LM and evaluated on WSJ-test. All hyperparameters except the number of layers in Tree Transformer and Transformer are set to be the same and optimized by the same optimizer. We use `adam` as our optimizer with learning rate of 0.0001, $\beta_1 = 0.9$ and $\beta_2 = 0.999$. Our proposed Constituent Attention module increases about 10% hyperparameters to the original Transformer encoder and the computational speed is 1.2 times slower. The results with best performance on validation set are reported. Compared to the original Transformer, Tree Transformer achieves better performance on masked language modeling. As the performance gain is possibly due to more parameters, we adjust the number of layers or increase the number of hidden layers in Transformer $L = 10 - B$. Even with fewer parameters than Transformer, Tree Transformer still performs bet-

[3]The perplexity of masked words is $e^{\frac{-\sum \log(p)}{n_{mask}}}$, where p is the probability of correct masked word to be predicted and n_{mask} is the total number of masked words.

ter.

The performance gain is because the induced tree structures guide the self-attention processes language in a more straightforward and human-like manner, and thus the knowledge can be better generalized from training data to testing data. Also, Tree Transformer acquires positional information not only from positional encoding but also from the induced tree structures, where the words attend to other words from near to distant (lower layers to higher layers)[4].

7.6 Limitations and Discussion

It is worth mentioning that we have tried to initialize our Transformer model with pre-trained BERT, and then fine-tuning on WSJ-train. However, in this setting, even when the training loss becomes lower than the loss of training from scratch, the parsing result is still far from our best results. This suggests that the attention heads in pre-trained BERT learn quite different structures from the tree-like structures in Tree Transformer. In addition, with a well-trained Transformer, it is not necessary for the Constituency Attention module to induce reasonable tree structures, because the training loss decreases anyway.

8 Conclusion

This paper proposes Tree Transformer, a first attempt of integrating tree structures into Transformer by constraining the attention heads to attend within constituents. The tree structures are automatically induced from the raw texts by our proposed Constituent Attention module, which attaches the constituents to each other by self-attention. The performance on unsupervised parsing demonstrates the effectiveness of our model in terms of inducing tree structures coherent to human expert annotations. We believe that incorporating tree structures into Transformer is an important and worth exploring direction, because it allows Transformer to learn more interpretable attention heads and achieve better language modeling. The interpretable attention can better explain how the model processes the natural language and guide the future improvement.

[4]We do not remove the positional encoding from the Transformer and we find that without positional encoding the quality of induced parse trees drops.

Semantic Role Labeling with Iterative Structure Refinement

Abstract

Modern state-of-the-art Semantic Role Labeling (SRL) methods rely on expressive sentence encoders (e.g., multi-layer LSTMs) but tend to model only local (if any) interactions between individual argument labeling decisions. This contrasts with earlier work and also with the intuition that the labels of individual arguments are strongly interdependent. We model interactions between argument labeling decisions through *iterative refinement*. Starting with an output produced by a factorized model, we iteratively refine it using a refinement network. Instead of modeling arbitrary interactions among roles and words, we encode prior knowledge about the SRL problem by designing a restricted network architecture capturing non-local interactions. This modeling choice prevents overfitting and results in an effective model, outperforming strong factorized baseline models on all 7 CoNLL-2009 languages, and achieving state-of-the-art results on 5 of them, including English.

1 Introduction

Semantic role labeling (SRL), originally introduced by Gildea and Jurafsky (2000), involves the prediction of predicate-argument structure, i.e., identification of arguments and their assignment to underlying *semantic roles*. Semantic-role representations have been shown to be beneficial in many NLP applications, including question answering (Shen and Lapata, 2007), information extraction (Christensen et al., 2011) and machine translation (Marcheggiani et al., 2018). In this work, we focus on dependency-based SRL (Hajič et al., 2009), a popular version of the task which involves identifying syntactic heads of arguments rather than marking entire argument spans (see the graph in red in Figure 1). Edges in the dependency graphs are annotated with semantic roles (e.g., A0:PLEASER) and the predicates are labeled with their senses from a given sense inventory (e.g., SATISFY.01 in the example).

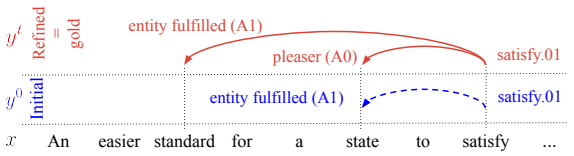

Figure 1: An example of structured refinement, the sentence fragment is from CoNLL-2009: the initial prediction by the factorized model in blue, the refined one (identical to the gold standard) in red.

Before the rise of deep learning methods, the most accurate SRL methods relied on modeling high-order interactions in the output space (e.g., between arguments or arguments and predicates) (Watanabe et al., 2010; Toutanova et al., 2008). Earlier neural methods can model such output interactions through a transition system, and achieve competitive performance (Henderson et al., 2013). However, current state-of-the-art SRL systems use powerful sentence encoders (e.g., layers of LSTMs (Li et al., 2018; He et al., 2017) or multi-head self-attention (Strubell et al., 2018)) and factorize over small fragments of the predicted structures. Specifically, most modern models process individual arguments and perform predicate disambiguation independently. The trend towards more factorizable models is not unique to dependency-based SRL but common for most structured prediction tasks in NLP (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017, 2018). The only major exception is language generation tasks, especially machine translation and language modeling, where larger amounts of text are typically used in training.

Powerful encoders, in principle, can capture long-distance dependencies and hence alleviate the need for modeling high-order interactions in

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1071–1082, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the output. However, capturing these interactions in the encoder would require substantial amounts of data. Even if we have domain knowledge about likely interactions between components of the predicted graphs, it is hard to inject this knowledge in an encoder.

Consider the example in Figure 1. The argument *'state'* appears in the highly ambiguous syntactic position '[.] *to satisfy*'. All three core semantic roles of the predicate SATISFY.01 can in principle appear here: patient (A1:ENTITY_FULFILLED, as in '*a sweet tooth to satisfy'*), instrument (A2:METHOD, as in '*a little dessert to satisfy your sweet tooth*') and agent (A0: PLEASER, as in our actual example). The basic factorized model got it wrong, assigning A1 to the argument *'state'*. However, taking into account other arguments, the model can correct the label. The configuration 'A1 *to satisfy*' is more likely when an agent (A0) is present in the sentence. The lack of an agent boosts the score for the correct configuration 'A0 *to satisfy*'.

Our *iterative refinement* approach encodes the above intuition. In iterative refinement (Lee et al., 2018), a refinement network repeatedly takes previous output as input and produces its refined version. Formally, we have

$$y^{t+1} = \text{Refine}(x, y^t).$$

Naturally, such refinement strategy also requires an initial prediction y^0, which is produced by a ('base') factorized model.

Refinement strategies have been successful in machine translation (Lee et al., 2018; Novak et al., 2017; Xia et al., 2017; Hassan et al., 2018), but their effectiveness in other NLP tasks is yet to be demonstrated.[1] We conjecture that this discrepancy is due to differences in data availability. Given larger amounts of training data typically used in machine translation, their base models and refinement networks overfit to a lesser extent. Overfitting in (1) the base model and (2) the refinement network are both problematic. The first implies that either there are no mistakes in the base models in the training set or their distribution is very different from that in the test regime, so the training material for the inference networks ends up being misleading. The second naturally means that refinement will fail at test time. We address both these issues by designing restricted inference networks and adding a specific form of noise when training them.

Our structured refinement network is simple but encodes non-local dependencies. Specifically, it takes into account the information about the role distributions on the previous iteration aggregated over the entire sentences but not the information what the other arguments are. It is a coarse compressed representation of the prediction, yet it represents long-distance information not readily available within the factorized base model. While this is not the only possible design, we believe that the empirical gains from using this simple refinement network, demonstrate the viability of our general framework of iterative refinement with restricted inference networks. They also suggest that intuitions underlying declarative constraints used in early work on SRL (Punyakanok et al., 2008; Das et al., 2012) can be revisited but now encoded in a flexible soft way to provide induction biases for the refinement networks. We leave this for future work.

We consider the CoNLL-2009 dataset (Hajič et al., 2009). We start with a strong factorized baseline model, which already achieves state-of-the-art results on a subset of the languages. Then, using our structure refinement network, we improve on this baseline on all 7 CoNLL-2009 languages. The model achieves best-reported results in 5 languages, including English. We also observe improvements on out-of-domain test sets, confirming the robustness of our approach. We perform experiments demonstrating the importance of adding noise, and ablation studies showing the necessity of incorporating output interactions. Furthermore, we provide analysis on constraint violations and errors on the English test set.[2]

2 Related Work

Learning to refine predictions from neural structured prediction models has recently received significant attention. Our approach bears similarity to methods used in machine translation (Lee et al., 2018; Novak et al., 2017; Xia et al., 2017). All these methods refine a translated sentence produced by a seq2seq model with another seq2seq model. Among them, the deliberation networks

[1] See extra discussion and related work in section 2.

[2] The code and experiment settings can be accessed at https://github.com/ChunchuanLv/Iterative_Inference

by Xia et al. (2017) rely on BiLSTMs and improve initial predictions from an competitive baseline and obtain state-of-art-results on English-to-French translation. Later, it has been shown that the deliberation networks can improve translation when used within the Transformer framework (Hassan et al., 2018).

Certain approaches, not necessarily directly optimized for refinement, can nevertheless be regarded as iterative refinement methods. Structured prediction energy networks (SPENs) are trained to assign global energy scores to output structures, and the gradient descent is used during inference to minimize the global energy (Belanger and McCallum, 2016). As the gradient descent involves iterative optimization, its steps can be viewed as iterative refinement. In particular, Belanger et al. (2017) build a SPEN for SRL, but for the span-based formalism, not the dependency one we consider in this work. While they improve over their baseline model, their baseline model used multi-layer perceptron to encode local factors, thus the encoder power is limited. Moreover their refined model performs worse in the out-of-domain setting than their baseline model, indicating overfitting (Belanger et al., 2017).

In the follow-up work, Tu and Gimpel (2018, 2019) introduce inference networks to replace gradient descent. Their inference networks directly refine the output. Improvements over competitive baselines are reported on part-of-speech tagging, named entity recognition and CCG supertagging (Tu and Gimpel, 2019). However, their inference networks are distilling knowledge from a tractable linear-chain conditional random field (CRF) model. Thus, these methods do not provide direct performance gains. More importantly, the interactions captured in these models are likely local, as they learn to mimic Markov CRFs.

Denoising autoencoders (Vincent et al., 2008) can also be used to refine structure. Indeed, image segmentation can be improved through iterative inference with denoising autoencoders (Romero et al., 2017; Drozdzal et al., 2018). Their framework is very similar to ours, albeit we are working in a discrete domain. One other difference is that by using a convolutional architecture in the refinement network, they are still modeling only local interactions. At a more conceptual level, Bengio et al. (2013) argued that a denoising autoencoder should not be too robust to the input variations as to ignore the input. This indicates that we should not expect refinement networks to correct all the errors, even in theory, and hence, the refinement networks do not need to be particularly powerful.

Very recently, Wang et al. (2019) used high order statistical model for Semantic Dependency Parsing (Oepen et al., 2015), and obtain improvements over strong baseline using BiLSTM. They attempted loopy belief propagation and mean field variational inference for inference, and train the model end to end. Such inference steps are well motivated. This work is similar to energy network approach (Belanger and McCallum, 2016), while a global score function is provided, and approximate inference steps are used. Comparing to ours, the inference can also be regarded as iterative structure refinement. Yet, we do not provide a global score and directly try to model the refinement. In principle, our formalization should give us more liberty in terms of designing the refinement network.

3 Dependency Semantic Role Labeling

In this section, we introduce the notation and present our factorized baseline model.

3.1 Notation

In dependency SRL, for each sentence of length n, we have a sequence of words w, dependency labels dep, part-of-speech tags pos, each being a discrete sequence of length n. To simplify notation, we consider one predicate at a time. We denote the number of roles by r, it includes the 'null' role, signifying that the corresponding word is not an argument of the predicate. Formally, $\mathrm{P} \in \Delta_{m-1}$ is the probability distribution over m predicate senses, and Δ_{m-1} represents the corresponding probability simplex. We also have predicate sense embeddings $\Pi \in \mathbb{R}^{m \times d_\pi}$, and index j, throughout the discussion, refers to the position of the target predicate in the sentence. $\mathrm{R} \in \Delta_{r-1}^{n}$ is a matrix of size $n \times r$ such that each row sums to 1, corresponding to a probability distribution over roles. In particular $\mathrm{R}_{i,0}$ is the probability of i-th word not being an argument of the predicate.

We index role label and sense predictions from different refinement iterations ('time steps') with t, i.e. P^t and R^t. The index t ranges from 0 to T, and P^0 and R^0 denotes the predictions from the factorized baseline model. Details (e.g., hyperparameters) are provided in the appendix.

3.2 Factorized Model

Similarly to recent approaches to SRL and semantic graph parsing (He et al., 2017; Li et al., 2018; Dozat and Manning, 2018), our factorized baseline model starts with concatenated embeddings x. Then, we encode the sentence with a BiLSTM, further extract features with an MLP (multilayer perceptron) and apply a bi-affine classifier to the resulting features to label the words with roles. We also use a predicate-dependent linear layer for sense disambiguation.

More formally, we start with getting a sentence representation by concatenating embeddings. We have $x^{\mathrm{w}} \in \mathbb{R}^{n \times d_w}$, $x^{\mathrm{dep}} \in \mathbb{R}^{n \times d_\delta}$, $x^{\mathrm{pos}} \in \mathbb{R}^{n \times d_p}$ for words, dependency labels and part-of-speech tags, respectively. We concatenate them to form a sentence representation:

$$x = x^{\mathrm{w}} \circ x^{\mathrm{dep}} \circ x^{\mathrm{pos}} \in \mathbb{R}^{n \times d_x} \tag{1}$$

We further encode the sentence with a BiLSTM:

$$\mathrm{h} = \mathrm{BiLSTM}(x) \in \mathbb{R}^{n \times d_h} \tag{2}$$

From these context-aware word representations, we produce features for argument identification and role labeling that will be used by a bi-affine classifier. Note that, for every potential predicate-argument dependency (i.e. a candidate edge), we need to produce representations of both endpoints: the argument and the predicate 'sides'. For the argument side, h^{ρ_0} will be used to compute the logits for argument identification and h^{ρ_1} will be used for deciding on its role:

$$\mathrm{h}^{\rho_0} = \mathrm{MLP}(\mathrm{h}) \in \mathbb{R}^{n \times d_{\rho_0}} \tag{3}$$

$$\mathrm{h}^{\rho_1} = \mathrm{MLP}(\mathrm{h}) \in \mathbb{R}^{n \times d_{\rho_1}} \tag{4}$$

Similarly, for the predicate side, we also extract two representations h^{ϱ}_0 and h^{ϱ_1} (recall that the predicate is at position j):

$$\mathrm{h}^{\varrho_0} = \mathrm{MLP}(\mathrm{h}_j) \in \mathbb{R}^{d_{\rho_0}} \tag{5}$$

$$\mathrm{h}^{\varrho_1} = \mathrm{MLP}(\mathrm{h}_j) \in \mathbb{R}^{d_{\rho_1}} \tag{6}$$

We then obtain logits I^{ρ_0} corresponding to the decision to label arguments as *null*, and logits I^{ρ_1} for other roles. So, we have:

$$\mathrm{I}^{\rho_0} = \mathrm{BiAffine}(\mathrm{h}^{\varrho_0}, \mathrm{h}^{\rho_0}) \in \mathbb{R}^{n} \tag{7}$$

$$\mathrm{I}^{\rho_1} = \mathrm{BiAffine}(\mathrm{h}^{\varrho_1}, \mathrm{h}^{\rho_1}) \in \mathbb{R}^{n \times (r-1)} \tag{8}$$

Unlike Dozat and Manning (2018), where argument identification and role labeling are trained with two losses,[3] we feed them together into a single softmax layer to compute the semantic-role distribution R^0:

$$\mathrm{I}^{\alpha} = \mathrm{I}^{\rho_0} \circ \mathrm{I}^{\rho_1} \in \mathbb{R}^{n \times r} \tag{9}$$

$$\mathrm{R}^0 = \mathrm{Softmax}(\mathrm{I}^{\alpha}) \in \Delta^{n}_{r-1} \tag{10}$$

Now, for sense disambiguation, we need to extract yet another predicate representation h^{π}:

$$\mathrm{h}^{\pi} = \mathrm{MLP}(\mathrm{h}_j) \in \mathbb{R}^{d_\pi} \tag{11}$$

In the formalism we use (PropBank), senses are predicate-specific, so we use predicate-specific sense embedding matrices Π. The matrix Π acts as a linear layer before softmax:

$$\mathrm{I}^{\pi} = \Pi \cdot \mathrm{h}^{\pi} \in \mathbb{R}^{m} \tag{12}$$

$$\mathrm{P}^0 = \mathrm{Softmax}(\mathrm{I}^{\pi}) \in \Delta_{m-1} \tag{13}$$

This ends the description of our baseline model, which we also use to get initial predictions for iterative refinement.

4 Structured Refinement Network

In this section, we introduce the structured refinement network for dependency SRL. When doing refinement, it has access to the roles distribution $\mathrm{R}^t \in \Delta^{n}_{r-1}$ and the sense distribution $\mathrm{P}^t \in \Delta_{m-1}$ computed at the previous iteration (i.e. time t). In addition, it exploits the sentence representation $x \in \mathbb{R}^{n \times d_x}$. Our refinement network is limited and structured, in the sense that it only has access to a compressed version of the previous prediction, and the network itself is a simple MLP.

Similarly to our baseline model, we extract feature vectors g from input x and further separately encode the argument representation g^{α} and the predicate token representation g^{π}:

$$\mathrm{g} = \mathrm{BiLSTM}(x) \in \mathbb{R}^{n \times d_h} \tag{14}$$

$$\mathrm{g}^{\alpha} = \mathrm{MLP}(\mathrm{g}) \in \mathbb{R}^{n \times d_g} \tag{15}$$

$$\mathrm{g}^{\pi} = \mathrm{MLP}(\mathrm{g}_j) \in \mathbb{R}^{d_g} \tag{16}$$

To simplify the notation, we omit indexing them by t, except for R^t and P^t. We use two refinement networks, one for roles and another one for predicate senses.

[3] The separate processing of I^{ρ_0} and I^{ρ_1} rather than using a single MLP for all roles, including *null*, results in extra representation power allocated for the argument identification subtask.

4.1 Role Refinement Network

First, we describe our structured refinement network for role labeling. We use i to index arguments. We obtain a compressed representation o_i used for refining R_i^t by summing up the probability mass for all roles, excluding the null role:

$$\mathrm{o}_{i,u} = \sum_{k \neq i} \mathrm{R}_{k,u}^t \in \mathbb{R} \quad (17)$$

$$\mathrm{o}_i = [\mathrm{o}_{i,u}] \in \mathbb{R}^{r-1} \quad (18)$$

Intuitively, o_i is the aggregation of all other roles being labeled by the current predicate. We concatenate o_i with feature vectors of the current argument g^α, predicate g^π, the relaxed predicate sense embedding $\Pi^\intercal \cdot \mathrm{P}^t$ and the role probability itself (R_i) to form the input to a two-layer network:

$$\mathrm{z}_i^\alpha = \mathrm{R}_i^t \circ \mathrm{o}_i \circ \mathrm{g}_i^\alpha \circ \mathrm{g}^\pi \circ (\Pi^\intercal \cdot \mathrm{P}^t) \quad (19)$$

$$\mathrm{z}_i^\alpha \in \mathbb{R}^{2r-1+2d_g+d_\pi}$$

$$\mathrm{M}_i^\alpha = W^\alpha \cdot \sigma(W_\alpha \cdot \mathrm{z}_i^\alpha) \in \mathbb{R}^r \quad (20)$$

$$\mathrm{M}^\alpha = [\mathrm{M}_{i,u}^\alpha] \in \mathbb{R}^{n \times r}, \quad (21)$$

where σ is the logistic sigmoid function, $W_\alpha \in \mathbb{R}^{d_r \times (2r-1+2d_g+d_\pi)}$, $W^\alpha \in \mathbb{R}^{r \times d_r}$ are learned linear mappings. We obtain our refined logits M_i^α for the i-th argument; M^α refers to the stacked matrix of logits for all arguments. To obtain the refined role distribution, we add up M^α and I^α that we got from the baseline model, and follow that by a softmax layer:

$$\mathrm{R}^{t+1} = \mathrm{Softmax}(\mathrm{M}^\alpha + \mathrm{I}^\alpha) \in \Delta_{r-1}^n \quad (22)$$

4.2 Sense Refinement Network

To build a representation for sense disambiguation, we simply compute the probability mass for each role (excluding the null role) to obtain r^π, and concatenate this with g^π and $\Pi^\intercal \cdot \mathrm{P}^t$:

$$\mathrm{r}^\pi = \sum_k \mathrm{R}_{k,1:}^t \in \mathbb{R}^{r-1} \quad (23)$$

$$\mathrm{z}^\pi = (\Pi^\intercal \cdot \mathrm{P}^t) \circ \mathrm{r}^\pi \circ \mathrm{g}^\pi \in \mathbb{R}^{r-1+d_g+d_\pi} \quad (24)$$

Differently from the role refinement network, sense prediction is predicate-specific. Therefore, we first map z^π to $\mathbb{R}^{d_\pi}$, and then take the inner product with the predicate-specific sense embeddings Π to get the refined logits:

$$\mathrm{M}^\pi = \Pi \cdot W^\pi \cdot \sigma(W_\pi \cdot \mathrm{z}^\pi) \in \mathbb{R}^m \quad (25)$$

Similarly to role refinement, σ is the logistic function, $W_\pi \in \mathbb{R}^{d_r \times (r-1+d_g+d_\pi)}$, $W^\pi \in \mathbb{R}^{m \times d_r}$ are learned linear mappings. Again, we combine the logits M^π and I^π before the softmax layer:

$$\mathrm{P}^{t+1} = \mathrm{Softmax}(\mathrm{M}^\pi + \mathrm{I}^\pi) \in \Delta_{m-1} \quad (26)$$

4.3 Weight Tying

Our refinement networks are similar to the denoising autoencoders (DAEs; Vincent et al. 2008), so we use the weight-tying technique popular with DAEs. We believe that the technique may be even more effective here as the amount of labeled data for SRL is lower than in many usual applications of DAEs. We tie W_α with a subset of W^α rows: specifically with the rows acting on R_i^t in the computation of M_i^α (see equations 19 and 20). Similarly, we tie W_π with the part of W^π corresponding to $\Pi^\intercal \cdot \mathrm{P}^t$ (see equations 24 and 25). Formally,

$$W^\alpha = W_\alpha^\intercal[: r] \quad (27)$$

$$W^\pi = W_\pi^\intercal[: d_\pi] \quad (28)$$

where $W[: k]$ takes the first k rows of matrix W.

4.4 Self Refinement

We describe a simpler version of the refinement network which we will use in experiments to test whether the improvements with the structured refinement network over the factorized baseline are genuinely coming from modeling interaction between arguments rather than from simply combining multiple classifiers. This simpler refinement network does not account for any interactions between arguments. Instead of equations 19 and 24, we have:

$$\mathrm{z}_i^\alpha = \mathrm{R}_i^t \circ \mathrm{g}_i^\alpha \circ \mathrm{g}^\pi \in \mathbb{R}^{r+2d_g+d_\pi} \quad (29)$$

$$\mathrm{z}^\pi = (\Pi^\intercal \cdot \mathrm{P}^t) \circ \mathrm{g}^\pi \in \mathbb{R}^{d_g+d_\pi} \quad (30)$$

Everything else is kept the same as in the full model, expect that the size of W^α and W^π needs to be adjusted. We refer to this ablated network as the *self-refinement network*.

5 Training for Iterative Structure Refinement

In this section, we describe our training procedure.

5.1 Two-Stage Training

We have two models: the baseline model, producing the initial predictions, and the iterative refinement network, correcting them. While it is possible to train them jointly, we find joint training slow

to converge. Instead, we train the factorized baseline model first and then optimize the refinement networks while keeping the baseline model fixed.

5.2 Stochastic Training

Our baseline model overfits to the training set, and, if simply training on its output, our refinement network would learn to copy the base predictions. Instead, we perturb the baseline prediction during training. Naturally, we can add dropout (Srivastava et al., 2014) and recurrent dropout (Gal and Ghahramani, 2016) to our neural networks. However, for the smaller data set we use, we find this not sufficient. In particular, we use Gumbel-Softmax instead of Softmax. $\text{Gumbel-Softmax}(\mathrm{I}) = \text{Softmax}(\mathrm{I} + \lambda_g \epsilon)$, where the random variable ϵ is drawn from the standard Gumbel distribution (Maddison et al., 2017; Jang et al., 2017), and λ_g is a hyper-parameter controlling decoding stochasticity.[4]

5.3 Loss for Iterative Refinement

Let us denote gold-standard labels for roles and predicates as R^* and P^*. We use two separate losses $\mathcal{L}_{\text{base}}(\mathrm{R}^*, \mathrm{P}^*, x)$ and $\mathcal{L}_{\text{refine}}(\mathrm{R}^*, \mathrm{P}^*, x)$ for our two-stage training. We define losses for predictions from each refinement iteration and sum them up:

$$\mathcal{L}_{\text{base}}(\mathrm{R}^*, \mathrm{P}^*, x) = \mathcal{L}(\mathrm{R}^*, \mathrm{R}^0) + \mathcal{L}(\mathrm{P}^*, \mathrm{P}^0) \tag{31}$$

$$\mathcal{L}_{\text{refine}}(\mathrm{R}^*, \mathrm{P}^*, x) = \sum_{t=1}^{T} \mathcal{L}(\mathrm{R}^*, \mathrm{R}^t) + \mathcal{L}(\mathrm{P}^*, \mathrm{P}^t) \tag{32}$$

We adopt the Softmax-Margin loss (Gimpel and Smith, 2010; Blondel et al., 2019) for individual $\mathcal{L}$. Effectively, we subtract 1 from the logit of the gold label, and apply the cross entropy loss.

6 Experiments

Datasets We conduct experiments on CoNLL-2009 (Hajič et al., 2009) data set for all languages, including Catalan (Ca), Chinese (Zh), Czech (Cz), English (En), German (De), Japanese (Jp) and Spanish (Es). We use the predicted part-of-speech tags, dependency labels, and pre-identified predicate, provided with the dataset. The statistics of datasets are shown in Table 2.

[4] A more canonical way of controlling stochasticity is to use the temperature but we prefer not to scale the gradient.

Hyperparameters We use ELMo (Peters et al., 2018) for English, and FastText embeddings (Bojanowski et al., 2017; Grave et al., 2018) for all other languages. We train and run the refinement networks for two iterations. All other hyperparameters are the same for all languages, except BiLSTMs for English is larger than others.

Training Details Training the refinement network takes roughly 2 times more time than the baseline models, as it requires running BiLSTMs. The extra computation for the structured refinement network is minimal. For English, training the iterative refinement model for 1 epoch takes about 6 minutes on one 1080ti GPU. Adam is used as the optimizer (Kingma and Ba, 2015), with the learning rate of 3e-4. We use early stopping on the development set. We run 600 epochs for all baseline models, and 300 epochs for the refinement networks. Batch sizes are chosen from 32, 64, or 128 to maximize GPU memory usage. Our implementation is based on PyTorch and AllenNLP (Paszke et al., 2017; Gardner et al., 2018).

6.1 Results and Discussions

Test Results Results for all CoNLL-2009 languages on the standard (in-domain) datasets are presented in Table 1. We compare our best model to the best previous single model for the corresponding language (excluding ensemble ones). Most research has focused on English, but we include results of recent models which were evaluated on at least 3 languages. When compared to the previous models, both our models are very competitive, with the exception of German. On the German dataset, Mulcaire et al. (2018) also report a relatively weak result, when compared to Roth and Lapata (2016). The German dataset is the smallest one in terms of the number of predicates. Syntactic information used by Roth and Lapata (2016) may be very beneficial in this setting and may be the reason for this discrepancy. Our structured refinement approach improves over the best previous results on 5 out of 7 languages. Note that hyper-parameters of the refinement network are not tuned for individual languages, suggesting that the proposed method is robust and may be easy to apply to new languages and/or new base models. The only case where the refinement network was not effective is Chinese, where it achieved only a negligible improvement.

Out-of-Domain Results on the out-of-domain

Table 2: Number of sentences and predicates in training set of different languages.

testing sets are presented in Table 4.[5] We observe improvements from using refinement in all the cases. This shows that our refinement approach is robust against domain shift.

Ablations We report development set results in different settings in Table 3. Our full model performs 2 refinement iterations, uses weight tying, and the Gumbel noise.[6] We select the best configuration for each language to report the test set performance in Table 1 and Table 4.

As expected, weight tying is beneficial for lower-resource languages such as Catalan, Japanese and Spanish (see Table 2 for dataset characteristics). The Gumbel noise helps for all languages except for Czech and English, the two largest datasets. In particular, we observe almost no improvement on the Spanish dataset without using the Gumbel noise. We note relatively consistent but small gains from using 2 refinement iterations. The magnitude of the gains may be an artifact of us having the loss terms $\mathcal{L}(\mathrm{R}^*, \mathrm{R}^t)$ and $\mathcal{L}(\mathrm{P}^*, \mathrm{P}^t)$, encouraging not only the final (second), but also the first, iteration to produce accurate predictions. A potential alternative explanation is that our refinement network is restricted to simple interactions, resulting in the fixed point reachable in one step.

Constraints Violation We consider violation of unique core roles (U), continuation roles (C) and reference roles (R) constraints from Punyakanok et al. (2008); FitzGerald et al. (2015) in Table 6. U is violated if a core role (A0 - A5, AA) appears more than once; C is violated when the C-X role is not preceded by the X role (for some X); R is violated if R-X role does not appear. Our approach results in a large reduction in the uniqueness constraint violations. Our model slightly reduces the number of R violations, while He et al. (2017) reported that deterministically enforcing constraints is not helpful (albeit in span-based SRL). However learning those constraints in a soft way might be beneficial.

Argument Interaction vs. No Argument Interaction We compare the structured refinement network and the self-refinement network in Table 5. Both networks share the same hyperparameters. The structured refinement network consistently outperforms the self-refinement counterpart. This suggests that the refinement model benefits from accessing information about other arguments when doing refinement. In other words, modeling argument interaction appears genuinely useful.

Improvement Decomposition We report labeled role precision, recall and sense disambiguation accuracy in Table 7. Our structured refinement approach consistently improves over the baseline model in all metrics. While we cannot assert the improvements on all metrics are significant, this suggests that it learns some non-trivial interactions instead of merely learning to balance precision and

[5] Roth and Lapata (2016) has better in-domain testing score, but did not report the out-of-domain score.

[6] We set $\lambda_g^{\alpha} = 5$ for role and $\lambda_g^{\pi} = 50$ for sense, so that initial predictions contain around 20% errors.

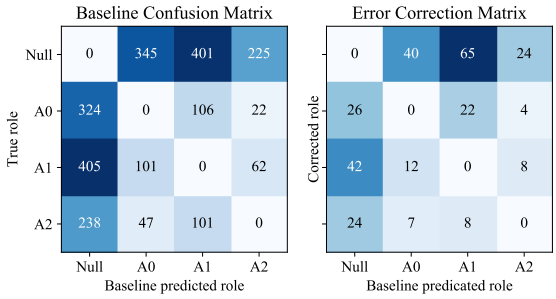

Figure 2: Confusion matrix for the baseline model, and a correction matrix where the errors were corrected by the refinement network. Only Null, A0, A1, A2 are presented here.

recall.

Error Correction Analysis We show the errors that the structured refinement network corrects in Figure 2. In the baseline confusion matrix, we see the errors are fairly balanced for all the roles we consider here. In the error correction matrix, the corrections are also fairly evenly distributed. Yet, this is not completely uniform. There is a tendency towards filtering out arguments rather than generating new ones.

7 Conclusions and Future Work

We propose the structured refinement network for dependency semantic role labeling. The structured refinement network corrects predictions made by a strong factorized baseline model while modeling interactions in the predicated structure. The resulting model achieves state-of-the-art results on 5 out of 7 languages in the CoNLL-2009 data set, and substantially outperforms the factorized model on all of these languages.

For the future work, the structured refinement network can be further improved. For example, we can take an inspiration from either declarative constraints used in the previous work (Punyakanok et al., 2008) or from literature on lexical semantics of verbs, studying patterns of event and argument realization (e.g., Levin 1993). Indeed, the unique role constraint as a declarative constraint is one of the motivation for the concurrent work on modeling argument interaction in SRL (Chen et al., 2019). That work relies on capsule networks (Sabour et al., 2017) and focuses primarily on enforcing the role uniqueness constraint.

The framework can be extended to other tasks. For example, in syntactic dependency parsing: the refinement network can rely on representations of grandparent nodes, siblings and children to propose a correction. In general, structure refinement networks should allow domain experts to incorporate prior knowledge about output dependencies and improve model performance.

Entity Projection via Machine Translation for Cross-Lingual NER

Abstract

Although over 100 languages are supported by strong off-the-shelf machine translation systems, only a subset of them possess large annotated corpora for *named entity recognition*. Motivated by this fact, we leverage machine translation to improve annotation-projection approaches to cross-lingual named entity recognition. We propose a system that improves over prior entity-projection methods by: (a) leveraging machine translation systems twice: first for translating sentences and subsequently for translating entities; (b) matching entities based on orthographic and phonetic similarity; and (c) identifying matches based on distributional statistics derived from the dataset. Our approach improves upon current state-of-the-art methods for cross-lingual named entity recognition on 5 diverse languages by an average of 4.1 points. Further, our method achieves state-of-the-art F_1 scores for Armenian, outperforming even a monolingual model trained on Armenian source data.[1]

1 Introduction

While machine learning methods for various *Natural Language Processing (NLP)* tasks have progressed rapidly, the benefits accrue disproportionately among languages endowed with large annotated corpora. Owing to the dependence of state-of-the-art deep learning approaches on massive amounts of data, creating suitable datasets can be prohibitively expensive. This asymmetry between resource-rich and relatively under-resourced languages has inspired work on *cross-lingual* approaches that leverage annotated datasets from the former to build strong models for the latter.

This paper focuses on cross-lingual approaches to *Named Entity Recognition (NER)*, owing to NER's importance as a core component in *information retrieval* and *question answering* systems. Specifically, we focus on **medium-resource** languages. We define these to be languages for which although annotated NER corpora do not exist, off-the-shelf *Machine Translation (MT)* systems, such as Google Translate[2], do. We are motivated by the fact that although there are fewer than 50 languages for which large NER datasets (greater than 200k tokens) with gold annotations are publicly available[3], many more languages are supported by good-quality MT (**?**). Google Translate alone supports 103 languages[4], many of which have either no, or only small, NER datasets.

We address the setting where annotated corpora exist in the source (resource-rich) language—English in our experiments—but for the target (medium-resource) language, we can only afford to label a small validation set. We tackle this problem by first creating an unlabeled dataset in the target language by translating each sentence in the source dataset to the target language. For MT, we use Google Translate, motivated by its large coverage. Next, we annotate this dataset via *entity projection*—first aligning every entity in a source sentence with its counterpart in the corresponding target sentence (*entity alignment*) and then projecting the tags from source to target in the aligned entity pairs (*tag projection*). One consequence of relying on MT as opposed to word-by-word or phrase-by-phrase translation is that the entity projection step can be difficult, owing to the frequency with which original sentences and their translated counterparts are not word-for-word aligned.

Our proposed solution to this problem consists of (a) leveraging MT again for translating entities; (b) matching entities based on orthographic and

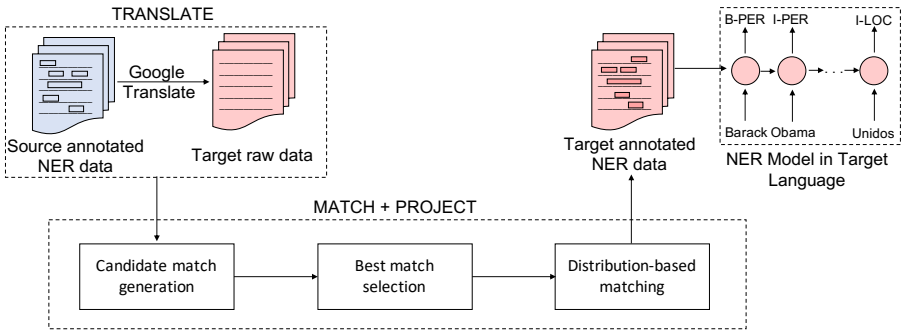

Figure 1: A schematic diagram representing the chief steps in our method.

phonetic similarity; and (c) identifying matches based on distributional statistics derived from the dataset. *Importantly, while our method depends on several matching heuristics, these techniques are remarkably portable across target languages, requiring the tuning of only two hyperparameters.* Our method achieves state-of-the art F_1 scores for cross-lingual NER for Spanish ($+1.1$ points), German ($+1.4$ points), and Chinese ($+5$ points) and beats state-of-the-art baselines on Hindi ($+2.1$ points) and Tamil ($+5$ points). Further, it achieves state-of-the-art F_1 scores for Armenian, a medium-resource language, beating a monolingual model trained on Armenian source data by 0.4 points.

2 Related Work

Cross-lingual approaches have been applied to many NLP tasks, including part-of-speech tagging (**????**), parsing (**????**), and semantic role labeling (**????**). Prior cross-lingual NLP papers cleave roughly into two distinct approaches: *direct model transfer* and *annotation projection*.

2.1 Direct model transfer

These approaches apply models trained on the source language absent modification (to the model) to data from the target language by exploiting a shared representation for the two languages (**?????**). However, direct model transfer techniques face a problem when applied to markedly dissimilar languages: they lack of lexicalized (especially character-based) features, which are known to have predictive power for tasks such as NER. **?** provide evidence for this in the cross-lingual setting, comparing otherwise similar annotation projection approaches that differ in their use of lexicalized features.

2.2 Annotation projection

These approaches to cross-lingual NLP train a model in the target language. This requires first projecting annotations from the source data to the (unlabeled) target data. Many approaches in this category rely upon parallel corpora (**??????**), first annotating the source data using a trained model and then projecting the annotations. Only a few works explore the use of MT to first translate a gold annotated corpus to obtain a *synthetic* parallel corpus and then project annotations (**?**). **?** go in the opposite direction, translating target to source using Google Translate, annotating the translated source sentences using a trained NER system and then projecting annotations back.

When projecting annotations, one encounters the problem of word alignment. Most of the existing works (**???**) rely upon unsupervised alignment models from statistical MT literature, such as IBM Models 1-6 (**??**). Other works focus on low-resource settings (**??**) perform translation word-by-word or phrase-by-phrase, and thus do not need to perform word alignment. Several papers explore heuristics such as using Wikipedia links across languages to align entities (**???**), matching tokens based on their surface forms and transliterations either in an unsupervised manner (**??**) or as features in a supervised model trained on a small *seed* dataset (**?**). Many of these papers often rely on language-specific features (**?**) and evaluate their alignment methods on only a few languages.

To our knowledge, few works effectively use translation for annotation projection for NER, especially for medium-resource languages for which strong MT systems exist. Motivated by this research gap, we explore the use of MT systems for translating the dataset and for annotation projection and thus do not rely on parallel corpora. However, we demonstrate the efficacy of our projection

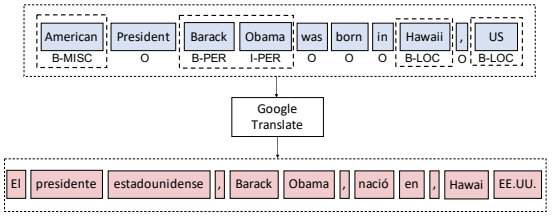

Figure 2: The *Translate* step of our method.

method in all three settings: (a) translation from source to target, (b) using parallel corpora and (c) translation from target to source.

3 The Translate-Match-Project Method

In our formulation, we are given an annotated NER corpus in the source language: $\mathcal{D}_A^S = \{(x^{Si}, y^{Si}) : i = 1, 2, ..., N\}$, where $x^{Si} = (x_1^{Si}, ..., x_{L^{Si}}^{Si})$ is the ith source sentence with L^{Si} tokens and $y^{Si} = (y_1^{Si}, ..., y_{L^{Si}}^{Si})$ are the NER tags from a fixed tag set. We work with four tags: PER (person), ORG (organisation), LOC (location), and MISC (miscellaneous). We follow the commonly-used IOB (Inside Outside Beginning) tagging format (**?**). In our experiments, we work with English as the source language due to the availability of high-quality annotated corpora, e.g., CoNLL 2002 (**?**) and OntoNotes 4.0 (**?**). However, our method can easily be applied to any other resource-rich source language as well. See Figure 2 for an example of an annotated source sentence (blue), (x^{Si}, y^{Si}).

We are given a small labeled development set data (but no training data) in the target language T for tuning hyperparameters. Our method, denoted *Translate-Match-Project (TMP)*, proceeds in three steps: First, we translate the annotated corpus in S to T using an off-the-shelf MT system (Google Translate). This results in an un-labeled dataset in the target language, $\mathcal{D}^T = \{x^{Ti} : i = 1, 2, ..., N\}$ (Figure 2); Second, we identify and tag all named entities in the translated target sentences by entity projection, which involves entity alignment and tag projection. We perform entity alignment by first constructing a set of potential matches in the target sentence for every entity in the source sentence (*candidate match generation*, Section 3.1) and then by selecting the best matching pairs of source and target entities (*best match selection*, Section 3.2); Third, after alignment, we project the tag type (PER, LOC, etc.) from the source to the target entity in every pair of aligned entities by adhering to the IOB tagging scheme in target. In Figure 1, we depict the complete pipeline.

3.1 Candidate match generation

To generate candidate matches for an entity in a source sentence, we construct a set of its potential translations and then find matches for each in the corresponding target sentence. We find these matches by token-level matching and then *concatenate matched tokens to obtain multi-token matches*. We drop the index i below for ease of notation.

Token-level matching Consider a source entity $e^S = (x_j^S, ..., x_k^S)$. For every $e^S \in \mathcal{E}^S$, where $\mathcal{E}^S$ is the set of all entities in a source sentence, we obtain a set of potential translations in the target language, $\mathcal{T}(e^S)$, via MT. However, in some cases, translating a standalone entity produces a different translation from that which emerges when translating a full sentence. For example, Google Translate maps the source entity "UAE" to "Emiratos Árabes Unidos" in most sentences but the word-by-word translation is "EAU". Similarly, the (person) name "Tang" (e.g., "Mr. Tang") remains "Tang" in translated sentences, but is translated to "Espiga" (Spanish for "spike", synonymous with the English word "tang"). We address these problems by augmenting $\mathcal{T}(\cdot)$ with translations from *publicly available* bilingual lexicons ("UAE" translates to "Emiratos Árabes Unidos" in one of the lexicons we use) and retain a copy of the source entity ("Tang" will now find a match in the target sentence). Finally, $\mathcal{T}$("UAE") looks roughly like: {"EAU" [Google Translate], "UAE" [copy], "Emiratos Árabes Unidos" [lexicon]}. We note that lexicons exist for a large number of languages today[5]. However, we demonstrate that our method also works in absence of such lexicons in our case study for Armenian (Section 4.3).

Next, we tokenize each candidate translation in $\mathcal{T}(e^S)$ to obtain a set of translation tokens for e^S, $\mathcal{T}^w(e^S)$. For example, $\mathcal{T}^w$("UAE") = {"EAU", "UAE", "Emiratos", "Árabes", "Unidos"}. We do this to allow for soft token-level matches because we observed empirically that matching exact entity phrases might result in few matches. Next, we obtain a match for each hypothesis token $h \in \mathcal{T}^w(e^S)$ by matching it with each reference token $x_l^S \ \forall \ l \in \{1, ..., L^T\}$ in the target sentence $x^T = (x_1^T, ..., x_{L^T}^T)$ of length L^T. This match is carried out at (a) the orthographic (surface

[5]Panlex (**?**) has lexicons for 10k different languages.

form) level; and (b) the phonetic level, by matching transliterations in the International Phonetic Alphabet (IPA) of the two tokens. In either case, we look for the longest sequence of characters in h that are an affix (prefix or suffix) of x_l^T. This soft *affix-matching heuristic* allows for inflection in morphologically-rich target languages. The (token-level) score for the match is given as follows:

$$s^w(h, x_l^T) = \min\left\{\frac{n_l}{L_h}, \frac{n_l}{L_{x_l^T}}\right\}$$

Here, L_h and $L_{x_l^T}$ are the lengths (in characters) of the hypothesis and reference tokens and n_l is the number of matching characters. We take minimum in order to enforce a stricter notion of fractional (soft) match. For example, the phrase "German first-time registrations..." [English] gets translated to "Los registros Alemanes por primera..." [Spanish]. Using our matching heuristic, "Alemán" $\in \mathcal{T}^w$("German") matches to the reference token "Alemanes" with a score of 0.5, since $n_l = 4$ ("Alem") and $L_{x_l^T} = 8 > L_h = 6$. Next, we define the matching (entity-level) score between a source entity e^S and any target token x_l^T as follows:

$$s^e(e^S, x_l^T) = \max_{h \in \mathcal{T}^w(e^S)} s^w(h, x_l^T)$$

Note that the token-level scores, s^w, include scores based on both orthographic and phonetic match, and thus, the entity-level scores, s^e, correspond to the best token-level match (orthographic or phonetic) between any hypothesis token $h \in \mathcal{T}^w(e^S)$ and a target token x_l^T. In Figure 3, we depict the token-level matching procedure. The score between the entity "American" and the target "estadounidense"(labeled 3 in the figure) is the maximum over matching scores between any token in {"americano", "american", "estadounidense"} and the target token ("estadounidense"), i.e., 1.0 (exact match) since the scores for the first two tokens in $\mathcal{T}^w(\cdot)$ are 0. Note some artifacts of token-level matching: (a) our matching heuristic currently handles prefixes or suffixes, but can potentially be extended with character edit distance for other types of affixes (e.g., circumfix) (b) every target token can match with multiple source entities (for e.g., "El" matches with both "American" and "US") and (c) some source entities might fail to find their true match ("US" fails to match with "EE.UU.", a possibly erroneous translation of "US" provided by Google Translate). Further, many matches are of very poor quality (especially those with stop words such as "El" and "en"). We address these issues and describe how to convert these token-level matches into spans to get multi-token target entities next.

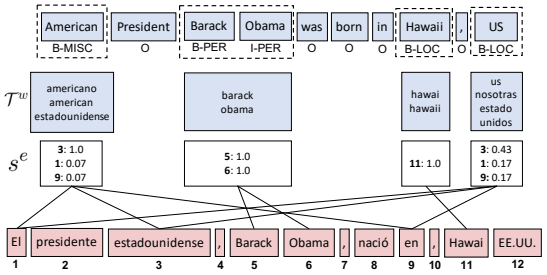

Figure 3: Token-level matching: Blue boxes in row-2 ($\mathcal{T}^w$) show sets of potential translations and white boxes in row-3 (s^e) show target tokens (numbered) each source entity can match with, with their scores.

Span match generation After token-level matching, we construct a list of potential entity spans in the target sentence that match with a given source entity e^S by grouping adjacent target tokens for which a token-level matching score $s^e(e^S, \cdot)$ is above a threshold δ (to remove spurious matches). In other words, we construct the following set:

$$\mathcal{M}(e^S) = \{\text{span}(q, r) : s^e(e^S, x_u^T) \geq \delta \quad \forall\ q \leq u \leq r\}$$

Here, $\text{span}(q, r) = (x_q^T, ..., x_r^T)$ is the phrase spanning tokens indexed from q to r ($1 \leq q, r \leq L^T$) in the target sentence. Further, we require $\text{span}(q, r)$ to be maximal in the sense that $\forall\ q' < q$ and $\forall\ r' > r$, $\text{span}(q', r') \notin \mathcal{M}(\cdot)$, i.e., any target token before or after the span have at best a weak match ($s^e(e^S, \cdot) < \delta$) with e^S.

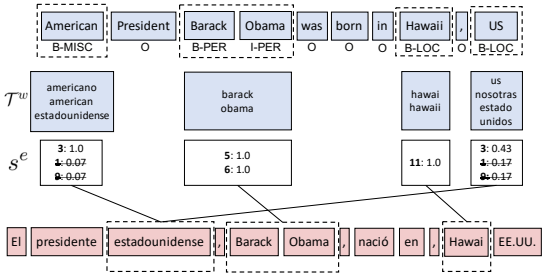

Figure 4: Span match generation: Adjacent target tokens with matching scores higher than a threshold (0.25 here) are concatenated to form span-level matches.

In our running example, choosing $\delta = 0.25$ results in the spans shown in Figure 4, eliminating spurious matches (with "El" and "en") and concatenating "Barack" and "Obama" in the target sentence. However, the token "estadounidense" is

still matched with two different source entities. We solve this problem in the next step.

3.2 Best match selection

For selecting the best matching pair of entities, we first expand the set of potential translations $\mathcal{T}(\cdot)$ to include all possible token-level permutations of the translations. We call this set $\mathcal{T}^p(\cdot)$. For example, $\mathcal{T}^p$("UAE") = {"EAU", "UAE", "Emiratos Árabes Unidos", "Emiratos Unidos Árabes", "Árabes Emiratos Unidos", ...}. Then, we greedily align e^S with the target entity span from the set $\mathcal{M}(e^S)$, with the least character edit distance $d_E(\cdot,\cdot)$ from any translation in $T^p(e^S)$, i.e.,

$$e^T = \underset{\text{span}(\cdot,\cdot)\in\mathcal{M}(e^S)}{\text{argmin}} \; d_E(e^S, \text{span}(\cdot,\cdot))$$

In this manner, we form aligned entity pairs (e^S, e^T), along which tags can then be projected. In our running example, since the edit distance between "estadounidense" (in $\mathcal{T}^p(\cdot)$) and the target single-token span "estadounidense" is 0, and is lower than that with "estado", we match "estadounidense" with "American", tagging it B-MISC.

3.3 Distribution-based matching

After selecting best matching pairs, there still remain some source entities that do not find any matching target entity ("US" in our example). These arise either due to significant differences between word-by-word and contextual sentence-level translations either due to literal (e.g., "West Bank" gets translated to "Cisjordania" in sentences and "Banco Oeste" otherwise) or possibly incorrect translations (e.g., "U.S." gets translated to "EE.UU." in sentences and "NOSOTRAS" otherwise).

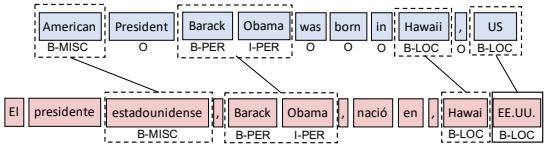

Figure 5: Final aligned pairs and projected tags.

We remedy this by exploiting corpus-level consistency in such discrepancies. For every unmatched source entity, we construct a set of top-k potential matches ordered by their tf-idf (term frequency—inverse document frequency) scores, where tf is calculated over all sentences containing at least one unmatched entity and the idf score is calculated over the entire dataset to severely penalize commonly occurring tokens. Finally, we match each unmatched source entity with an unmatched span in its top-k list with the highest tf-idf score. Figure 5 shows the final matches and tags.

4 Experimental Evaluation

Data In order to compare our method against benchmarks reported for prior approaches, we evaluate its performance on three European languages: Spanish (*es*), Dutch (*nl*) and German (*de*). Further, for a more extensive evaluation, we conduct additional experiments in an Indo-Aryan language (Hindi (*hi*)), a Dravidian language (Tamil (*ta*)), and Simplified Chinese (*zh*).

For all languages except Chinese, we use English NER training data from the CoNLL 2003 shared task (**?**) to translate into the target language. For Chinese, we sample the same number of sentences as in the CoNLL 2003 corpus (14,041) from the OntoNotes 4.0 (2012) dataset for English (**?**) to minimize distribution shift from Chinese development data. The development and test datasets for Spanish, Dutch and German are obtained from CoNLL 2002 (**?**) and CoNLL 2003 shared tasks. For Hindi and Tamil, we obtain the NER corpus from FIRE 2013 shared task[6]. Since this task doesn't provide the test dataset, we create our own splits: two-thirds for training and one-sixth each for development and test (to match with the proportions in the CoNLL dataset). For Chinese, we use the OntoNotes 4.0 development and test datasets. English, Spanish, Dutch and German contain PER, ORG, LOC and MISC tags, while Hindi, Tamil and Chinese were preprocessed to contain only PER, LOC and ORG tags. We use MUSE ground-truth bilingual lexicons[7] (gold lexicon) for augmenting the set of potential entity translations and use Epitran (**?**) for obtaining IPA transliterations.

Baselines We compare against four other annotation projection approaches that have achieved state-of-the-art results on some of our datasets. **?** (BWET) use a bilingual lexicon induced using monolingual corpora (**?**) to translate each source sentence word-by-word and then copy the corresponding NER tags using gold lexicons. As a ceiling for their method, **?** used Google Translate with fast-align (**?**) (fast-align), an unsupervised expectation maximization based algorithm, for entity alignment. Since this algorithm can produce multiple matches for a given source entity, we post-process

Table 1: Test F_1 scores for our method (TMP), 4 cross-lingual baselines and a model trained on monolingual data.

the alignments produced by this algorithm and select the longest match and then project tags in the same way as our method. Our third baseline is **?** (Co-decoding), who use a co-decoding scheme on two different NER models. We also compare our method with Polyglot-NER (**?**) who use Wikipedia links to project entities. Finally, we also compare our performance with a model trained on annotated data in target language (Monolingual).

NER Model We use the state-of-the-art neural NER tagging model from (**?**) to train TMP and fast-align baseline for all languages. This model adds a self-attention layer to the character- and word-based BiLSTM + CRF model due to **?**. For each experiment, we run our models 5 times using different seeds and report the mean and standard deviation (as recommended by **?**) of F_1 measure.

Hyperparameters For the fast-align baseline, we tune their λ parameter, which controls how much the model deviates from perfectly diagonal alignments, for each language separately. For TMP, we tune δ, the score threshold and k, the number of top candidates selected in distribution-based matching. We use the same hyperparameters for the NER model as **?** for all our experiments.

4.1 Results

Our technique outperforms previous state-of-the-art cross-lingual methods on Spanish, German, Chinese, Hindi and Tamil and performs competitively on Dutch (Table 1). In particular, our method shows marked improvements over BWET, a word-by-word translation baseline, for languages such as German, Hindi, Tamil and Chinese that differ markedly in word ordering (with respect to English), demonstrating the impact of improved machine translation quality on final NER tagging accuracy. For more distant languages, word ordering can drastically affect the position of entities in a sentence, which can hurt performance on a test set in the target language. For instance, consider the Hindi word-by-word translation in Figure 6 (c), which is incoherent and violates the Subj-Obj-Verb ordering of Hindi. On languages that are closer to English, like Spanish and Dutch, the gains are comparatively modest, indicating that word order and quality MT is not critical for such languages.

We also show improvements over the fast-align baseline, which performs unsupervised word-level alignment over the full sequence. This can lead to alignment errors for named entities, which tend to be low-frequency words. Moreover, since fast-align allows for multiple target words to be aligned to a given source word, several noisy tags are added to the target sentence (see Figures 6 (a) and (b)).

4.2 Comparison of projection settings

Having established the performance of TMP as a method for cross-lingual NER, in this section, we conduct deeper experiments to evaluate the effectiveness of the matching (M) and projection (P) steps of TMP over the other projection baseline, fast-align. As mentioned in Section 2, there are variants of the annotation projection paradigm for cross-lingual NER that require an entity projection step, namely (i) reversing the direction of machine translation and (ii) using parallel corpora. We compare MP with fast-align for Spanish and Hindi languages under both these settings.

Lang.	Method	Forward	Reverse	Parallel
es	MP	**73.5 ± 0.4**	65.3	61.2 ± 1.2
	fast-align	65.0 ± 1.2	57.8	39.3 ± 0.5
hi	MP	41.7 ± 1.3	47.7	**52.8 ± 1.4**
	fast-align	39.6 ± 1.1	34.3	51.8 ± 1.5

Table 2: Performance of MP and fast-align on Forward, Reverse and Parallel settings in terms of F_1.

Reversing the direction of translation In this setting, we translate the target test set into the source language using Google Translate and then use the NER tagger with state-of-the-art results

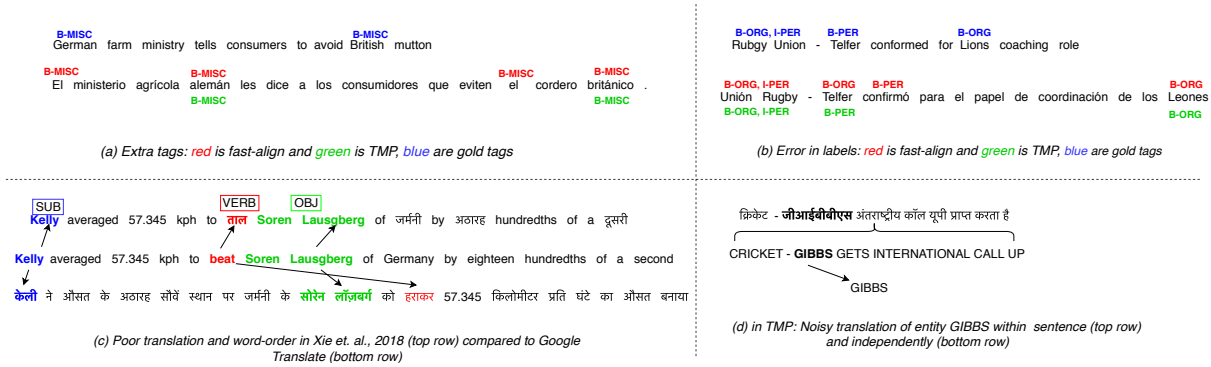

Figure 6: Examples of different errors (details in individual captions).

Flair[8] to tag entities in the translated English sentences. Finally, we employ MP/fast-align to project the tagged entities back to the target sentence. As shown in table 2, MP outperforms fast-align for both Spanish and Hindi and performs better than the forward direction translation for Hindi. This can be attributed to (a) the inherent difficulty of NER tagging in Hindi, which is morphologically richer than English and (b) the superior quality of the English NER model.

Parallel corpora In order to remove translation errors while evaluating TMP and fast-align, we experiment with parallel corpora. For English-Spanish, we use the Europarl corpus (**?**) and for English-Hindi, the IIT Bombay parallel corpus (**?**). We again use *Flair* to obtain NER tags in English, which are then projected to their corresponding target sentences to generate a training dataset, which is used to train an NER model in the target language. To minimize confounding variables, we sample 14k (same as CoNLL) high quality tagged sentences (average confidence score > 0.9). Results in Table 2 show that MP once again outperforms fast-align. Further, it performs better than Forward for Hindi by a significant margin possibly because the chosen parallel corpus is closer in time period to the test set, thereby reducing distribution shift.

4.3 Case study: Armenian

So far, we have only evaluated the performance of our method on languages for which large or moderately-sized gold annotated corpora already exist that provide an upper-bound for cross-lingual NER methods. Here, we evaluate our method on a true medium-resource language, Armenian. Recently, **?** introduced a ground truth test corpus for Armenian along with a train corpus with silver annotations extracted from Wikipedia. This test dataset is comprised of 2566 sentences (53k tokens) from political, sports, local and world news between August 2012 and July 2018. Since the English CoNLL 2003 dataset contains sentences nearly two decades older, we expect to see significant distribution shift if we follow TMP (Forward approach). Further, we are not aware of any large English-Armenian parallel corpora. So, we choose the Reverse paradigm for this problem. We achieve an F_1 score of 62.6, which is significantly higher than that achieved by fast-align (44.8). Further, this is 0.4 points higher than the current state-of-the-art model trained on over 160k tokens of Armenian. Note that our model does not make use of any external resources for Armenian (gold lexicons, Epitran, etc.) other than an MT system. This provides evidence towards our proposed approach being an effective and generalizable cross-lingual NER method that can be used for rapid deployment to new languages.

5 Analysis

Measuring alignment accuracy Since we do not possess ground truth word alignments for the "synthetic" parallel corpus generated through translation, we rely on heuristics to measure the accuracy of alignments. We measure the annotation *miss rate* among target sentences with equal or fewer tagged entities as compared to source. We also calculate the *excess rate*, representing the fraction of excess entities among sentences with more tagged entities. Both methods perform similarly in terms of miss rate, 0.79 % (MP) vs 0.83 % (fast-align) on Spanish and 3.96 % (MP) vs 3.48 % (fast-align) on Hindi. However, fast-align seems to add more noisy annotations as compared to MP, with

[8] https://github.com/zalandoresearch/flair

higher excess rates for both Spanish (8.29 % vs 0.49 %) and Hindi (6.35 % vs 2.20 %). A representative illustration of these noisy tags is shown in Figure 6 (a). where fast-align tags frequent words like "El", "de", "en" as entities. To offer a more fine-grained evaluation of alignment performance, we manually annotate 100 examples from the translated Spanish and Hindi training data and calculate precision, recall and F_1 score. MP outperforms fast-align for both the languages (Table 3).

Lang.	Method	Precision	Recall	F_1
es	MP	**96.2**	**96.7**	**96.4**
	fast-align	84.6	87.4	85.9
hi	MP	**87.4**	**77.6**	**82.2**
	fast-align	82.0	76.8	79.3

Table 3: Alignment performance on 100 sentences.

Ablation of features for alignment We also conduct an ablation study (Table 4) to understand the sources of our gains beyond a base model that uses translations only from Google Translate and orthographic affix matching. To this base model, we successively add various features of our method: phonetic matching, exact copy translations, gold lexicons and finally distribution-based alignment (dist) of remaining entities. For both languages, we observe that every additional feature improves the performance of tagging, with the most important features being phonetic matching for Spanish and use of gold lexicons for Hindi. Interestingly, addition of phonetic matching hurts Hindi because of the low value of the threshold ($\delta = 0.25$), which results in spurious matches due to phonetic matching. In Table 4, we also see that the number of entities tagged (as a fraction of total entities) increase with the introduction of almost every feature (however, all matches might not be correct). This underscores the correlation between quality of entity alignment and performance on the downstream tagging task.

Model	es		hi	
	% **Entities**	F_1	% **Entities**	F_1
Base model	91.8	67.8	77.9	37.7
+phonetic	93.7	71.4	83.0	35.0
+copy	97.2	72.2	85.4	37.6
+gold	98.3	73.3	88.5	42.0
+dist	99.9	74.2	94.9	43.4

Table 4: Ablation study for Spanish and Hindi

Sources of errors in TMP We also analyze mistakes made by TMP in aligning entities. Many false negative errors can be traced back to a high threshold δ, resulting in an empty set of candidate matches. Errors also arise due to noise and variation introduced in the contextual sentence level translation of a word (Figure 6 (c) where GIBBS is interpreted as an acronym, (d) where MEDVEDEV is mistranslated). This causes discrepancies between translations of standalone entities and those in context, thereby, causing TMP to not find a match. However, these errors can be reduced as off-the-shelf MT systems continue to improve.

6 Conclusion

In this paper, we tackled the problem of entity projection for cross-lingual NER. Our proposed method leverages MT for translating entities, matches entities based on orthographic and phonetic similarity, and identifies matches based on distributional statistics derived from the dataset to achieve state-of-the-art results for cross-lingual NER on a diverse set of languages. Further, our method beats state-of-the-art monolingual baseline for Armenian, an actual medium-resource language (off-the-shelf translation systems exist, but large-scale NER corpora do not). In the future, we would like to explore ways to extend our method to languages not supported by Google Translate through the use of pivot languages.

While dependence on MT restricts our approach to languages covered by off-the-shelf MT systems, these systems continue to improve in coverage and quality, outpacing the availability of large-scale corpora for a variety of other tasks. Moreover as translation quality improves, approaches like ours are poised to benefit. Finally, although our method beats state-of-the-art baselines, not surprisingly, it falls short of NER models trained on large monolingual corpora. We suspect that a significant portion of this degradation is due to distribution shift (as evidenced by improvement in Hindi F_1 in Parallel regime). Thus one promising route to improving our models might be to incorporate domain adaptation techniques, which aim to build classifiers robust to various forms of distribution shift.

A Bayesian Approach for Sequence Tagging with Crowds

Edwin Simpson and Iryna Gurevych

Abstract

Current methods for sequence tagging, a core task in NLP, are data hungry, which motivates the use of crowdsourcing as a cheap way to obtain labelled data. However, annotators are often unreliable and current aggregation methods cannot capture common types of span annotation errors. To address this, we propose a Bayesian method for aggregating sequence tags that reduces errors by modelling sequential dependencies between the annotations as well as the ground-truth labels. By taking a Bayesian approach, we account for uncertainty in the model due to both annotator errors and the lack of data for modelling annotators who complete few tasks. We evaluate our model on crowdsourced data for named entity recognition, information extraction and argument mining, showing that our sequential model outperforms the previous state of the art. We also find that our approach can reduce crowdsourcing costs through more effective active learning, as it better captures uncertainty in the sequence labels when there are few annotations.

1 Introduction

Current methods for *sequence tagging*, a core task in NLP, use deep neural networks that require tens of thousands of labelled documents for training (Ma and Hovy, 2016; Lample et al., 2016). This presents a challenge when facing new domains or tasks, where obtaining labels is often time-consuming or costly. Labelled data can be obtained cheaply by crowdsourcing, in which large numbers of untrained workers annotate documents instead of more expensive experts. For sequence tagging, this results in multiple sequences of unreliable labels for each document.

Probabilistic methods for aggregating crowdsourced data have been shown to be more accurate than simple heuristics such as majority voting (Raykar et al., 2010; Sheshadri and Lease, 2013; Rodrigues et al., 2013; Hovy et al., 2013). However, existing methods for aggregating sequence labels cannot model dependencies between the annotators' labels (Rodrigues et al., 2014; Nguyen et al., 2017) and hence do not account for their effect on annotator noise and bias. In this paper, we remedy this by proposing a sequential annotator model and applying it to tasks that follow a *beginning, inside, outside* (*BIO*) scheme, in which the first token in a span of type 'x' is labelled 'B-x', subsequent tokens are labelled 'I-x', and tokens outside spans are labelled 'O'.

When learning from noisy or small datasets, commonly-used methods based on maximum likelihood estimation may produce over-confident predictions (Xiong et al., 2011; Srivastava et al., 2014). In contrast, Bayesian inference accounts for model uncertainty when making predictions. Unlike alternative methods that optimize the values for model parameters, Bayesian inference integrates over all possible values of a parameter, weighted by a prior distribution that captures background knowledge. The resulting posterior probabilities improve downstream decision making as they include the probability of errors due to a lack of knowledge. For example, during active learning, posterior probabilities assist with selecting the most informative data points (Settles, 2010).

In this paper, we develop *Bayesian sequence combination (BSC)*, building on prior work that has demonstrated the advantages of Bayesian inference for aggregating unreliable classifications (Kim and Ghahramani, 2012; Simpson et al., 2013; Felt et al., 2016; Paun et al., 2018). BSC is the first fully-Bayesian method for aggregating sequence labels from multiple annotators. As a core component of BSC, we also introduce the *sequential confusion matrix (seq)*, a probabilistic model

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1093–1104,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

of annotator noise and bias, which goes beyond previous work by modelling sequential dependencies between annotators' labels. Further contributions include a theoretical comparison of the probabilistic models of annotator noise and bias, and an empirical evaluation on three sequence labelling tasks, in which *BSC* with *seq* consistently outperforms the previous state of the art. We make all of our code and data freely available[1].

2 Related Work

Sheshadri and Lease (2013) benchmarked several aggregation models for non-sequential classifications, obtaining the most consistent performance from that of Raykar et al. (2010), who model the reliability of individual annotators using probabilistic confusion matrices, as proposed by Dawid and Skene (1979). Simpson et al. (2013) showed that a Bayesian variant of Dawid and Skene's model can outperform maximum likelihood approaches and simple heuristics when combining crowds of image annotators. This Bayesian variant, independent Bayesian classifier combination (*IBCC*) (Kim and Ghahramani, 2012), was originally used to combine ensembles of automated classifiers rather than human annotators. While traditional ensemble methods such as boosting focus on how to generate new classifiers (Dietterich, 2000), IBCC is concerned with modelling the reliability of each classifier in a given set of classifiers. To reduce the number of parameters in multi-class problems, Hovy et al. (2013) proposed *MACE*, and showed that it performed better under a Bayesian treatment on NLP tasks. Paun et al. (2018) further illustrated the advantages of Bayesian models of annotator ability on NLP classification tasks with different levels of annotation sparsity and noise.

We expand this previous work by detailing the relationships between several annotator models and extending them to sequential classification. Here we focus on the core annotator representation, rather than extensions for clustering annotators (Venanzi et al., 2014; Moreno et al., 2015), modeling their dynamics (Simpson et al., 2013), adapting to task difficulty (Whitehill et al., 2009; Bachrach et al., 2012), or time spent by annotators (Venanzi et al., 2016).

Methods for aggregating sequence labels include *CRF-MA* (Rodrigues et al., 2014), a CRF-based model that assumes only one annotator is correct for any given label. Recently, Nguyen et al. (2017) proposed a hidden Markov model (HMM) approach that outperformed CRF-MA, called *HMM-crowd*. Both CRF-MA and HMM-crowd use simpler annotator models than Dawid and Skene (1979) that do not capture the effect of sequential dependencies on annotator reliability. Neither CRF-MA nor HMM-crowd use a fully Bayesian approach, which has been shown to be more effective for handling uncertainty due to noise in crowdsourced data for non-sequential classification (Kim and Ghahramani, 2012; Simpson et al., 2013; Venanzi et al., 2014; Moreno et al., 2015). In this paper, we develop a sequential annotator model and an approximate Bayesian method for aggregating sequence labels.

3 Modeling Sequential Annotators

When combining multiple annotators with varying skill levels, we can improve performance by modelling their individual noise and bias using a probabilistic model. Here, we describe several models that do not consider dependencies between annotations in a sequence, before defining *seq*, a new extension that captures sequential dependencies. Probabilistic annotator models each define a different function, A, for the likelihood that the annotator chooses label c_τ given the true label t_τ, for the τth token in a sequence.

Accuracy model (acc): the basis of several previous methods (Donmez et al., 2010; Rodrigues et al., 2013), *acc* uses a single parameter for each annotator's accuracy, π:

$$A = p(c_\tau = i | t_\tau = j, \pi) = \begin{Bmatrix} \pi & \text{where } i = j \\ \frac{1-\pi}{J-1} & \text{otherwise} \end{Bmatrix}, \quad (1)$$

where J is the number of classes. This may be unsuitable when one class label dominates the data, since a spammer who always selects the most common label will nonetheless have a high π.

Spamming model (spam): proposed as part of MACE (Hovy et al., 2013), this model also assumes constant accuracy, π, but that when an annotator is incorrect, they label according to a spamming distribution, $\boldsymbol{\xi}$, that is independent of

[1] http://github.com/ukplab/arxiv2018-bayesian-ensembles

the true label, t_τ.

$$A = p(c_\tau = i | t_\tau = j, \pi, \boldsymbol{\xi}) = \begin{cases} \pi + (1-\pi)\xi_j & \text{where } i = j \\ (1-\pi)\xi_j & \text{otherwise} \end{cases}. \quad (2)$$

This addresses the case where spammers choose the dominant label but does not explicitly model different error rates in each class. For example, if an annotator is better at detecting type 'x' spans than type 'y', or if they frequently miss the first token in a span, thereby labelling the start of a span as 'O' when the true label is 'B-x', this would not be explicitly modelled by *spam*.

Confusion vector (CV): this approach learns a separate accuracy for each class label (Nguyen et al., 2017) using parameter vector, $\boldsymbol{\pi}$, of size J:

$$A = p(c_\tau = i | t_\tau = j, \boldsymbol{\pi}) = \begin{cases} \pi_j & \text{where } i = j \\ \frac{1-\pi_j}{J-1} & \text{otherwise} \end{cases}. \quad (3)$$

This model does not capture spamming patterns where one of the incorrect labels has a much higher likelihood than the others.

Confusion matrix (CM) (Dawid and Skene, 1979): this model can be seen as an expansion of the confusion vector so that $\boldsymbol{\pi}$ becomes a $J \times J$ matrix with values given by:

$$A = p(c_\tau = i | t_\tau = j, \boldsymbol{\pi}) = \pi_{j,i}. \quad (4)$$

This requires a larger number of parameters, J^2, compared to the $J + 1$ parameters of MACE or J parameters of the confusion vector. Like *spam*, *CM* can model spammers who frequently chose one label regardless of the ground truth, but also models different error rates and biases for each class. However, *CM* ignores dependencies between annotations in a sequence, such as the fact that an 'I' cannot immediately follow an 'O'.

Sequential Confusion Matrix (seq): we introduce a new extension to the confusion matrix to model the dependency of each label in a sequence on its predecessor, giving the following likelihood:

$$A = p(c_\tau = i | c_{\tau-1} = \iota, t_\tau = j, \boldsymbol{\pi}) = \pi_{j,\iota,i}, \quad (5)$$

where $\boldsymbol{\pi}$ is now three-dimensional with size $J \times J \times J$. In the case of disallowed transitions, e.g. from $c_{\tau-1}$ ='O' to c_τ ='I', the value $\pi_{j,c_{\tau-1},c_\tau} \approx 0$, $\forall j$ is fixed *a priori*. The sequential model can capture phenomena such as a tendency toward overly long sequences, by learning that I is more likely to follow another I, so that $\pi_{O,I,I} > \pi_{O,I,O}$. A tendency to split spans by inserting 'B' in place of 'I' can be modelled by increasing the value of $\pi_{I,I,B}$ without affecting $\pi_{I,B,B}$ and $\pi_{I,O,B}$.

The annotator models presented in this section include the most widespread models for NLP annotation tasks, and can be seen as extensions of one another. The choice of annotator model for a particular annotator depends on the developer's understanding of the annotation task: if the annotations have sequential dependencies, this suggests the *seq* model; for non-sequential classifications *CM* may be effective with small (≤ 5) numbers of classes; *spam* may be more suitable if there are many classes, as the number of parameters to learn is low. However, there is also a trade-off between the expressiveness of the model and the number of parameters that must be learned. Simpler models with fewer parameters may be effective if there are only small numbers of annotations from each annotator. The next section shows how these annotator models can be used as components of a complete model for aggregating sequential annotations.

4 A Generative Model for Bayesian Sequence Combination

To construct a generative model for *Bayesian sequence combination (BSC)*, we first define a hidden Markov model (HMM) with states $t_{n,\tau}$ and observations $x_{n,\tau}$ using categorical distributions:

$$t_{n,\tau} \sim \text{Cat}(\boldsymbol{T}_{t_{n,\tau-1}}), \quad (6)$$

$$x_{n,\tau} \sim \text{Cat}(\boldsymbol{\rho}_{t_{n,\tau}}), \quad (7)$$

where $\boldsymbol{T}_j$ is a row of a transition matrix $\boldsymbol{T}$, and $\boldsymbol{\rho}_j$ is a vector of observation likelihoods for state j. For text tagging, n indicates a document and τ a token index, while each state $t_{n,\tau}$ is a true sequence label and $x_{n,\tau}$ is a token. To provide a Bayesian treatment, we assume that $\boldsymbol{T}_j$ and $\boldsymbol{\rho}_j$ have Dirichlet distribution priors as follows:

$$T_j \sim \text{Dir}(\boldsymbol{\gamma}_j), \qquad \boldsymbol{\rho}_j \sim \text{Dir}(\boldsymbol{\kappa}_j), \quad (8)$$

where $\boldsymbol{\gamma}_j$ and $\boldsymbol{\kappa}_j$ are hyperparameters.

Next, we assume one of the annotator models described in Section 3 for each of K annotators. Selecting an annotator model is a design choice, and all can be coupled with the Bayesian HMM above to form a complete BSC model. In

our experiments in Section 6, we compare different choices of annotator model as components of BSC. All the parameters of these annotator models are probabilities, so to provide a Bayesian treatment, we assume that they have Dirichlet priors. For annotator k's annotator model, we refer to the hyperparameters of its Dirichlet prior as $\boldsymbol{\alpha}^{(k)}$. The annotator model defines a categorical likelihood over each annotation, $\boldsymbol{c}_{n,\tau}^{(k)}$:

$$c_{n,\tau}^{(k)} \sim \text{Cat}([A^{(k)}(t_{n,\tau}, 1, \boldsymbol{c}_{n,\tau-1}^{(k)}), ..., A^{(k)}(t_{n,\tau}, J, \boldsymbol{c}_{n,\tau-1}^{(k)})]). \quad (9)$$

The annotators are assumed to be conditionally independent of one another given the true labels, $\boldsymbol{t}$, which means that their errors are assumed to be uncorrelated. This is a strong assumption when considering that the annotators have to make their decisions based on the same input data. However, in practice, dependencies do not usually cause the most probable label to change (Zhang, 2004), hence the performance of classifier combination methods is only slightly degraded, while avoiding the complexity of modelling dependencies between annotators (Kim and Ghahramani, 2012).

Joint distribution: the complete model can be represented by the joint distribution, given by:

$$p(\boldsymbol{t}, \boldsymbol{A}, \boldsymbol{T}, \boldsymbol{\rho}, \boldsymbol{c}, \boldsymbol{x} | \boldsymbol{\alpha}^{(1)}, ..., \boldsymbol{\alpha}^{(K)}, \boldsymbol{\gamma}, \boldsymbol{\kappa}) \quad (10)$$

$$= \prod_{k=1}^{K} \left\{ p(A^{(k)}|\boldsymbol{\alpha}^{(k)}) \prod_{n=1}^{N} p(\boldsymbol{c}_n^{(k)}|A^{(k)}, \boldsymbol{t}) \right\}$$

$$\prod_{n=1}^{N} \prod_{\tau=1}^{L_n} p(t_{n,\tau}|\boldsymbol{T}_{t_{n,\tau-1}}) p(x_{n,\tau}|t_{n,\tau}, \boldsymbol{\rho}_{t_{n,\tau}})$$

$$\prod_{j=1}^{J} p(\boldsymbol{T}_j|\boldsymbol{\gamma}_j) p(\boldsymbol{\rho}_j|\boldsymbol{\kappa}_j) \quad (11)$$

where $\boldsymbol{c}$ is the set of annotations for all documents from all annotators, $\boldsymbol{t}$ is the set of all sequence labels for all documents, N is the number of documents, L_n is the length of the nth document, J is the number of classes, $\boldsymbol{x}$ is the set of all word sequences for all documents and $\boldsymbol{\rho}$, $\boldsymbol{\gamma}$ and $\boldsymbol{\kappa}$ are the sets of parameters for all label classes.

5 Inference using Variational Bayes

Given a set of annotations, $\boldsymbol{c}$, we obtain a posterior distribution over sequence labels, $\boldsymbol{t}$, using *variational Bayes* (*VB*) (Attias, 2000). Unlike maximum likelihood methods such as standard expectation maximization (EM), VB considers prior distributions and accounts for parameter uncertainty due to noisy or sparse data. In comparison to other Bayesian approaches such as Markov chain Monte Carlo (MCMC), VB is often faster, readily allows incremental learning, and provides easier ways to determine convergence (Bishop, 2006). It has been successfully applied to a wide range of methods, including being used as the standard learning procedure for LDA (Blei et al., 2003), and to combining non-sequential crowdsourced classifications (Simpson et al., 2013).

The trade-off is that we must approximate the posterior distribution with an approximation that factorises between subsets of latent variables:

$$p(\boldsymbol{t}, \boldsymbol{A}, \boldsymbol{T}, \boldsymbol{\rho} | \boldsymbol{c}, \boldsymbol{x}, \boldsymbol{\alpha}, \boldsymbol{\gamma}, \boldsymbol{\kappa})$$

$$\approx \prod_{k=1}^{K} q(A^{(k)}) \prod_{j=1}^{J} \{q(\boldsymbol{T}_j) q(\boldsymbol{\rho}_j)\} \prod_{n=1}^{N} q(\boldsymbol{t}_n). \quad (12)$$

VB performs approximate inference by updating each variational factor, $q(z)$, in turn, optimising the approximate posterior distribution until it converges. Details of the theory are beyond the scope of this paper, but are explained by Bishop (2006). The VB algorithm is described in Algorithm 1, making use of update equations for the variational factors given below.

Input: Annotations $\boldsymbol{c}$, tokens $\boldsymbol{x}$

Compute initial values of $\mathbb{E} \ln A^{(k)}, \forall k$, $\mathbb{E} \ln \rho_j, \forall j$, $\mathbb{E} \ln \boldsymbol{T}_j, \forall j$ from their prior distributions.

while not_converged$(r_{n,\tau,j}, \forall n, \forall \tau, \forall j)$ **do**

  Update $r_{j,n,\tau}$, $s_{t_{j,n,\tau-1}, t_{\iota,n,\tau}}, \forall j, \forall \tau, \forall n, \forall \iota$, using forward-backward algorithm given $\boldsymbol{x}$, $\boldsymbol{c}$, $\mathbb{E} \ln \boldsymbol{T}_j, \forall j$, $\mathbb{E} \ln \boldsymbol{\rho}_j, \forall j$, $\mathbb{E} \ln \boldsymbol{A}^{(k)}, \forall k$.

  Update $\mathbb{E} \ln A^{(k)}, \forall k$, given $\boldsymbol{c}$, $r_{j,n,\tau}$.

  Update $\mathbb{E} \ln T_{j,\iota}, \forall j, \forall \iota$, given $s_{t_{j,n,\tau-1}, t_{\iota,n,\tau}}$.

  Update $\mathbb{E} \ln \rho_j, \forall j$ given $\boldsymbol{x}$, $r_{j,n,\tau}$.

end

Output: Label posteriors, $r_{n,\tau,j}, \forall n, \forall \tau, \forall j$, most probable sequence of labels, $\hat{\boldsymbol{t}}_n, \forall n$ using Viterbi algorithm

Algorithm 1: The VB algorithm for BSC.

We compute the posterior probability of each true token label, $r_{n,\tau,j} = \mathbb{E}[p(t_{n,\tau} = j|\boldsymbol{c})]$, and

of each label transition, $s_{n,\tau,j,\iota} = \mathbb{E}[p(t_{n,\tau-1} = j, t_{n,\tau} = \iota|\boldsymbol{c})]$, using the forward-backward algorithm (Ghahramani, 2001). In the forward pass, we compute:

$$\ln r^{-}_{n,\tau,j} = \ln \sum_{\iota=1}^{J} \left\{ r^{-}_{n,\tau-1,\iota} \mathrm{e}^{\mathbb{E}\ln T_{\iota,j}} \right\} + ll_{n,\tau}(j),$$

$$ll_{n,\tau}(j) = \sum_{k=1}^{K} \mathbb{E}\ln A^{(k)}\left(j, c^{(k)}_{n,\tau}, c^{(k)}_{n,\tau-1}\right) \mathbb{E}\ln \rho_{j,x_{n,\tau}}, \tag{13}$$

and in the backward pass we compute:

$$\ln \lambda_{n,\tau,j} = \ln \sum_{\iota=1}^{J} \exp\big\{ \ln \lambda_{i,\tau+1,\iota} + \mathbb{E}\ln T_{j,\iota} + ll_{n,\tau+1}(\iota) \big\}. \tag{14}$$

Then we can calculate the posteriors as follows:

$$r_{n,\tau,j} \propto r^{-}_{n,\tau,j} \lambda_{n,\tau,j}, \tag{15}$$

$$s_{n,\tau,j,\iota} \propto r^{-}_{n,\tau-1,j} \lambda_{n,\tau,\iota} \exp\{\mathbb{E}\ln T_{j,\iota} + ll_{n,\tau}(\iota)\}. \tag{16}$$

The expectations of $\ln \boldsymbol{T}$ and $\ln \boldsymbol{\rho}$ can be computed using standard equations for a Dirichlet distribution:

$$\mathbb{E}\ln T_{j,\iota} = \Psi(N_{j,\iota} + \gamma_{j,\iota}) - \Psi\left(\sum_{i=1}^{J} (N_{j,i} + \gamma_{j,i})\right), \tag{17}$$

$$\mathbb{E}\ln \rho_{j} = \Psi(o_{j,w} + \kappa_{j,w}) - \Psi\left(\sum_{v=1}^{J} (o_{j,v} + \kappa_{j,v})\right), \tag{18}$$

where Ψ is the digamma function, $N_{j,\iota} = \sum_{n=1}^{N}\sum_{\tau=1}^{L_n} s_{n,\tau,j,\iota}$ is the expected number of times that label ι follows label j, and $o_{j,w}$ is the expected number of times that word w occurs with sequence label j. Similarly, for the *seq* annotator model, the expectation terms are:

$$\mathbb{E}\ln A^{(k)}(j,l,m) = \Psi\left(N^{(k)}_{j,l,m}\right) - \Psi\left(\sum_{m'=1}^{J}\left(N^{(k)}_{j,l,m'}\right)\right). \tag{19}$$

$$N^{(k)}_{j,l,m} = \alpha^{(k)}_{j,l,m} + \sum_{n=1}^{N}\sum_{\tau=1}^{L_n} r_{n,\tau,j}\delta_{l,c^{(k)}_{n,\tau-1}}\delta_{m,c^{(k)}_{n,\tau}}, \tag{20}$$

where δ is the Kronecker delta. For other annotator models, this equation is simplified as the values of the previous labels $c^{(k)}_{n,\tau-1}$ are ignored.

5.1 Most Likely Sequence Labels

The approximate posterior probabilities of the true labels, $r_{j,n,\tau}$, provide confidence estimates for the labels. However, it is often useful to compute the most probable sequence of labels, $\hat{\boldsymbol{t}}_n$, using the Viterbi algorithm (Viterbi, 1967). The most probable sequence is particularly useful because, unlike $r_{j,n,\tau}$, the sequence will be consistent with any transition constraints imposed by the priors on the transition matrix $\boldsymbol{T}$, such as preventing 'O'→'I' transitions by assigning them zero probability.

6 Experiments

Datasets. We compare BSC to alternative methods on three NLP datasets containing both crowdsourced and gold sequential annotations. *NER*, the CoNLL 2003 named-entity recognition dataset (Tjong Kim Sang and De Meulder, 2003), which contains gold labels for four named entity categories (PER, LOC, ORG, MISC), with crowdsourced labels provided by (Rodrigues et al., 2014). *PICO* (Nguyen et al., 2017), consists of medical paper abstracts that have been annotated by a crowd to indicate text spans that identify the population enrolled in a clinical trial. *ARG* (Trautmann et al., 2019) contains a mixture of argumentative and non-argumentative sentences, in which the task is to mark the spans that contain pro or con arguments for a given topic. Dataset statistics are shown in Table 1. The datasets differ in typical span length, with argument components in ARG the longest, while named entities in NER spans are often only one token long.

The gold-labelled documents are split into validation and test sets. For NER, we use the split given by Nguyen et al. (2017), while for PICO and ARG, we make random splits since the splits from previous work were not available[2].

Evaluation metrics. For NER and ARG we use the CoNLL 2003 F1-score, which considers only

[2]The data splits are available from our Github repository. Since we use different splits, our results for PICO are not identical to Nguyen et al. (2017).

Table 2: Aggregating crowdsourced labels: estimating true labels for documents labelled by the crowd.

exact span matches to be correct. Incomplete named entities are typically not useful, and for ARG, it is desirable to identify complete argumentative units that make sense on their own. For medical trial populations, partial matches still contain useful information, so for PICO we use a relaxed F1-score, as in Nguyen et al. (2017), which counts the matching fractions of spans when computing precision and recall.

We also compute the cross entropy error (*CEE*, also known as log-loss). While this is a token-level rather than span-level metric, it evaluates the quality of the probability estimates produced by aggregation methods, which are useful for tasks such as active learning, as it penalises over-confident mistakes more heavily.

Evaluated Methods. We evaluate BSC in combination with all of the annotator models described in Section 4. As well-established non-sequential baselines, we include token-level majority voting (*MV*), *MACE* (Hovy et al., 2013) which uses the *spam* annotator model, Dawid-Skene (*DS*) (Dawid and Skene, 1979), which uses the *CM* annotator model, and independent Bayesian classifier combination (*IBCC*) (Kim and Ghahramani, 2012), which is a Bayesian treatment of Dawid-Skene. We also compare against the state-of-the-art sequential *HMM-crowd* method (Nguyen et al., 2017), which uses a combination of maximum *a posteriori* (or smoothed maximum likelihood) estimates for the *CV* annotator model and variational inference for an integrated hidden Markov model (HMM). HMM-Crowd and DS use non-Bayesian inference steps and can be compared with their Bayesian variants, BSC-CV and IBCC, respectively.

Besides the annotator models, BSC also makes use of text features and a transition matrix, $\boldsymbol{T}$, over true labels. We test the effect of these components by running BSC-CM and BSC-seq with no text features (*notext*), and without the transition matrix, which is replaced by simple independent class probabilities (labelled $\backslash \boldsymbol{T}$).

We tune the hyperparameters using grid search on the development sets. To limit the number of hyperparameters to tune, we optimize only three values for BSC: hyperparameters of the transition matrix, $\boldsymbol{\gamma}_j$, are set to the same value, γ_0, except for disallowed transitions, (O→I and transitions between types, e.g. I-PER→I-ORG), which are set to $1e-6$; for the annotator models, all values are set to α_0, except for disallowed transitions, which are set to $1e^{-6}$, then ϵ_0 is added to hyperparameters corresponding to correct annotations (e.g. diagonal entries in a confusion matrix). This encodes the prior assumption that annotators are more likely to have an accuracy greater than random, which avoids the non-identifiability problem in which the class labels are switched around.

Aggregation Results. This task is to combine multiple crowdsourced labels and predict the true labels. The results are shown in Table 2. BSC-seq outperforms the other approaches, including the previous state of the art, HMM-crowd (sig-

Table 3: Counts of different types of span errors.

nificant on all datasets with $p \ll .01$ using a two-tailed Wilcoxon signed-rank test). Without the text model (BSC-seq-notext) or the transition matrix (BSC-seq$\backslash \boldsymbol{T}$), BSC-seq performance decreases heavily, while BSC-CM-notext and BSC-CM$\backslash \boldsymbol{T}$ in some cases outperform BSC-CM. This suggests that *seq*, with its greater number of parameters to learn, is most effective in combination with the transition matrix and simple text model. On the ARG dataset, the scores are close to zero for BSC-seq$\backslash \boldsymbol{T}$. Further investigation shows that this is because BSC-seq$\backslash \boldsymbol{T}$ identifies many spans with one or two incorrect labels. Since we use exact span matches to compute true and false positives, these small errors reduce the scores substantially. In particular, we find a large number of missing B tags at the start of spans and misplaced O tags that split spans in the middle.

The performance of all methods across the three datasets varies greatly. With NER, the spans are short and the task is less subjective than PICO or ARG, hence its higher F1 scores. PICO uses a relaxed F1 score, meaning its scores are only slightly lower despite being a more ambiguous task. The constitution of an argument is also ambiguous, so ARG scores are lower, particularly as we use strict span-matching to compute the F1 scores. Raising the scores may be possible in future by using expert labels as training data, i.e. as known values of $\boldsymbol{t}$, which would help to put more weight on annotators with similar labelling patterns to the experts.

We categorise the errors made by key methods and list the counts for each category in Table 3. All machine learning methods tested here reduce the number of spans that were completely missed by majority voting. Note that BSC completely removes all "invalid" spans (O→I transitions) due to the sequential model with prior hyperparameters set to zero for those transitions. For PICO and ARG, which contain longer spans, BSC-seq has lower "length error" than other methods, which is the mean difference in number of tokens between the predicted and gold spans. It also reduces the number of missing spans, although in NER and ARG that comes at the cost of producing more false positives (predicting spans where there are none). Overall, BSC-seq appears to be the best choice for identifying exact span matches and reducing missed spans.

Visualising Annotator Models. To determine whether, in practice, BSC-seq really learns distinctive confusion matrices depending on the previous labels, we plot the learned annotator models for PICO as probabilistic confusion matrices in Figure 1 (for an alternative visualisation, see Figure 3 in the appendix). We clustered the confusion matrices into five groups by applying K-means to their posterior expected values, then plotted the means for each cluster. Each column in the figure shows the confusion matrices corresponding to the same cluster of annotators. In all clusters, BSC-seq learns different confusion matrices depending on the previous label. There are also large varia-

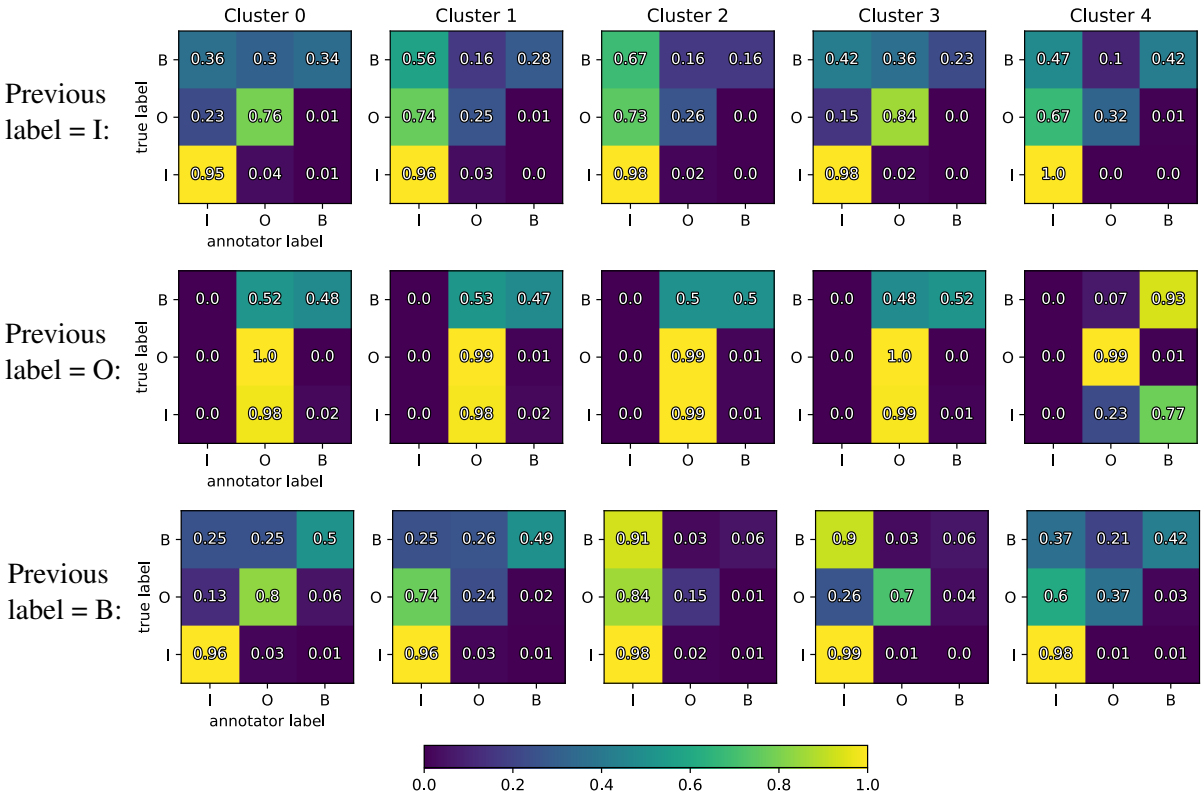

Figure 1: Clusters of annotators in the PICO dataset. Each column shows the mean of the confusion matrices in the *seq* annotator model for the members of one cluster, as inferred by BSC-seq. Each row corresponds to the mean confusion matrices conditioned on the annotator's previous label. The confusion matrices are plotted as heatmaps, where colours indicate the probabilities, which are also given by the numbers in each square.

tions between the clusters. The third column, for example, shows annotators with a tendency toward B→I transitions regardless of the true label, while other clusters indicate very different labelling behaviour. The model therefore appears able to learn distinct confusion matrices for different workers given previous labels, which supports the use of sequential annotator models.

Active Learning. Active learning is an iterative process that can reduce the amount of labelled data required to train a model. At each iteration, the active learning strategy selects informative data points, obtains their labels, then re-trains a labelling model given the new labels. The updated model is then used in the next iteration to identify the most informative data points.

We simulate active learning in a crowdsourcing scenario where the goal is to learn the true labels, $\boldsymbol{t}$, by selecting documents for the crowd to label. Each document can be labelled multiple times by different workers. In contrast, in a passive learning setup, the number of annotations per document is usually constant across all documents. For example, in the PICO dataset, each document was labelled six times. The aim of active learning is to decrease the number of annotations required by avoiding relabelling documents whose true labels can be determined with high confidence from fewer labels.

We simulate active learning using the *least confidence* strategy, shown to be effective by Settles and Craven (2008), as described in Algorithm 2. At each iteration, we estimate $\boldsymbol{t}$ from the current set of crowdsourced labels, $\boldsymbol{c}$, using one of the methods from our previous experiments as the labelling model, then use this model to determine the least confident $batch_size$ documents to be labelled by the crowd. If the simulation has requested all the labels for a document that are available in our dataset, this document is simply ignored when choosing new batches and is not selected again.

We hypothesise that BSC will learn more quickly than non-sequential and non-Bayesian methods in the active learning simulation. Bayesian methods such as BSC account for

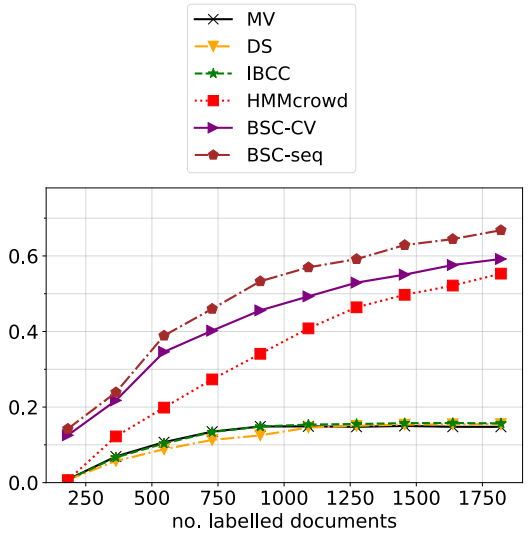

Figure 2: F1 scores for active learning simulations on NER using least-confidence uncertainty sampling.

uncertainty in the model parameters when estimating confidence, hence can be used to choose data points that rapidly improve the model itself. Sequential models such as BSC can also account for dependencies between sequence labels when estimating confidence.

Input: A random $initial_set$ of training labels, the same for all methods.

Set training set $\boldsymbol{c} = initial_set$

while *training set size* $< max_no_labels$ **do**

  Train model on $\boldsymbol{c}$

  For each document n, compute $LC_n = 1 - p(\boldsymbol{t}_n^*|\boldsymbol{c})$, where $\boldsymbol{t}_n^*$ is the probability of the most likely sequence of labels for n.

  Obtain annotations for $batch_size$ documents with the highest values of LC (least confidence), and add them to $\boldsymbol{c}$

end

Algorithm 2: Active learning simulation using least-confidence sampling.

Figure 2 plots the mean F1 scores over ten repeats of the active learning simulation on the NER dataset (for clarity, we only plot key methods). When the number of iterations is very small, neither IBCC nor DS are able to outperform majority vote, and only produce a very small benefit as the number of labels grows. This highlights the need for a sequential model such as BSC or HMM-crowd for effective active learning with small numbers of labels. IBCC learns slightly quicker than DS, while BSC-CV clearly outperforms HMM-crowd: we believe this difference is due to the Bayesian treatment of IBCC and BSC, which means they are better able to estimate confidence than DS and HMM-crowd, which use maximum likelihood and maximum a posteriori inference. BSC-seq produces the best overall performance, and the gap grows as the number of labels increases, since more data is required to learn the more complex annotator model.

7 Conclusions

We proposed BSC, a novel Bayesian approach to aggregating sequence labels that can be combined with several different models of annotator noise and bias. To model the effect of dependencies between labels on annotator noise and bias, we introduced the *seq* annotator model. Our results demonstrated the benefits of BSC over established non-sequential methods, such as MACE, Dawid-Skene (DS), and IBCC. We also showed the advantages of a Bayesian approach for active learning, and that the combination of *BSC* with the *seq* annotator model improves the state-of-the-art over HMM-crowd on three NLP tasks with different types of span annotations.

In future work, we plan to adapt active learning methods for easy deployment on crowdsourcing platforms, and to investigate techniques for automatically selecting good hyperparameters without recourse to a development set, which is often unavailable at the start of a crowdsourcing process.

A Discussion of Variational Approximation

In Equation 12, each subset of latent variables has a variational factor of the form $\ln q(z) = \mathbb{E}[\ln p(z|\boldsymbol{c}, \neg z)]$, where $\neg z$ contains all the other latent variables excluding z. We perform approximate inference by using coordinate ascent to update each variational factor, $q(z)$, in turn, taking expectations with respect to the current estimates of the other variational factors. Each iteration reduces the KL-divergence between the true and approximate posteriors of Equation 12, and hence optimises a lower bound on the log marginal likelihood, also called the evidence lower bound or ELBO (Bishop, 2006; Attias, 2000).

Conjugate distributions: The prior distributions chosen for our generative model are conjugate to the distributions over the latent variables and model parameters, meaning that each $q(z)$ is the same type of distribution as the corresponding prior distribution defined in Section 4. The parameters of each variational distribution are computed in terms of expectations over the other subsets of variables.

B Update Equations for the Forward-Backward Algorithm

For the true labels, $\boldsymbol{t}$, the variational factor is:

$$\ln q(\boldsymbol{t}_n) = \sum_{n=1}^{N}\sum_{\tau=1}^{L_n}\sum_{k=1}^{K} \mathbb{E}\ln A^{(k)}\Big(t_{n,\tau}, c_{n,\tau}^{(k)}, c_{n,\tau-1}^{(k)}\Big) + \mathbb{E}\ln T_{t_{n,\tau-1},t_{n,\tau}} + \text{const.} \tag{21}$$

The forward-backward algorithm consists of two passes. The *forward pass* for each document, n, starts from $\tau = 1$ and computes:

$$\ln r^{-}_{n,\tau,j} = \ln \sum_{\iota=1}^{J}\left\{ r^{-}_{n,\tau-1,\iota} \mathrm{e}^{\mathbb{E}\ln T_{\iota,j}} \right\} + ll_{n,\tau}(j),$$

$$ll_{n,\tau}(j) = \sum_{k=1}^{K} \mathbb{E}\ln A^{(k)}\left(j, c_{n,\tau}^{(k)}, c_{n,\tau-1}^{(k)}\right) \tag{22}$$

where $r^{-}_{n,0,\iota} = 1$ where $\iota =$'O' and 0 otherwise. The *backwards pass* starts from $\tau = L_n$ and scrolls backwards, computing:

$$\ln \lambda_{n,L_n,j} = 0, \qquad \ln \lambda_{n,\tau,j} = \ln \sum_{\iota=1}^{J} \exp\big\{ \ln \lambda_{i,\tau+1,\iota} + \mathbb{E}\ln T_{j,\iota} + ll_{n,\tau+1}(\iota)\big\}. \tag{23}$$

By applying Bayes' rule, we arrive at $r_{n,\tau,j}$ and $s_{n,\tau,j,\iota}$:

$$r_{n,\tau,j} = \frac{r^{-}_{n,\tau,j}\lambda_{n,\tau,j}}{\sum_{j'=1}^{J} r^{-}_{n,\tau,j'}\lambda_{n,\tau,j'}} \tag{24}$$

$$s_{n,\tau,j,\iota} = \frac{\tilde{s}_{n,\tau,j,\iota}}{\sum_{j'=1}^{J}\sum_{\iota'=1}^{J}\tilde{s}_{n,\tau,j',\iota'}} \tag{25}$$

$$\tilde{s}_{n,\tau,j,\iota} = r^{-}_{n,\tau-1,j}\lambda_{n,\tau,\iota}\exp\{\mathbb{E}\ln T_{j,\iota} + ll_{n,\tau}(\iota)\}.$$

Each row of the transition matrix has the factor:

$$\ln q(\boldsymbol{T}_j) = \ln \mathrm{Dir}\left([N_{j,\iota} + \gamma_{j,\iota}, \forall \iota \in \{1,..,J\}]\right), \tag{26}$$

where $N_{j,\iota} = \sum_{n=1}^{N}\sum_{\tau=1}^{L_n} s_{n,\tau,j,\iota}$ is the expected number of times that label ι follows label j. The forward-backward algorithm requires expectations of $\ln \boldsymbol{T}$ that can be computed using standard equations for a Dirichlet distribution:

$$\mathbb{E}\ln T_{j,\iota} = \Psi(N_{j,\iota} + \gamma_{j,\iota}) - \Psi\left(\sum_{\iota=1}^{J}(N_{j,\iota} + \gamma_{j,\iota})\right), \tag{27}$$

where Ψ is the digamma function.

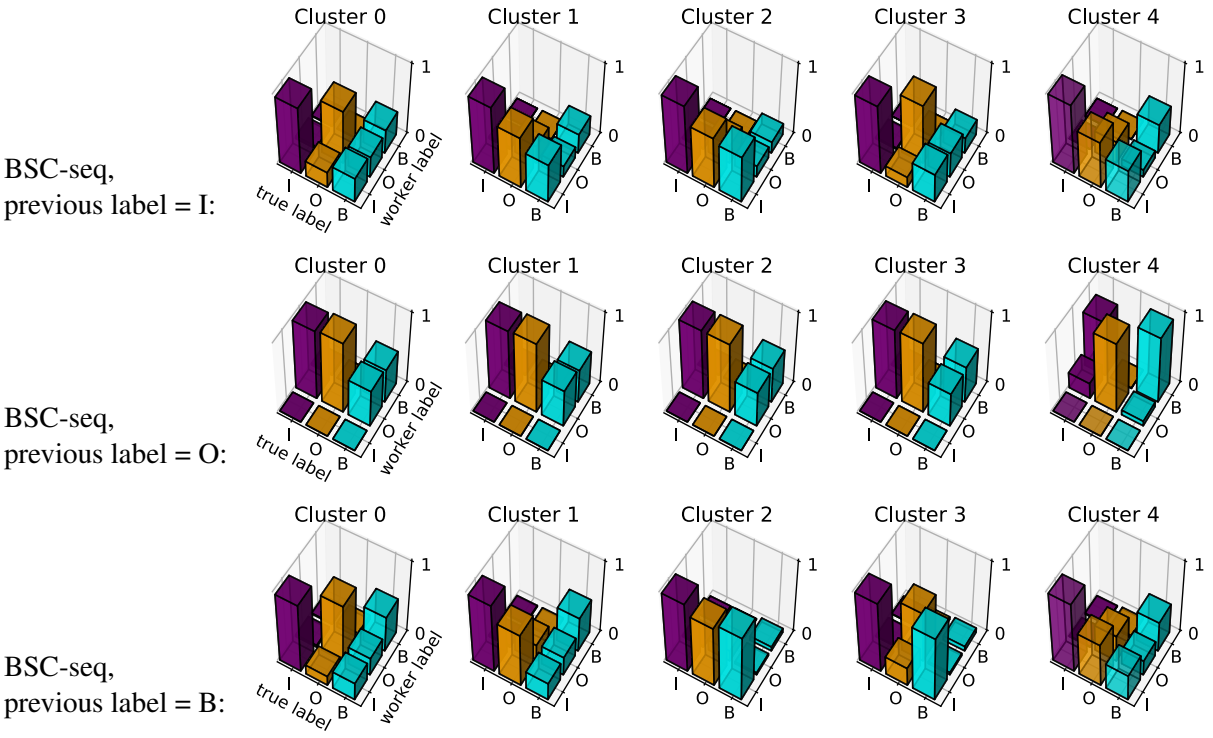

Figure 3: Clusters of annotators in PICO represented by the mean confusion matrices from BSC-seq. Heights of bars indicate likelihood of a worker (or annotator) label given the true label.

The variational factor for each annotator model is a distribution over its parameters, which differs between models. For *seq*, the variational factor is:

$$\ln q\left(A^{(k)}\right) = \sum_{j=1}^{J}\sum_{l=1}^{J} \mathrm{Dir}\left(\left[\boldsymbol{N}_{j,l,m}^{(k)} \forall m \in \{1,..,J\}\right]\right)$$

$$N_{j,l,m}^{(k)} = \alpha_{j,l,m}^{(k)} + \sum_{n=1}^{N}\sum_{\tau=1}^{L_n} r_{n,\tau,j}\,\delta_{l,c_{n,\tau-1}^{(k)}}\,\delta_{m,c_{n,\tau}^{(k)}}, \quad (28)$$

where δ is the Kronecker delta. For *CM*, *MACE*, *CV* and *acc*, the factors follow a similar pattern of summing pseudo-counts of correct and incorrect answers.

C Visualising Annotator Models

Figure 3 provides an alternative visualisation of the *seq* models inferred by BSC-seq for annotators in the PICO dataset. The annotators were clustered as described in Section 6 of the main paper, and the mean confusion matrices for each cluster are plotted in Figure 3 using 3D plots to emphasise the differences between the likelihoods of annotators in each cluster providing a particular label given the true label value.

A systematic comparison of methods for low-resource dependency parsing on genuinely low-resource languages

Clara Vania[1] **Yova Kementchedjhieva**[2] **Anders Søgaard**[2] **Adam Lopez**[1]

Abstract

Parsers are available for only a handful of the world's languages, since they require lots of training data. How far can we get with just a small amount of training data? We systematically compare a set of simple strategies for improving low-resource parsers: data augmentation, which has not been tested before; cross-lingual training; and transliteration. Experimenting on three typologically diverse low-resource languages—North Sámi, Galician, and Kazah—We find that (1) when only the low-resource treebank is available, data augmentation is very helpful; (2) when a related high-resource treebank is available, cross-lingual training is helpful and complements data augmentation; and (3) when the high-resource treebank uses a different writing system, transliteration into a shared orthographic spaces is also very helpful.

1 Introduction

Large annotated treebanks are available for only a tiny fraction of the world's languages, and there is a wealth of literature on strategies for parsing with few resources (Hwa et al., 2005; Zeman and Resnik, 2008; McDonald et al., 2011; Søgaard, 2011). A popular approach is to train a parser on a related high-resource language and adapt it to the low-resource language. This approach benefits from the availability of Universal Dependencies (UD; Nivre et al., 2016), prompting substantial research (Tiedemann and Agic, 2016; Agić, 2017; Rosa and Mareček, 2018), along with the VarDial and the CoNLL UD shared tasks (Zampieri et al., 2017; Zeman et al., 2017, 2018).

But low-resource parsing is still difficult. The organizers of the CoNLL 2018 UD shared task (Zeman et al., 2018) report that, in general, results on the task's nine low-resource treebanks "are extremely low and the outputs are hardly useful for downstream applications." So if we want to build a parser in a language with few resources, what can we do? To answer this question, we systematically compare several practical strategies for low-resource parsing, asking:

1. What can we do with only a very small *target* treebank for a low-resource language?
2. What can we do if we also have a *source* treebank for a related high-resource language?
3. What if the source and target treebanks do not share a writing system?

Each of these scenarios requires different approaches. **Data augmentation** is applicable in all scenarios, and has proven useful for low-resource NLP in general (Fadaee et al., 2017; Bergmanis et al., 2017; Sahin and Steedman, 2018). Transfer learning via **cross-lingual training** is applicable in scenarios 2 and 3. Finally, **transliteration** may be useful in scenario 3.

To keep our scenarios as realistic as possible, we assume that no taggers are available since this would entail substantial annotation. Therefore, our neural parsing models must learn to parse from words or characters—that is, they must be **lexicalized**—even though there may be little shared vocabulary between source and target treebanks. While this may intuitively seem to make cross-lingual training difficult, recent results have shown that lexical parameter sharing on characters and words can in fact improve cross-lingual parsing (de Lhoneux et al., 2018); and that in some circumstances, a lexicalized parser can outperform a delexicalized one, even in a low-resource setting (Falenska and Çetinoğlu, 2017).

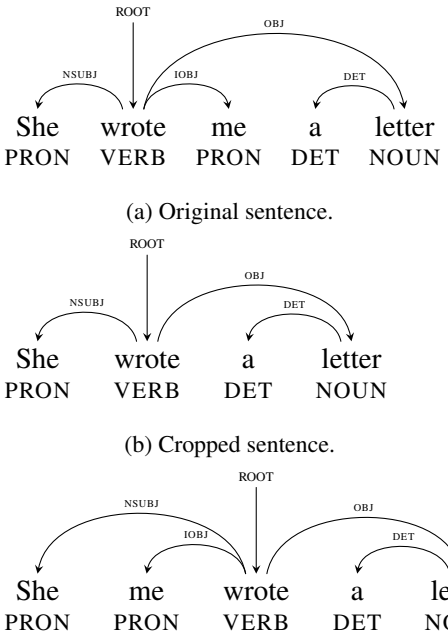
We experiment on three language pairs from different language families, in which the first of each is a genuinely low-resource language: North

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1105–1116,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Sámi and Finnish (Uralic); Galician and Portuguese (Romance); and Kazakh and Turkish (Turkic), which have different writing systems[1]. To avoid optimistic evaluation, we extensively experiment only with North Sámi, which we also analyse to understand *why* our cross-lingual training outperforms the other parsing strategies. We treat Galician and Kazakh as truly held-out, and test only our best methods on these languages. Our results show that:

1. When no source treebank is available, data augmentation is very helpful: dependency tree morphing improves labeled attachment score (LAS) by as much as 9.3%. Our analysis suggests that syntactic rather than lexical variation is most useful for data augmentation.

2. When a source treebank is available, cross-lingual parsing improves LAS up to 16.2%, but data augmentation still helps, by an additional 2.6%. Our analysis suggests that improvements from cross-lingual parsing occur because the parser learns syntactic regularities about word order, since it does not have access to POS and has little reusable information about word forms.



3. If source and target treebanks have different writing systems, transliterating them to a common orthography is very effective.

2 Methods

We describe three techniques for improving low-resource parsing: (1) two data augmentation methods which have not been applied before for dependency parsing, (2) cross-lingual training, and (3) transliteration.

2.1 Data augmentation by dependency tree morphing (Morph)

Sahin and Steedman (2018) introduce two operations to augment a dataset for low-resource POS tagging. Their method assumes access to a dependency tree, but they do not test it for dependency parsing, which we do here for the first time. The first operation, *cropping*, removes some parts of a sentence to create a smaller or simpler, meaningful

(a) Original sentence.

(b) Cropped sentence.

(c) Rotated sentence.

Figure 1: Examples of dependency tree morphing operations on the sentence "She wrote me a letter".

sentence. The second operation, *rotation*, keeps all the words in the sentence but re-orders subtrees attached to the *root* verb, in particular those attached by NSUBJ (nominal subject), OBJ (direct object), IOBJ (indirect object), or OBL (oblique nominal) dependencies. Figure 1 illustrates both operations.

It is important to note that while both operations change the set of words or the word order, they do not change the dependencies. The sentences themselves may be awkward or ill-formed, but the corresponding analyses are still likely to be correct, and thus beneficial for learning. This is because they provide the model with more examples of variations in argument structure (cropping) and in constituent order (rotation), which may benefit languages with flexible word order and rich morphology. Some of our low-resource languages have these properties—while North Sámi has a fixed word order (SVO), Galician and Kazakh have relatively free word order. All three languages use case marking on nouns, so word order may not be as important for correct attachment.

Both rotation and cropping can produce many trees. We use the default parameters given in (Sahin and Steedman, 2018).

[1]We select high-resource language based on language family, since it is the most straightforward way to define language relatedness. However, other measurement (e.g., WALS (Dryer and Haspelmath, 2013) properties) might be used.

2.2 Data augmentation by nonce sentence generation (Nonce)

Our next data augmentation method is adapted from Gulordava et al. (2018). The main idea is to create *nonce* sentences by replacing some of the words which have the same syntactic annotations. For each training sentence, we replace each content word—nouns, verbs, or adjective—with an alternative word having the same universal POS, morphological features, and dependency label.[2] Specifically, for each content word, we first stochastically choose whether to replace it; then, if we have chosen to replace it, we uniformly sample the replacement word type meeting the corresponding constraints. For instance, given a sentence "*He borrowed a book from the library.*", we can generate the following sentences:

(1) a. He bought a book from the shop .

b. He wore a umbrella from the library .

This generation method is only based on syntactic features (i.e., morphology and dependency labels), so it sometimes produces nonsensical sentences like 1b. But since we only replace words if they have the same morphological features and dependency label, this method preserves the original tree structures in the treebank. Following (Gulordava et al., 2018), we generate five nonce sentences for each original sentence.

2.3 Cross-lingual training

When a source treebank is available, model transfer is a viable option. We perform model transfer by cross-lingual parser training: we first train on both source and target treebanks to produce a single model, and then fine tune the model only on the target treebank. In our preliminary experiments (Appendix A), we found that fine tuning on the target treebank was effective in all settings, so we use it in all applicable experiments reported in this paper.

2.4 Transliteration

Two related languages might not share a writing system even when they belong to the same family. We evaluate whether a simple transliteration would be helpful for cross-lingual training in this case. In our study, the Turkish treebank is written in extended Latin while the Kazakh treebank is written in Cyrillic. This difference potentially makes model transfer less useful, and means we might not be able to leverage lexical similarities between the two languages. We pre-process both treebanks by transliterating them to the same "pivot" alphabet, basic Latin.[3]

The mapping from Turkish is straightforward. Its alphabet consists of 29 letters, 23 of which are in basic Latin. The other six letters, 'ç','ğ', 'ı', 'ö', 'ş', and 'ü', add diacritics to basic Latin characters, facilitating different pronunciations.[4] We map these to their basic Latin counterparts, e.g., 'ç' to 'c'. For Kazakh, we use a simple dictionary created by a Kazakh computational linguist to map each Cyrillic letter to the basic Latin alphabet.[5].

3 Experimental Setup

3.1 Dependency Parsing Model

We use the Uppsala parser, a transition-based neural dependency parser (de Lhoneux et al., 2017a,b; Kiperwasser and Goldberg, 2016). The parser uses an arc-hybrid transition system (Kuhlmann et al., 2011), extended with a static-dynamic oracle and SWAP transition to allow non-projective dependency trees (Nivre, 2009).

Let $w = w_0, \ldots, w_{|w|}$ be an input sentence of length $|w|$ and let w_0 represent an artificial ROOT token. We create a vector representation for each input token w_i by concatenating $(;)$ its word embedding, $\mathbf{e}_w(w_i)$ and its character-based word embedding, $\mathbf{e}_c(w_i)$:

$$\mathbf{x}_i = [\mathbf{e}_w(w_i); \mathbf{e}_c(w_i)] \quad (1)$$

Here, $\mathbf{e}_c(w_i)$ is the output of a *character-level* bidirectional LSTM (biLSTM) encoder run over the characters of w_i (Ling et al., 2015); this makes the model fully open-vocabulary, since it can produce representations for any character sequence. We then obtain a *context-sensitive* encoding $\mathbf{h}_i$ using a *word-level* biLSTM encoder:

$$\mathbf{h}_i = [\text{LSTM}_f(\mathbf{x}_{0:i}); \text{LSTM}_b(\mathbf{x}_{|w|:i})] \quad (2)$$

We then create a configuration by concatenating the encoding of a fixed number of words on the top of the stack and the beginning of the buffer. Given

[2]The dependency label constraint is new to this paper.

[3]Another possible pivot is phonemes (Tsvetkov et al., 2016). We leave this as future work.

[4]https://www.omniglot.com/writing/turkish.htm

[5]The mapping from Kazakh Cyrilic into basic Latin alphabet is provided in Appendix B

Language	Treebank ID	train	dev.	test
Finnish	fi_tdt	14981	1875	1555
North Sámi	sme_giella	1128	1129	865
Portuguese	pt_bosque	8329	560	477
Galician	gl_treegal	300	300	400
Turkish	tr_imst	3685	975	975
Kazakh	kk_ktb	15	16	1047

Table 1: Train/dev split used for each treebank.

this configuration, we predict a transition and its arc label using a multi-layer perceptron (MLP). More details of the core parser can be found in de Lhoneux et al. (2017a,b).

3.2 Parameter sharing

To train cross-lingual models, we use the strategy of de Lhoneux et al. (2018) for parameter sharing, which uses *soft* sharing for word and character parameters, and *hard* sharing for the MLP parameters. Soft parameter sharing uses a language embedding, which, in theory, learns what parameters to share between the two languages. Let $\mathbf{c}_j$ be an embedding of character c_j in a token w_i from the treebank of language k, and let $\mathbf{l}_k$ be the language embedding. For sharing on characters, we concatenate character and language embedding: $[\mathbf{c}_j; \mathbf{l}_k]$ for input to the character-level biLSTM. Similarly, for input to the word-level biLSTM, we concatenate the language embedding to the word embedding, modifying Eq. 1 to

$$\mathbf{x}_i = [\mathbf{e}_w(w_i); \mathbf{e}_c(w_i); \mathbf{l}_k] \quad (3)$$

We use the default hyperparameters of de Lhoneux et al. (2018) in our experiments. We fine-tune each model by training it further only on the target treebank (Shi et al., 2016). We use early stopping based on Label Attachment Score (LAS) on development set.

3.3 Datasets

We use Universal Dependencies (UD) treebanks version 2.2 (Nivre et al., 2018). None of our target treebanks have a development set, so we generate new train/dev splits by 50:50 (Table 1). Having large development sets allow us to perform better analysis for this study.

4 Parsing North Sámi

North Sámi is our largest low-resource treebank, so we use it for a full evaluation and analysis of different strategies before testing on the other languages. To understand the effect of target treebank size, we generate three datasets with different *training* sizes: $\mathcal{T}_{10}$ (~10%), $\mathcal{T}_{50}$ (~50%), and $\mathcal{T}_{100}$ (100%). Table 2 reports the number of training sentences after we augment the data using methods described in Section 2. We apply MORPH and NONCE separately to understand the effect of each method and to control the amount of noise in the augmented data.

	original	+Morph	+Nonce
$\mathcal{T}_{100}$	1128	7636	4934
$\mathcal{T}_{50}$	564	3838	2700
$\mathcal{T}_{10}$	141	854	661

Table 2: Number of North Sámi training sentences.

We employ two baselines: a monolingual model (§3.1) and a cross-lingual model (§2.3), both *without* data augmentation. The monolingual model acts as a simple baseline, to resemble a situation when the target treebank does not have any source treebank (i.e., no available treebanks from related languages). The cross-lingual model serves as a strong baseline, simulating a case when there is a source treebank. We compare both baselines to models trained with MORPH and NONCE augmentation methods. Table 3 reports our results, and we review our motivating scenarios below.

Scenario 1: we only have a very small target treebank. In the monolingual experiments, we observe that both dependency tree morphing (MORPH) and nonce sentence generation (NONCE) improve performance, indicating the strong benefits of data augmentation when there are no other resources available except the target treebank itself. In particular, when the number of training data is the lowest ($\mathcal{T}_{10}$), data augmentations improves performance up to 9.3% LAS.

Scenario 2: a source treebank is available. We see that the cross-lingual training (cross-base) performs better than monolingual models even with augmentation. For the $\mathcal{T}_{10}$ setting, cross-base achieves almost twice as much as the monolingual baseline (mono-base). The benefits of data augmentation are less evident in the cross-lingual setting, but in the $\mathcal{T}_{10}$ scenario, data augmentation still clearly helps. Overall, cross-lingual combined with data augmentation yields the best result.

	MONOLINGUAL			CROSS-LINGUAL		
size	mono-base	+Morph	+Nonce	cross-base	+Morph	+Nonce
$\mathcal{T}_{100}$	53.3	56.0 (+3.3)	56.3 (+3.0)	61.3 (+8.0)	60.9 (+7.6)	**61.7 (+8.4)**
$\mathcal{T}_{50}$	42.5	46.6 (+4.1)	46.5 (+4.0)	52.0 (+9.5)	51.7 (+9.2)	**52.0 (+9.5)**
$\mathcal{T}_{10}$	18.5	27.1 (+8.6)	27.8 (+9.3)	34.7 (+16.2)	**37.3 (+18.8)**	35.4 (+16.9)

Table 3: LAS results on North Sámi development data. *mono-base* and *cross-base* are models without data augmentation. % improvements over *mono-base* shown in parentheses.

4.1 What is learned from Finnish?

Why do cross-lingual training and data augmentation help? To put this question in context, we first consider their relationship. Finnish and North Sámi are mutually unintelligible, but they are typologically similar: of the 49 (mostly syntactic) linguistic features annotated for North Sámi in the Word Atlas of Languages (WALS; Dryer and Haspelmath, 2013), Finnish shares the same values for 42 of them.[6] Despite this and their phylogenetic and geographical relatedness, they share very little vocabulary: only 6.5% of North Sámi tokens appear in Finnish data, and these words are either proper nouns or closed class words such as pronouns or conjunctions. However, both languages do share many character-trigrams (72.5%, token-level), especially on suffixes.

Now we turn to an analysis of the $\mathcal{T}_{10}$ data setting, where we see the largest gains for all methods.

4.2 Analysis of data augmentation

For dependency parsing, POS features are important because they can provide strong signals whether there exists dependency between two words in a given sentence. For example, *subject* and *object* dependencies often occur between a NOUN and a VERB, as can be seen in Fig. 1a. We investigate the extent to which data augmentation is useful for learning POS features, using diagnostic classifiers (Veldhoen et al., 2016; Adi et al., 2016; Shi et al., 2016) to probe our model representations. Our central question is: do the models learn useful representations of POS, despite having no direct access to it? And if so, is this helped by data augmentation?

After training each model, we freeze the parameters and generate *context-dependent* representations (i.e., the output of *word-level* biLSTM, $\mathbf{h}_i$ in Eq. 2), for the training and development data. We then train a feed-forward neural network classifier to predict the POS tag of each word, using only the representation as input. To filter out the effect of cross-lingual training, we only analyze representations trained using the *monolingual* models. Our training and development data consists of 6321 and 7710 tokens, respectively. The percentage of OOV tokens is 40.5%.

POS	%dev	baseline	%diff. with	
			+Morph	+Nonce
INTJ	0.1	0.0	20.0	20.0
PART	1.5	70.1	7.7	0.8
NUM	1.9	19.2	15.1	-4.1
ADP	1.9	15.7	24.5	19.7

AUX	3.2	26.3	27.2	-4.9
CCONJ	3.4	91.3	-0.8	-4.2
PROPN	4.7	5.9	5.9	-5.9
ADJ	6.5	12.7	3.8	0.2
ADV	9.0	42.9	11.8	11.5
PRON	13.4	63.2	5.4	-2.7
VERB	25.7	72.4	-6.2	-4.5
NOUN	26.4	67.0	8.6	13.2

Table 4: Results for the monolingual POS predictions, ordered by the frequency of each tag in the dev split (%dev). %diff shows the difference between each augmentation method and monolingual models.

Table 4 reports the POS prediction accuracy. We observe that representations generated with monolingual MORPH seem to learn better POS, for most of the tags. On the other hand, representations generated with monolingual NONCE sometimes produce lower accuracy on some tags; only on nouns the accuracy is better than monolingual MORPH. We hypothesize that this is because NONCE sometimes generates meaningless sentences which confuse the model. In parsing this effect is less apparent, mainly because monolingual NONCE has the poorest POS representation for infrequent tags (%dev), and better representa-

[6] There are 192 linguistic features in WALS, but only 49 are defined for North Sámi. These features are mostly syntactic, annotated within different areas such as morphology, phonology, nominal and verbal categories, and word order.

North Sámi	Top nearest Finnish words	
	char-level	word-level
borrat (VERB; eat)	*herrat* (NOUN; gentleman) *kerrat* (NOUN; time) *naurat* (VERB; laugh)	*käydä* (VERB; go) *otan* (VERB; take) *sain* (VERB; get)
veahki (NOUN; help)	*nuuhki* (VERB; sniff) *väki* (NOUN; power) *avarsi* (VERB; expand)	*tyhjäksi* (ADJ; empty) *johonki* (PRON; something) *lähtökohdaksi* (NOUN; basis)
divrras (ADJ; expensive)	*harras* (ADJ; devout) *reipas* (ADJ; brave) *sarjaporras* (NOUN; series)	*välttämätöntä* (ADJ; essential) *mahdollista* (ADJ; possible) *kilpailukykyisempi* (ADJ; competitive)

Table 5: Most similar Finnish words for each North Sámi word based on cosine similarity.

tion of nouns.

4.3 Effects of cross-lingual training

Next, we analyze the effect of cross-lingual training by comparing the monolingual baseline to the cross-lingual model with MORPH.

Cross-lingual representations. The fact that cross-lingual model improves parsing performance is interesting, since Finnish and North Sámi have so little common vocabulary. What linguistic knowledge is transferred through cross-lingual training? We analyze whether words with the same POS category from the source and target treebanks have similar representations. To do this, we analyze the *head predictions*, and collect North Sámi tokens for which only the cross-lingual model correctly predicts the headword.[7] For these words, we compare token-level representations of North Sámi *development* data to Finnish *training* data.

We ask the following questions: Given the representation of a North Sámi word, what is the Finnish word with the most similar representation? Do they share the same POS category? Information other than POS may very well be captured, but we expect that the representations will reflect similar POS since POS is highly revelant to parsing. We use *cosine distance* to measure similarity.

We look at four categories for which cross-lingual training substantial improves results on the development set: adjectives, nouns, pronouns, and verbs. We analyze representations generated by two layers of the model in §3.1: (1) the output of character-level biLSTM (char-level), $\mathbf{e}_c(w_i)$ and (2) the output of word-level biLSTM (word-level), i.e., $\mathbf{h}_i$ in Eq. 2.

POS	char-level (%)	word-level (%)
ADJ	12.1	37.1
NOUN	55.8	63.5
PRON	12.9	68.0
VERB	34.2	69.0

Table 6: # of North Sámi tokens for which the most similar Finnish word has the same POS.

Table 5 shows examples of top three closest Finnish training words for a given North Sámi word. We observe that character-level representation focuses on orthographic similarity of suffixes, rather than POS. On the word-level representations, we find more cases when the top closest Finnish words have the same POS with the North Sámi word. In fact, when we compare the most similar Finnish word (Table 6) quantitatively, we find that the word-level representations of North Sámi are often similar to Finnish word with the same POS; the same trend does not hold for character-level representations. Since very few word tokens are shared, this suggests that improvements in cross-lingual training might simply be due to syntactic (i.e. word order) similarities between the two languages, captured in the dynamics of the biLSTM encoder—despite the fact that it knows very little about the North Sámi tokens themselves. The word-level representation has advantage over the char-level representation in the way that it has access to contextual information like word order, and it has knowledge about the other words in the sentence.

Head and label prediction. Lastly, we analyze the parsing performance of the monolingual com-

[7] Another possible way is to look at the label predictions. But since the monolingual baseline LAS is very low, we focus on the unlabeled attachment prediction since it is more accurate.

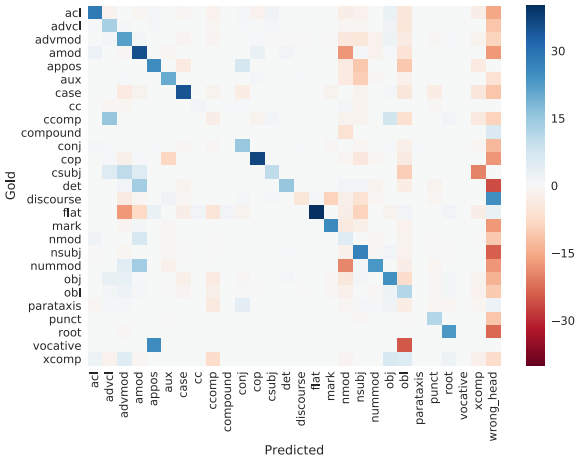

Figure 2: Differences between cross-lingual vs. monolingual confusion matrices. The last column represents cases of *incorrect* heads and the other columns represent cases for *correct* heads, i.e., each row summing to 100%. Blue cells show higher cross-lingual values and red cells show higher monolingual values.

pared to the cross-lingual models. Looking at the produced parse trees, one striking difference is that monolingual model sometimes predicts a "rootless" tree. That is, it fails to assign a head of any word with index '0' and label the dependency with a *root* label. In cases where the monolingual model predicts wrong parses and the cross-lingual model predicts the correct ones, we find that the "rootless" trees are predicted more than 50% of the time.[8] Meanwhile, the cross-lingual model learns to assign a word with head index '0', although sometimes it is the incorrect word (e.g., it is the second word, but the parser predicts the fifth word). This pattern suggests that more training examples at least helps the model to learn structural properties of a well-formed tree.

The ability of a parser to predict labels is contingent on its ability to predict heads, so we focus our analysis on two cases. How do monolingual and cross-lingual head prediction compare? And if both models predict the correct head, how do they compare on label prediction?

Figure 2 shows the *difference* between two confusion matrices: one for cross-lingual and one for monolingual models. The last column shows cases of *incorrect* heads and the other columns show label predictions when the heads are *correct*, i.e., each row summing to 100%. Here, blue cells highlight confusions that are more common for the cross-lingual model, while red cells highlight those more common for the monolingual model. For head prediction (last column), we observe that monolingual model makes higher errors especially for nominals and modifier words. In cases when both both models predict the correct heads, we observe that cross-lingual training gives further improvements in predicting most of the labels. In particular, regarding the "rootless" trees discussed before, we see evidence that cross-lingual training helps in predicting the correct root index, and the correct *root* label.

[8]The parsing model enforces the constraint that every tree should have a head, i.e., an arc pointing from a dummy root to a node in the tree. It does not, however, enforce that this arc be labeled *root*—the model must learn the labeling.

		CROSS-LINGUAL	
Language	zero-shot	+fastText	+Morph
Galician	51.9	**72.8**	71.0
Kazakh	12.5	27.7	**28.4**
Kazakh (translit.)	21.2	31.1	**36.7**

Table 7: LAS results on **development sets**. *zero-shot* denotes results where we predict using model trained only on the source treebank.

5 Parsing truly low-resource languages

Now we turn to two truly low-resource treebanks: Galician and Kazakh. These treebanks are most analogous to the North Sami $\mathcal{T}_{10}$ setting and therefore we apply the best approach, cross-lingual training with MORPH augmentation. Table 1 provides the statistics of the augmented data. For Galician, we use the Portuguese treebank as source while for Kazakh we use Turkish. Portuguese and Galician have high vocabulary overlap; 62.9% of Galician tokens appear in Portuguese data, while for Turkish and Kazakh they do not share vocabulary since they use different writing systems. However, after transliterating them into the same basic Latin alphabet, we observe that 9.5% of Kazakh tokens appear in the Turkish data. Both language pairs also share many (token-level) character trigrams: 96.0% for Galician-Portuguese and 66.3% for transliterated Kazakh-Turkish.

To compare our best approach, we create two baselines: (1) a pre-trained parsing model of the source treebank (zero-shot learning), and (2) a cross-lingual model initialized with *monolingual* pre-trained word embeddings. The first serves as a weak baseline, in a case where training on the target treebank is not possible (e.g., Kazakh only has 15 sentences for training). The latter serves as

			CROSS-LINGUAL		
	baseline	best system	+fastText	+Morph	rank
Galician	66.16	74.25	**70.46**	69.21	10/27
Kazakh (translit.)	24.21	31.93	25.28	**28.23**	2/27

Table 8: Comparison to CoNLL 2018 UD Shared Task on **test sets**. *best system* is the state-of-the-art model for each treebank: UDPipe-Future (Straka, 2018) for Galician and Uppsala (Smith et al., 2018) for Kazakh. *rank* shows our best model position in the shared task ranking for each treebank.

a strong baseline, in a case when we have access to pre-trained word embeddings, for the source and/or the target languages.

We treat a pre-trained word embedding as an external embedding, and concatenate it with the other representations, i.e., modifying Eq. 3 to $\mathbf{x}_i = [\mathbf{e}_w(w_i); \mathbf{e}_p(w_i); \mathbf{e}_c(w_i); \mathbf{l}_k]$, where $\mathbf{e}_p(w_i)$ represents a pre-trained word embedding of w_i, which we update during training. We use the pre-trained monolingual fastText embeddings (Bojanowski et al., 2017).[9] We concatenate the source and target pre-trained word embeddings.[10] For our experiments with transliteration (§2.4), we transliterate the entries of both the source and the target pre-trained word embeddings.

5.1 Experimental results

Table 7 reports the LAS performance on the development sets. MORPH augmentation improves performance over the zero-shot baseline and achieves comparable or better LAS with a cross-lingual model trained with pre-trained word embeddings.

Next, we look at the effects of transliteration (see Kazakh vs Kazakh (translit.) in Table 7). In the zero-shot experiments, simply mapping both Turkish and Kazakh characters to the Latin alphabet improves accuracy from 12.5 to 21.2 LAS. Cross-lingual training with MORPH further improves performance to 36.7 LAS.

5.2 Comparison with CoNLL 2018

To see how our best approach (i.e., cross-lingual model with MORPH augmentation) compares with the current state-of-the-art models, we compare it to the recent results from CoNLL 2018 shared task. Training state-of-the-art models may require lots of engineering and data resources. Our goal, however, is not to achieve the best performance, but rather to systematically investigate how far simple approaches can take us. We report performance of the following: (1) the shared task baseline model (UDPipe v1.2; Straka and Straková, 2017) and (2) the best system for each treebank, (3) our best approach, and (4) a cross-lingual model with fastText embeddings.

Table 8 presents the overall comparison on the test sets. For each treebank, we apply the same sentence segmentation and tokenization used by each best system.[11] We see that our approach outperforms the baseline models on both languages. For Kazakh, our model (with transliteration) achieves a competitive LAS (28.23), which would be the second position in the shared task ranking. As comparison, the best system for Kazakh (Smith et al., 2018) trained a multi-treebank model with four source treebanks, while we only use one source treebank. Their system use predicted POS as input, while ours depends solely on words and characters. The use of more treebanks and predicted POS is beyond the scope of our paper, but it is interesting that our approach can achieve the second best with such minimal resources. For Galician, our best approach outperforms baseline by 8.09 LAS points. Note that, Galician treebank does not come with training data. We use 50:50 train/dev split, while other teams might use higher split for training (for example, the best system (Straka, 2018) uses 90:10 train/dev split). Since we treat Galician as our test data, we did not tune on the proportion for training data, but we guess that this is the main reason why our system achieve rank 10 out of 27.

Compared to cross-lingual models with fastText embeddings (fastText vs. MORPH), we observe that our approach achieve better or comparable performance, showing its potential when there is

[9] The embeddings are available at https://fasttext.cc/docs/en/pretrained-vectors.html.

[10] If a word occurs in both source and target, we use the word embedding of the source language.

[11] UD shared task only provides unsegmented (i.e., sentence-level and token-level) raw test data. However, participants were allowed to use predicted segmentation and tokenization provided by the baseline UDPipe model.

not enough monolingual data available for training word embeddings.

6 Conclusions

In this paper, we investigated various low-resource parsing scenarios. We demonstrate that in the extremely low-resource setting, data augmentation improves parsing performance both in monolingual and cross-lingual settings. We also show that transfer learning is possible with *lexicalized* parsers. In addition, we show that transfer learning between two languages with different writing systems is possible, and future work should consider transliteration for other language pairs.

While we have not exhausted all the possible techniques (e.g., use of external resources (Rasooli and Collins, 2017; Rosa and Mareček, 2018), predicted POS (Ammar et al., 2016), multiple source treebanks (Lim et al., 2018; Stymne et al., 2018), among others), we show that simple methods which leverage the linguistic annotations in the treebank can improve low-resource parsing. Future work might explore different augmentation methods, such as the use of *synthetic* source treebanks (Wang and Eisner, 2018) or contextualized language model (Peters et al., 2018; Howard and Ruder, 2018; Devlin et al., 2018) for scoring the augmented data (e.g., using perplexity).

Finally, while the techniques presented in this paper might be applicable to other low-resource languages, we want to also highlight the importance of understanding the characteristics of languages being studied. For example, we showed that although North Sami and Finnish do not share vocabulary, cross-lingual training is still helpful because they share similar syntactic structures. Different language pairs might benefit from other types of similarity (e.g., morphological) and investigating this would be another interesting future work for low-resource dependency parsing.

Abstract

Prior work on cross-lingual dependency parsing often focuses on capturing the commonalities between source and target languages and overlooks the potential of leveraging linguistic properties of the languages to facilitate the transfer. In this paper, we show that weak supervisions of linguistic knowledge for the target languages can improve a cross-lingual graph-based dependency parser substantially. Specifically, we explore several types of *corpus linguistic statistics* and compile them into *corpus-wise constraints* to guide the inference process during the test time. We adapt two techniques, Lagrangian relaxation and posterior regularization, to conduct inference with corpus-statistics constraints. Experiments show that the Lagrangian relaxation and posterior regularization inference improve the performances on 15 and 17 out of 19 target languages, respectively. The improvements are especially significant for target languages that have different word order features from the source language.

1 Introduction

Natural language processing (NLP) techniques have achieved remarkable performance in a variety of tasks when sufficient training data is available. However, obtaining high-quality annotations for low-resource language tasks is challenging, and this poses great challenges to process low-resource languages. To bridge the gap, cross-lingual transfer has been proposed to transfer models trained on high-resource languages (e.g., English) to low-resource languages (e.g., Tamil) to combat the resource scarcity problem. Recent studies have demonstrated successes of transferring models across languages without retraining for NLP tasks, such as named entity recognition (Xie et al., 2018), dependency parsing (Tiedemann, 2015; Agić et al., 2014), and question answering (Joty et al., 2017), using a shared multi-lingual word embedding space (Smith et al., 2017) or delexicalization approaches (Zeman and Resnik, 2008; McDonald et al., 2013).

One key challenge for cross-lingual transfer is the *differences* among languages; for example, languages may have different word orders. When transferring a model learned from a source language to target languages, the performance may drop significantly due to the differences. To tackle this problem, various approaches have been proposed to better capture the *commonalities* between the source and the target languages (McDonald et al., 2011; Guo et al., 2016; Täckström et al., 2013; Agić, 2017; Ahmad et al., 2019); however, they overlook the potential to leverage linguistic knowledge about the target language to account for the *differences* between the source and the target languages to facilitate the transfer.

In this paper, we propose a complementary approach that studies how to leverage the linguistic knowledge about the target languages to help the transfer. Specifically, we use corpus linguistic statistics of the target languages as weak supervision signals to guide the test-time *inference* process when parsing with a graph-based parser. This approach is effective as the model only need to be trained *once* on the source language and applied to many target languages using different constraints *without retraining* the model.

We argue that certain corpus linguistic statistics such as the word order (e.g., how often an adjective appears before or after a noun) can be easily obtained from available resources such as World Atlas of Language Structures (WALS) (Dryer and Haspelmath, 2013). To incorporate the corpus linguistic statistics to a cross-lingual parser, we compile them into corpus-wise constraints and adopt two families of methods: 1) Lagrangian relaxation (LR) and 2) posterior regularization (PR) to

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1117–1128, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

solve the constrained inference problem. The algorithms take the original graph-based parsing inference as a sub-routine, and LR iteratively adjusts the pair-wise potentials until the constraints are (loosely) satisfied, while PR finds a feasible distribution and do inference based on that. The constrained inference framework is general and supports any knowledge that can be formulated as a first-order logic (Roth and Yih, 2004).

We evaluate the proposed approach under the single-source transfer setting using English as the source language and test on 19 target languages covering a broad range of language families with low-resource languages such as Tamil and Welsh. We demonstrate that by adding three simple corpus-wise constraints derived from WALS features, the performances improve in 15 and 17 out of 19 languages when using Lagrangian relaxation and posterior regularization techniques, respectively. The improvements are especially substantial when the target language features are distant from the source language. For example, our framework improves the UAS score of Urdu by 15.7%, and Tamil by 7.3%.[1]

2 Constrained Cross-Lingual Parsing

Our work focuses on the graph-based dependency parser (McDonald et al., 2005) in the zero-shot single-source transfer setting as in Ahmad et al. (2019). However, the proposed algorithms can be extended other transfer settings. Given a trained model, we derive corpus-statistics constraints and apply them to correct errors caused by word order differences between the source and the target language *during the inference time*. Figure 1 shows an example of how constraints can influence the inference results.

In this section, we first give a quick review of the graph-based parser and introduce the notations. We then discuss how to formulate corpus-wise constraints based on corpus linguistic statistics for guiding the graph-based parser.

2.1 Background: Graph-Based Parser

A graph-based parser learns a scoring function for every pair of words in a sentence and conducts inference to derive a directed spanning tree with the highest accumulated score. Formally, given the k-th sentence $\mathbf{w}_k = (w_{k1}, \ldots, w_{kL(k)})$ where $L(k)$ denotes the length of the k-th sentence, a graph-based parser learns a score matrix $S^{(k)}$, where $S^{(k)}_{ij}$ denotes the score to form an arc from word w_{ki} to word w_{kj}. Let y_k be an indicator function that $y_k(i,j) \in \{0,1\}$ denotes the arc from w_{ki} to w_{kj}. The maximum directed spanning tree inference can be formulated as an integer linear programming (ILP) problem:

$$y^*_k = \arg\max_{y_k \in \mathcal{Y}_k} \sum_{i,j} S^{(k)}_{ij} y_k(i,j), \qquad (1)$$

where $\mathcal{Y}_k$ is the set of legal dependency trees of sentence k. In recent years, neural network approaches (Kiperwasser and Goldberg, 2016; Wang and Chang, 2016; Kuncoro et al., 2016; Dozat and Manning, 2017) have been applied to modeling the scoring matrix $S^{(k)}$ and have achieved great performance in dependency parsing.

From the probabilistic point of view, if we assume for different i, j, the edge probabilities $P(y_k(i,j) = 1|\mathbf{w}_k)$ are mutually conditional independent, the probability of a whole parse tree can be written as

$$P(y_k|\mathbf{w}_k) = \prod_{i,j} P(y_k(i,j) = 1|\mathbf{w}_k)^{y_k(i,j)}. \quad (2)$$

If we set $S^{(k)}_{ij} = \log P(y_k(i,j) = 1|\mathbf{w}_k) + Z'_j$, where Z'_j is a constant term, then Eq. (1) can be regarded as the following maximum a posteriori (MAP) inference problem:

$$\begin{aligned} y^*_k &= \arg\max_{y_k \in \mathcal{Y}_k} P(y_k|\mathbf{w}_k) \\ &= \arg\max_{y_k \in \mathcal{Y}_k} \sum_{i,j} \log P(y_k(i,j) = 1|\mathbf{w}_k) y_k(i,j). \end{aligned} \qquad (3)$$

2.2 Corpus-Wise Constraints

Given the inference problems as in equations (1) and (3), additional constraints can be imposed to incorporate expert knowledge about the languages to help yield a better parser. Instance-level constraints have been explored in the literature of dependency parsing, both in the monolingual (Dryer, 2007) and cross-lingual transfer (Täckström et al., 2013) settings. However, most word order features for a language are non-deterministic and cannot be compiled into instance-wise constraints.

In this work, we introduce corpus-wise constraints to leverage the non-deterministic features for cross-lingual parser. We compile the following two types of corpus-wise constraints based on corpus linguistics statistics:

[1] The code and data are available at https://github.com/MtSomeThree/CrossLingualDependencyParsing.

- *Unary* constraints consider statistics regarding a particular POS tag (POS).
- *Binary* constraints consider statistics regarding a pair of POS tags (POS_1, POS_2).

Specifically, a unary constraint specifies the ratio r of the heads of a particular POS appears on the left of that POS.[2] Similarly, a binary constraint specifies the ratio r of POS_1 being on the left of POS_2 when there is an arc between POS_1 and POS_2.

The ratios r for the constraints are called corpus statistics, which can be estimated in one of the following ways: a) leveraging existing linguistics resources or consulting linguists; b) leveraging a higher-resource language that is similar to the target language (e.g., Finnish and Estonian) to collect the statistics. In this paper, we explore the first option and leverage the WALS features, which provide a reference for word order typology, to estimate the ratios.

Compile Constraints From WALS Features. For a particular language, once we collect the corpus-statistics of a pair of POS tags, we can formulate a binary constraint. There are different ways to estimate the corpus-statistics. For example, Östling (2015) utilizes a small amount of parallel data to estimate the dominant word orders. In this paper, we simply utilize a small subset of WALS features that show the dominant order of some POS pairs (e.g. adjective and noun) in a language. They can be directly compiled into binary constraints.

Similarly, we can estimate the ratio for unary constraints based on WALS features. For a particular POS tag, we choose all WALS features related to it to formulate a feature vector f. The mapping from the vector f to the unary constraint ratio r is learnable: for each language with annotated data, we can get a WALS feature vector f_{lang} and a ratio r_{lang} from the annotation. We only need a small amount of data to estimate r_{lang} well. Given a set of languages with feature vectors and estimated ratios, we can learn the mapping by a simple linear regression, and apply it to estimate the ratio of any target language to compile a unary constraint.

2.3 Formulate Constraints

In the following, we mathematically formulate the corpus-wise constraints. Note that these constraints are based on the statistics over the entire corpus. For a unary constraint $C_u^{(POS)}$, let P denotes a set of word with part-of-speech tag POS. We define $C_u^+ := \{(k,i,j)|w_{kj} \in P \wedge i < j\}$ as the set of arcs where the head of word in P is on its left and $C_u^- := \{(k,i,j)|w_{kj} \in P \wedge i > j\}$, conversely.

For a binary constraint $C_b^{(POS_1,POS_2)}$, we denotes P_1, P_2 as a set of word with part-of-speech tag POS_1, POS_2, respectively. We then define C_b^+ as the set of arcs with two ends $w_{ki} \in P_1$ and $w_{kj} \in P_2$, and w_{ki} is on the left of w_{kj}. We define C_b^- Similarly. Formally,

$$\begin{aligned} C_b^+ :=& \{(k,i,j)|w_{ki} \in P_1 \wedge w_{kj} \in P_2 \wedge i < j\} \\ & \cup \{(k,j,i)|w_{ki} \in P_1 \wedge w_{kj} \in P_2 \wedge i < j\}, \\ C_b^- :=& \{(k,i,j)|w_{ki} \in P_1 \wedge w_{kj} \in P_2 \wedge i > j\} \\ & \cup \{(k,j,i)|w_{ki} \in P_1 \wedge w_{kj} \in P_2 \wedge i > j\}. \end{aligned}$$

For notational simplicity, we use C to denote all constraints including both the unary and binary ones. The ratio function $R(C,Y)$ for a constraint C given the parse trees Y can be defined as:

$$R(C,Y) = \frac{\sum_k \sum_{(i,j):(k,i,j)\in C^+} y_k(i,j)}{\sum_k \sum_{(i,j):(k,i,j)\in C^+ \cup C^-} y_k(i,j)}.$$

We want to enforce the ratio $R(C,Y)$ estimated from Y to be consistent with a value r (see Sec. 2.2), which formulates a constraint

$$r - \theta \leq R(C,Y) \leq r + \theta$$

where θ is a tolerance margin. Note that the instance-level hard constraint is a special case of

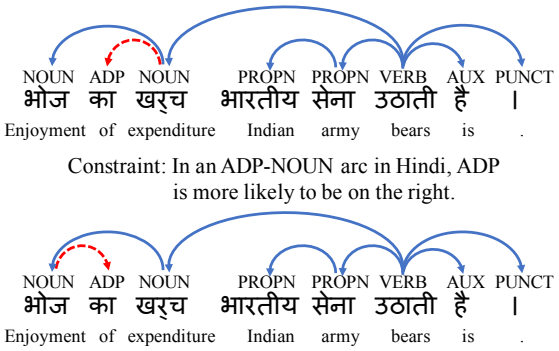

Figure 1: An running example of Hindi. On the top there is the inference result of a baseline model trained on English. In English, ADP is mostly on the left of the NOUN, so the potential of the correct ADP-NOUN arc is lower. With the help of corpus-statistics constraints, the potential is adjusted and the model gets correct inference result as shown in the bottom. The dashed lines highlight the difference.

[2] The ratio for the head being on the right of that POS is thereby $1 - r$.

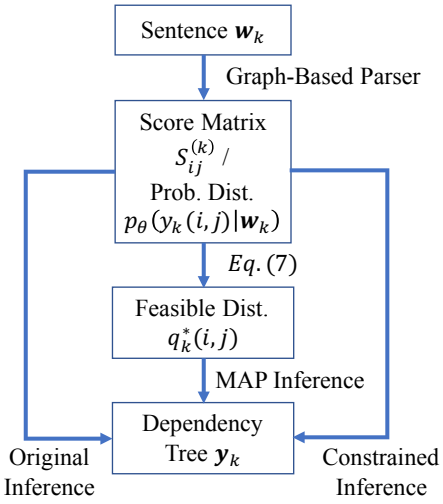

Figure 2: The pipelines of the baseline method (left), Lagrangian relaxation (right) and posterior regularization (middle). Lagrangian relaxation converts constrained inference to an unconstrained optimization problem using Lagrange's method. Posterior regularization method is working on the distribution space. For a given distribution, PR finds the closest feasible distribution and conduct MAP inference.

the corpus-statistics constraint when $r = 0$ or $r = 1$.

Given a set of corpus-statistics constraints $\mathcal{C} = \{C_1, C_2, \ldots, C_n\}$ with corresponding corpus statistics $\mathbf{r} = \{r_1, r_2, \ldots, r_n\}$, the objective of the constrained inference is:

$$\begin{aligned} \max_{Y \in \mathcal{Y}} \quad & \sum_k \sum_{i,j \le L(k)} S_{ij}^{(k)} y_k(i,j), \\ \text{s.t.} \quad & r_i - \theta_i \le R(C_i, Y) \le r_i + \theta_i, i \in [N], \end{aligned} \tag{4}$$

where $\mathcal{Y}$ denotes the set of all possible dependency trees. As all the constraints can be written as a linear inequality with respect to $y_k(i,j)$. Eq. (4) is an ILP.

3 Inference with Corpus-Statistics Constraints

The ILP problem in Eq. (4) is in general an NP-hard problem; especially, it involves variables associated with the entire corpus. Without constraints, Eq. (4) can be decoupled into K subproblems, and the inference with respect to each sentence can be solved independently as in Eq. (1). In this way, an efficient inference algorithm such as maximum directed spanning tree algorithm (Chu and Liu, 1965) can be used.

However, with the corpus-wise constraints, directly solving Eq. (4) is infeasible. Therefore, we explore two algorithms for inference with corpus-statistics constraints: Lagrangian relaxation and posterior regularization (Ganchev et al., 2010). The Lagrangian relaxation algorithm introduces Lagrangian multipliers to relax the constraint optimization problem to an unconstrained optimization problem, and estimates the Lagrangian multipliers with gradient-based methods. The posterior regularization algorithm uses the constraints of the target language to define a feasible set of parse tree distributions, and find a feasible distribution that is closest to the parse tree distribution trained on the source language by minimizing the KL-divergence. The constrained inference problem can then be converted into an MAP inference problem on the best feasible distribution. Figure 2 illustrates the procedure of the original inference, Lagrangian relaxation, and posterior regularization.

3.1 Lagrangian Relaxation

Lagrangian relaxation has been applied in various NLP applications (Rush and Collins, 2012, 2011). In Eq. (4), each constraint C_i involves two inequality constraints: $R(C_i, Y) - r_i + \theta \ge 0$, and $r_i + \theta - R(C_i, Y) \ge 0$. Instead of treating these two constraints separately, we consider a heuristic to optimize with equality constraints $R(C_i, Y) = r_i, i \in [N]$ and terminate earlier when constraints in Eq. (4) are satisfied. Despite this approach does not guarantee the solution is optimal if all the constraints are satisfied as the original Lagrangian relaxation algorithm does, in practice, the inference converges faster (as the number of Lagrangian multipliers is half) and the parsing performance maintains.

In the following, we derive the constrained inference algorithm for corpus-statistics constraints. First, we rewrite the equality constraint $R(C, Y) = r$ by substituting $R(C, Y)$ with Eq. (2.3):

$$\begin{aligned} &(1-r) \sum_k \sum_{(i,j):(k,i,j) \in C_i^+} y_k(i,j) \\ &-r \sum_k \sum_{(i,j):(k,i,j) \in C_i^-} y_k(i,j) = 0, \end{aligned} \tag{5}$$

We use F(C) to denote the left-hand-side of Eq. (5), which is linear w.r.t. y_k. Then, the Lagrangian relaxation of the constrained inference problem can be written as:

$$L(Y, \lambda; \mathcal{C}) = \sum_k \sum_{i,j} S_{ij}^{(k)} y_k(i,j) + \sum_{i \in [N]} \lambda_i F(C_i),$$

Algorithm 1 Lagrangian Relaxation for Constraint Inference

Input: Constraints $\mathcal{C} = \{C_i\}_{i=1}^N$, corresponding ratio $\mathbf{r} = \{r_i\}_{i=1}^N$, tolerance margin $\theta = \{\theta_i\}_{i=1}^N$, learning rate decay η, initial learning rate α_0

Output: parse trees $\hat{Y}$

$\alpha \leftarrow \alpha_0$
$\lambda_i \leftarrow 0,\ i \in [N]$
repeat
  $\hat{Y} \leftarrow \arg\max_{Y \in \mathcal{Y}} L(Y, \lambda; \mathcal{C})$
  $\hat{r_i} \leftarrow R(C_i, \hat{Y}),\ i \in [N]$
  if $\forall i, abs(r_i - \hat{r_i}) \leq \theta$ **then**
    return $\hat{Y}$
  $\lambda_i \leftarrow \alpha(\hat{r_i} - r_i),\ i \in [N]$
  $\alpha \leftarrow \eta\alpha$
until MAX_ITER times
return $\hat{Y}$

where λ_i is called Lagrangian multiplier. It is well-known that we can solve the dual form of the constrained inference problem:

$$\max_{Y \in \mathcal{Y}} \min_{\lambda \geq 0} L(Y, \lambda; \mathcal{C}).$$

To solve the dual form, we initialize λ_i to be 0. At iteration t, we firstly conduct an constraint-augmented inference with a fixed $\lambda^{(t)}$:

$$\hat{Y}^{(t)} = \max_{Y \in \mathcal{Y}} L(Y, \lambda^{(t)}; \mathcal{C}). \tag{6}$$

As $F(C)$ is a linear function w.r.t y_k, we combine it with $S_{ij}^{(k)} y_k(i,j)$. In this way, the inference problem Eq. (6) can be treated as a special case of Eq. (1) with a different scoring matrix $S^{(k)}$. In this way, we can treat the inference on every sentence independently and leverage existing inference techniques.

After solving the constraint-augmented inference, we compute the ratio of every constraint $\hat{r_i}^{(t)} = R(C_i, \hat{Y}^{(t)})$, and use gradient ascent algorithm to update the Lagrangian multipliers

$$\lambda_i^{(t+1)} = \lambda_i^{(t)} + \alpha^{(t)}(r_i - \hat{r_i}).$$

Here $\alpha^{(t)}$ denote the step size at iteration t. The algorithm is shown in Algorithm 1.

3.2 Posterior Regularization

From a probabilistic point of view, the parser model learns parameters θ to realize Eq. (2). During the inference, the model predict a probability distribution $p_\theta(\mathbf{Y}|\mathbf{W})$ over possible parse trees given a sentence. The posterior regularization algorithm first defines a feasible set of the probability distributions w.r.t the given constraints, and looks for the closest feasible distribution $q^*(\mathbf{Y})$ to the model distribution $p_\theta(\mathbf{Y}|\mathbf{W})$. The best parse tree is given by $\arg\max_{\mathbf{Y}} q^*(\mathbf{Y})$. Specifically, we define the feasible set as:

$$Q = \{q(\mathbf{Y}) | r_i - \theta_i \leq R(C_i, q(\mathbf{Y})) \leq r_i + \theta_i, i \in [N]\},$$

where $R(C, q) = \frac{\sum_k \sum_{(i,j):(k,i,j) \in C^+} q_k(i,j)}{\sum_k \sum_{(i,j):(k,i,j) \in C^+ \cup C^-} q_k(i,j)}$, with $q_k(i,j) = E_{Y \sim q(Y)}[y_k(i,j)]$.

To measure the distance between two distribution, we use the KL-divergence, and find the best feasible distribution $q^*(\mathbf{Y})$:

$$q^*(\mathbf{Y}) = \arg\min_{q \in Q} KL(q(\mathbf{Y}) \| p_\theta(\mathbf{Y}|\mathbf{W})). \tag{7}$$

If the feasible set has the expectation form:

$$\{q | \mathbb{E}_{\mathbf{Y} \sim q}[\phi(\mathbf{Y})] \leq \mathbf{b}\}, \tag{8}$$

Eq. (7) has a simple close form solution (Ganchev et al., 2010):

$$q^*(\mathbf{Y}) = \frac{p_\theta(\mathbf{Y}|\mathbf{W}) \exp(-\lambda^* \cdot \phi(\mathbf{Y}))}{Z(\lambda^*)}, \tag{9}$$

where λ^* is the solution of

$$\begin{aligned} \lambda^* &= \arg\max_{\lambda \geq 0} -\mathbf{b} \cdot \lambda - \log Z(\lambda), \\ Z(\lambda) &= \sum_{\mathbf{Y}'} p_\theta(\mathbf{Y}'|\mathbf{W}) \exp(-\lambda^* \cdot \phi(\mathbf{Y}')). \end{aligned} \tag{10}$$

In the rest of this section, we first show that the feasible set Q we considered above can be reformulated in the form of Eq. (8), and then we discuss how to solve Eq. (10). To show that the inequality $R(C, q(\mathbf{Y})) \leq r$, in Q can be formulated in the form of Eq. (8), we set

$$\phi_C(\mathbf{Y}) = \sum_{k,i,j} y_k(i,j) \phi_C(k,i,j),$$

and

$$\phi_C(k,i,j) = \begin{cases} 1 - r & (k,i,j) \in C^+ \\ -r & (k,i,j) \in C^- \\ 0 & (k,i,j) \notin C^+ \cup C^-. \end{cases} \tag{11}$$

Similarly, we can derive $R(C, q(\mathbf{Y})) \geq r$, into the same form and rewrite Q as

$$Q = \{q(\mathbf{Y}) \mid \mathbb{E}_{\mathbf{Y} \sim q} \phi(\mathbf{Y}) \leq \mathbf{0}\},$$

Algorithm 2 Posterior Regularization

Input: Constraints $\mathcal{C} = \{C_i\}_{i=1}^N$, corresponding ratio $\mathbf{r} = \{r_i\}_{i=1}^N$, tolerance margin $\theta = \{\theta_i\}_{i=1}^N$
Output: parse trees $\hat{Y}$

$p_\theta(y_k(i,j)=1) \leftarrow \text{normalize}\Big(\exp\Big(S_{ij}^{(k)}\Big)\Big)$
$\phi \leftarrow$ defined by Eq. (11)
$\lambda_i \leftarrow 0,\ i \in [N]$
repeat
  estimate $\mathbf{g} \leftarrow \partial \log Z(\lambda)/\partial\lambda$ in a batch
  update λ based on $\mathbf{g}$
until MAX_ITER times
for each (k,i,j) **do**
  $q_k(i,j) \leftarrow$ defined by Eq. (12)
$\hat{Y} \leftarrow$ MAP inference based on q
return $\hat{Y}$

where $\phi = (\phi_{C_1}, \phi_{C_2}, ..., \phi_{C_N})$ is a collection of the constraints. The detailed derivations can be found in Appendix A.

We solve Eq. (10) by sub-gradient descent[3]. Noting that there can be exponential number of terms in $Z(\lambda)$, we firstly need to factorize $Z(\lambda)$ from corpus level to instance level and arc level, and compute the gradient. The technical details are in Appendix A. With the optimal λ^*, we can compute the feasible distribution $q^*(\mathbf{Y})$ given p_θ and $\mathbf{W}$. Noting that the solution Eq. (9) can also be factorized to arc-level:

$$q_k^*(i,j) \propto p_\theta(y_k(i,j)|\mathbf{w_k}) \exp(-\lambda^* \cdot \phi(k,i,j)), \tag{12}$$

here $q_k^*(i,j)$ denote the arc-level distribution $q^*(y_k(i,j)=1)$ satisfying Eq. (3). We then do MAP inference based on q, which is actually a minimal spanning tree problem same as before. Algorithm 2 summarizes the process.

4 Experiments

In this section, we evaluate the proposed algorithms by transferring an English dependency parser to 19 target languages covering 13 language families of real low-resource languages. We first introduce the experimental setup including data selection and constraint details and then discuss the results as well as in-depth analysis.

4.1 Setup

Model and Data We train the best performing Att-Graph parser proposed in Ahmad et al. (2019) on English and transfer it to 19 target languages in UD Tree Bank v2.2 (Nivre et al., 2018).[4] The model takes words and predicted POS tags[5] as input, and achieve transfer by leveraging pre-trained multi-lingual FastText (Bojanowski et al., 2017) embeddings that project the word embeddings from different languages into the same space using an offline transformation method (Smith et al., 2017; Conneau et al., 2018). The SelfAtt-Graph model uses a Transformer (Vaswani et al., 2017) with relative position embedding as the encoder and a deep biaffine scorer (Dozat and Manning, 2017) as the decoder. We follow the setting in Ahmad et al. (2019) to train and tune only on the source language (English) and directly transfer to all the target languages. We modify their decoder to incorporate constraints with the proposed constrained inference algorithms during the transfer phase without retraining the model. All the hyper-parameters are specified in Appendix Table 4 together with hyper-parameters for the inference algorithms in Appendix Table 5.

Constraints We consider two types of constraints: 1) instance-level projective constraints for avoiding creating crossing arcs in the dependency trees, 2) corpus-statistics constraints constructed by the process described in Section 2.2. We consider the following three corpus-statistics constraints: $C1 = (NOUN)$, $C2 = (NOUN, ADP)$, $C3 = (NOUN, ADJ)$; intuitively, $C1$ concerns about the ratio of nouns being on the right of their heads; $C2$ concerns about the ratio of nouns being on the left of adpositions among all noun-adposition arcs; $C3$ concerns about the ratio of nouns being on the left of adjectives among all noun-adjective arcs.

For binary constraints, $C2$ and $C3$ can be directly compiled from WALS feature $85A$ and $87A$ respectively. We encode "dominant order" specified in WALS as the ratio being always greater than 0.75 (i.e., $r = 0.875$ and $\theta = 0.125$). If there is no dominant order or the feature is missing, we set $r = 0.5$ and $\theta = 0.25$. Some WALS features like $82A, 83A$ are also about word order, but we need to specify the arc types to utilize them. For simplicity, we only consider forming constraints from the POS tags in this paper. To estimate the

[3] In implementation, we use stochastic gradient descent with Adam optimizer (Kingma and Ba, 2015)

[4] We make the selection to prioritize the coverage of language families and low resource languages. The language family information can be found in Table 1.

[5] We use predicted POS tags provided in UD v2.2.

Table 1: Cross-lingual transfer performances for dependency parsing on 19 languages from 13 different families, with the performance on the source language (English) as a reference. Performances are reported per UAS (we observe similar trends for LAS and details can be found in the appendix Table 7). We compare the baseline model (Ahmad et al., 2019) with our two algorithms (Lagrangian relaxation and posterior regularization) considering the oracle constraints, and the corpus-statistics constraints compiled from WALS. Columns ΔWALS denote the improvements bring by leveraging WALS feature as constraints. We also create a Features column to show three WALS features [83A,85A,87A] for each language. The values {1, -1, 0, ?} stand for the same as English, opposite to English, no dominant order, and feature missing, respectively.

ratio for unary constraint $C1$, we use the WALS features $82A, 83A, 85A, 86A, 87A, 88A, 89A$ that are related to $NOUN$ to form feature vectors, and do regression on languages in the test set except the target language to predict the constraint ratio. The process guarantees the target language remain unseen during the ratio estimation process. The ratios on the regression training languages are estimated by sampling 100 sentences in the training set per language.

We also consider an oracle setting where we collect a "ground-truth" ratio of each constraint for the target language to estimate an upper bound of our inference algorithms. In the oracle setting, we estimate the ratio on the whole training corpus of the target language and set the margin to $\theta = 0.01$.

4.2 Parsing Performances

We first compare the performances of the cross-lingual dependency parser with or without constraints. Table 1 illustrates the results for the 19 target languages we selected,[6] along with the performance on the source language (English). The performance on English is not as high as the dependency parsers specialized for English, because to achieve transfer, we have to freeze the pre-trained multi-lingual word embeddings. Yet this parser achieved the best single-source transfer performances according to Ahmad et al. (2019).

As is shown in Table 1, the improvements by our constrained inference algorithms are dramatic in a few languages that have very distinct word order features from the source language. For example, the parsing performance of Hindi (hi) improves about 15% in UAS with WALS features via both Lagrangian relaxation and posterior regularization inference. The improvements are less

[6] We also run on all languages in Ahmad et al. (2019) for completeness and observe similar trends. The results can be found in Appendix Table 7.

obvious for languages that are in the same family as English such as Danish(da) and Dutch(nl). This is expected as the corpus linguistic statistics of these languages are similar to English thus the constraints are mostly satisfied with the baseline parser. Comparing Lagrangian relaxation and posterior regularization, we find posterior regularization being more robust and less sensitive to the errors in the corpus-statistics estimation, while Lagrangian relaxation gives a higher improvement on average. Overall, the two proposed constrained inference algorithms improved the transfer performance by 3.5% and 3.1% per UAS on average on 19 target languages.

For languages like Finnish (fi) and Estonian (et), the WALS setting works even better than the oracle. We suspect the reason being the large margin we set in the WALS setting. When the estimated corpus-statistics is different from the real ratio in the test set, the large margin relaxes the constraints, thus could result in better performances.

Discussion. Despite the major experiments and analysis are conducted using English as the only source language, our approach is general and does not have restriction on the choice of the source language(s). To verify this claim, we run experiments with Hebrew as the source language. Under the oracle setting, Lagrangian relaxation and posterior regularization improve the baseline by 4.4% and 4.1%, respectively.

We observed that if we compile WALS features into hard constraints (i.e., set $r = 0$ or 1), the constraint inference framework only improves performance on half of the languages. For example, in Estonian (et), the performance *drops* about 3%. This is because WALS only provides the dominant order. Therefore, treating WALS as hard constraints introduces error to the inference.

Finally, we assume if we can access to native speakers, the corpus-statistics can be estimated by a few partial annotations of parse trees. In our simulation, using less than 300 arcs, we can achieve the same performance as using the oracle.

4.3 Contributions of Individual Constraints

We analyze the contribution of each constraint demonstrated in Table 2. Here we use the oracle setting to reduce the noise introduced by corpus-statistics estimation errors. The results are based on Lagrangian relaxation inference. As shown in Table 2, Despite some languages have non-projective dependencies, we observed performance improvements on almost all the languages when the projective constraint is enforced. All the constraints we formulated have positive contributions to the performance improvements. $C1 = (NOUN)$ brings the largest gain probably because its widest coverage.

Model	UAS	coverage	Δ
baseline	54.3	N/A	N/A
+Proj.	54.6	N/A	+0.3
+Proj.+C1	57.0	0.24	+2.4
+Proj.+C2	55.7	0.08	+1.1
+Proj.+C3	55.0	0.07	+0.4
oracle	58.4	N/A	+4.1

Table 2: Ablation study: average UAS of baseline model with different sets of constraints. Proj. represent projective constraints. C1-C3 and oracle are introduced in 4.1. The improvements for projective constraint and oracle are compared to baseline. For the other three constraint sets the improvement is compared to model with projective constraint.

Const.	statistics	improvement
+Proj.	N/A	+0.1
C1	0.30/0.36/0.94	+6.9
C2	0.00/0.06/1.00	+11.3
C3	0.14/0.27/0.12	+0.5
All	N/A	+18.1

Table 3: Contribution of individual constraints and their statistics in Hindi. The second column lists the ratios estimated from oracle in English/ baseline in Hindi/ oracle in Hindi, respectively. The improvement is measured in UAS. The improvement of constraints is computed same as Table 2

Table 1 shows that the performance of Hindi improves from 34% to over 51% per UAS for both inference algorithms. To better understand where the improvements come from, we conduct an analysis to breakdown the contribution of each individual constraint for Hindi. Table 3 shows the results. We can see that since the corpus linguistic statistics between Hindi and English are distinct, the baseline model only achieves low performance. With the constrained inference, especially the postposition constraint (C2), the proposed inference algorithm bring significant improvement.

To verify the effectiveness of the constraints, we analyze the relation between the performance improvements and corpus statistics ratio gaps between the source and the target languages. To quantify the ratio gap, we weight constraints by

their coverage rate and compute the weighted average of the ratio difference between source and target languages. Results show that the performance improvement is highly related to the ratio gap. The Pearson Correlation Coefficient is $\mathbf{0.938}$. The figure showing the correlation between performance gap (as per UAS) and the corpus statistics ratio gap is in the Appendix Figure 3.

5 Related Work

Cross-Lingual Transfer for Parsing Many approaches have been developed to transfer a dependency parser. However, they mainly focus on better capture information from the source language(s). McDonald et al. (2011); Guo et al. (2016); Täckström et al. (2013); Chen et al. (2019) consider transferring a parser trained on multiple source languages. Agić (2017); Lin et al. (2019) selects good source languages by comparing part-of-speech tags sequences. Søgaard (2011); Täckström et al. (2013) chooses suitable data points from the source language. Pires et al. (2019) uses multilingual BERT to leverage language features from multiple languages. Ahmad et al. (2019) design an order-free model to take out the order features from the source language. Xiao and Guo (2014); Guo et al. (2015) learn an alignment from source words to target words. Ponti et al. (2018) learn an anisomorphism from the source parsing tree to target. Rasooli and Collins (2019) reorder the source data before training. In contrast, we focus on incorporating linguistic properties in the target languages.

Constrained Inference for Parsing Several previous studies show that adding constraints in inference time improves the performance of models. Grave and Elhadad (2015) consider incorporating constraints to promote popular types of arcs in an unsupervised setting. Naseem et al. (2010); Li et al. (2019) train a parser with constraints compiled from the frequency of particular arcs. Compared with the previous work, we focus on cross-lingual transfer with word order constraints.

Finally, prior studies have noticed that the word order information is significant for parsing and use it as features (Ammar et al., 2016; Naseem et al., 2012; Rasooli and Collins, 2017; Zhang and Barzilay, 2015; Dryer, 2007). Täckström et al. (2013) further propose to decompose these features from models for adapting target languages. Wang and Eisner (2018a) use the statistics of surface part-of-speech (POS) tags of target languages to learn the word order. Wang and Eisner (2018b) use POS tags of target languages together with a similar language, and design a stochastic permutation process to synthetic the word order. However, none of them consider using the word order features as constraints.

Incorporating Constraints In NLP Tasks Constraints are widely incorporated in variety of NLP tasks. To name a few, Roth and Yih (2004) propose to formulate constrained inferences in NLP as integer linear programming problems. To solve the intractable structure, Rush and Collins (2012) decompose the structure and incorporate constraints on some composite tasks. To improve the performance of a model, Chang and Collins (2011); Peng et al. (2015) incorporate constraints on exact decoding tasks and inference tasks on graphical models, and Chang et al. (2013); Dalvi (2015); Martins (2015) incorporate corpus-level constraints on semi-supervised multilabel classification and coreference resolution. Zhao et al. (2017) incorporate corpus-level constraints to avoid amplifying gender bias on visual semantic role labeling and multilabel classification. In contrast to previous work, we incorporate corpus-level constraints to facilitate dependency parser in the cross-lingual transfer setting.

6 Conclusion

We propose to leverage corpus-linguistic statistics to guide the inference of cross-lingual dependency parsing. We compile these statistics into corpus-statistic constraints and design two inference algorithms on top of a graph-based parser based on Lagrangian relaxation and posterior regularization. Experiments on 19 languages show that our approach improves the performance of the cross-lingual parser substantially. In the future, we plan to study the design and incorporation of fine-grained constraints considering multipule languages for cross-lingual transfer. We also plan to adapt this constrained inference framework to other cross-lingual structured prediction problems, such as semantic role labeling.

Abstract

Computing devices have recently become capable of interacting with their end users via natural language. However, they can only operate within a limited "supported" domain of discourse and fail drastically when faced with an out-of-domain utterance, mainly due to the limitations of their semantic parser. In this paper, we propose a semantic parser that generalizes to out-of-domain examples by learning a general strategy for parsing an *unseen* utterance through adapting the logical forms of *seen* utterances, instead of learning to generate a logical form from scratch. Our parser maintains a memory consisting of a representative subset of the seen utterances paired with their logical forms. Given an unseen utterance, our parser works by looking up a similar utterance from the memory and adapting its logical form until it fits the unseen utterance. Moreover, we present a data generation strategy for constructing utterance-logical form pairs from different domains. Our results show an improvement of up to 68.8% on one-shot parsing under two different evaluation settings compared to the baselines.

1 Introduction and Background

Speech recognition technologies are achieving human parity (Xiong et al., 2016). As a result, end users can now access different functionalities of their phones and computers through spoken instructions via a natural language processing interface referred to as a conversational agent. Current commercial conversational agents such as Siri, Alexa or Google Assistant come with a fixed set of simple functions like setting alarms and making reminders, but are often not able to cater to the specific phrasing of a user or the specific action a user needs. However, it has recently been shown that it is possible to add new functionalities to an agent through natural language *instruction* (Azaria et al., 2016; Labutov et al., 2018).

For example, assume that the user wants to add a functionality for resetting an alarm based on the weather forecast for the next day, as demonstrated by the following utterance: "whenever it snows at night, wake me up 30 minutes early". The user can instruct this task to the agent by breaking it down into a sequence of actions that the agent already knows.

- check the weather app,
- see if the forecast is calling for snow,
- if yes, then reset the time of the alarm to 30 minutes earlier.

This set of instructions result in a logical form or a semantic parse for this specific new utterance. However, this approach can be used in practice only if the agent is capable of generalizing from this single new utterance to similar utterances such as "if the weather is rainy, then set an alarm for 1 hour later". We refer to this problem as *one-shot semantic parsing*.

In this paper, we address this one-shot semantic parsing task and present a semantic parser that generalizes to out-of-domain utterances by seeing a single example from that domain. While state of the art neural semantic parsers are flexible to language variations, they need plenty of examples from the new domain to be able to parse an utterance from that domain, which is not possible in our scenario. On the other hand, grammar parsers are not robust to the flexibility of language because of their use of string matching. Therefore, we propose a method that preserves the robustness of neural semantic parsers while addressing

the data sparsity of the one-shot semantic parsing task. We present a general strategy for "adapting" logical forms rather than constructing them from scratch by "looking up" similar sentences that we know how to parse and changing their logical forms until they fit the new utterances. These logical forms are looked-up from a memory that contains a representative subset of previously seen utterance-logical form pairs. Once this general strategy is learned, the parser can be extended to parse an utterance from a new domain by adding one new example of that domain to the memory.

We propose a dataset generation method that allows us to evaluate the effectiveness of our model in a one-shot setting. We show that we generate reasonably good utterances while creating different experimental setups and scenarios for evaluation.

Summary of Results In this paper we propose a novel neural semantic parser for the task of one-shot semantic parsing. We design two different experiments to evaluate the parsing accuracy. We show that our approach improves the performance of neural semantic parsers by a significant margin across 6 different domains of discourse. Moreover, we present a detailed analysis of our proposed model and the performance of its different components through an oracle study.

2 Problem Definition

In this section, we introduce the basic terminology used in the paper and formally define the task of one-shot semantic parsing.

A semantic parser takes as input an *utterance* and outputs a corresponding *logical form*. An utterance is a sequence of words and a logical form is an s-expression capturing the meaning of the utterance.

For example, "parents of John's friends" is an utterance and `(field parent (field friend John))` is its logical form.

We use a synchronous context free grammar (SCFG), which is a generalization of the context-free grammar (CFG), to generate grammar rules (Chiang, 2006). A rule in an SCFG has a left hand side, which is a non-terminal category, and two right hand sides, referred to as the source and the target. For our semantic parsing task, the source corresponds to an utterance, and the target corresponds to a logical form. We denote a grammar rule with the small letter g. A set of grammar rules, denoted by the capital letter G, span a domain of utterances. In this paper, we define $domain(G)$ as the set of all *utterance-logical form* pairs generated by a set of grammar rules G. A sample SCFG G_{sample} with its domain are provided in Tables 5 of Appendix A and Table 1 below, respectively.

Utterance	Logical Form
John	`john`
Mary	`mary`
parents	`parent`
children	`child`
parents of John	`(field parent john)`
parents of Mary	`(field parent mary)`
children of John	`(field child john)`
children of Mary	`(field child mary)`
John 's parents	`(field parent john)`
Mary 's parents	`(field parent mary)`
John 's children	`(field child john)`
Mary 's children	`(field child mary)`

Table 1: Domain of the sample SCFG G_{sample}. The rules of this SCFG are presented in the Appendix A. The domain of the sample SCFG is the set of all ⟨source, `target`⟩ pairs listed in this table.

In **one-shot semantic parsing** we are given as input a subset of utterance and logical form pairs from $domain(G)$ and a single utterance and logical form pair from $domain(G')$. The goal of one-shot semantic parsing is to parse utterances from $domain(G')$ that are not in the input.

Let us provide an example to make this more clear. Consider that we are given utterance and logical form pairs from $domain(G_{\text{sample}})$ in Table 1 as well as the following utterance and logical form pair as input.

⟨friends of John, `(field friend john)`⟩

The goal of one-shot semantic parsing is to parse examples such as

⟨friends of Mary, `(field friend Mary)`⟩ (1)

⟨parents of Mary's friends, `(field parent(field friend Mary)`⟩ (2)

which are not in $domain(G_{\text{sample}})$.

This is a challenging task for a complex grammar since the domain of a typical grammar consists of hundreds of thousand of examples. Therefore, being able to parse all variations of utterances in the domain by seeing only a single example from it does not have a trivial solution. Grammar-based semantic parsers usually

rely on string matching which limits their robustness to natural language variation. Neural semantic parsers are more robust compared to grammar-based parsers. However, their performance significantly drops in such a data-hungry setting. In the next section, we present our look-up adapt semantic parser that addresses the challenges of neural semantic parsers in a data-sparse scenario.

3 Look-up and Adapt

In this section, we propose a novel neural network architecture for one-shot semantic parsing. We are given a set of utterance-logical form pairs as input and our goal is to output a semantic parse for an unseen query utterance. Our model is able to generate a logical form for the utterance by "looking up" a similar utterance from a pool of utterance-logical form pairs and "adapting" its logical form. This pool of utterances is maintained in a "memory" and consist of a representative subset of the input utterance-logical form pairs. We will show that in the data-sparse scenario of one-shot semantic parsing, adapting known logical forms is easier compared to generating a logical form from scratch. We will also discuss that it is important what subset of the data is included in the memory.

Our model consists of two main modules, namely look-up § 3.1 and adapt § 3.2. Figure 1 shows a sketch of our proposed model and the main look-up adapt algorithm is given in Algorithm 1. The look-up module is responsible for retrieving utterance-logical form pairs from the memory, using two Bidirectional LSTM encoders. The adapt module is responsible for adapting the retrieved logical form until it results in the correct semantic parse. The adapt module has two sub-modules, namely the aligner and the discriminator. The aligner is responsible for aligning the logical form with the query utterance and the discriminator decides which parts of the logical form should be swapped with a new one from the memory. In the following sections, we will define each sub-module of our proposed model in detail and propose a loss for training the model in an end-to-end fashion.

Before describing the model components, let us start by introducing the notation we will use in the following sections. Bold capital letters represent matrices, and bold lower case letters represent vectors. $\boldsymbol{X}$ denotes a distributed representation of an utterance, where each column of $\boldsymbol{X}$ is the representation for a word in the utterance. $\boldsymbol{Y}$ denotes a distributed representation of a logical form, where each column of $\boldsymbol{Y}$ is the representation for a predicate in the logical form. `T` is a tree representation of the logical form. $\boldsymbol{w}$ and $\boldsymbol{w}'$ denote attention weights that sum to at least 0 and at most 1.

Algorithm 1 LookUpAndAdapt

```
function LookUpAndAdapt(Memory, X', w')
    (X, Y, T) ← LookUp(Memory, X', w')
    for all t in T.children do
        t' ← Adapt(Memory, X', Y, t, w')
        T.children.replace(t, t')
    return T
```

3.1 Look-up

In this section, we describe our look-up strategy and discuss its sub-modules in detail.

Encoder Bidirectional RNNs have been successfully used to represent sentences in many areas of natural language processing such as question answering, neural machine translation, and semantic parsing (Bengio and LeCun, 2015; Hermann et al., 2015; Dong and Lapata, 2016). We use Bidirectional LSTMs where the forward LSTM reads the input in the utterance word order $(x_1, x_2, ..., x_T)$ and the backward LSTM reads the input in reversed order $(x_T, x_{T-1}, ..., x_1)$. The output for each word x_i is the concatenation of the ith hidden state h_i^{fwd} of the forward LSTM and the $T - i$th hidden state h_{T-i}^{bck} of the backward LSTM. As shown in Figure 1, we use two Bidirectional LSTMs, one to encode the utterance, and one to encode the logical form. The utterance is treated as a sequence of words, where each word is represented as a pretrained GloVe (Pennington et al., 2014) embedding. The logical form is treated as a sequence of predicates and parentheses, each of which is also represented as a pretrained GloVe embedding. The motivation to use GloVe embeddings for both words and predicates is to avoid the problem of unknown words/predicates encountered in the one-shot utterance's domain.

Retrieving from the memory The memory consists of a subset of the utterance-logical form pairs given as input to the algorithm. We refer to the number of pairs in the memory as its size and denote it with n. We would like to note that the algorithm's success depends on having a memory that captures the structure of the domain. In this

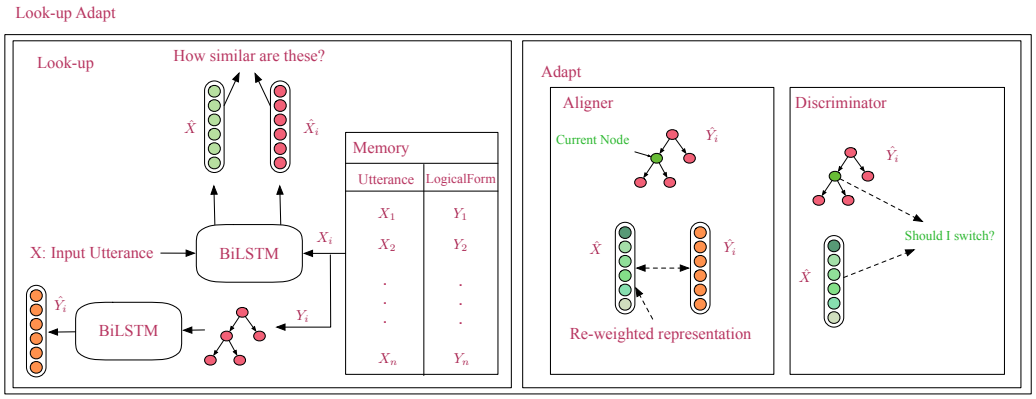

Figure 1: Look-up Adapt semantic parser. Our model consists of two main modules, namely "Look-up" (left box) and "Adapt" (right box). The look-up module is responsible for retrieving utterance-logical form pairs from the memory that are similar to an input query utterance X. The 'Adapt" module is further broken down into two modules "Aligner" and "Discriminator". Given a looked-up utterance and logical form pair, the aligner module traverses the logical form tree and updates the utterance representation accordingly while the discriminator module decides weather to switch the current node with another one from the memory or keep it as is.

paper, we make a simplifying assumption that the memory is given by an oracle, and it consists of one example per grammar rule. Other choices for the memory are also possible but exploring them falls out of the scope of this paper. An interested reader is referred to Appendix B for a more detailed discussion. In the future we wish to automate the acquisition of this memory.

Given an encoded query utterance $\boldsymbol{X}'$, we model the retrieval as a classification over examples in the memory. We compute a fixed size query vector $\boldsymbol{x}' = \boldsymbol{X}' \cdot \boldsymbol{w}'$ which is a weighted average of the column vectors in $\boldsymbol{X}'$. We compute a fixed-size key vector for every example in the memory $\boldsymbol{x} = \sum_{i=1}^{T} \boldsymbol{X}_i$, as the mean of the column vectors of $\boldsymbol{X}$.

Given a query vector $\boldsymbol{x}'$ and vectors $\boldsymbol{x}_i$ from the memory for $i = 1, 2, ..., n$ where n is the memory size, we model the probability of retrieving the ith entry from memory using equation 3

$$P(i|\boldsymbol{x}') = \frac{\exp(e_i)}{\sum_{j=1}^{n} \exp(e_j)} \quad (3)$$

where

$$e_i = f([\boldsymbol{x}', \boldsymbol{x}_i, \boldsymbol{x}' \odot \boldsymbol{x}_i, |\boldsymbol{x}' - \boldsymbol{x}_i|, \boldsymbol{x}'^T W_1 \boldsymbol{x}_i]) \quad (4)$$

where $\odot$ is element-wise product,$[a, b]$ is concatenation of vectors a and b, and f is a Multi-Layer-Perceptron with a single hidden layer and ReLU activation function. This way of featurizing $\boldsymbol{x}'$ and $\boldsymbol{x}$ was adapted from (Kumar et al., 2016). LOOKUP greedily returns the example with the highest probability of being selected.

3.2 Adapt

The algorithm for ADAPT is given in Algorithm 2. The adaptation is two phase. First an alignment from `T` to relevant words in the new utterance $\boldsymbol{X}'$ is computed. Then a decision is made on whether this subtree fails to match the relevant words in the utterance and needs to be replaced. If yes, a recursive call to LOOKUPANDADAPT will be made with an updated attention $\boldsymbol{w}$ to focus on words relevant to the subtree, and the returned value will be propagated and eventually used as a replacement for the current subtree. Otherwise, recursive calls to ADAPT will be made to check the children of the current subtree. For an example see Table 9.

The input `Memory` to the algorithm is used in case a recursive call to LookUpAndAdapt is needed. $\boldsymbol{X}'$ is the representation of the new utterance. $\boldsymbol{Y}$ is the representation of the current logical form. `T` is a subtree of $\boldsymbol{Y}$ that we wish to adapt. $\boldsymbol{w}'$ is the attention weights of the parent of `T`, to be used as a mask when the alignment of `T` is computed. In the following space we describe the aligner module for alignment and the discriminator module for scoring a match between a subtree and part of the new utterance.

Aligner Module The aligner module produces an attention score over the new utterance given a subtree of a logical form. Inspired by the gating attention mechanism in (Kumar et al., 2016), we model attention for every word in the utterance as the maximum attention given by any predicate in the subtree `T`.

Algorithm 2 Adapt

function ADAPT(`Memory`, $\boldsymbol{X}', \boldsymbol{Y}$, `T`, $\boldsymbol{w}'$)
  Phase 1: aligning `T` to relevant words in $\boldsymbol{X}'$
  $\boldsymbol{w} \leftarrow$ ALIGN($\boldsymbol{X}', \boldsymbol{Y}$, `T`, $\boldsymbol{w}'$)
  $\boldsymbol{x}' \leftarrow \boldsymbol{X}' \cdot \boldsymbol{w}$
  if $\sum_i \boldsymbol{w}_i > 1$ **then**
    $\boldsymbol{x}' \leftarrow \boldsymbol{x}' \div \sum_i \boldsymbol{w}_i$

  Phase 2: deciding whether to replace `T` and then recurse
  $P(fail\ to\ match) \leftarrow$ DISCRIMINATE($\boldsymbol{x}', \boldsymbol{Y}$, `T`)
  if $P(fail\ to\ match) > 0.5$ **then**
    return LOOKUPANDADAPT(`Memory`, $\boldsymbol{X}', \boldsymbol{w}$)
  else
    for all `t` **in** `T.children` **do**
      `t'` $\leftarrow$ ADAPT(`Memory`, $\boldsymbol{X}', \boldsymbol{Y}$, `t`, $\boldsymbol{w}$)
      `T.children.replace(t, t')`
    return T

$$\boldsymbol{w}_i = \max_{j \in span(\texttt{T})} \sigma(s_{ij}) \tag{5}$$

where σ is the sigmoid function and

$$s_{ij} = g([\boldsymbol{X}_i, \boldsymbol{Y}_j, \boldsymbol{Y}_p, \boldsymbol{X}_i \odot \boldsymbol{Y}_j, \boldsymbol{X}_i \odot \boldsymbol{Y}_p, |\boldsymbol{X}_i - \boldsymbol{Y}_j|, |\boldsymbol{X}_i - \boldsymbol{Y}_p|, \boldsymbol{X}_i^T W_2 \boldsymbol{Y}_j, \boldsymbol{X}_i^T W_p \boldsymbol{Y}_p]) \tag{6}$$

where $\odot$ is element-wise product, $[a, b]$ is concatenation of vectors a and b, $\boldsymbol{X}_i$ is the ith column of $\boldsymbol{X}$, $\boldsymbol{Y}_i$ is the ith column of $\boldsymbol{Y}$, and g is a learnable linear transformation. $\boldsymbol{Y}_p$ is the representation of the parent predicate of the subtree `T` (e.g. the parent predicate is `field` for subtree `john` of logical form `(field parent john)`). We found that adding this feature helps the model learn to align arguments of predicates better.

We also found that constraining the attention further by requiring that the attention of a child node $\boldsymbol{w}$ be a refinement of the attention of a parent node $\boldsymbol{w}'$ facilitates good alignment. This is modeled by the update rule

$$\boldsymbol{w}_i \leftarrow \boldsymbol{w}_i \cdot \sqrt{\boldsymbol{w}'_i} \tag{7}$$

Observe that if the attention score of the parent node is very low for some word, the child is not going to be able to look at it. This encourages the parent node to attend to words not just relevant to itself but also the children, and encourages the child to refine rather than drastically change from the alignment of the parent node.

Given the output weights of the aligner module, we compute a fixed-size representation for the relevant words in the utterance to the current subtree `T` by first taking the weighted average $\boldsymbol{x}' = \boldsymbol{X}' \cdot \boldsymbol{w}$ where $\cdot$ is matrix product. If $\sum_i \boldsymbol{w}'_i > 1$, we will divide $\boldsymbol{x}'$ by $\sum_i \boldsymbol{w}'_i$ to normalize it. $\boldsymbol{x}'$ is then compared against the representation of the subtree by the discriminator to produce a confidence score indicating whether the subtree matches the words it aligns to in the utterance.

Discriminator Module The discriminator module learns to tell when a subtree fails to match the meaning of the words in its alignment. Given a subtree `T` of a logical form $\boldsymbol{Y}$, its fixed-size representation is computed as a mean of the representations for each predicate in the subtree using the formula $\boldsymbol{y} = \sum_{i \in span(\texttt{T})} \boldsymbol{Y}_i$, where $\boldsymbol{Y}_i$ is the ith column of $\boldsymbol{Y}$, and $span(\texttt{T})$ is the set of indices corresponding to all the predicates in the subtree `T`. For example, the fixed-size representation for the subtree `john` in logical form `(field parent john)` is just $\boldsymbol{Y}_4$ (indexing from 1, and also counting parentheses because they are also encoded in $\boldsymbol{Y}$).

We model the confidence that the subtree representation $\boldsymbol{y}$ fails to match the meaning of the aligned words $\boldsymbol{x}'$ as

$$P(fail\ to\ match | \boldsymbol{x}', \boldsymbol{y}) = \sigma(d) \tag{8}$$

where σ is the sigmoid function and

$$d = h([\boldsymbol{x}', \boldsymbol{y}, \boldsymbol{x}' \odot \boldsymbol{y}, |\boldsymbol{x}' - \boldsymbol{y}|, \boldsymbol{x}'^T W_3 \boldsymbol{y}]) \tag{9}$$

$\odot$ is element-wise product, $[a, b]$ is concatenation of vectors a and b, and h is a learnable linear transformation. This confidence score is used by Algorithm 2 to decide whether to replace the subtree or to keep it.

4 Training

In training, we maximize the log conditional likelihood of the data. Due to our selection of memory (one example for each grammar rule in G), for a given x there is a unique sequence of retrieval and adaptation actions that lead to the production of the correct y. Specifically, letting a_i be the ith action in the correct sequence of l actions, we define the probability of producing y given x as the probability of taking the sequence of actions $a_1, ..., a_l$. We decompose this joint probability into products of conditional probabilities of taking action i given the previous actions and the input x

$$P(y|x) = \prod_{i=1}^{l} P(a_i | a_1, a_2, ..., a_{i-1}, x) \tag{10}$$

If a_i is a retrieval action,

$$P(a_i|a_1, a_2, ..., a_{i-1}, x) = P(i|\boldsymbol{x}') \quad (11)$$

where $P(i|\boldsymbol{x}')$ is defined in Equation 3. If a_i is an adaptation decision, i.e. to replace a particular subtree

$$P(a_i|a_1, a_2, ..., a_{i-1}, x) = P(fail\,to\,match|\boldsymbol{x}', \boldsymbol{y}) \quad (12)$$

where $P(fail\,to\,match|\boldsymbol{x}', \boldsymbol{y})$ is defined in Equation 8.

5 Dataset Generation

Using existing semantic parsing datasets to directly evaluate one-shot parsing is difficult, because evaluation of one-shot parsing requires grouping of utterances by structural similarity to construct domains.

Therefore, we generate our own data [1] based on a synchronous context free grammar. We evaluate our approach on the generated dataset. Although our dataset is synthetic, it has the properties needed to evaluate one-shot parsing:

- clear distinction of domains
- plenty of examples for rules in the old domain
- one example for each rule in the new domain
- a separate evaluation set containing variations of the new rules

It is worth noting that although datasets such as OVERNIGHT (Wang et al., 2015) do have clear domain distinction, they do not have the other properties needed for a good evaluation of one-shot parsing. In the future, we are planning to use crowd-sourcing to rephrase the generated utterances in order to make them more natural.

We have two topics of discourse in the SCFG that we use to generate our data. The first is accessing some field of some object, and the second is setting some field of some object to some value or some field of another object. These are general purpose instructions that can express many common intents, such as looking up the location of a restaurant, getting the phone number of a contact, and setting reminders and alarms.

We have six domains of discourse in the SCFG that we use to generate our data – *person*, *restaurant*, *event*, *course*, *animal*, and *vehicle*. Table 2 includes sample sentences and their logical form for every domain of discourse.

Since one-shot parsing has two phases, our dataset is slightly different from a typical dataset consisting of a single collection of *utterance-logical form* pairs. In the following space we describe the sets of data generated for each domain. In the next section we describe how we can use this dataset to design two different one-shot parsing evaluation setups.

For each domain d, we define a G_d and randomly generate examples from $domain(G_d)$ to construct an "old" set of examples $D_{old,d}$. We also generate a representative subset $M_{old,d}$ to be used as the memory of our model. As described in § 3.1, $M_{old,d}$ contains one example for each grammar rule in G_d.

In addition, we define a set of new rules G'_d disjoint from G_d for each domain and generate one example $e_{i,d}$ for each new rule $g'_{i,d} \in G'_d$, and store them into the memory $M'_{new,d}$. These are the one-shot examples. The extended memory $M_{new,d} = M_{old,d} \cup M'_{new,d}$.

Finally, we generate evaluation sets $E_{old,d} \subset domain(G_d)$ and $E_{new,d} \subset domain(G_d \cup G'_d) - domain(G_d)$ where $-$ denotes set difference. In our experiments we split the evaluation sets randomly into a development set and a test set of the same size.

Some statistics of our generated dataset is presented in Appendix D. In the next section, we describe how we use this data to generate two different experimental scenarios for evaluating one-shot semantic parsing.

6 Results and Evaluation

We evaluate our approach in six domains, namely person, restaurant, event, course, animal, and vehicle, and in two one-shot parsing scenarios, namely *extension* and *transfer*. In the next section we define these two different scenarios. We compare the performance to a sequence-to-sequence parser with attention which is defined in the following paragraphs.

Baseline Our baseline is a sequence-to-sequence parser with attention. We use a 1-layer Bidirectional LSTM as the encoder for the utterance, and a 1-layer LSTM as the decoder for the logical form. We initialize the decoder with a learned projection of the last hidden state of the encoder. The inputs to the encoder are GloVe

[1] Our dataset can be accessed at https://github.com/zhichul/lookup-and-adapt-parser-data.

	Domain	Utterance & Logical Form
a_1	*person*	the hometown field of john
		(field (relation hometown) (person john))
a_2	*person*	set her 's parents with classmates
		(set (field (relation parent) (person reference)) (person classmate))
b_1	*restaurant*	irish restaurant instances 's price field
		(field (relation price) (restaurant irish))
b_2	*restaurant*	set address field of all irish restaurant as indian restaurant 's price
		(set (field (relation address) (restaurant irish)) (field (relation price) (restaurant indian)))
c_1	*event*	the start time of lectures
		(field (relation start) (event lecture))
c_2	*event*	set the attendants of that event to organizers field of receptions instances
		(set (field (relation attendant) (event reference)) (field (relation organizer) (event reception)))
d_1	*course*	size of my history course instances
		(field (relation size) (course history))
d_2	*course*	set all history course instances 's prerequisite field as physics course
		(set (field (relation prerequisite) (course history)) (course physics))
e_1	*animal*	life span of all lion instances
		(field (relation span) (animal lion))
e_2	*animal*	set fish instances 's family field with dog
		(set (field (relation family) (animal fish)) (animal dog))
f_1	*vehicle*	the source field of all buses
		(field (relation source) (vehicle bus))
f_2	*vehicle*	set operators of all subways as buses instances
		(set (field (relation operator) (vehicle subway)) (vehicle bus))

Table 2: Sample utterance-logical form pairs from each domain of discourse. Sentences a_1 ... f_1 parse to commands that retrieve a field of an object. Sentences a_2 ... f_2 parse to commands which set a field of an object to a constant or a field of another object. The grammar we use do not constrain the type of the set command. As a consequence, some sentences generated are not semantically correct according to a human interpreter but still they preserve the sentence structure. Sentence b_2, e_2, and f_2 are examples of this phenomena.

word embeddings, and the inputs to the decoder are concatenations of embeddings of logical predicates and context vectors. Context vectors are attention weighted averages of projected encoder states. The attention weights over the utterance for each decoding step t is computed by taking the dot product of the hidden state of the decoder at step t and the projected encoder state for each word in the utterance, normalized using the softmax function. The output of a decoding step t is a probability distribution over all the logical predicates. The distribution is modeled as a dot product between a projection of the overall decoding state at time t, and the embedding for each logical predicate, normalized using the softmax function. The overall decoding state at time t is the concatenation of the hidden state of the decoder at time t and the context vector at time t. Decoding of a logical form given an utterance is done as a greedy search over all possible logical forms to output.

Evaluation Metric Our evaluation metric is parsing accuracy. We define parsing accuracy as the ratio of the correctly parsed utterances in the test set. An utterance is parsed correctly if its generated logical form matches the annotated logical form exactly. E.g. `(field (relation parent) (person john))` is a correct parse of "parents of John". We report accuracy percentage in Tables 3 and 4.

6.1 Discussion

We design two different scenarios for one-shot parsing evaluation, namely the *extension* and the *transfer* scenarios. We define and discuss the results of each scenario in the following sections.

Extension This scenario tests one-shot parsing of new rules within the same domain that the model is trained on. In this case, we hold out several rules and their corresponding utterance-logical form pairs for evaluation and train on the remaining ones.

The results of this experiment are presented in Table 3. Each column indicates the evaluation results on each domain. The *full* scores refer to the overall percentage of correct parses on the entire test data, the *d=2* scores refer to the percentage of correct parses on examples with logical form

depth 2 and the *d=3* scores refer to the percentage of correct parses on examples with logical form depth 3.

As it can be seen in the table, our model is able to consistently improve the sequence-to-sequence baseline on all the domains by a significant margin of 68.8%.

Transfer This scenario tests one-shot parsing of new rules in a domain different from the one that the model is trained on. For example, in the *transfer* scenario for domain *person* the model is trained on examples from the other domains *restaurant*, *event*, *course*, *animal*, and *vehicle* and tested on samples from domain *person*. This is harder compared to the extension setup since it requires generalization to a completely new domain.

The results of this section are reported in Table 4. As it can be seen, the performance is improved by up to 36.6% compared to the baseline model.

In order to have a better understanding of the model and indicate why it is performing comparable to the baseline on some of the domains setting, we carry out a model analysis in the next section.

Model Analysis We add two variations of our model ORACLE-DISCRIM and PRETRAIN-ENC for the transfer scenario to see the performance improvements gained from replacing different components of our model with an oracle/near oracle. This identifies potential bottlenecks of the model.

In ORACLE-DISCRIM, we load a trained model from LOOKUPADAPT but replace the discriminator with an oracle during evaluation. As the numbers in row 3 of Table 4 show, using an oracle discriminator improves the model performance by more than 10% in the *vehicle* domain and *course* domain, and by smaller amounts in the other domains. On one hand, this suggests that the discriminator has room for improvement. On the other hand, the numbers suggest that there is still a much larger room for improvement for the encoder, aligner, and look-up components. Our hypothesis is that the encoder components are likely the main bottleneck because during evaluation in the *transfer* scenario they have to produce good representations for utterances and logical forms very different from the ones which they have seen during training. We found evidence supporting this hypothesis in the PRETRAIN-ENC variation.

In PRETRAIN-ENC, we pretrain our model on all the domains, which ensures that the two encoders see all domains. We then use the encoder parameters of this all-domain pretrained model to initialize the encoders in the experiments for the *transfer* scenario. We then fix the encoders and train only the aligner, discriminator, and look-up parameters. This results in near perfect generalization to the test domain by the aligner, discriminator, and look-up components, which are trained only on the other domains. This suggests that the encoder is the main bottleneck of our model since using a near-oracle version boosts its performance to perfect. The results for this variation is shown in row 4 of Table 4.

7 Related Work

Semantic parsing is the task of mapping utterances to a formal representation of their meaning. Researchers have used grammar-based methods as well as machine learning-based methods to address this problem. Grammar-based parsers work by having a set of grammar rules that are either learned or hand-written, an algorithm for generating a set of candidate logical forms by recursive application of the grammar rules, and a criterion for picking the best candidate logical form within that set (Liang and Potts, 2015; Zettlemoyer and Collins, 2005, 2007). However, they are brittle to the flexibility of language. To improve this limitation, supervised sequence-based neural semantic parsers have been proposed (Dong and Lapata, 2016). Herzig and Berant (2017) improved the performance of neural semantic parsers by training over multiple knowledge bases and providing the domain encoding at decoding time. In addition to supervised learning, reinforcement learning methods for neural semantic parsing have been explored in (Zhong et al., 2017).

Retrieve-and-edit style semantic parsing is gaining popularity. Hashimoto et al. (2018) proposed a retrieve and edit framework that can efficiently learn to embed utterances in a task-dependent way for easy editing. Our work differs in that we perform hierarchical retrievals and edits, and that we evaluate on cross-domain data and focus on one-shot semantic parsing. It is worth noting that retrieve-and-edit as a general framework is not limited to semantic parsing and is applicable to other areas such as sentence generation. Gu et al. (2018).

Another line of research maps semantic parsing under cross-domain setting to a domain adaptation problem (Su and Yan, 2017). In their work, the model is trained on a certain domain and then fine tuned to parse data from another domain. This is in essence different from our work in that we do not adapt the model, rather we adapt seen samples to form parses of new samples. Moreover, We do not fine-tune any part of the model in the new domain and focus on one-shot semantic parsing.

Most of these models need many data-points to train. Therefore, there has been recent attempts at zero-shot semantic parsing. Dadashkarimi et al. (2018) proposed a transfer learning approach where a domain label is predicted first and then the parse. Ferreira et al. (2015) and Herzig and Berant (2018) proposed slot-filling methods for semantic parsing based on general word embeddings. Bapna et al. (2017) focuses on zero-shot frame semantic parsing by leveraging the description of slots to be filled.

8 Conclusion and Future Work

As speech recognition technologies mature, more computing devices support spoken instructions via a conversational agent. However, most agents do not adapt to the phrasing and interest of a specific end user. It has recently been shown that new functionalities can be added to an agent from user instruction (Azaria et al., 2016; Labutov et al., 2018). However, the user instruction only provides one instance of a general instruction template and the agent is challenged to generalize to variations of the instance given during instruction. We define the *one-shot parsing* task for measuring a semantic parser's ability to generalize to new instances of user-taught commands from only one example. We propose a new semantic parser architecture that learns a general strategy of retrieving seen utterances similar to an unseen utterance and adapting the logical forms of seen utterances to fit the unseen utterance. Our results show an improvement of up to 68.8% on one-shot parsing under two different evaluation settings compared to the baselines. We found that the BiLSTM encoders are likely bottlenecks for the model. Some future directions include exploring the effects of contents in the memory, automating memory extraction from dataset, and improving the encoder.

Abstract

The segmentation problem is one of the fundamental challenges associated with name entity recognition (NER) tasks that aim to reduce the boundary error when detecting a sequence of entity words. A considerable number of advanced approaches have been proposed and most of them exhibit performance deterioration when entities become longer. Inspired by previous work in which a multi-task strategy is used to solve segmentation problems, we design a similarity based auxiliary classifier (SAC), which can distinguish entity words from non-entity words. Unlike conventional classifiers, SAC uses vectors to indicate tags. Therefore, SAC can calculate the similarities between words and tags, and then compute a weighted sum of the tag vectors, which can be considered a useful feature for NER tasks. Empirical results are used to verify the rationality of the SAC structure and demonstrate the SAC model's potential in performance improvement against our baseline approaches.

1 Introduction

Named entity recognition (NER) focuses on extracting a specific sequence and then classifying the sequence as a predefined category. As a fundamental and important task in natural language understanding and information extraction, NER can be considered a sequence labelling task, which includes part-of-speech (POS) tagging, chunking, and semantic role labelling (SRL) (Collobert et al., 2011). Owing to the growing popularity of deep learning techniques, a considerable number of neural network-based approaches and traditional conditional random fields (CRF) have been proposed and are widely used in many sequence labelling tasks to obtain magnificent results (Ye and Ling, 2018; Wu et al., 2018; Ghaddar and Langlais, 2018).

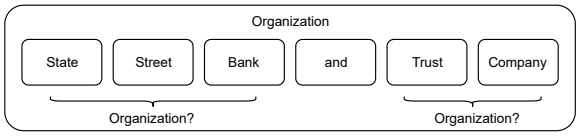

Figure 1: The segmentation problem in NER. "State Street Bank and Trust Company" is an organization entity with six words, it would be unsatisfactory if we consider "State Street Bank" and "Trust Company" to be two entities

To enhance NER's performance, significant effort has been devoted in this area, and one direction is to employ useful information at the input end. This mechanism can be realized by including hand-crafted features (Collobert et al., 2011; Passos et al., 2014; Huang et al., 2015). To eventually reduce heavy feature engineering, some researchers have argued for the exclusion of task-specific features and for the automatic mining of character level features and word level features (Ma and Hovy, 2016; Liu et al., 2018). Such end-to-end models can potentially improve performance with the exclusion of hand-crafted features.

While character and word level features demonstrate promising results, Ye and Ling (2018) determined that such methods (i.e. LM-BiLSTM-CRF (Liu et al., 2018)) will be relatively less effective for longer entity recognition. As indicated by Zhuo et al. (2016), NER is a segment-level task, and such NER models should be able to extract segment information while word-level labels might tend to learn more word level information than segment level information. Such limitations can manifest as entity boundary errors, referred to as the segmentation problem. This problem is illustrated in Figure 1.

There have been many attempts to address the segmentation problem. Some researchers employed segment level information, e.g., Semi-CRF

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1140–1149,

(SCRF) (Zhuo et al., 2016), to address this challenge. Though SCRF exhibits promising results in the case of longer entity recognition, it requires additional feature extractors and exhibits some limitations in the case of shorter entity recognition. Ye and Ling (2018) proposed using CRF jointly with SCRF to address this problem. On the other hand, researchers have also adopted a multi-task strategy to predict boundaries. For example, Stratos (2016) divides NER into a two-step task in which the boundary is first predicted and then the entity type of the boundary is determined. Though this method is easy to implement, it relies heavily on the accuracy of the first step. Another alternative thought is to employ auxiliary tasks to address this problem. For example, Aguilar et al. (2017) created two auxiliary tasks to help determine entity boundaries and types. However, the authors considered the auxiliary tasks to be supervisors, which means that the outputs of the auxiliary tasks are not fully utilized.

In this study, inspired by the research indicated previously, we design an auxiliary classification task that aims to distinguish entity words from non-entity words before executing the main NER task. Unlike prior studies, the outputs of the auxiliary task do not directly determine the entity boundaries but rather serve as features for assisting the main task. Therefore, the auxiliary task is more like an "advisor" rather than supervisor to the entire model. Our auxiliary classifier is different from conventional classifiers, which compute the probability of an entity word using the $softmax$ function. Instead, we initialize two trainable vectors for the classifier to identify "True" and "False" tags, and then we determine the similarity scores between each word and the two tag vectors to indicate the probability whether the word is an entity word. The hypothesis is that tag vectors can serve as helpful features that are shared by a majority of entity words and non-entity words in NER tasks. Finally, we obtain the weighted sum of the tag vectors by using the similarity scores. In this study, this process is referred to as a similarity based auxiliary classifier (SAC).[1] The empirical results verify the rationality of SAC's structure and demonstrate that the SAC model can reduce segmentation problems and exhibit good performance in recognizing entities of different lengths.

The contributions of this paper are as follows: 1) We introduce a similarity based auxiliary classifier (SAC), which allows the model to determine whether a word is an entity word before predicting its entity label to overcome the segmentation problem. 2) By analyzing the experimental results, we verify the rationality of SAC's structure and demonstrate the advantages of using the weighted sum of tag vectors compared to a list of scores denoting classification results. 3) Without using any hand-crafted features, NeuralCRF+SAC outperforms existing state-of-the-art end-to-end models on CoNLL 2003 and Ontonotes 5.0. When using external resource like ELMo, NeuralCRF+SAC still exhibits comparable results.

2 Related work

NER is a fundamental task, and traditional methods usually adopt statistical machine learning models e.g., Hidden Markov Models (HMM), Maximum-entropy Markov Models (MEMM), and Conditional Random Fields (CRF) (Bikei et al., 1998; McCallum et al., 2000; Lafferty et al., 2001). To improve overall performance, many hand-crafted features such as POS chunking tags and gazetteers are required and integrated into the task (Chieu and Ng, 2002; Florian et al., 2003; Ando and Zhang, 2005).

With the growing popularity of deep learning techniques, neural networks have been widely adopted for NER tasks. Collobert et al. (2011) initiated the trend of using neural networks for sequence labelling tasks. Huang et al. (2015) combined BiLSTM with CRF for NER tasks. Because of the powerful feature mining ability of neural networks, some end-to-end models employ neural structures to extract character features and obtain state-of-the-art results without using hand-crafted features (Lample et al., 2016; Ma and Hovy, 2016; Liu et al., 2018). Hand-crafted features such as POS tags, word capitalization, and lexicons are commonly used (Chiu and Nichols, 2016; Ghaddar and Langlais, 2018; Wu et al., 2018). It was recently proved that using contextualized representations from pretrained language models can significantly improve performance (Peters et al., 2017, 2018; Devlin et al., 2018).

To address the segmentation problem, several methods have been proposed, among which Semi-CRF(SCRF) is a successful solution for segment-

[1] code available at https://github.com/XiaoShiyuan/NCRF-SAC

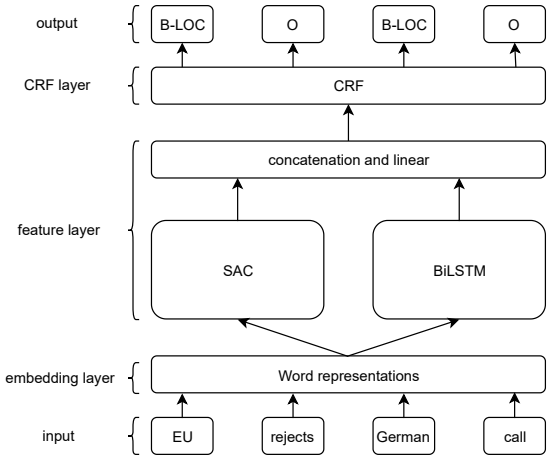

Figure 2: Overall architecture of NeuralCRF+SAC

level modeling (Zhuo et al., 2016). Ye and Ling (2018) proposed an improved version of SCRF, namely HSCRF. Using a multi-task strategy to combine HSCRF and CRF, the HSCRF model exhibits state-of-the-art results without using external resources. In particular, HSCRF resolves the segmentation problem by matching entity lengths. In addition, there are other approaches that consider multi-task learning to predict entity boundaries. Stratos (2016) divides NER into two tasks. First, CRF is used to predict the location and boundary of entities and to classify the entities. Aguilar et al. (2017) used the outputs of their feature extractor to perform segmentation, categorization, and then sequential classification.

Our method exploits the features of multi-task learning and proposes a similarity based auxiliary classifier (SAC). Compared to existing studies that usually consider auxiliary tasks to be supervisors, we also use the output of SAC to support the NER task. Meanwhile, we employ vectors to denote "True" and "False" tags, which contain more useful information compared to simply using "1" and "0" to denote tags.

3 Methodology

3.1 Overall Architecture

We implement the framework based on BiLSTM-CNN-CRF(NeuralCRF) (Ma and Hovy, 2016), a robust and widely used neural network in English NER tasks, and we build our SAC parallel to BiLSTM. The overall architecture of NeuralCRF+SAC is presented in Figure 2.

Embedding layer. Denoting input sequences as $X = \{x_1, x_2, ..., x_T\}$, we first obtain the word-level vector $W = \{w_1, w_2, ..., w_T\}$. Next, a Char-CNN is employed to obtain character-level features $C = \{c_{w_1}, c_{w_2}, ..., c_{w_T}\}$ (Santos and Zadrozny, 2014; Chiu and Nichols, 2016; Ma and Hovy, 2016). Finally, we obtain $[w_i; c_{w_i}]$ to denote x_i, where [;] indicates concatenation.

Feature layer. In this layer, we employ BiLSTM to extract contextual features and SAC to generate weighted vectors. The calculations can be expressed as follows:

$$\overrightarrow{h_i} = LSTM(\overrightarrow{h_{i-1}}, [w_i; c_{w_i}]) \quad (1)$$

$$\overleftarrow{h_i} = LSTM(\overleftarrow{h_{i-1}}, [w_i; c_{w_i}]) \quad (2)$$

$$h_{a_i} = SAC([w_i; c_{w_i}]) \quad (3)$$

Here, we use SAC to denote all operations of the classifier and we will introduce it in detail in Section 3.2. The three outputs are then concatenated and operated as $z_i = Linear([\overrightarrow{h_i}; \overleftarrow{h_i}; h_{a_i}])$, where $Linear$ denotes a linear calculation.

CRF layer. Because of the ability to utilize information from neighboring labels, CRF is widely employed in sequence tagging tasks. Denoting label sequences as $Y = \{y_1, y_2, ..., y_T\}$, the collection of all possible labels as $\mathcal{Y}$, and semantic feature sequence as $Z = \{z_1, z_2, ..., z_T\}$, CRF can be described as a family of conditional probabilities $p(y|Z)$:

$$p(y|Z) = \frac{\prod_{i=1}^{T} \phi_i(y_{i-1}, y_i, z_i)}{\sum_{y' \in \mathcal{Y}} \prod_{i=1}^{T} \phi_i(y'_{i-1}, y'_i, z_i)} \quad (4)$$

where $\phi_i(y_{i-1}, y_i, z_i) = exp(W_{y_{i-1},y} z_i + b_{y_{i-1},y_i})$ is the potential function and $Z = \{z_1, z_2, ..., z_T\}$ are the outputs of the feature layer.

For the training process, we minimize the negative log likelihood:

$$\mathcal{L}_{\mathcal{CRF}} = -\sum_i log(p(y_i|Z)) \quad (5)$$

while the Viterbi algorithm (Forney, 1973) is used to decode the best label sequence.

3.2 Similarity based Auxiliary Classifier

We believe that SAC can concentrate on one word and on the nearest neighbors of the word rather than on long-term dependency because we believe that information from the word itself and its nearest neighbors contribute the most in determining whether the word is an entity word. Compared to RNN, CNN exhibits a distinct advantage that

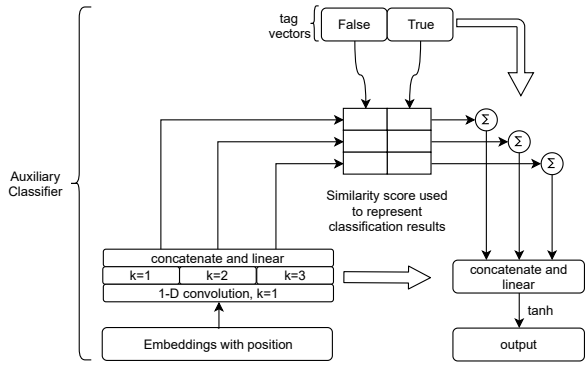

Figure 3: The architecture of SAC. Notice that the convolutional block (lower left) includes 4 1-dimentional convolutional neural networks, which share the same filter settings. Kernel size is marked out.

it can accurately control the length of the context, which satisfies our requirement. Therefore, SAC is based on CNN. The structure of this module is presented in Figure 3. To prevent the loss of positional information while using CNN, we implement a position encoder (Vaswani et al., 2017) to generate position vectors $p_i \in \mathbb{R}^d$, where d is configurable and p_i is concatenated with $[w_i; c_{w_i}]$ to form new embeddings $[w_i; c_{w_i}; p_i]$. The new embeddings are then sent to the convolutional block to extract uni-gram, bi-gram and tri-gram information. We denote the output of this convolutional block as $H_c = \{h_{c_1}, h_{c_2}, ..., h_{c_T}\}$, where $h_{c_i} \in \mathbb{R}^n$.

Intuitively, we adopt a multiplicative attention mechanism (Luong et al., 2015) for computing similarity. For the purpose of classifying entity words and non-entity words, we use $t_i, (i \in \{0, 1\})$ to denote non-entity words and entity words, respectively. Then, we randomly initialize two tag vectors $v_i \in \mathbb{R}^{d_h}, (i \in \{0, 1\})$ as semantic representations of $t_i, (i \in \{0, 1\})$. We express the computation as follows:

$$e_{ij} = v_i^T W_n h_{c_j} \tag{6}$$

$$a_{ij} = \frac{exp(e_{ij})}{\sum_{k=0}^{1} exp(e_{kj})} \tag{7}$$

$$s_j = \sum_{i=0}^{1} a_{ij} v_i \tag{8}$$

$$h_{a_j} = tanh(W_a[h_{c_j}; s_j] + b_a) \tag{9}$$

where $W_n \in \mathbb{R}^{d_h \times n}$, $W_a \in \mathbb{R}^{n \times (n+d_h)}$ and $b_a \in \mathbb{R}^n$. Innovatively, we use a_{ij}, the similarity score between i^{th} tag and h_{c_j} as the classification result.

Dataset		train	dev	test
CoNLL 2003	#tok	204567	51578	46666
	#ent	23499	5942	5648
Ontonotes 5.0	#tok	1088503	147724	152728
	#ent	81828	11066	11257
WNUT 2017	#tok	62729	15733	23394
	#ent	3160	1250	1589

Table 1: Statistics of these three datasets, #tok denotes tokens and #ent denotes entities.

For instance, if the j^{th} word is an entity word, its feature representation h_{c_j} must have a higher similarity score with v_1. Therefore, SAC operates in a manner that is similar to a "supervised cluster," separating entity words from non-entity words, and denoting two "clustering centers" with two tag vectors. According to Equation 8 and 9, classification information related to the j^{th} word can be expressed as a weighted sum s_j and is then concatenated with h_{c_j}. Finally, we obtain the output $H_a = \{h_{a_1}, h_{a_2}, ..., h_{a_T}\}$.

To train this auxiliary classifier, we define attention loss as follows:

$$\mathcal{L}_{\mathcal{A}} = -\frac{1}{T} \sum_{j=1}^{T} \sum_{i=0}^{1} t_i log(a_{ij}) \tag{10}$$

By combining $\mathcal{L}_{\mathcal{CRF}}$ and $\mathcal{L}_{\mathcal{A}}$, we obtain the loss function:

$$\mathcal{L} = \mathcal{L}_{\mathcal{CRF}} + \lambda \mathcal{L}_{\mathcal{A}} \tag{11}$$

We obtain the best and most stable $\lambda = 0.05$ when using the IOBES tag scheme.

4 Experiments

4.1 Experiments Setup

Dataset. We performed experiments on CoNLL 2003 (Tjong Kim Sang and De Meulder, 2003), Ontonotes 5.0 (Hovy et al., 2006) and WNUT 2017 shared tasks (Derczynski et al., 2017). CoNLL 2003 is a widely used dataset comprising data extracted from Reuters news articles. Ontonotes 5.0 is a large-scale dataset comprising data collected from news, weblogs, etc. WNUT 2017 is a small dataset consisting primarily of emerging entities. All datasets have been separated into training/dev/test sets and they include 4/18/6 entity types, respectively. Table 1 presents some statistics of the 3 datasets.

Configuration. All models were implemented with TensorFlow [2]. We used GloVe (Pennington

CNN	**97.87**	**91.65**

Table 3: Comparing different structure of SAC. Accuracy indicates that of an auxiliary classification task and F1 for an NER task

et al., 2014) (300-dim, trained on 840B corpus[3]) pretrained word embeddings, and the same hyper-parameters on BiLSTM-CNN-CRF(NeuralCRF) and NeuralCRF+SAC. To determine performance using external resources, we included ELMo representations. All hyper-parameters, most of which are empirical parameters, are listed in Table 2 and an early stopping strategy was adopted. The main experiments were tested for 5 times to obtain the mean and standard deviation of F1 score.

Evaluation. After training, the latest 50 checkpoints were preserved and we obtained the checkpoint with the highest word-level F1-score to make predictions on the test set. Following this, we used the official CoNLL evaluation script on the CoNLL 2003 dataset and ontonotes 5.0 and the WNUT evaluation script on the WNUT 2017 dataset.

4.2 Development experiments

To verify the rationality of the structure of SAC and the role of the tag vectors, we designed two development experiments on the CoNLL 2003 dataset. One experiment compared the CNN structure in SAC with the BiLSTM structure. The other one compared SAC with a modified TextCNN.

Comparing with an RNN structure We believe that if a word is an entity word, its nearest neighbors are very likely to be entity words as well. Although there are many one-word entities, these entities always share an obvious feature such as capital letters, which can be easily captured by a char-CNN. On the contrary, if a word is a non-entity word, under most circumstances, there would be at most one entity word among the adjacent words. However, when considering long-term dependency, a word can be affected by several former or latter words, which could weaken the influence of adjacent words and introduce unnecessary noise. Therefore, we chose CNN instead of RNN in SAC and we set the max kernel size to 3.

To verify if a CNN structure is more suitable in SAC, we replace the convolutional block with BiLSTM. In Table 3, we can observe that the maximum F1 value of the entire model is 91.65 when employing a CNN structure compared to 91.20 when using BiLSTM. To determine the reason for a large performance drop, we compare the performances of the two structures in the face of different entity lengths. From Figure 4, we can observe that if SAC uses a BiLSTM structure, the overall performance will still deteriorate as entities become long, indicating that SAC appears to be redundant for the entire model. Maybe it is because BiLSTM also exists in NeuralCRF, and using BiLSTM in SAC may cause NeuralCRF and SAC to obtain duplicate features.

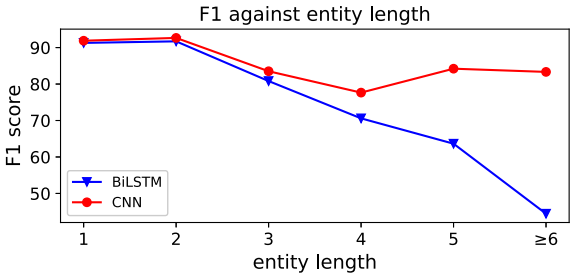

Figure 4: Comparing the ability of SAC with different structures to identify different length entities.

	max	**91.65**

Table 5: Results on CoNLL 2003 NER task without external resources.

Comparing with TextCNN In addition, we employed a conventional classifier like TextCNN (Kim, 2014) to replace SAC. As is known, TextCNN predicts a set of scores for each sentence according to the number of categories. The position of the largest score indicates the category of the sentence. As is shown in Figure 5, to enable TextCNN to predict scores for each word, and to make a fair comparison with SAC, we remove the pooling layer of TextCNN and adopt the same convolutional structure as SAC. Meanwhile, both outputs of TextCNN and SAC include features mined by their convolutional layers. The difference lies in the other part of their outputs in which TextCNN includes a series of scores while SAC provides the weighted sum of the tag vectors.

Table 4 demonstrates that NeuralCRF+SAC obtains a maximum F1 score of 91.65 while NeuralCRF+TextCNN receives a score of 91.47. However, we can observe that TextCNN exhibits higher accuracy on its own classification task. We must declare that the accuracy of SAC has different meanings in terms of the accuracy of TextCNN. For TextCNN, an accuracy score of 98.29 only means that TextCNN assigns 98.29% of the words with the right tags. However, for SAC, an accuracy score of 97.87% also means that 97.87% of the words share common traits in which a majority of entity words are similar to the "True" tag vector, while the majority of non-entity words are similar to "False" tag vector. Therefore, because of the higher F1 score obtained from NeuralCRF+SAC, the two tag vectors can be viewed as features that are helpful for the NER task. Just like our baseline approach, NeuralCRF, uses char-CNN to mine character-level features. SAC automatically mines features that are shared by entity words or non-entity words.

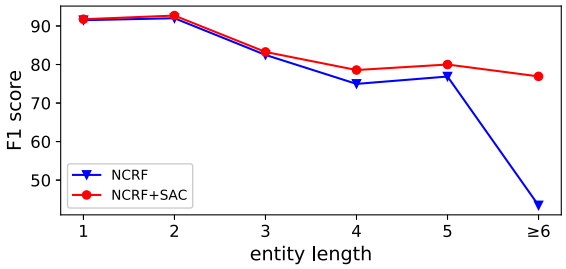
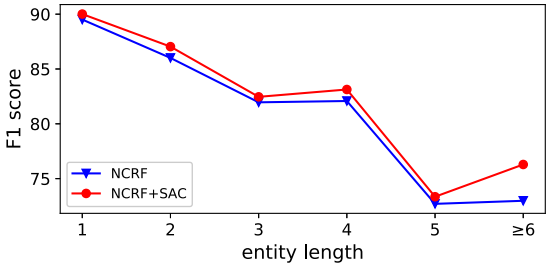
cause of the popularity of contextualized representation, we introduce EMLo[5] in the embedding layer as a form of external resources and results, which are presented in Table 6. Observe that our model still exhibits a 0.37 F1 improvement over the base model, which verifies the effects of the SAC. Despite using BERT(LARGE), we still obtain state-of-the-art results, even though it requires a considerable number of resources to be expended. In contrast, our method is flexible and resources friendly.



4.4 Results on Ontonotes 5.0 dataset

We present the experimental results on Ontonotes 5.0 in Table 7. Without using external resources, our model exhibits a mean F1 score of 87.24, which still exceeds the previous end-to-end model. When employing ELMo as external resources, we obtain a mean F1 score of 89.05. Comparing to NeuralCRF, SAC brings 0.59 and 0.64 F1 improvements respectively.



4.5 Results on WNUT 2017 shared task

Experimental results on the WNUT17 dataset are presented in Table 8. Owing to the facts that this task focuses on unusual and previously-unseen entities, all existing models incorporate some handcrafted features. We include ELMo representations in this experiment. SAC exhibits a 0.84 improvement in F1(entity) and 1.49 improvement in F1(surface).

(b) F1 against entity length(Ontonotes 5.0)

(c) F1 against entity length(WNUT 2017, with ELMo)

Figure 6: F1 against length test on all three datasets.

4.6 Analysis

Performance against entity length. We believe that before using CRF to predict the final label of a word, using a classifier to determine whether the word is an entity word helps in addressing problems related to segmentation, particularly when entities become long. Following Ye and Ling (2018)'s study, we compared the performance of NeuralCRF and NeuralCRF+SAC in identifying entities of different lengths on three datasets. The experimental results of the CoNLL 2003, Ontonotes 5.0, and WNUT 2017 datasets are presented in Figure 6. To eliminate the impact of external resources, we use the end-to-end approach as far as possible. But because the WNUT 2017 datasets are relatively small and most of them are emerging entities, which makes both

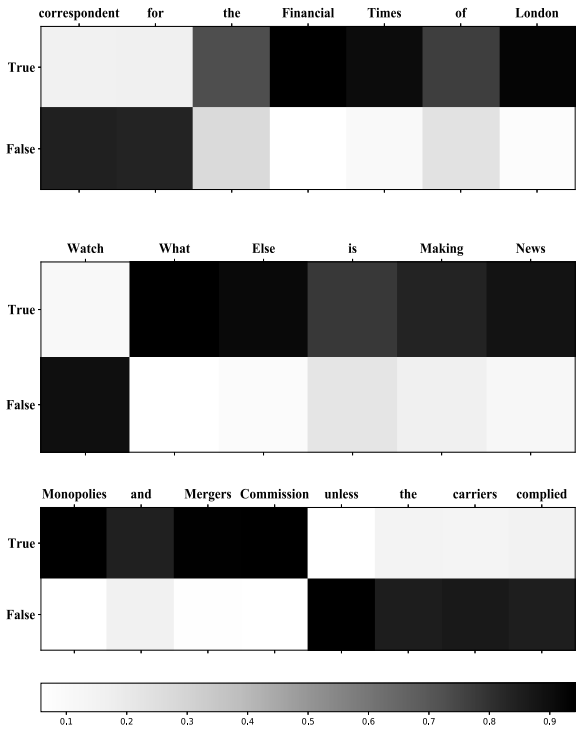

Figure 7: Similarity scores of three examples

models incapable of recognizing entities consisting of 4 or more words, we employed ELMo in WNUT 2017.

Observe that Figure 6(a) indicates a big improvement when entity lengths are equal to or greater than 4 and Figures 6(b) and 6(c) illustrate even improvements against different lengths.

In addition, we compared NeuralCRF+SAC with Ye and Ling (2018)' work in Table 9. The two models perform comparably when the entity length is less than 4, but NeuralCRF+SAC exhibits even improvements when the entity length is equal to or larger than 4, which demonstrates that SAC can improve the overall performance in long entity recognition.

Case study. We examined the manner in which SAC handles long entities. Table 10 presents three cases from 3 datasets, respectively. We observe that these 3 cases are quite similar and NeuralCRF makes almost the same mistake on each of them. Generally speaking, character level features are quite powerful for the NER task that words written in uppercase letters are easily recognized as entity words. In addition, if all the letters of a word are lowercase letters, they are more likely to be classified as non-entity words. Therefore, we can observe that cases in which meeting words like "of", "is" and "and" are too normal to be considered entity words, it is very easy for NeuralCRF to predict an "O" label for these words. In fact, many long entities exhibit a pattern in which almost all words are written in uppercase letters except one. Therefore, it is common that the segmentation problem grows in severity as entities become longer. However, these three examples indicate that SAC can address this problem to some extent. We obtain the similarity scores of these examples and present them in Figure 7. It is obvious that SAC assigns a high similarity score to "of", "is" and "and" even though they hardly include any features of entity words.

A possible reason is that the CNN structure of SAC plays a role. As discussed in Section 4.2, CNN can control the length of the context. When the kernel sizes are set to 1, 2 and 3, CNN layers can extract uni-gram, bi-gram and tri-gram features that enable SAC to learn a considerable number of samples that exhibit the same structure as "Time of London." Therefore, SAC reduces truncation errors for long entities caused by lowercase words.

5 Conclusion

In this work, we extended the BiLSTM-CNN-CRF architecture with SAC to address the segmentation problem. By computing the similarity scores between words and two tag vectors, respectively, SAC provides the weighted sum of tag vectors together with features it mined to support the main NER task. Because of the higher accuracy of SAC, the two tag vectors can be considered features that are shared between entity words and non-entity words. By reducing the boundary errors, SAC addresses the segmentation problem and improves overall performance, particularly when entities become long. Experimental results demonstrate that NeuralCRF+SAC surpasses previous state-of-the-art end-to-end models on the CoNLL 2003 and Ontonotes 5.0 datasets without using external resources. Moreover, when including ELMo, SAC still improves overall performance and is comparable to current state-of-the-art models.

Abstract

This paper describes a method of variable beam size inference for Recurrent Neural Network Grammar (RNNG) by drawing inspiration from sequential Monte-Carlo methods such as particle filtering.

The paper studies the relevance of such methods for speeding up the computations of direct generative parsing for RNNG. But it also studies the potential cognitive interpretation of the underlying representations built by the search method (beam activity) through analysis of neuro-imaging signal through correlations with the neuro-imaging signal during naturalistic text listening

1 Introduction

The paper provides a preliminary investigation of how the improvements in natural language parsing techniques can be used for modelling brain activity during online sentence comprehension. Specifically, we focus on the RNNG generative parsing framework (Dyer et al., 2016), that allows us to extract information-theoretic measures that are relevant for cognitive studies such as surprisal or entropy (Hale, 2016).

RNNG is essentially a generative parsing framework but it is not straightforward to design a one-step generative parser. Dyer et al. (2016) achieves generative parsing with RNNG in two steps: by reranking a discriminative parser. Stern et al. (2017) points out that the main difficulty comes from lexical biases using naive beam search. They propose new methods for modifying a classical word-synchronized beam search for avoiding the lexical bias problem.

The paper presents a substantially different search method for parsing in one-step with a neural generative parser, proposing a method inspired by sequential Monte-Carlo sampling and particle filtering (Doucet and Johansen, 2011; Buys and Blunsom, 2015).

Crucially, the proposed method is naturally not sensitive to problems of lexical biases faced by standard beam search. As a result, the parser is framed as generative and strictly incremental (without lookahead) while remaining quite accurate and generally more efficient than a more traditional beam search method. Not only, the proposed search method is a variable-beam search method, but as such, it naturally provides an additional method to measure the activity required to make the parser progress incrementally and word-by-word that can, in principle, be used for cognitive modelling purposes.

Taking advantage of our search method properties, we introduce new parsing complexity measures such as beam-size and beam-activity, adding to the well known entropy or surprisal that are already provided by the generative model. Finally, we evaluate the potential cognitive relevance of such measures for analyzing neuro-imaging data. Instantiating syntactic processing in terms of parser's analyses has already highlighted the language brain network to a large extent in the neuroimaging literature, we therefore expect that the goodness of fit of our parsing model with fMRI signal can be taken as an index of cognitive relevance. In other words, we aim at using our parsers' beam activity as a *proxy* modelling the kind of processes that might take place during online sentence comprehension, and thus investigate the potential cross-fertilization between computational solutions and cognitive-neuro imaging approaches to human parsing. The paper is organized as follows. Section 2 first describes an in-order variant of RNNG that is used as underlying formal framework supporting our experiments. It describes the variable beam search method inspired by particle filtering and finally introduces metrics quantifying

online parsing process. Section 3 provides empirical measures and quantifies the behaviour of the parser and of the proposed search method. Section 4 describes the relationship between the parsing model and the analysis of neuro-imaging data, section 5 presents the results.

2 RNNG and language modelling

2.1 In-order RNNG

We use an in-order variant of RNNG (Liu and Zhang, 2017; Kuncoro et al., 2017) where the set of transitions echoes the one of a left-corner parser. A configuration is a triple $\langle \mathbf{S}, \mathbf{B}, n \rangle$ where $\mathbf{S}$ is a stack, $\mathbf{B}$ is a buffer and n a counter of open brackets.

Init $\langle \emptyset, x_1 \dots x_n, 0 \rangle$

Goal $\langle S_0 \bullet, \emptyset, 0 \rangle$

Generate(x) $\frac{\langle \mathbf{S}, \bullet x_i | \mathbf{B}, n \rangle}{\langle \mathbf{S} | x_i \bullet, \mathbf{B}, n \rangle}$

Open(N) $\frac{\langle \mathbf{S} | S_0 \bullet, \mathbf{B}, n \rangle}{\langle \mathbf{S} | \bullet N | S_0 \bullet, \mathbf{B}, n+1 \rangle}$

Close $\frac{\langle \mathbf{S} | \bullet N_i | \dots | S_0 \bullet, \mathbf{B}, n \rangle}{\langle \mathbf{S} | N \bullet, \mathbf{B}, n-1 \rangle}$

Each **Open** action is parametrized by a nonterminal symbol, thus there are as many nonterminals in the set A of actions as there are nonterminal symbols. As the parser is generative, there are as many generate actions as there are words x in the vocabulary X. Note however that we constrain the generate action to be the words $x_1 \dots x_n$ of the actual sentence to parse. Observe also that the set of actions differs from the standard top down formulation of RNNG (Dyer et al., 2016) and from the in-order transition system of (Liu and Zhang, 2017) only because of the definition of the **Open** action: our formulation pops from the stack the left corner constituent S_0 and pushes back on the stack the predicted category $\bullet N$ before S_0. That is, during parsing, the stack keeps the same internal structure as in the top down version (Dyer et al., 2016) but the tree traversal is different.

A derivation $(\mathbf{x}, \mathbf{y}) = a_1 \dots a_m$ of an RNNG is a sequence of actions $a_1 \dots a_m$. The weight of a derivation of length m is defined as

$$P(\mathbf{x}, \mathbf{y}) = \sum_{j=1}^{m} \log P(a_j | a_1 \dots a_{j-1})$$

At each inference step the parser has to score the set of actions. The neural model seeks to assign a probability distribution $\mathbf{p}$ to the set A of actions given the parsing context:

$$\mathbf{p} = \textsc{Softmax}(\mathbf{W}\mathbf{h} + \mathbf{b})$$

The parsing context $\mathbf{h}$ is itself encoded by a stack-LSTM (Dyer et al., 2016):

$$\mathbf{h} = \textsc{Stack-Lstm}(\mathbf{e}_1 \dots \mathbf{e}_n)$$

where each $\mathbf{e}_i$ is either a word $\mathbf{e}_i^W$, a nonterminal $\mathbf{e}_i^N$, or a tree embedding $\mathbf{e}_i^T$. Word representations are pushed on the stack-LSTM by the **generate** action and are the concatenation of a word embedding $\mathbf{w}$ and an embedding of the word's characters $c_1 \dots c_n$:

$$\mathbf{e}_i^W = [\mathbf{w}; \textsc{Bi-Lstm}(c_1 \dots c_n)]$$

Nonterminal $\mathbf{e}_i^N$ and tree embeddings $\mathbf{e}_i^T$ are computed using the same methods as in (Dyer et al., 2016).

As $\mathbf{p}$ encodes the conditional distribution $P(a_i | a_1 \dots a_{i-1})$, the network is trained on treebank data of N sentences to maximize the log likelihood:

$$\ell(\boldsymbol{\theta}) = \sum_{i=1}^{N} \sum_{j=1}^{m} \log P(a_j | a_1 \dots a_{j-1})$$

2.2 Variable beam-size inference

Problem with naive beam search RNNG is initially formalized as a two stage parsing process (Dyer et al., 2016): first a discriminative model with lookahead is run on input sentences and then a generative model without lookahead is used to rerank the best hypotheses.

However direct generative parsing with RNNG is difficult because word generation transitions have significantly lower probabilities than structural transitions, such as open and close transitions. Thus, inside a beam at the same temporal step, these lexical transitions are likely to be pruned. This situation creates a bias towards parsing with additional spurious structure.

Some solutions already described in Stern et al. (2017) and Hale et al. (2018) manage to deal with this problem for direct generative parsing but this solution still requires to use rather large beams to yield accurate results, hence entailing significant computational overhead in time.

Among the alternative ways to solve the issue, the two stage architecture (Dyer et al., 2016) is not

an option in our case because it relies on a discriminative model with lookahead that would break the strict incrementality property that we want to preserve for the cognitive perspective. Furthermore, in our scientific context, we have to study two inference problems: (1) the usual search for a best parse that is required for assessing the model accuracy with known metrics, and (2) for the purpose of fMRI modelling, we also have to compute the marginal probabilities required to compute the probabilities relevant for language modelling.

Proposed solution We therefore study another solution to this problem that is inspired by Sequential importance sampling methods (Doucet and Johansen, 2011; Buys and Blunsom, 2015) and that can be interpreted as a variable beam search strategy where the search method carefully avoids to compare apples and oranges within the same beam. Specifically, the method ensures that comparisons between derivations are made only if derivations have an identical number of generated lexical elements.

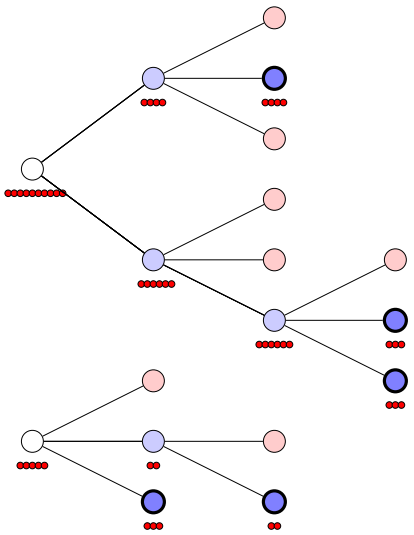

Figure 1: Example of a sampling step from derivations generating x_i (white nodes) to derivations generating x_{i+1} (circled blue nodes) with a budget of $K = 15$ particles. Inference may stop because of a lack of budget ($\pi(\mathbf{x}, \mathbf{y}) = 0$) as illustrated by red nodes. Derivations are never compared to each other during the sampling step, hence avoiding lexical biases that hamper the process of beam search.

For a sequence of words $\mathbf{x} = x_1 \dots x_i \dots x_n$, we note $\mathbf{x}_i$ the prefix $x_1 \dots x_i$ and $\mathbf{y}_i = a_1 \dots a_k$ a derivation whose last element generates x_i. We let $\mathcal{Y}(\mathbf{x}_i)$ denote the set of such derivations.

The search method essentially performs iteratively a move from word x_i to its successor x_{i+1} using the following procedure: given a distribution $P(\mathbf{x}_i, \mathbf{y}_i)$ over derivations at x_i, the algorithm samples the distribution $P(\mathbf{x}_{i+1}, \mathbf{y}_{i+1})$ with a swarm of particles. This procedure is decomposed in two steps:

Step 1: Sampling. Let ($\mathbf{x}$,$\mathbf{y}$) be a derivation together with its associated number of particles $\pi(\mathbf{x}, \mathbf{y})$, then each of its successors ($\mathbf{x}$,$\mathbf{y}a$) ($a \in A$) gets its particles assigned using the following recurrence[1]:

$$\pi(\mathbf{x}, \mathbf{y}a) = \lfloor \pi(\mathbf{x}, \mathbf{y}) P^*(a|\mathbf{x}, \mathbf{y}) \rceil \quad (1)$$

This step involves expanding the set of derivations. Each derivation ($\mathbf{x}$,$\mathbf{y}$) is expanded iteratively until either the word x_{i+1} is generated or ($\mathbf{x}$,$\mathbf{y}$) has no more particle ($\pi(\mathbf{x}, \mathbf{y}) = 0$). This procedure is illustrated in Figure 1.

We have to emphasize, however, that contrary to $P(a|\mathbf{x}, \mathbf{y})$, the chosen importance distribution $P^*(a|\mathbf{x}, \mathbf{y})$ locally sums to one. It is indeed defined as:

$$P^*(a|\mathbf{x}, \mathbf{y}) = \frac{P(a|\mathbf{x}, \mathbf{y})}{\sum_{a' \in A^*} P(a'|\mathbf{x}, \mathbf{y})} \quad (2)$$

where $A^* \subseteq A$ is a set of allowed actions given $(\mathbf{x}, \mathbf{y})$. Using the importance distribution prevents particles to get lost because of deficient probability distributions. Observe that $P(a|\mathbf{x}, \mathbf{y})$ does not sum to one because the generative model prevents a subset of actions to be undertaken at any time step. This is crucially the case for lexical actions when parsing: only the next word form given in the input sentence can be generated at any time step while there are lexical actions for generating every word in the vocabulary. This causes $P(a|\mathbf{x}, \mathbf{y})$ to be deficient.

A connection with importance sampling is established if we define the importance weight of a derivation as:

$$w(\mathbf{x}, \mathbf{y}) = \frac{P(\mathbf{x}, \mathbf{y})}{P^*(\mathbf{x}, \mathbf{y})}$$

where $P^*(\mathbf{x}, \mathbf{y}) = \prod_{i=1}^{m} P^*(a_j|a_1 \dots a_m)$. We can then observe the relation between the three notions by developing:

$$\begin{aligned} P(\mathbf{x}, \mathbf{y}) &= \frac{P(\mathbf{x}, \mathbf{y})}{P^*(\mathbf{x}, \mathbf{y})} P^*(\mathbf{x}, \mathbf{y}) \\ &= w(\mathbf{x}, \mathbf{y}) P^*(\mathbf{x}, \mathbf{y}) \end{aligned} \quad (3)$$

[1] We use $\lfloor x \rceil$ to denote the rounding of x to the nearest integer.

Step 2: Reweighting and **Filtering**. Observe, however, that the recurrence (1) spawns a search tree and that the mass of particles assigned to search branches gets increasingly scattered as the process progresses with further time steps. To counter this effect, we reweight the branches by synchronizing the search process on word generation events. In other words, each derivation $(\mathbf{x}_{i+1}, \mathbf{y}_{i+1}) \in \tilde{\mathcal{Y}}(\mathbf{x}_{i+1})$ that successfully generated the word x_{i+1} is reweighted by normalizing its importance weight:

$$w'(\mathbf{x}_{i+1}, \mathbf{y}_{i+1}) = \frac{w(\mathbf{x}_{i+1}, \mathbf{y}_{i+1})\pi(\mathbf{x}_{i+1}, \mathbf{y}_{i+1})}{\sum_{\mathbf{y}'} w(\mathbf{x}_{i+1}, \mathbf{y}')\pi(\mathbf{x}_{i+1}, \mathbf{y}')} \tag{4}$$

We subsequently reassign each derivation with a number of particles $\pi'(\mathbf{x}_{i+1}, \mathbf{y}_{i+1})$ proportional to its normalized weight. Let K be the global number of particles available, then we reallocate particles to each derivation as follows:

$$\pi(\mathbf{x}_{i+1}, \mathbf{y}_{i+1}) = \lfloor K w'(\mathbf{x}_{i+1}, \mathbf{y}_{i+1}) \rceil$$

Derivations without particles are filtered out at this stage ($\pi(\mathbf{x}_{i+1}, \mathbf{y}_{i+1}) = 0$). Figure 2 summarizes the search algorithm with pseudo code. It can be interpreted as an adaptation of particle filtering (Doucet and Johansen, 2011) to our generative parsing task.

Marginal probabilities The proposed exploration method of the search space finds a direct application to computing marginal probabilities for sentential prefixes of the form $P(\mathbf{x}_i)$. For our purposes, one key interest of the generative parsing model lies in its capacity to compute transition probabilities $P(x_i|x_1 \dots x_{i-1})$ informed by the syntactic structures of the sentence. This enables the computation of metrics that have been shown relevant for psycho-linguistic analysis such as surprisal and entropy, among others.

We briefly summarize in the following how this is achieved through the computation of marginal probabilities. We can define the probability of a prefix as:

$$P(\mathbf{x}_i) = \sum_{\mathbf{y}_i \in \mathcal{Y}(\mathbf{x}_i)} P(\mathbf{x}_i, \mathbf{y}_i) \tag{5}$$

Thus computing transition probabilities can be simply performed as:

$$P(x_i|x_1 \dots x_{i-1}) = \frac{P(\mathbf{x}_i)}{P(\mathbf{x}_{i-1})} \tag{6}$$

Figure 2: Variable beam search pseudo-code

The naive computation of marginal probabilities stated in (5) requires to process a set $\mathcal{Y}(\mathbf{x}_i)$ growing exponentially in size with the length of the input sequence. Such a computation can however be approximated by Monte-Carlo simulation:

$$P(\mathbf{x}_i) \approx \lim_{K \to \infty} \frac{1}{K} \sum_{j=1}^{K} w(\mathbf{x}_i, \mathbf{y}_i^j) \tag{7}$$

This involves sampling derivations $\mathbf{y}_i^1 \dots \mathbf{y}_i^K$ from $P^*(\mathbf{x}, \mathbf{y})$, and is justified by observing that the marginalisation of equation (3) actually states an expectation:

$$P(\mathbf{x}_i) = \sum_{(\mathbf{x},\mathbf{y}) \in \mathcal{Y}(\mathbf{x}_i)} w(\mathbf{x}, \mathbf{y}) P^*(\mathbf{x}, \mathbf{y}) \tag{8}$$

which is precisely the one computed by (7). As our exploration method does not directly samples K individual derivations but clusters the K particles on a smaller number of derivations with the recurrence (1). We reformulate (8) not directly as (7) but rather as:

$$
\begin{aligned}
P(\mathbf{x}_i) &= \sum_{(\mathbf{x},\mathbf{y})\in\tilde{\mathcal{Y}}(\mathbf{x}_i)} w(\mathbf{x},\mathbf{y})P^*(\mathbf{x},\mathbf{y}) \\
&= \sum_{(\mathbf{x},\mathbf{y})\in\tilde{\mathcal{Y}}(\mathbf{x}_i)} P(\mathbf{x},\mathbf{y})\frac{P^*(\mathbf{x},\mathbf{y})}{P^*(\mathbf{x},\mathbf{y})} \\
&= \sum_{(\mathbf{x},\mathbf{y})\in\tilde{\mathcal{Y}}(\mathbf{x}_i)} P(\mathbf{x},\mathbf{y})
\end{aligned}
$$

That is we approximate the sum on the full set of parses $\mathcal{Y}(\mathbf{x}_i)$ by the sum of the set of parses found in the beam $\tilde{\mathcal{Y}}(\mathbf{x}_i)$ and sampled with the importance distribution $P^*(\mathbf{x},\mathbf{y})$.

Parsing problem Actual parsing is performed by collecting all successful derivations $\text{succ}(\mathbf{x})$ found during the search process and by returning the best scoring derivation:

$$
(\mathbf{x},\hat{\mathbf{y}}) = \underset{(\mathbf{x},\mathbf{y})\in\text{succ}(\mathbf{x})}{\text{argmax}} P(\mathbf{x},\mathbf{y})
$$

2.3 Measures extracted from the parser

We now define several measures extracted from the parsing process that might be relevant for fMRI modelling.

The first is the **beam size**, that is the size of the beam at word x_i and it is directly measured as $B = |\tilde{\mathcal{Y}}(\mathbf{x}_i)|$

Next we define the **beam successful activity**. Let the set of transitions of a derivation be: $T(\mathbf{y}) = T(a_1 \dots a_m) = \{(a_1,a_2)\dots(a_{m-1},a_m)\}$ and the set of transitions $\mathbf{S}(\mathbf{x}_i) = \bigcup_{\mathbf{y}\in\tilde{\mathcal{Y}}(\mathbf{x}_i)} T(\mathbf{y})$ be the set of transitions leading successfully to x_i.

Then, the beam successful activity at x_i is defined as the size of the set of transitions within x_i and x_{i-1}, that is :

$$
s(x_i) = |\,\mathbf{S}(\mathbf{x}_i) - [\mathbf{S}(\mathbf{x}_i) \cap \mathbf{S}(\mathbf{x}_{i-1})]\,|
$$

Intuitively, the beam successful activity metric measures the amount of nodes depicted in blue in Figure 1.

A dead-end is a derivation $\mathbf{y}$ such that $\pi(\mathbf{y}) > 0$ and $\pi(\mathbf{y}a) = 0 \quad (\forall a \in A)$. Let $\mathcal{D}(\mathbf{x}_i)$ be the set of such dead-ends between x_{i-1} and x_i and the set of transitions $\mathbf{D} = \bigcup_{\mathbf{y}\in\tilde{\mathcal{D}}(\mathbf{x}_i)} T(\mathbf{y})$, then we define the **beam unsuccessful activity** as:

$$
u(x_i) = |\,\mathbf{D}(\mathbf{x}_i) - [\mathbf{D}(\mathbf{x}_i) \cap \mathbf{S}(\mathbf{x}_{i-1})]\,|
$$

Intuitively, the beam unsuccessful activity metric measures the amount of nodes depicted in red in Figure 1. Finally, let $\mathbf{A}(\mathbf{x}_i) = \mathbf{S}(\mathbf{x}_i) \cup \mathbf{D}(\mathbf{x}_i)$, then we define an overall **beam activity** at x_i to be:

$$
o(x_i) = |\,\mathbf{A}(\mathbf{x}_i) - [\mathbf{A}(\mathbf{x}_i) \cap \mathbf{S}(\mathbf{x}_{i-1})]\,|
$$

As our model is generative, information theoretic metrics, such as surprisal and entropy, that are crucially dependant of the computation of lexical transition probabilities of the form $P(x_i|x_1\dots x_{i-1})$ can be computed too. **Surprisal** is a classic complexity measure (Hale, 2016) defined as:

$$
\textbf{surprisal}(x_i) = -\log_2 P(x_i|x_1\dots x_{i-1})
$$

and that is computed with equation (6).

For **entropy**, let $H[\mathcal{Y}(\mathbf{x}_i)]$ be the entropy of the set of prefix derivations at word i that is defined as:

$$
H[\mathcal{Y}(\mathbf{x}_i)] = -\sum_{\mathbf{y}\in\mathcal{Y}(\mathbf{x}_i)} \frac{P(\mathbf{x}_i,\mathbf{y})}{P(\mathbf{x}_i)} \log_2\left(\frac{P(\mathbf{x}_i,\mathbf{y})}{P(\mathbf{x}_i)}\right)
$$

However in the context of a beam with variable size, these entropy measures cannot be directly compared at different time steps $i, i', i'' \dots$ because the size of the set $\mathcal{Y}(\mathbf{x}_i)$ is variable accross time steps. Therefore we use a **normalized entropy** whose values range in the interval $[0,1]$. As the maximum of the entropy measured on a set of n elements is $\log(n)$, we use the normalized entropy measure:

$$
H_n[\mathcal{Y}(\mathbf{x}_i)] = \frac{H[\mathcal{Y}(\mathbf{x}_i)]}{\log_2(B)}
$$

To conclude this section, we introduced a search method for generative neural parsing that aims to overcome the problems of lexical biases (Stern et al., 2017) by drawing inspiration from particle filtering methods. In section 3 we motivate and study some properties of the method from a computational perspective and we explore in section 5 the potential of the overall beam activity predictors for modelling and analyzing fMRI data (Table 3).

3 Computational experiments

We report a few experiments designed to better understand the computational properties of the search method described so far. All the experiments are performed on the Penn-Treebank (Marcus et al., 1994), using sections 2-21 as training, section 22 as development and section 23 as test.

We preprocess the data for numbers replaced by a unique `num` token and we replace word occurrences with frequency one by the token `unk`.

Our development experiments compare our variable-size beam method with more traditional beam search. As standard naive beam search is not appropriate to generative parsing, we directly compare with the word-synchronous beam search method of Stern et al. (2017), applied to RNNG, with the so-called fast track extension. Our implementation of word synchronous beam search follows closely that of Hale et al. (2018). We select the settings found in the literature: for a beam of size $B = k$, a lexical beam of size $k/10$ and a fast-track of size $k/100$.

MODEL	F-SCORE	PPL	BEAM ACTIVITY
K=1000-base	86.29	107.89	153.17
K=1000	90.75	86.00	66.3
K=10000	91.12	84.25	153.6
K=50000	**91.26**	83.50	380.3
B=100	87.21	95.97	416.9
B=400	90.50	**82.39**	1775.1

Table 1: Development scores.

By observing the development measures in Table 1, the first thing to note is the lack of accurracy of the vanilla application of our *base* method, as can be seen on the first line of the Table, when parsing with $K = 1000$ particles for searching. This *base* model uses straightforwardly the reweighting step stated in (4). We observed however that the low accurracy of this model is a consequence of a rounding issue when using discretized particle counts. To avoid this problem we used the alternative reweighting scheme:

$$w'(\mathbf{x}_{i+1}, \mathbf{y}_{i+1}) = \frac{P(\mathbf{x}_{i+1}, \mathbf{y}_{i+1})}{\sum_{\mathbf{y}' \in \tilde{\mathcal{Y}}(\mathbf{x}_{i+1})} P(\mathbf{x}_{i+1}, \mathbf{y}')}$$

that avoids this rounding problem and all the other results reported in Table 1 use instead this alternative scheme.

From the development set we can also point out that our beam baselines are almost identical to those of Hale et al. (2018) on beams $B = 100$ and $B = 400$. Note that the authors managed to reach an F-score of 91.2 on the development with $B = 2000$. By comparison, our particle method tends to produce high F-scores even with limited K. Although the perplexity of the beam method remains generally lower, as shown in Table 1.

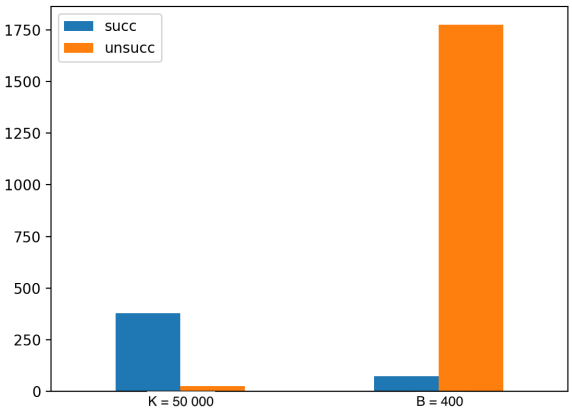

Figure 3: Successful and unsuccessful beam activities.

The main difference comes from computation time that we measure with an averaged beam activity metric defined earlier on: as we can see our most expensive model $K = 50000$ requires to perform less computations than the smallest beam tested. This striking difference can be further explained by comparing the successful and unsuccessful beam activities.

Figure 3 plots those activities for models $B = 400$ and $K = 50000$. The more traditional beam search spends most of its time performing unsuccessful computations while our method spends most of its time performing successful computations. All these observations have practical consequences: the beam method takes hours to complete the parsing of the Wall Street Journal (wsj, see Table 2) development while the particle search takes minutes on a standard workstation.

MODEL	F-SCORE	PPL (wsj)	PPL (prince)
K=50000	**91.02**	94.35	154.93
B=400	90.15	**93.02**	139.76
IKN5	-	155.02	309.54
LSTM-LM	-	141.28	204.06
(Dyer et al. 2016)	93.3	105.2*	unknown
(Fried et al. 2017a)	92.56	unknown	unknown
(Kitaev et al. 2018)	**93.55**	-	-

∗A different preprocessing is used. The comparison remains indicative

Table 2: Test results.

For the test, we observe again from Table 2 that our search method ($K = 50000$) gets better F-score and worse perplexity than the beam method.

The most important observation comes from the comparison between the language model perplexities and parsing perplexities. On a small data set such as the Penn Treebank, the parser has a much better perplexity than traditional 5-grams Interpolated Kneser Ney (IKN5) or vanilla LSTM-LM with a comparable configuration to that of the parser. It is quite clear that state of the art language models outperform the parsing language model by a large margin, at the cost of much larger training sets (Radford et al., 2019). The perplexities reported as *Prince* in Table 2 are the perplexities resulting from processing the *Little Prince* corpus used later in the paper for analyzing neuro-imaging data. The table allows to measure the amount of drop in perplexity that can be explained by corpus domain change.

We also compare with parsers without strict incrementality restrictions: Dyer et al. (2016) is an RNNG as a reranker with a discriminative first step (that is with lookahead). Stern et al. (2017) are the results reported with a beam of size 2000 using the generative model described by Choe and Charniak (2016) with a substantially different preprocessing of the data than the one used with RNNG (Hale et al., 2018). Finally, Kitaev and Klein (2018) is the current state of the art single parser with a discriminative model.

4 Neuro-imaging and Parsing Models

A number of studies observed a positive correlation between behavioural and psycho-linguistic data like reading times and entropy measures derived from probabilistic parsers' computations (Levy, 2008). Eye-movements (Demberg and Keller, 2008) and Event-Related Potentials (ERPs, Frank et al. (2015) were recorded during reading performance or sentence completion tasks have allegedly contributed in giving a cognitive dimension to the Surprisal Theory (Levy, 2008).

Parsers Actions and Neuro-imaging Further empirical proofs of the link between information-theoretic measures and cognitive processes showed a correlation between the *output* or internal state of syntactic parsers and cerebral activity. In a seminal work based on a 30 minutes recording from the English text *Alice in wonderland*, Brennan and colleagues (2012; 2016) modeled brain activity with a simple word-by-word measure of Node counts, featuring an estimate of the amount syntactic structure analyzed so far, as the number of phrases closed at each word. This computationally assessed phrase-structure building process showed to involve Inferior Frontal Gyrus and Anterior Temporal regions, which was found consistent with earlier studies on sentence structure building (Pallier et al., 2011; Snijders et al., 2009).

Parsing strategy in Neuro-imaging Other fMRI studies started to use another computationally derived complexity metric to quantify structure-building and processing effort in the brain. The number of rules applied during the parser's computational procedure, between each word of a sentence, was taken to define an incremental index of computational syntactic "work"(e.g. Bhattasali et al. 2019).

A recent intracranial recording work correlated brain activity with computational metrics from alternative grammar types (e.g. context-free, Minimalist) and different parsing strategies (e.g. left-corner, top-down, bottom-up) (Nelson et al., 2017). Phrase-structure appeared, like in more traditional approaches (Friederici and Gierhan, 2013; Snijders et al., 2009; Hickok and Poeppel, 2007), as a major determinant of the dynamic profile of brain activity in language areas. Superior temporal and inferior frontal areas provided a good fit of the brain-activity data for bottom-up and left-corner parsing strategies, in left superior temporal, inferior frontal, dorsal and midline frontal sites.

Based on this set of empirical evidence, showing that syntactic structure-building implicates frontal regions, such as the Pars Triangularis and Pars Opercularis of the Inferior Frontal Gyrus (IFG-Broca) and anterior temporal areas, neuro-imaging signals can be used nowadays to adjudicate between competing parsing mechanisms. The present paper, goes a step further, using the beam internal state in two different Search methods in a generative RNNG architecture, to shed light on the potential benefits of beam-size variation for the cognitive modelling of sentence processing.

5 fMRI: Method and Results

The analyzed text was the transcribed version of the English audio-book of Antoine de Saint-Exupéry *The Little Prince*, translated by David Wilkinson and read by Nadine Eckert-Boulet. This text comprises 19,171 tokens and 15,388 words, grouped in 1388 sentences. The imaging data-set analysed in this paper comprises 50

Predictors	Description
Overall Beam activity K50000 or B400	word-by-word measure of beam activity (§2.3)
Word rate	tagging spoken words on the fMRI signal
Word frequency	word-by-word log-frequency in movie subtitles
RMS amplitude	an acoustic correlate of volume every 10ms

Table 3: Predictors used in the fMRI Analysis. RMS (Root Mean Square) encodes the amplitude of spoken narration, it reflects the intensity.

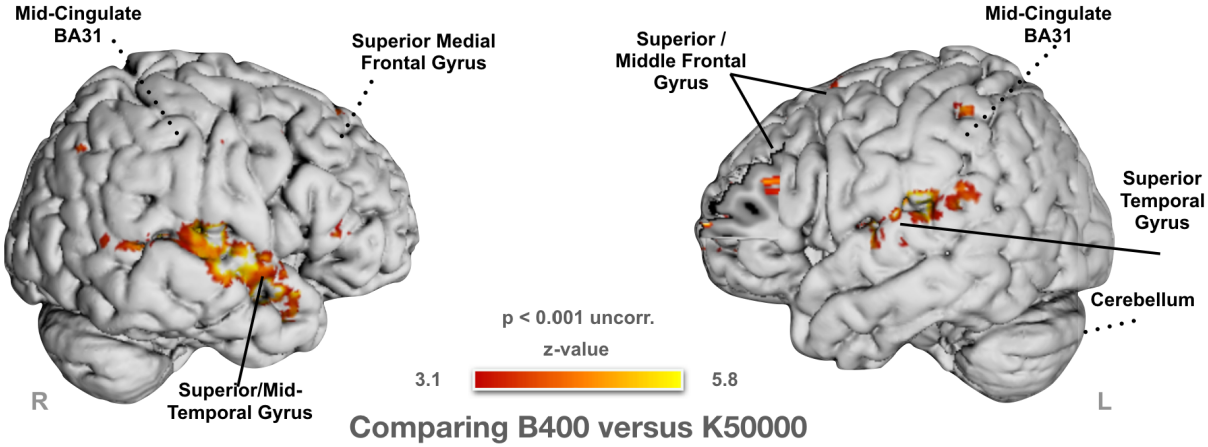

Figure 4: Brain z-maps showing the significant clusters (K>25) for the model comparison between Overall Beam Activity calculated in the fix-beam B400 versus variable-beam K50000 RNNG parser, p < .001 uncorr.

right-handed native English participants who listened to the entire audio-book during 1h38 minutes. Imaging was performed in a 3 Tesla MRI scanner (Discovery MR750 GE, Milwaukee, WI) with a 32-channel head coil at the Cornell MRI Facility as part of a naturalistic listening neuro-imaging project. Details of preprocessing are presented in the Supplementary Materials.

5.1 Statistical Analysis

r^2 Model comparison - General Linear Model The research questions presented above in section 2.2 motivates a statistical analysis that performs a comparison where fMRI signal is modeled (GLM) by B400 fix beam parser versus the K50000 parsing system adopting a variable beam.

Single-subject statistics At the single subject level, the observed time-course of the brain hemodynamic response (BOLD - Blood Oxygenation Level Dependent) in each voxel was modeled by the Overall Beam Activity measure (cf. 2.3) calculated for B400 and K50000 parsers, and time-locked at the offset of each word in the audio-book. Model comparisons using cross-validated coefficient of determination (r2) maps was carried out in order to evaluate the goodness of fit of the two beam search methods with BOLD signal. The predictors shown in Table 3 were convolved using SPM's (Friston et al., 2007) canonical HRF (Hemodynamic Response Function). The two neuro-imaging models (i.e. K50000 and B400) also included in the GLM three control variables: *Root Mean Square intensity* (RMS) an indicator of intensity at every 10 ms of the audio; *word rate* as a stick function marking the offset of each spoken word; *frequency* of the individual words in movie subtitles from (Brysbaert and New, 2009).

Such predictors are here to ensure that conclusions about parsing difficulty would be specific to the processes they instantiate, as opposed to more general aspects of speech perception. Specifically, lexical frequency was added as a covariate of non-interest, to statistically factor out effects of general word frequency (generally used in psycholinguistics), that may correlate with other types of expectations. For every subject, we compute how much the inclusion of each variable of interest (i.e. B400 and K50000) increases the cross-validated r^2, from a baseline model that does not include them, see Table 3). Hence, the r^2 scores represent the variance explained in each voxel by the variable instantiating the two beam-search methods.

Regions for K50000 vs B400	Cluster size (in voxels)	MNI Coordinates x	y	z	p-value (uncorrected)	z-score (peak)
R Superior / Mid-Temporal Gyrus	2307	54	-8	-2	0.000	5.79
L Superior Temporal Gyrus / Insula	1442	-52	-12	2	0.000	5.73
R Superior Medial Frontal Gyrus (BA9/10)	114	4	56	24	0.000	4.89
R Mid-Cingulate Gyrus (BA31)	95	4	-42	40	0.000	4.30
L Middle Frontal Gyrus	58	-40	36	22	0.000	4.13
L Cerebellum - Crus I/II	34	-22	-74	-36	0.000	4.02
L Superior Frontal Gyrus (10)	34	-28	58	2	0.001	3.64
L Mid-Cingulate Gyrus (BA31)	95	-6	-28	44	0.001	3.66

Table 4: Clusters showing a significant better fit for B400 fix beam-size search method in the RNNG parser, p< 0.001 (z-score $>$ 3.1) uncorrected at k$>$ 25 cluster threshold.

Group-level statistics To compare the impact of beam-search on fMRI signal explanation (i.e. r^2 increase of each variable) we performed a paired t-test on each individual r^2 map, and obtained Figure 4 showing where one variable explains significantly better the signal than the other (cf. Tab. 4).

5.2 Results - Fit with fMRI signal

We performed an r^2 comparison to test which beam search method provided the better fit to the fMRI data recorded during *The Little Prince*. The two different search methods were tested (K50000 variable beam and B400 fix beam), and B400 was shown to be the best fitting the BOLD signal of these models. Figure 4 (clusters coordinates and statistics, cf. Table 4), shows the significance (z-scores, $p < 0.001$ uncorrected) of the difference in r^2 scores with a cluster threshold of 25 voxels. Considering the cluster with a larger extent, we might also have captured some acoustic parameter that was not included in the GLM model, although further analyses showed that adding a prosodic predictor does not have a major impact.

Of the two parsers' search methods, the fix beam one had a significant predictive value in well-known language areas, namely temporal areas and sub-parts core frontal regions. Our particle filtering based method is used to maintain the beam and limit its size, while experiments show that the proposed method achieves higher parsing accuracy than a fixed-size beam search baseline, the fixed-size beam search is shown here to be a better model than the proposed method in predicting brain activities. This result could be related to its tendency to keep ambiguities longer along the sentence, and thus model the computational load of a larger spectrum of hypotheses without pruning immediately the hypothesis space (cf. Fig. 3).

6 Discussion & Conclusion

The paper investigates the relevance of a sequential Monte-Carlo inspired search method for generative parsing. The proposed search method is in principle very general although we tested its relevance to overcome lexical biases inherent to direct generative parsing for RNNG. We found out that the method's main benefit is an increased processing efficiency. The measures instantiating variable-beam and fixed-beam search were used to quantify the amount of structure-building "work" the parser performs in the course of word-by-word processing of a given sentence. Our current neuro-imaging results suggest that the fixed-size beam activity is a better predictor of brain activity than the variable-size beam activity. The original methodology presented in this paper paves the way for further computational work in quantifying parsing complexity and thus fine-grained modelling of human sentence processing.

Abstract

Crowdsourcing has been the prevalent paradigm for creating natural language understanding datasets in recent years. A common crowdsourcing practice is to recruit a small number of high-quality workers, and have them massively generate examples. Having only a few workers generate the majority of examples raises concerns about data diversity, especially when workers freely generate sentences. In this paper, we perform a series of experiments showing these concerns are evident in three recent NLP datasets. We show that model performance improves when training with annotator identifiers as features, and that models are able to recognize the most productive annotators. Moreover, we show that often models do not generalize well to examples from annotators that did not contribute to the training set. Our findings suggest that annotator bias should be monitored during dataset creation, and that test set annotators should be disjoint from training set annotators.

1 Introduction

Generating large datasets has become one of the main drivers of progress in natural language understanding (NLU). The prevalent method for creating new datasets is through crowdsourcing, where examples are generated by workers (Zaidan and Callison-Burch, 2011; Richardson et al., 2013; Bowman et al., 2015; Rajpurkar et al., 2016; Trischler et al., 2017). A common recent practice is to choose a small group of workers who produce high-quality annotations, and massively generate examples using these workers.

Having only a few workers annotate the majority of dataset examples raises concerns about data diversity and the ability of models to generalize, especially when the crowdsourcing task is to generate free text. If an annotator consistently uses language patterns that correlate with the labels, a neural model can pick up on those, which can lead to an over-estimation of model performance.

In this paper, we continue recent efforts to understand biases that are introduced during the process of data creation (Levy et al., 2015; Schwartz et al., 2017; Gururangan et al., 2018; Glockner et al., 2018; Poliak et al., 2018; Tsuchiya, 2018; Aharoni and Goldberg, 2018; Paun et al., 2018). We investigate this form of bias, termed *annotator bias*, and perform multiple experiments over three recent NLU datasets: MNLI (Williams et al., 2018), OpenBookQA. (Mihaylov et al., 2018), and CommonsenseQA (Talmor et al., 2019).

First, we establish that annotator information improves model performance by supplying annotator IDs as part of the input features. Second, we show that models are able to recognize annotators that generated many examples, illustrating that annotator information is captured by the model. Last, we test whether models generalize to annotators that were not seen at training time. We observe that often generalization to new annotators fails, and that augmenting the training set with a small number of examples from these annotators substantially increases performance.

Taken together, our experiments show that annotator bias exists in current NLU datasets, which can lead to problems in model generalization to new users. Hence, we propose that annotator bias should be monitored at data collection time and to tackle it by having the test set include examples from a disjoint set of annotators.

2 Crowdsourcing Practice

Crowdsourcing has become the prominent paradigm for creating NLP datasets (Callison-Burch et al., 2015; Sabou et al., 2014). It has been used for various NLU tasks, including Question Answering (Rajpurkar et al., 2018; Mihaylov

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1161–1166,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

et al., 2018; Dua et al., 2019), commonsense and visual reasoning (Talmor et al., 2019; Zellers et al., 2019; Suhr et al., 2018), and Natural Language Inference (NLI) (Williams et al., 2018).

In a typical process, annotators are recruited and screened (Sabou et al., 2014), often resulting in a small group that creates most of the dataset examples. Mihaylov et al. (2018) recruited a few dozens of qualified workers that wrote 5,957 questions. Suhr et al. (2018) recruited 99 workers for a sentence writing task, who created more than 100,000 examples. Williams et al. (2018) recruited 387 workers for writing over 400,000 sentences, while Krishna et al. (2017) had 33,000 workers contributing 1.7 million examples.

These examples demonstrate that datasets are often constructed using a small number of annotators, approximately 1 annotator per 10^2–10^3 examples. Furthermore, (see Section 3), the annotator distribution is skewed with a few annotators creating the vast majority of the dataset. In tasks that involve creative language writing, this may have implications on data diversity, and lead to an over-estimation of model performance.

3 Experimental Setup

We focus on crowdsourcing tasks where workers produce full-length sentences. We first describe the datasets we test our hypothesis on, and then provide details on the model and training.

Datasets We consider recent NLU datasets, for which the annotator IDs are available.

- **MNLI** (matched) (Williams et al., 2018): A NLI dataset. Each example was created by introducing an annotator with a premise sentence and asking her to write a hypothesis sentence that is either entailed, contradicted or is neutral with respect to the premise.
- **OpenBookQA** (Mihaylov et al., 2018): A multiple-choice question answering dataset, focusing on multi-hop reasoning. Each question and its answer distractors were written by a worker, based on a given scientific fact.
- **CommonsenseQA** (Talmor et al., 2019): A multiple-choice question answering dataset, focused on commonsense knowledge. Questions were written by crowdworkers, who try to bridge between two concepts extracted from ConceptNet (Speer et al., 2017)

	# examples	# annotators
MNLI (matched)	402,517	380
OpenBookQA	5,457	84
CommonsenseQA	11,096	132

Table 1: Statistics for datasets used in our experiments.

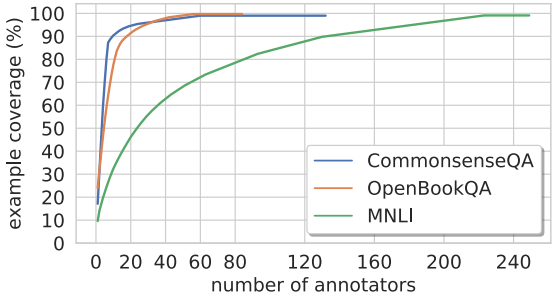

Figure 1: Proportion of examples covered by number of annotators (sorted by number of annotations).

Table 1 summarizes the size and number of annotators who worked on each dataset. Figure 1 shows the fraction of examples covered by the number of annotators, sorted by the number of examples they annotated. In all datasets, and specifically in OpenBookQA and CommonsenseQA, most of the examples were generated by a small number of annotators.

Model We use the pretrained BERT-base (Devlin et al., 2018), a strong model obtaining close to state-of-the-art performance on all three datasets. We add a single linear layer over BERT outputs and apply the same fine-tuning procedure in all experiments: fine-tuning for 3 epochs, using batch size 10, learning rate 2×10^{-5}, and maximum sequence length of 128 word pieces.

4 Experiments and Results

We now describe a series of experiments for quantifying annotator bias, aiming to answer the following questions: 1) Do models perform better when exposed to the annotator ID? 2) Can models detect the annotators from their generated examples? 3) Do models generalize across annotators?

The utility of annotator information Our first experiment aims to determine whether models perform better given *perfect* information on the annotator ID. To this end, we follow the standard way of feeding input to BERT (Devlin et al., 2018) and concatenate the annotator ID as an additional feature to every example in every dataset. Formally, we replace every example ($x =$

$(w_1, ..., w_{|x|}), y)$ created by annotator z, with the example $((z, w_1, ..., w_{|x|}), y)$, where z is a textual unique annotator identifier, x is the input sequence and y is the gold label.

We compare performance on the original datasets and their new version. Adding the annotator ID improves model performance across all datasets (Table 2), showing that perfect annotator information is useful for prediction, and there is incentive for the model to capture this information.

	Without ID	With ID	p-value
OPENBOOKQA	52.2	56.4	$1.83e^{-2}$
COMMONSENSEQA	53.6	55.3	$11.98e^{-2}$
MNLI	82.9	84.5	$5.13e^{-7}$

Table 2: Model development performance, after training with/without annotator IDs as additional inputs. Following Dror et al. (2018), p-values were calculated using the McNemar's test (McNemar, 1947) for MNLI and the Bootstrap test (Berg-Kirkpatrick et al., 2012) for OPENBOOKQA and COMMONSENSEQA.

Annotator recognition Perfect annotator information improves performance, but it is possible that a model can recognize the annotators from the input sequence only, even without being exposed to the annotator ID explicitly. In the next experiment, we investigate the ability of models to recognize the annotators from the input.

To this end, we fine-tune BERT-base to predict annotator IDs from examples. We limit the task to 6 labels of the top-5 most productive annotators of each dataset and an OTHER label for all other annotators. Formally, we replace every example (x, y) created by annotator z, with the example $(x, \bar{z})$, where $\bar{z} = z$ if z is in the top-5 annotators and $\bar{z} =$ OTHER otherwise.

Figure 2 shows the F1-score for the top-5 annotators of every dataset (y-axis), and the fraction of dataset examples created by each annotator (x-axis). Overall, annotators who write many examples are recognized better by the model: The model struggles to recognize MNLI annotators with F1 scores below 0.5, and excels at recognizing annotators from COMMONSENSEQA with scores between 0.76–0.91. For the top annotator of OPENBOOKQA, who created 24% of the dataset examples, the model obtains a high F1 score of 0.8. To conclude the first two experiments, annotator ID information is useful for the downstream task, and also can be predicted with high probability from the input for a large fraction of the examples.

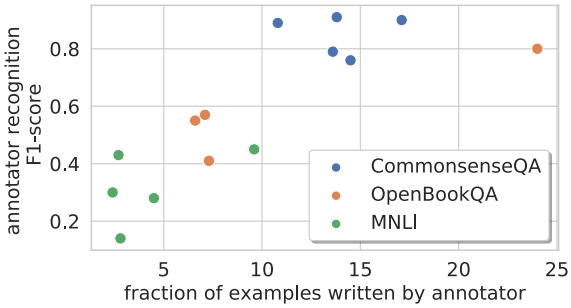

Figure 2: Annotator recognition F1-scores for the top-5 annotators of each dataset. For OPENBOOKQA only 4 data points are plotted, as the second annotator is not in the original development set.

Generalization across annotators In our final experiment, we examine whether trained models generalize to new annotators. To address this question, we re-split each dataset, creating a training and development set with disjoint annotators: Given a dataset with example set $\mathcal{S}$, we denote by $\mathcal{S}_z \subset \mathcal{S}$ the subset of examples created by annotator z. Similarly, for a set of annotators $\mathcal{Z}$, let $\mathcal{S}_\mathcal{Z} = \bigcup_{z \in \mathcal{Z}} \mathcal{S}_z$. We rank annotators by the number of examples they generated, and for each dataset $\mathcal{S}$, we create two types of data splits. For each annotator z in the top-5 annotators, we create a *single-annotator* data split with $\mathcal{S} \backslash \mathcal{S}_z$ and $\mathcal{S}_z$ as the train and development sets, respectively. Namely, we consider the examples created by annotator z as the development set, while using all other examples for training. In addition, we pick 5 sets of 5 annotators, who annotated a small number of examples, and for each such set $\mathcal{Z}$, we create a *multi-annotator* split with $\mathcal{S} \backslash \mathcal{S}_\mathcal{Z}$ and $\mathcal{S}_\mathcal{Z}$ as the train and development sets, respectively. Namely, we consider the examples created by the 5 annotators $\mathcal{Z}$ as the development set, while using all other examples for training. Overall, there are 5 single-annotator splits and 5 multi-annotator splits for each dataset.

We fine-tune BERT-base and evaluate it on the development set, and compare the results to a random data split of identical size. We repeat every experiment 3 times, except for multi-annotator experiments on OPENBOOKQA and COMMONSENSEQA which we repeat 9 times due to high variance. Table 3 shows the mean and standard deviation of performance difference (p.d.) between each annotator(s) split and its corresponding ran-

dom split, where negative numbers indicate that performance on the annotator split was lower.

Our clearest finding is that in OPENBOOKQA performance on the the multi-annotator split is dramatically lower than on a random split in all 5 annotator sets, where performance drops by up to 23 accuracy points. This shows that the model does not generalize to examples generated by unseen annotators. In the other datasets, results on the multi-annotator split are more varied, where performance drops in roughly half the cases, sometimes substantially – up to 10 accuracy points in COMMONSENSEQA and 5 in MNLI.

In the single-annotator splits, in roughly half the cases performance on the annotator split was lower than the random split. However, measuring p.d. only for single annotators might be misleading, because specific annotators vary in the difficulty of examples they produce. Thus, running a model on a new annotator that produces easy examples will not result in decreased performance. Next, we propose a more fine-grained experiment that controls for these two confounding factors.

COMMONSENSEQA-single		COMMONSENSEQA-multi	
4.2 ± 0.7	17.1%	-9.5 ± 8.3	0.9%
7.7 ± 1.9	14.5%	6.5 ± 7.0	0.6%

2.9 ± 0.2	2.8%	-4.6 ± 0.8	1.5%
0.8 ± 0.7	2.7%	-1.5 ± 0.2	1.5%
4.6 ± 0.2	2.4%	0.5 ± 0.2	1.5%

Table 3: Performance difference (p.d.) between single- and multi- annotator splits and random splits of identical size. Each cell shows the p.d. mean and standard deviation, as well as the development set relative size.

Separating annotator bias from annotator difficulty To mitigate the effect of annotator difficulty, we perform an augmentation experiment. Assume a development set $\mathcal{S}_{\text{dev}}$, for which performance is low. Our hypothesis is that if $\mathcal{S}_{\text{dev}}$ is inherently difficult, then moving a small portion of examples from $\mathcal{S}_{\text{dev}}$ to the training set $\mathcal{S}_{\text{train}}$ should not change performance on $\mathcal{S}_{\text{dev}}$ substantially. However, if performance on $\mathcal{S}_{\text{dev}}$ is low due to annotator bias, then moving examples to $\mathcal{S}_{\text{train}}$ would expose the model to the annotator and performance should go up.

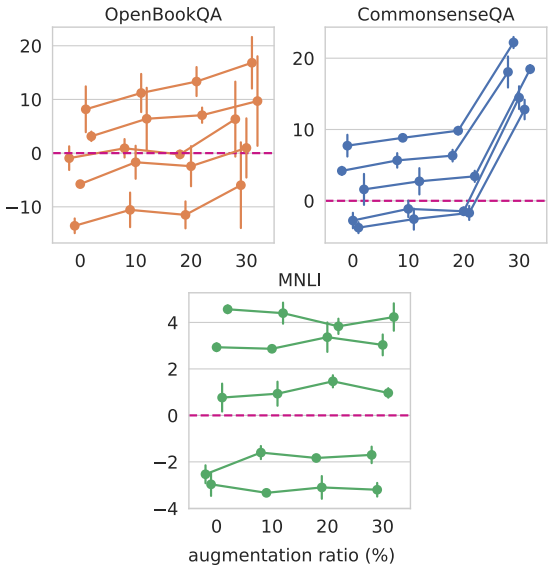

Figure 3: Performance difference between single-annotator splits and random splits of identical size. The x-axis indicates the fraction of examples taken from the development set to augment the training set.

For every single-annotator data split $\mathcal{S}_{\text{train}}$, $\mathcal{S}_{\text{dev}}$, we perform a series of augmentation experiments, where we move a random fraction of k examples from $\mathcal{S}_{\text{dev}}$ to $\mathcal{S}_{\text{train}}$, for $k = 0.1, 0.2, 0.3$. We keep the size of $\mathcal{S}_{\text{train}}$ constant by randomly removing examples from it before augmentation. We repeat experiments multiple times as before, and report the p.d mean and standard deviation in Figure 3.

Results for both COMMONSENSEQA and OPENBOOKQA show a rapid increase of 10-20 accuracy point for all top-5 annotators, given only a small number of their generated examples. This shows that the examples generated by these annotators are not inherently difficult, and that the model can substantially improve performance by being exposed to the language that the annotators generate. Conversely, performance changes are marginal for MNLI, suggesting generalization patterns are mostly due to example difficulty. The different results for MNLI compared to those observed for OPENBOOKQA and COMMONSENSEQA may be attributed to the less-skewed annotator distribution and large number of examples in MNLI (see Figure 1 and Table 1), which make the model more robust to small perturbations in the data distribution.

5 Discussion and Conclusions

This study set out to investigate whether prevalent crowdsourcing practices for building NLU datasets introduce an annotator bias in the data that leads to an over-estimation of model performance. We established that perfect annotator information can improve model performance, and that the language generated by annotators often reveals their identity. Moreover, we tested the ability of models to generalize to unseen annotators in three recent NLU datasets, and found that in two of these datasets annotator bias is evident. These findings may be explained by the annotator distributions and the size of these datasets. Skewed annotator distributions with only a few annotators creating the vast majority of examples are more prone to biases.

Our results suggest that annotator bias should be monitored in crowdsourcing tasks involving free text generation by annotators. This can be done by testing model performance on new annotators during data collection. Moreover, to tackle annotator bias, we propose that training set annotators should be separated from test-set annotators.

Abstract

We design a generic framework for learning a robust text classification model that achieves high accuracy under different selection budgets (a.k.a selection rates) at test-time. We take a different approach from existing methods and learn to dynamically filter a large fraction of unimportant words by a low-complexity selector such that any high-complexity classifier only needs to process a small fraction of text, relevant for the target task. To this end, we propose a data aggregation method for training the classifier, allowing it to achieve competitive performance on fractured sentences. On four benchmark text classification tasks, we demonstrate that the framework gains consistent speedup with little degradation in accuracy on various selection budgets.

1 Introduction

Recent advances in deep neural networks (DNNs) have achieved high accuracy on many text classification tasks. These approaches process the entire text and encode words and phrases in order to perform target tasks. While these models realize high accuracy, the computational time scales linearly with the size of the documents, which can be slow for a long document. In this context, various approaches based on modifying the RNN or LSTM architecture have been proposed to speed up the process (Seo et al., 2018; Yu et al., 2017). However, the processing in these models is still fundamentally sequential and needs to operate on the whole document which limits the computational gain. In contrast to previous approaches, we propose a novel framework for efficient text classification on long documents that mitigates sequential processing. The framework consists of a *selector* and a *classifier*. Given a selection budget as input, the *selector* performs a coarse one-shot selection deleting unimportant words and pass the remainder to the *classifier*. The *classifier* then takes the sentence fragments as an input and performs the target task. Figure 1 illustrates the procedure. This framework is general and agnostic to the architecture of the downstream *classifier* (e.g., RNN, CNN, Transformer).

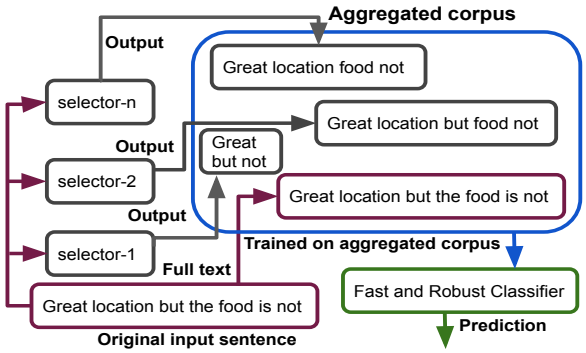

Figure 1: Our proposed framework. Given a selection rate, a *selector* is designed to select relevant words and pass them to the *classifier*. To make the classifier robust against fractured sentences, we aggregate outputs from different *selectors* and train the *classifier* on the aggregated corpus.

However, three challenges arise. First, to build a computationally inexpensive system, the *selector* must have negligible overhead. We adopt two effective yet simple architectures to design *selectors* based on word embeddings and bag-of-words. Second, training multiple distinct models for different budgets is unfeasible in practice, especially when model size is large. Hence, our goal is to learn a single *classifier* that can adapt to the output of any *selector* operating at any budget. Consequently, this *classifier* must be robust so that it can achieve consistent performance with different budgets. Third, the input to the *classifier* in our framework is a sequence of fractured sentences which is incompatible with a standard *classifier* that trained on the full texts, causing its performance degrades significantly. One potential but unfeasible solution is to train the *classifier* with a diverse collection of sentence fragments which is

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

combinatorially numerous. Another approach is to randomly blank out text (a.k.a. blanking-noise), leads to marginalized feature distortion (Maaten et al., 2013) but this also leads to poor accuracy as DNNs leverage word combinations, sentence structure, which this approach does not account for. To mitigate this problem, we propose a data aggregation framework that augments the training corpus with outputs from *selector*s at different budget levels. By training the *classifier* on the aggregated *structured* blank-out text, the *classifier* learns to fuse fragmented sentences into a feature representation that mirrors the representation obtained on full sentences and thus realizes high-accuracy. We evaluate our approach through comprehensive experiments on real-world datasets. [1]

2 Related Work

Several approaches have been proposed to speed up the DNN in test time (Wu et al., 2017; Choi et al., 2017). LSTM-jump (Yu et al., 2017) learns to completely skip words deemed to be irrelevant and skim-RNN (Seo et al., 2018) uses a low-complexity LSTM to skim words rather than skipping. Another version of LSTM-jump, LSTM-shuttle (Fu and Ma, 2018) first skips a number of words, then goes backward to recover lost information by reading some words skipped before. All these approaches require to modify the architecture of the underlying classifier and cannot easily extend to another architecture. In contrast, we adopt existing *classifier* architectures (e.g., LSTM, BCN (McCann et al., 2017)) and propose a meta-learning algorithm to train the model. Our framework is generic and a *classifier* can be viewed as a black-box. Similar to us, Lei et al. (2016) propose a *selector-classifier* framework to find text snippets as justification for text classification but their *selector* and *classifier* have similar complexity and require similar processing times; therefore, it is not suitable for computation gain. Various feature selection approaches (Chandrashekar and Sahin, 2014) have been discussed in literature. For example, removing predefined stop-words (see Appendix A), attention based models (Bahdanau et al., 2015; Luong et al., 2015), feature subspace selection methods (e.g., PCA), and applying the L1 regularization (e.g., Lasso (Tibshirani, 1996) or Group Lasso (Faruqui et al., 2015), BLasso (Gao et al., 2007)). However, these approaches either cannot obtain sparse features or cannot straightforwardly be applied to speed up a DNN *classifier*. Different from ours, Viola and Jones (2001); Trapeznikov and Saligrama (2013); Karayev et al. (2013); Xu et al. (2013); Kusner et al. (2014); Bengio et al. (2016); Leroux et al. (2017); Zhu et al. (2019); Nan and Saligrama (2017); Bolukbasi et al. (2017) focus on gating various components of existing networks. Finally, aggregating data or models has been studied under different contexts (e.g., in context of reinforcement learning (Ross et al., 2011), Bagging models (Breiman, 1996), etc.) while we aggregate the data output from *selectors* instead of models.

3 Classification on a Test-Time Budget

Our goal is to build a robust *classifier* along with a suite of *selectors* to achieve good performance with consistent speedup under different selection budgets at test-time. Formally, a *classifier* $C(\hat{x})$ takes a word sequence $\hat{x}$ and predicts the corresponding output label y, and a *selector* $S_b(x)$ with selection budget b takes an input word sequence $x = \{w_1, w_2, \ldots, w_N\}$ and generates a binary sequence $S_b(x) = \{z_{w_1}, z_{w_2}, \ldots, z_{w_N}\}$ where $z_{w_k} \in \{0, 1\}$ represents if the corresponding word w_k is selected or not. We denote the sub-sequence of words generated after filtering by the *selector* as $I\big(x, S_b(x)\big) = \{w_k : z_{w_k} = 1, \forall w_k \in x\}$. We aim to train a *classifier* C and the *selector* S_b such that $I\big(x, S_b(x)\big)$ is sufficient to make accurate prediction on the output label (i.e., $C\Big(I\big(x, S_b(x)\big)\Big) \approx C(x)$). The selection budget (a.k.a selection rate) b is controlled by the hyper-parameters of the *selector*. Higher budget often leads to higher accuracy and longer test time.

3.1 Learning a *Selector*

We propose two simple but efficient *selector*s. **Word Embedding (WE) *selector*.** We consider a parsimonious word-selector using word embeddings (e.g., GloVe (Pennington et al., 2014)) as features to predict important words. We assume the informative words can be identified independently and model the probability that a word w_k is selected by $P(z_{w_k} = 1|w_k) = \sigma(\theta_S^T \vec{w}_k)$, where θ_S is the model parameters of the *selector* S_b, $\vec{w}_k$ is the corresponding word vector, and σ is the sigmoid function. As we do not have explicit anno-

tations about which words are important, we train the *selector* S_b along with a *classifier* C in an end-to-end manner following Lei et al. (2016), and an L1-regularizer is added to control the sparsity (i.e., selection budget) of $S_b(x)$.

Bag-of-Words *selector*. We also consider using an L1-regularized linear model (Zou and Hastie, 2005; Ng, 2004; Yuan et al., 2010) with bag-of-words features to identify important words. In the bag-of-words model, for each document x, we construct a feature vector $\vec{x} \in \{0,1\}^{|V|}$, where $|V|$ is the size of the vocabulary. Each element of the feature vector $\vec{x}_w$ represents if a specific word w appearing in the document x. Given a training set $\mathcal{X}$, the linear model optimizes the L1-regularized task loss. For example, in case of a binary classification task (output label $y \in \{1, -1\}$),

$$J(x_t, y_t) = \log\left(1 + \exp(-y_t \theta^T \vec{x_t})\right)$$

$$\theta^* = \arg\min_\theta \sum_{(x_t,y_t)\in\mathcal{X}} J(x_t, y_t) + \frac{1}{b}\|\theta\|_1,$$

where $\theta \in R^{|V|}$ is a weight vector to be learned, θ_w corresponds to word $w \in V$, and b is a hyper-parameter controlling the sparsity of θ^* (i.e., selection budget). The lower the budget b is, the sparser the selection is. Based on the optimal θ^*, we construct a *selector* that picks word w if the corresponding θ^*_w is non-zero. Formally, the bag-of-words *selector* outputs $S_b(x) = \{\delta(\theta_w \neq 0) : w \in x\}$, where δ is an indicator function.

3.2 The Data Aggregation Framework

In order to learn to fuse fragmented sentences into a robust feature representation, we propose to train the *classifier* on the aggregated corpus of structured blank-out texts.

Given a set of training data $\mathcal{X} = \{(x_1, y_1), .., (x_t, y_t), .., (x_m, y_m)\}$, we assume we have a set of selectors $\mathcal{S} = \{S_b\}$ with different budget levels trained by the framework discussed in Section 3.1. To generate an aggregated corpus, we first apply each *selector* $S_b \in \mathcal{S}$ on the training set, and generate corresponding blank-out corpus $\mathcal{I}(\mathcal{X}, S_b) = \{I(x_t, S_b(x_t)), \forall x_t \in \mathcal{X}\}$. Then, we create a new corpus by aggregating the blank-out corpora: $\mathcal{T} = \bigcup_{S_b\in\mathcal{S}} \mathcal{I}(\mathcal{X}, S_b)$.[2] Finally, we train the *classifier* $C_\mathcal{T}$ on the aggregated corpus $\mathcal{T}$. As $C_\mathcal{T}$ is trained on documents with distortions, it learns to make predictions with different budget levels. The training procedure is summarized in Algorithm 1. In the following, we discuss two extensions of our data aggregation framework.

Algorithm 1: Data Aggregated Training Schema

Input: Training corpus $\mathcal{X}$, a set of *selectors* with different budget levels $\mathcal{S} = \{S_b\}$, *classifier* class C

Output: A robust *classifier* $C_\mathcal{T}$

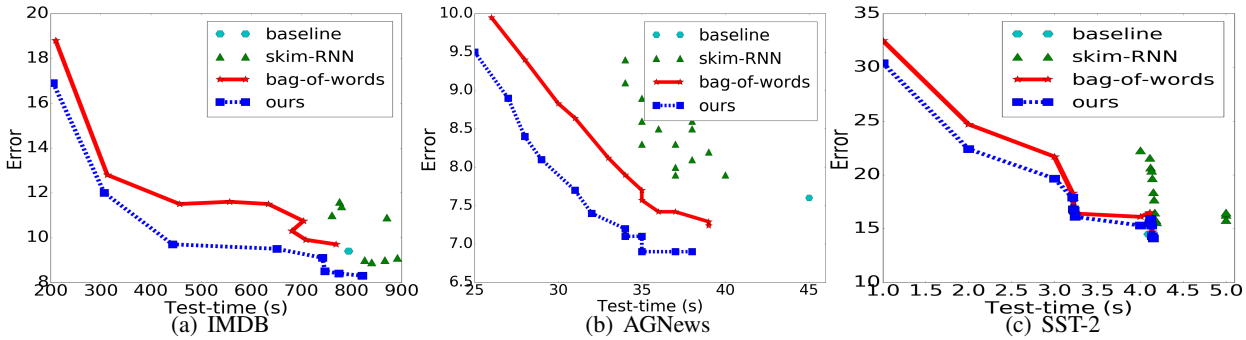
```
Initialize the aggregated corpus: T ← X
for S_b ∈ S do
    S_b ← Train a selector S_b ∈ S with budget level b on X
    Generate a blank-out dataset I(X, S_b)
    Aggregate data: T ← T ∪ I(X, S_b)
C_T ← Train a classifier C on T
return C_T
```

First, the blank-out data can be generated from different classes of *selectors* with different features or architectures. Second, the blank-out and selection can be done in phrase or sentence level. Specifically, if phrase boundaries are provided, a phrase-level aggregation can avoid a *selector* from breaking compound nouns or meaningful phrases (e.g., "Los Angeles", "not bad"). Similarly, for multi-sentenced documents, we can enforce the *selector* to pick a whole sentence if any word in the sentence is selected.

4 Experiments

To evaluate the proposed approach, we consider four benchmark datasets: *SST-2* (Socher et al., 2013), *IMDB* (Maas et al., 2011), *AGNews* (Zhang et al., 2015), and *Yelp* (Conneau et al., 2016) and two widely used architectures for classification: *LSTM*, and *BCN* (McCann et al., 2017). The statistics of the datasets are summarized in Table 2. We evaluate the computation gain of models in terms of overall test-time, and the performance in terms of accuracy. We follow Seo et al. (2018) to estimate the test-time of models on CPU[3] and exclude the time for data loading.

In our approach, we train a *classifier* with both WE and bag-of-words *selector*s with 6 selection budgets[4] {50%, 60%, ..., 100%} by the word-



[2] Note that, the union operation is used just to aggregate the train instances which does not hinder the model training (e.g., discrete variables).

[3] Machine specification is in Appendix C.

[4] For the very large Yelp dataset, 3 selection budgets {50%, 60%, 70%} are used.

Model	SST-2				IMDB				AGNews				Yelp			
	acc.	selection(%)	time	speedup	acc.	selection(%)	time	speedup	acc.	selection(%)	time	speedup	acc.	selection(%)	time	speedup
Baseline	**85.7**	100	9	1x	91.0	100	1546	1x	92.3	100	59	1x	**66.5**	100	3487	1x
Bag-of-Words	78.8	75	5.34	1.7x	91.5	91	1258	**1.2x**	92.9	97	48	1.2x	59.7	55	2325	**1.6x**
Our framework	82.6	65	4.6	**2x**	92.0	91	1297	**1.2x**	93.1	91	46	**1.3x**	64.8	55	2179	**1.6x**
	85.3	0	9	1x	**92.1**	0	1618	1x	**93.2**	0	57	1x	66.3	0	3448	1x

Table 1: Accuracy and speedup on the test datasets. Test-times are measured in seconds. The speedup rate is calculated as the running time of a model divided by the running time of the corresponding baseline. For our framework, top row denotes the best speedup and the bottom row denotes the best test accuracy achieved. Overall best accuracies and best speedups are boldfaced. Our framework achieves accuracies better than baseline with a speedup of **1.2x** and **1.3x** on IMDB, and AGNews respectively. With same or higher speedup, our accuracies are much better than Bag-of-Words.

(a) IMDB (b) AGNews (c) SST-2

Figure 2: Performance under different test-times on IMDB, AGNews, and SST-2. All the approaches use the same LSTM model as the back-end. Bag-of-Words model and our framework have the same bag-of-words *selector* cascaded with this LSTM *classifier* trained on the original training corpus and aggregated corpus, respectively. Our model (blue dashed line) significantly outperform others for any test-time budget. Also its performance is robust, while results of skim-RNN is inconsistent with different budget levels.

Dataset	#class	Vocabulary	Size (Train/Valid/Test)	Avg. Len
SST	2	13,750	6,920/872/1,821	19
IMDB	2	61,046	21,143/3,857/25,000	240
AGNews	4	60,088	101,851/18,149/7,600	43
Yelp	5	1,001,485	600k/50k/50k	149

Table 2: Dataset statistics.

level data aggregation framework. We evaluate the computation gain of the proposed method through a comparative study of its performance under different test-times by varying the selection budgets[5] in comparison to the following approaches: (1) *Baseline*: the original *classifier* (i.e., no *selector*, no data aggregation) (2) *skim-RNN*: we train a skim-RNN model and vary the amount of text to skim (i.e., test-time) by tuning θ parameter as in Seo et al. (2018). (3) Bag-of-Words: filtering words by the bag-of-words *selector* and feeding the fragments of sentences to the original *classifier* (i.e., no data aggregation). This approach serves as a good baseline and has been considered in the context of linear models (e.g., Chang and Lin (2008)). For a fair comparison, we implement all approaches upon the same framework using AllenNLP library[6], including a re-implementation of the existing state-of-art speedup framework skim-RNN (Seo et al., 2018)[7]. As skim-RNN is designed specifically for accelerating the LSTM model, we only compare with skim-RNN using LSTM *classifier*. Each corresponding model is selected by tuning parameters on validation data. The model is then frozen and evaluated on test-data for different selection budgets.

Figure 2 demonstrates the trade-off between the performance, and the test-time for each setting. Overall, we expect the error to decrease with a larger test-time budget. From Figure 2, on all of the IMDB, AGNews, and SST-2 datasets, LSTM *classifier* trained with our proposed data aggregation not only achieves the lowest error curve but also the results are robust and consistent. That is our approach achieves higher performance across different test-time budgets and its performance is a predictable monotonic function of the test-time budget. However, the performance of skim-RNN exhibits inconsistency for different budgets. As a matter of fact, for multiple budgets, none of the skim-RNN, and LSTM-jump address the prob-

[5] In Appendix B, we discuss how to vary these budgets.

lem of different word distribution between training and testing. Therefore, similar to skim-RNN, we anticipate that the behavior of LSTM-jump will be inconsistent as well[8]. Additionally, since LSTM-jump has already been shown to be outperformed by skim-RNN, we do not further compare with it. Next, we show that our framework is generic and can incorporate with other different *classifier*s, such as BCN (see Table 1).[9] When phrase boundary information is available, our model can further achieve **86.7** in accuracy with **1.7x** speedup for BCN on SST-2 dataset by using phrase-level data aggregation. Finally, one more advantage of the proposed framework is that the output of the *selector* is interpretable. In Table 3, we present that our framework correctly selects words such as "Nokia", "telecom", and phrases such as "searched by police", "software security" and filters out words like "Aug.", "users" and "products".

Note that nevertheless we focus on efficient inference, empirically our method is no more complex than the baseline during training. Despite the number of training instances increases, and so does the training time for each epoch, the number of epochs we require for obtaining a good model is usually smaller. For example, on the Yelp corpus, we only need 3 epochs to train a BCN *classifier* on the aggregated corpus generated by using 3 different *selector*s, while training on the original corpus requires 10 epochs.

5 Conclusion

We present a framework to learn a robust *classifier* under test-time constraints. We demonstrate that the proposed *selector*s effectively select important words for *classifier* to process and the data aggregation strategy improves the model performance. As future work we will apply the framework for other text reading tasks. Another promising direction is to explore the benefits of text classification model in an edge-device setting. This problem naturally arises with local devices (e.g., smart watches or mobile phones), which do not have sufficient memory or computational power to execute a complex *classifier*, and instances must be sent to the cloud. This setting is particularly suited to ours since we could choose to send only the important words to the cloud. In contrast, skim-RNN and LSTM-jump, which process the text sequentially, have to either send the entire text to the server or require multiple rounds of communication between the server and local devices resulting in high network latency.

[8] As an example, from Table 6 in Yu et al. (2017), the performance of LSTM-jump drops from 0.881 to 0.854 although it takes longer test-time (102s) than the baseline (81.7s).

[9] Because of the inherent accuracy/inference-time trade-off, it is difficult to depict model comparisons. For this reason, in Figure 2, we plot the trade-off curve to demonstrate the best speedup achieved by our model for achieving near state-of-art performance. On the other hand, test results are tabulated in Table 1 to focus attention primarily on accuracy.

Commonsense Knowledge Mining from Pretrained Models

Abstract

Inferring commonsense knowledge is a key challenge in natural language processing, but due to the sparsity of training data, previous work has shown that supervised methods for commonsense knowledge mining underperform when evaluated on novel data. In this work, we develop a method for generating commonsense knowledge using a large, pre-trained bidirectional language model. By transforming relational triples into masked sentences, we can use this model to rank a triple's validity by the estimated pointwise mutual information between the two entities. Since we do not update the weights of the bidirectional model, our approach is not biased by the coverage of any one commonsense knowledge base. Though this method performs worse on a test set than models explicitly trained on a corresponding training set, it outperforms these methods when mining commonsense knowledge from new sources, suggesting that unsupervised techniques may generalize better than current supervised approaches.

1 Introduction

Commonsense knowledge consists of facts about the world which are assumed to be widely known. For this reason, commonsense knowledge is rarely stated explicitly in natural language, making it challenging to infer this information without an enormous amount of data (Gordon and Van Durme, 2013). Some have even argued that machine learning models cannot learn common sense implicitly (Davis and Marcus, 2015).

One method for mollifying this issue is directly augmenting models with commonsense knowledge bases (Young et al., 2018), which typically contain high-quality information but with low coverage. These knowledge bases are represented as a graph, with nodes consisting of conceptual entities (i.e. `dog`, `running away`, `excited`, etc.) and the pre-defined edges representing the nature of the relations between concepts (`IsA`, `UsedFor`, `CapableOf`, etc.). Commonsense knowledge base completion (CKBC) is a machine learning task motivated by the need to improve the coverage of these resources. In this formulation of the problem, one is supplied with a list of candidate entity-relation-entity triples, and the task is to distinguish which of the triples express valid commonsense knowledge and which are fictitious (Li et al., 2016).

Several approaches have been proposed for training models for commonsense knowledge base completion (Li et al., 2016; Jastrzebski et al., 2018). Each of these approaches uses some sort of supervised training on a particular knowledge base, evaluating the model's performance on a held-out test set from the same database. These works use relations from ConceptNet, a crowd-sourced database of structured commonsense knowledge, to train and validate their models (Liu and Singh, 2004). However, it has been shown that these methods generalize poorly to novel data (Li et al., 2016; Jastrzebski et al., 2018). Jastrzebski et al. (2018) demonstrated that much of the data in the ConceptNet test set were simply rephrased relations from the training set, and that this train-test set leakage led to artificially inflated test performance metrics. This problem of train-test leakage is typical in knowledge base completion tasks (Toutanova et al., 2015; Dettmers et al., 2018).

Instead of training a predictive model on any specific database, we attempt to utilize the world knowledge of large language models to identify commonsense facts directly. By constructing a candidate piece of knowledge as a sentence, we can use a language model to approximate the likelihood of this text as a proxy for its truthfulness.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1173–1178,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

In particular, we use a masked language model to estimate point-wise mutual information between entities in a possible relation, an approach that differs significantly from fine-tuning approaches used for other language modeling tasks. Since the weights of the model are fixed, our approach is not biased by the coverage of any one dataset. As we might expect, our method underperforms when compared to previous benchmarks on the ConceptNet common sense triples dataset (Li et al., 2016), but demonstrates a superior ability to generalize when mining novel commonsense knowledge from Wikipedia.

Related Work Schwartz et al. (2017) and Trinh and Le (2018) demonstrate a similar approach to using language models for tasks requiring commonsense, such as the Story Cloze Task and the Winograd Schema Challenge, respectively (Mostafazadeh et al., 2016; Levesque et al., 2012). Bosselut et al. (2019) and Trinh and Le (2019) use unidirectional language models for CKBC, but their approach requires a supervised training step. Our approach differs in that we intentionally avoid training on any particular database, relying instead on the language model's general world knowledge. Additionally, we use a bidirectional masked model which provides a more flexible framework for likelihood estimation and allows us to estimate point-wise mutual information. Although it is beyond the scope of this paper, it would be interesting to adapt the methods presented here for the related task of generating new commonsense knowledge (Saito et al., 2018).

2 Method

Given a commonsense head-relation-tail triple $x = (\mathbf{h}, r, \mathbf{t})$, we are interested in determining the validity of that tuple as a representation of a commonsense fact. Specifically, we would like to determine a numeric score $y \in \mathbb{R}$ reflecting our confidence that a given tuple represents true knowledge.

We assume that heads and tails are arbitrary-length sequences of words in a vocabulary $\mathcal{V}$ so that $\mathbf{h} = \{h_1, h_2, \ldots, h_n\}$ and $\mathbf{t} = \{t_1, t_2, \ldots, t_m\}$. We further assume that we have a known set of possible relations $\mathcal{R}$ so that $r \in \mathcal{R}$.

The goal is to determine a function f that maps relational triples to validity scores. We propose decomposing $f(x) = \sigma(\tau(x))$ into two subcomponents: a sentence generation function τ which maps a triple to a single sentence, and a scoring model σ which then determines a validity score y.

Our approach relies on two types of pretrained language models. Standard unidirectional models are typically represented as autoregressive probabilities:

$$p(w_1, w_2, \ldots, w_m) = \prod_i^m p(w_i | w_1, \ldots, w_{i-1})$$

Masked bidirectional models such as BERT, proposed by Devlin et al. (2018), instead model in both directions, training word representations conditioned both on future and past words. The masking allows any number of words in the sequence to be hidden. This setup provides an intuitive framework to evaluate the probability of any word in a sequence conditioned on the rest of the sequence,

$$p(w_i | w'_{1:i-1}, w'_{i+1:m})$$

where $w' \in \mathcal{V} \cup \{\kappa\}$ and κ is a special token indicating a masked word.

2.1 Generating Sentences from Triples

We first consider methods for turning a triple such as `(ferret, AtLocation, pet store)` into a sentence such as "the ferret is in the pet store". Our approach is to generate a set of candidate sentences via hand-crafted templates and select the best proposal according to a language model.

For each relation $r \in \mathcal{R}$, we hand-craft a set of sentence templates. For example, one template in our experiments for the relation `AtLocation` is, "you are likely to find `HEAD` in `TAIL`". For the above example, this would yield the sentence, "You are likely to find ferret in pet store".

Because these sentences are not always grammatically correct, such as in the above example, we apply a simple set of transformations. These consist of inserting articles before nouns, converting verbs into gerunds, and pluralizing nouns which follow numbers. See the supplementary materials for details and Table 1 for an example. We then enumerate a set of alternative sentences $\mathcal{S} = \{S_1, \ldots, S_j\}$ resulting from each template and from all combinations of transformations. This yields a set of candidate sentences for each data point. We then select the candidate sentence with the highest log-likelihood according to a pre-trained unidirectional language model P_{coh}.

$$S^* = \arg\max_{S \in \mathcal{S}} \left[\log P_{\text{coh}}(S) \right]$$

Candidate Sentence S_i	$\log p(S_i)$
"musician can playing musical instrument"	-5.7
"musician can be play musical instrument"	-4.9
"musician often play musical instrument"	-5.5
"a musician can play a musical instrument"	$\mathbf{-2.9}$

Table 1: Example of generating candidate sentences. Several enumerated sentences for the triple `(musician, CapableOf, play musical instrument)`. The sentence with the highest log-likelihood according to a pretrained language model is selected.

We refer to this method of generating a sentence from a triple as COHERENCY RANKING. Coherency Ranking operates under the assumption that natural, grammatical sentences will have a higher likelihood than ungrammatical or unnatural sentences. See an example subset of sentence candidates and their corresponding scores in Table 1. From a qualitative evaluation of the selected sentences, we find that this approach produces sentences of significantly higher quality than those generated by deterministic rules alone. We also perform an ablation study in our experiments demonstrating the effect of each component on CKBC performance.

2.2 Scoring Generated Triples

Assuming we have generated a proper sentence from a relational triple, we now need a way to score its validity with a pretrained model that considers the relationship between the relation entities. We therefore propose using the estimated point-wise mutual information (PMI) of the head $\mathbf{h}$ and tail $\mathbf{t}$ of a triple conditioned on the relation r, defined as,

$$\text{PMI}(\mathbf{t}, \mathbf{h}|r) = \log p(\mathbf{t}|\mathbf{h}, r) - \log p(\mathbf{t}|r)$$

We can estimate these scores by using a masked bidirectional language model, P_{cmp}. In the case where the tail is a single word, the model allows us to evaluate the conditional likelihood of a single triple component $p(\mathbf{t}|\mathbf{h}, r)$ by computing $P_{\text{cmp}}(w_i = \mathbf{t}\ |w_{1:i-1}, w_{i+1:m})$ for the tail word.

In practice, the tail might be realized as a j-word phrase. To handle this complexity, we use a greedy approximation of its probability. We first mask all of the tail words and compute the probability of each. We then find the word with highest probability p_k, substitute it back in, and repeat j times. Finally, we calculate the total conditional likelihood of the tail by the product of these terms, $p(\mathbf{t}|\mathbf{h}, r) = \prod_{k=1}^{j} p_k$.

The marginal $p(\mathbf{t}|r)$ is computed similarly, but in this case we mask the head throughout. For example, to compute the marginal tail probability for the sentence, "You are likely to find a ferret in the pet store" we mask both the head and the tail and then sequentially unmask the tail words only: "You are likely to find a κ_{h1} in the κ_{t1} κ_{t2}". If κ_{t2} = "store" has a higher probability than κ_{t1} = "pet", we unmask "store" and compute "You are likely to find a κ_{h1} in the κ_{t1} store". The marginal likelihood $p(\mathbf{t}|r)$ is then the product of the two probabilities.

The final score combines the marginal and conditional likelihoods by employing a weighted form of the point-wise mutual information,

$$\text{PMI}_\lambda(\mathbf{t}, \mathbf{h}|r) = \lambda \log p(\mathbf{t}|\mathbf{h}, r) - \log p(\mathbf{t}|r)$$

where λ is treated as a hyperparameter. Although exact PMI is symmetrical, the approximate model itself is not. We therefore average $\text{PMI}_\lambda(\mathbf{t}, \mathbf{h}|r)$ and $\text{PMI}_\lambda(\mathbf{h}, \mathbf{t}|r)$ to reduce the variance of our estimates, computing the masked head values rather than the tail values in the latter.

3 Experiments

To evaluate the Coherency Ranking approach we measure whether it can distinguish between valid and invalid triples. For our masked model, we use BERT-large (Devlin et al., 2018). For sentence ranking, we use the GPT-2 117M LM (Radford et al., 2019). The relation templates and grammar transformation rules which we use can be found in the supplementary materials.

We compare the proposed method to several baselines. Following Trinh and Le (2018), we evaluate a simple CONCATENATION method for generating sentences, splitting the relation r into separate words and concatenating it with the head and tail. For the triple `(ferret, AtLocation, pet store)`, the Concatenation approach would yield, "ferret at location pet store".

We also evaluate CKBC performance when we construct sentences by applying a single handcrafted template. Since each triple is mapped to a sentence with a single template without any grammatical transformations, we refer to this as the TEMPLATE method. Using the Template approach, `(ferret, AtLocation, pet store)`

Model	Task 1	Task 2
Unsupervised		
CONCATENATION	68.8	2.95 ± 0.11
TEMPLATE	72.2	2.98 ± 0.11
TEMPL.+GRAMMAR	74.4	2.56 ± 0.13
COHERENCY RANK	78.8	$\mathbf{3.00} \pm 0.12$
Supervised		
DNN	**89.2**	2.50
FACTORIZED	89.0	2.61
PROTOTYPICAL	79.4	2.55

Table 2: Main results for Task 1: Commonsense knowledge base completion (test F1 score) and Task 2: Wikipedia mining (quality scores out of 4). Results are included from the sentence generation methods of simple concatenation, hand-crafted templates, templates plus grammatical transformations, and coherency ranking. DNN, Factorized, and Prototypical models are described in Jastrzebski et al. (2018).

would become "You are likely to find ferret in pet store" using the template "you are likely to find HEAD in TAIL".

Next, we extend the Template method by applying deterministic grammatical transformations, which we refer to as the TEMPLATE + GRAMMAR approach. Like the full approach, these transformations involve adding articles before nouns, converting verbs into gerunds, and pluralizing nouns following numbers. The Template + Grammar approach differs from Coherency Ranking in that all transformations are applied to every sentence instead of applying combinations of transformations and templates, which are then ranked by a language model. Returning to our example, the Template + Grammar method produces "You are likely to find a ferret in a pet store". While this sentence is grammatical, applying this method to `(star, AtLocation, outer space)` yields "You are likely to find a star in an outer space", which is incorrect.

We compare our results to the supervised models from the work of Jastrzebski et al. (2018) and the best performing model from Li et al. (2016). Jastrzebski et al. (2018) introduce FACTORIZED and PROTOTYPICAL models. The Factorized model embeds the head, relation, and tail in a vector space and then produces a score by taking a linear combination of the inner products between each pair of embeddings. The Prototypical model is similar, but does not include the inner product between head and tail. Li et al. (2016) evaluate a deep neural network (DNN) for CKBC. They concatenate embeddings for the head, relation, and tail, which they then feed through a multilayer perceptron with one hidden layer. All three models are trained on 100,000 ConceptNet triples.

Task 1: Commonsense Knowledge Base Completion Our experimental setup follows Li et al. (2016), evaluating our model with their test set (n = 2400) containing an equal number of valid and invalid triples. The valid triples are from the crowd-sourced Open Mind Common Sense (OMCS) entries in the ConceptNet 5 dataset (Speer and Havasi, 2012). Invalid triples are generated by replacing an element of a valid tuple with another randomly selected element.

We use our scoring method to classify each tuple as valid or invalid. To this end, we use our method to assign a score to each tuple and then group the resulting scores into two clusters. Instances in the cluster with the higher mean PMI are labeled as valid, and the remainder are labeled as invalid. We use expectation-maximization with a mixture of Gaussians to cluster. We also tune the PMI weight via grid search over 90 points from $\lambda \in [0.5, 5.]$, using the Akaike information criterion of the Gaussian mixture model for evaluation (Akaike, 1974).

Table 2 shows the full results. Our unsupervised approach achieves a test set F1 score of 78.8, comparable to the 79.4 F1 score found by the supervised prototypical approach. The Factorized and DNN models significantly outperformed our approach with F1 scores of 89.2 and 89.0, respectively. Our grid search found an optimal λ value of 1.65 for the Concatenation sentence generation model and 1.55 for the Coherency Ranking model. The Template and Template + Grammar methods found lambda values of 1.20 and 0.95, respectively.

Task 2: Mining Wikipedia To assess the model's ability to generalize to unseen data, we evaluate our unsupervised model in comparison to previous supervised methods on the task of mining commonsense knowledge from Wikipedia. In their evaluations, Li et al. (2016) curate a set of 1.7M triples across 10 relations by applying part-of-speech patterns to Wikipedia articles. We sample 300 triples from each relation. We apply our

method to evaluate these 3000 triples. Using the approach described by Speer and Havasi (2012), and followed by Li et al. (2016) and Jastrzebski et al. (2018), two human annotators manually rate the 100 triples with the highest predicted score on a 0 to 4 scale: 0 (Doesn't make sense), 1 (Not true), 2 (Opinion/Don't know), 3 (Sometimes true), and 4 (Generally true). We tuned λ by measuring the quality of the 100 triples with the highest predicted score across $\lambda \in \{1, 2, \ldots, 9, 10\}$.

The top 100 triples selected by our model were assigned a mean rating of 3.00 ($\lambda = 4$) with a standard error of 0.11 under the Coherency Ranking approach, well exceeding the performance of current supervised methods (Table 2). Standard errors were calculated using 1000 bootstrap samples of the top 100 triples. The ratings assigned by the two human annotators had a 0.50 Pearson correlation and 0.23 kappa inter-annotator agreement. Rater disagreements occur most frequently when triples are ambiguous or difficult to interpret. Notably, if we bucket the five scores into just two categories of *true* and *false*, this disagreement rate drops by 50%. To give a sense of the types of commonsense knowledge our models struggle to capture, we report the top 100 most confident predictions that receive an average score below 3 in the supplementary material. Notably, some of the top 100 triples our model identified were indeed true, but would not be reasonably considered common sense (e.g. `(vector bundle, HasProperty, manifold)`). This suggests that our approach may be applicable to mining knowledge beyond common sense.

Analysis: Sentence Generation In order to measure the impact of sentence generation on our model, we select a sample of 100 sentences and group the results by a) whether the sentence contained a grammatical error, and b) whether the sentence misrepresented the meaning of the triple. For example, the triple `(golf, HasProperty, good)` yields the sentence "golf is a good", which is grammatically correct but conveys the wrong meaning. On both Wikipedia mining and CKBC, we find that misrepresenting meaning has an adverse impact on model performance. In CKBC, we also find that grammar has a high impact on the resulting F1 scores (Table 3). Future work could therefore focus on designing templates that more reliably encode a relation's true meaning.

Task 1	**N (/100)**	**F1 Score**
GRAMMATICAL	75	79.1
UNGRAMMATICAL	25	66.7
CORRECT MEANING	91	77.6
WRONG MEANING	9	66.7
Task 2	-	**Quality**
GRAMMATICAL	83	3.01
UNGRAMMATICAL	17	2.88
CORRECT MEANING	88	3.22
WRONG MEANING	12	1.18

Table 3: Test results examining the effect of sentence meaning and grammaticality on task performance. Scores are shown for a sample of 100 triples split by whether the generated sentence is grammatical and whether it conveys the correct meaning of the triple.

4 Conclusion

We introduce a robust unsupervised method for commonsense knowledge base completion using the world knowledge of pre-trained language models. We develop a method for expressing knowledge triples as sentences. Using a bidirectional masked language model on these sentences, we can then estimate the weighted point-wise mutual information of a triple as a proxy for its validity. Though our approach performs worse on a held-out test set developed by Li et al. (2016), it does so without any previous exposure to the ConceptNet database, ensuring that this performance is not biased. In the future, we hope to explore whether this approach can be extended to mining facts that are not commonsense and to generating new commonsense knowledge outside of any given database of candidate triples. We also see potential benefit in the development of a more expansive set of evaluation methods for commonsense knowledge mining, which would strengthen the validity of our conclusions.

Abstract

Neural models for NLP typically use large numbers of parameters to reach state-of-the-art performance, which can lead to excessive memory usage and increased runtime. We present a structure learning method for learning sparse, parameter-efficient NLP models. Our method applies group lasso to rational RNNs (Peng et al., 2018), a family of models that is closely connected to weighted finite-state automata (WFSAs). We take advantage of rational RNNs' natural grouping of the weights, so the group lasso penalty directly removes WFSA states, substantially reducing the number of parameters in the model. Our experiments on a number of sentiment analysis datasets, using both GloVe and BERT embeddings, show that our approach learns neural structures which have fewer parameters without sacrificing performance relative to parameter-rich baselines. Our method also highlights the interpretable properties of rational RNNs. We show that sparsifying such models makes them easier to visualize, and we present models that rely exclusively on as few as three WFSAs after pruning more than 90% of the weights. We publicly release our code.[1]

1 Introduction

State-of-the-art neural models for NLP are heavily parameterized, requiring hundreds of millions (Devlin et al., 2019) and even billions (Radford et al., 2019) of parameters. While over-parameterized models can sometimes be easier to train (Livni et al., 2014), they may also introduce memory problems on small devices and lead to increased carbon emission (Strubell et al., 2019; Schwartz et al., 2019).

In feature-based NLP, structured-sparse regularization, in particular the group lasso (Yuan and Lin, 2006), has been proposed as a method to reduce model size while preserving performance (Martins et al., 2011). But, in neural NLP, some of the most widely used models—LSTMs (Hochreiter and Schmidhuber, 1997) and GRUs (Cho et al., 2014)—do not have an obvious, intuitive notion of "structure" in their parameters (other than, perhaps, division into layers), so the use of structured sparsity at first may appear incongruous.

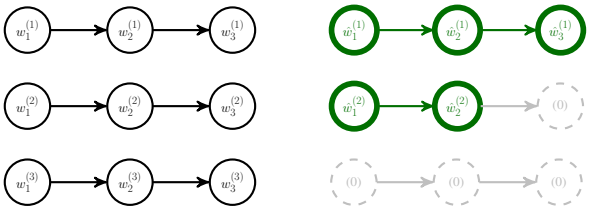

Figure 1: Our approach learns a sparse structure (right hand side) of a base rational RNN (left hand side) where each hidden unit corresponds to a WFSA (in this example, three hidden units, represented by the three rows). Grayed-out, dashed states are removed from the model, while retained states are marked in **bold green**.

In this paper we show that group lasso can be successfully applied to neural NLP models. We focus on a family of neural models for which the hidden state exhibits a natural structure: rational RNNs (Peng et al., 2018). In a rational RNN, the value of each hidden dimension is the score of a weighted finite-state automaton (WFSA) on (a prefix of) the input vector sequence. This property offers a natural grouping of the transition function parameters for each WFSA. As shown by Schwartz et al. (2018) and Peng et al. (2018), a variety of state-of-the-art neural architectures are rational (Lei et al., 2017; Bradbury et al., 2017; Foerster et al., 2017, *inter alia*), so learning parameter-efficient rational RNNs is of practical value. We

[1] https://github.com/dodgejesse/sparsifying_regularizers_for_RRNNs

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1179–1184, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

also take advantage of the natural interpretation of rational RNNs as "soft" patterns (Schwartz et al., 2018).

We apply a group lasso penalty to the WFSA parameters of rational RNNs during training, where each group is comprised of the parameters associated with one state in one WFSA (Fig. 1; §2). This penalty pushes the parameters in some groups to zero, effectively eliminating them, and making the WFSA smaller. When all of the states for a given WFSA are eliminated, the WFSA is removed entirely, so this approach can be viewed as learning the number of WFSAs (i.e., the RNN hidden dimension) as well as their size. We then retain the sparse structure, which results in a much smaller model in terms of parameters.

We experiment with four text classification benchmarks (§3), using both GloVe and BERT embeddings. As we increase the regularization strength, we end up with smaller models. These models have a better tradeoff between the number of parameters and model performance compared to setting the number of WFSAs and their lengths by hand or using hyperparameter search. In almost all cases, our approach results in models with fewer parameters and similar or better performance compared to our baselines.

In contrast to neural architecture search (Jozefowicz et al., 2015; Zoph and Le, 2017), which can take several GPU years to learn an appropriate neural architecture, our approach requires only two training runs: one to learn the structure, and the other to estimate its parameters. Other approaches either ignore the structure of the model and only look at the value of individual weights (Liu et al., 2019; LeCun et al., 1990; Lee et al., 2019; Frankle and Carbin, 2019) or only use high-level structures like the number of layers of the network (Wen et al., 2016; Scardapane et al., 2017; Gordon et al., 2018).

Finally, our approach touches on another appealing property of rational RNNs—their interpretability. Each WFSA captures a "soft" version of patterns like "such a great X", and can be visualized as such (Schwartz et al., 2018). By retaining a small number of WFSAs, model structures learned using our method can be visualized succinctly. In §4 we show that some of our sentiment analysis models rely exclusively on as few as *three* WFSAs.[2]

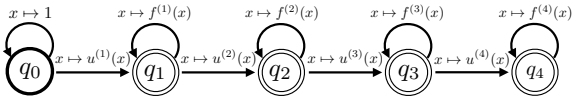

Figure 2: A 4-gram WFSA, from which we derive the rational RNN (§2). The rational RNN's hidden states correspond to a set of WFSAs, each separately parameterized. We apply group lasso to each WFSA.

2 Method

We describe the proposed method. At a high level, we follow the standard practice for using ℓ_1 regularization for sparsification (Wen et al., 2016):

1. Fit a model on the training data, with the group lasso regularizer added to the loss during training (the parameters associated with one state comprise one group).
2. After convergence, eliminate the states whose parameters are zero.
3. Finetune the resulting, smaller model, by minimizing the unregularized loss with respect to its parameters.

In this work, we assume a single layer rational RNN, but our approach is equally applicable to multi-layer models. For clarity of the discussion, we start with a one-dimensional rational RNN (i.e., one based on a single WFSA only). We then generalize to the d-dimensional case (computing the scores of d WFSAs in parallel).

Rational recurrent networks Following Peng et al. (2018), we parameterize the transition functions of WFSAs with neural networks, such that each transition (main path or self loop) defines a weighted function over the input word vector. We consider a 5-state WFSA, diagrammed in Fig. 2.

A path starts at q_0; at least four tokens must be consumed to reach q_4, and in this sense it captures 4-gram "soft" patterns (Peng et al., 2018; Schwartz et al., 2018). In addition to q_4, we also designate q_1, q_2, and q_3 as final states, allowing for the interpolation between patterns of different lengths.[3] The self-loop transitions over q_1, q_2, q_3, and q_4 aim to allow, but downweight, nonconsecutive patterns, as the self-loop transition functions yield values between 0 and 1 (using a sigmoid function). The recurrent function is equivalent to applying the Forward dynamic programming algorithm (Baum and Petrie, 1966).

[2] That is, a rational RNN with hidden size 3.

[3] We found this to be more stable than using only q_4.

Promoting sparsity with group lasso We aim to learn a sparse rational model with fewer WFSA states. This can be achieved by penalizing the parameters associated with a given state, specifically the parameters associated with *entering* that state, by a transition from another state or a self-loop on that state. For example, the parameters of the WFSA in Fig. 2 (excluding the word embedding parameters) are assigned to four nonoverlapping groups, one for each non-starting state.

During training, the regularization term will push all parameters toward zero, and some will converge close to zero.[4] After convergence, we remove groups for which the ℓ_2 norm falls below ϵ.[5] The resulting smaller model is then finetuned by continuing training without regularizing. With our linear-structured WFSA, zeroing out the group associated with a state in the middle effectively makes later states inaccessible. While our approach offers no guarantee to remove states from the end first (thus leaving no unreachable states), in our experiments it always did so.

d-dimensional Case To construct a rational RNN with d WFSAs (a d-dimensional model), we stack d one-dimensional models, each of them separately parameterized. The parameters of a d-dimensional rational model derived from the WFSA in Fig. 2 are organized into $4d$ groups, four for each dimension. Since there is no direct interaction between different dimensions (e.g., through an affine transformation), group lasso sparsifies each dimension/WFSA independently. Hence the resulting rational RNN can consist of WFSAs of different sizes, the number of which could be smaller than d if any of the WFSAs have all states eliminated.

One can treat the numbers and sizes of WFSAs as hyperparameters (Oncina et al., 1993; Ron et al., 1994; de la Higuera, 2010; Schwartz et al., 2018). By eliminating states from WFSAs with group lasso, we learn the WFSA structure *while* fitting the models' parameters, reducing the number of training cycles by reducing the number of tunable hyperparameters.

[4]There are optimization methods that achieve "strong" sparsity (Parikh and Boyd, 2013), where some parameters are exactly set to zero during training. Recent work has shown these approaches can converge in nonconvex settings (Reddi et al., 2016), but our experiments found them to be unstable.

[5]We use 0.1. This threshold was lightly tuned in preliminary experiments on the validation set and found to reliably remove those parameters which converged around zero without removing others.

3 Experiments

We run sentiment analysis experiments. We train the rational RNN models (§2) with group lasso regularization, using increasingly large regularization strengths, resulting in increasingly compact models. As the goal of our experiments is to demonstrate the ability of our approach to reduce the number of parameters, we only consider rational baselines: the same rational RNNs trained without group lasso.[6] We manually tune the number and sizes of the baselines WFSAs, and then compare the tradeoff curve between model size and accuracy. We describe our experiments below. For more details, see Appendix A.

Data We experiment with the Amazon reviews binary sentiment classification dataset (Blitzer et al., 2007), composed of 22 product categories. We examine the standard dataset (**original_mix**) comprised of a mixture of data from the different categories (Johnson and Zhang, 2015).[7] We also examine three of the largest individual categories as separate datasets (**kitchen**, **dvd**, and **books**), following Johnson and Zhang (2015). The three category datasets do *not* overlap with each other (though they do with **original_mix**), and are significantly different in size (see Appendix A), so we can see how our approach behaves with different amounts of training data.

Implementation details To classify text, we concatenate the scores computed by each WFSA, then feed this d-dimensional vector of scores into a linear binary classifier. We use log loss. We experiment with both type-level word embeddings (GloVe.6B.300d; Pennington et al., 2014) and contextual embeddings (BERT large; Devlin et al., 2019).[8] In both cases, we keep the embeddings fixed, so the vast majority of the learnable parameters are in the WFSAs. We train models using GloVe embeddings on all datasets. Due to memory constraints we evaluate BERT embeddings (frozen, not fine-tuned) only on the smallest

[6]Rational RNNs have shown strong performance on the dataset we experiment with: a 2-layer rational model with between 100–300 hidden units obtained 92.7% classification accuracy, substantially outperforming an LSTM baseline (Peng et al., 2018). The results of our models, which are single-layered and capped at 24 hidden units, are not directly comparable to these baselines, but are still within two points of the best result from that paper.

[7]http://riejohnson.com/cnn_data.html

[8]https://github.com/huggingface/pytorch-pretrained-BERT

dataset (**kitchen**).

Baselines As baselines, we train five versions of each rational architecture without group lasso, using the same number of WFSAs as our regularized models (24 for GloVe, 12 for BERT). Four of the baselines each use the same number of transitions for all WFSAs (1, 2, 3, and 4, corresponding to 2–5 states, and to 24, 48, 72, and 96 total transitions). The fifth baseline has an equal mix of all lengths (6 WFSAs of each size for GloVe, leading to 60 total transitions, and 3 WFSAs of each size for BERT, leading to 30 total transitions).

Each transition in our model is independently parameterized, so the total number of transitions linearly controls the number of learnable parameters (in addition to the parameters in the embedding layer).

Results Fig. 3 shows our classification test accuracy as a function of the total number of WFSA transitions in the model. We first notice that, as expected, the performance of our unregularized baselines improves as models are trained with more transitions (i.e., more parameters).

Compared to the baselines, training with group lasso provides a better tradeoff between performance and number of transitions. In particular, our heavily regularized models perform substantially better than the unigram baselines, gaining between 1–2% absolute improvements in four out of five cases. As our regularization strength decreases, we naturally gain less compared to our baselines, although still similar or better than the best baselines in four out of five cases.

4 Visualization

Using our method with a high regularization strength, the resulting sparse structures often contain only a handful of WFSAs. In such cases, building on the interpretability of individual WFSAs, we are able visualize every hidden unit, i.e., the entire model. To visualize a single WFSA $\mathcal{B}$, we follow Schwartz et al. (2018) and compute the score of $\mathcal{B}$ on every phrase in the training corpus. We then select the top and bottom scoring phrases for $\mathcal{B}$,[9] and get a prototype-like description of the pattern representing $\mathcal{B}$.[10]

		transition$_1$	transition$_2$	transition$_3$
Patt. 1	Top	not	worth	the time$_{SL}$ </s>
		not	worth	the 30$_{SL}$ </s>
		not	worth	it$_{SL}$ </s>
		not	worth	it$_{SL}$ </s>
	Bottom	extremely	pleased	$\ldots_{SL}$ </s>
		highly	pleased	$\ldots_{SL}$ </s>
		extremely	pleased	$\ldots_{SL}$ </s>
		extremely	pleased	$\ldots_{SL}$ </s>
Patt. 2	Top	miserable	</s>	
		miserable	$\ldots_{SL}$ </s>	
		miserable	$\ldots_{SL}$ </s>	
		returned	</s>	
	Bottom	superb	</s>	
		superb	</s>	
		superb	</s>	
		superb	choice$_{SL}$ </s>	
Patt. 3	Top	bad	$\ldots_{SL}$ ltd	$\ldots_{SL}$ buyer
		bad	$\ldots_{SL}$ ltd	$\ldots_{SL}$ buyer
		horrible	$\ldots_{SL}$ hl4040cn	$\ldots_{SL}$ expensive
		left	$\ldots_{SL}$ ltd	$\ldots_{SL}$ lens
	Bottom	favorite	$\ldots_{SL}$ ltd	$\ldots_{SL}$ lens
		really	$\ldots_{SL}$ ltd	$\ldots_{SL}$ buyer
		really	$\ldots_{SL}$ ltd	$\ldots_{SL}$ buyer
		best	$\ldots_{SL}$ hl4040cn	$\ldots_{SL}$ expensive

Table 1: Visualization of a sparse rational RNN trained on **original_mix** containing only 3 WFSAs. For each WFSA (i.e., pattern), we show the 4 top and bottom scoring phrases in the training corpus with this WFSA. Each column represents one main-path transition, plus potential self-loops preceding it (marked like this$_{SL}$). "$\ldots_{SL}$" marks more than 2 self loops. "</s>" marks an end-of-document token.

Table 1 visualizes a sparse rational RNN trained on **original_mix** with only *three* WFSAs, (8 main-path transitions in total).[11] The table shows that looking at the top scores of each WFSA, two of the patterns respectively capture the phrases "*not worth X </s>*" and "*miserable/returned X </s>*". Pattern 3 is not as coherent, but most examples do contain sentiment-bearing words such as *bad, horrible,* or *best*. This might be the result of the tuning process of the sparse rational structure simply learning a collection of words, rather than coherant phrases. As a result, this WFSA is treated as a unigram pattern rather than a trigram. The lowest scoring phrases show a similar trend. Appendix B shows the same visualization for another sparse rational RNN containing only four WFSAs and 11 main-path transitions, trained with BERT embeddings.

We observe another interesting trend: two of the three patterns prefer expressions that appear near the end of the document. This could result from the nature of the datasets (e.g., many reviews end

[9] As each WFSA score is used as a feature that is fed to a linear classifier, negative scores are also meaningful.

[10] While the WFSA scores are the sum of all paths deriving a document (plus-times semiring), here we search for the max (or min) scoring one. Despite the mismatch, a WFSA scores every possible path, and thus the max/min scoring path selection is still valid. As our examples show, many of these extracted paths are meaningful.

[11] The test performance of this model is 88%, 0.6% absolute below the average of the five models reported in Fig. 3.

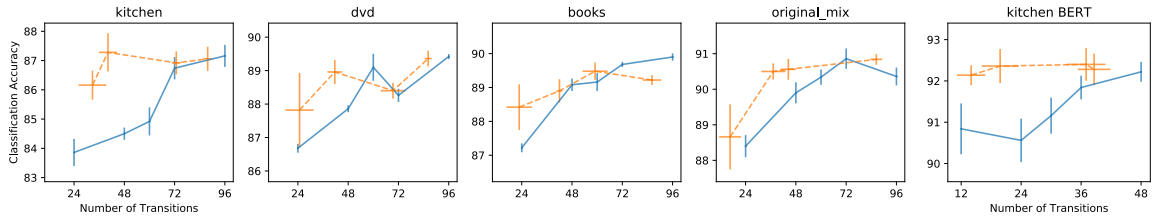

Figure 3: Text classification with GloVe embeddings (four leftmost graphs) and BERT (rightmost): accuracy (y-axis) vs. number of WFSA transitions (x-axis). **Higher** and to the **left** is better. Our method (dashed orange line, varying regularization strength) provides a better tradeoff than the baseline (solid blue line, directly varying the number of transitions). Vertical lines encode one standard deviation for accuracy, while horizontal lines encode one standard deviation in the number of transitions (applicable only to our method).

with a summary, containing important sentiment information), and/or our rational models' recency preference. More specifically, the first self loop has weight 1, and hence the model is not penalized for taking self loops before the match; in contrast, the weights of the last self loop take values in $(0, 1)$ due to the sigmoid, forcing a penalty for earlier phrase matches.[12]

5 Conclusion

We presented a method for learning parameter-efficient RNNs. Our method applies group lasso regularization on rational RNNs, which are strongly connected to weighted finite-state automata, and thus amenable to learning with structured sparsity. Our experiments on four text classification datasets, using both GloVe and BERT embeddings, show that our sparse models provide a better performance/model size tradeoff. We hope our method will facilitate the development of "thin" NLP models, that are faster, consume less memory, and are interpretable (Schwartz et al., 2019).

Analytical Methods for Interpretable Ultradense Word Embeddings

Philipp Dufter, Hinrich Schütze

Abstract

Word embeddings are useful for a wide variety of tasks, but they lack interpretability. By rotating word spaces, interpretable dimensions can be identified while preserving the information contained in the embeddings without any loss. In this work, we investigate three methods for making word spaces interpretable by rotation: Densifier (Rothe et al., 2016), linear SVMs and DensRay, a new method we propose. In contrast to Densifier, DensRay can be computed in closed form, is hyperparameter-free and thus more robust than Densifier. We evaluate the three methods on lexicon induction and set-based word analogy. In addition we provide qualitative insights as to how interpretable word spaces can be used for removing gender bias from embeddings.

1 Introduction

Distributed representations for words have been of interest in natural language processing for many years. Word embeddings have been particularly effective and successful. On the downside, embeddings are generally not interpretable. But interpretability is desirable for several reasons. i) Semantically or syntactically similar words can be extracted: e.g., for lexicon induction. ii) Interpretable dimensions can be used to evaluate word spaces by examining which information is covered by the embeddings. iii) Computational advantage: for a high-quality sentiment classifier only a couple of dimensions of a high-dimensional word space are relevant. iv) By removing interpretable dimensions one can remove unwanted information (e.g., gender bias). v) Most importantly, interpretable embeddings support the goal of interpretable deep learning models.

Orthogonal transformations have been of particular interest in the literature. The reason is twofold: under the assumption that existing word embeddings are of high-quality one would like to preserve the original embedding structure by using orthogonal transformations (i.e., preserving original distances). Park et al. (2017) provide evidence that rotating existing dense word embeddings achieves the best performance across a range of interpretability tasks.

In this work we modify the objective function of Densifier (Rothe et al., 2016) such that a closed form solution becomes available. We call this method DensRay. Following Amir et al. (2015) we compute simple linear SVMs, which we find to perform surprisingly well. We compare these methods on the task of lexicon induction.

Further, we show how interpretable word spaces can be applied to other tasks: first we use interpretable word spaces for debiasing embeddings. Second we show how they can be used for solving the set-based word analogy task. To this end, we introduce the set-based method IntCos, which is closely related to LRCos introduced by Drozd et al. (2016). We find IntCos to perform comparable to LRCos, but to be preferable for analogies which are hard to solve.

Our contributions are: **i)** We modify Densifier's objective function and derive an analytical solution for computing interpretable embeddings. **ii)** We show that the analytical solution performs as well as Densifier but is more robust. **iii)** We provide evidence that simple linear SVMs are best suited for the task of lexicon induction. **iv)** We demonstrate how interpretable embedding spaces can be used for debiasing embeddings and solving the set-based word analogy task. The source code of our experiments is available.[1]

2 Methods

2.1 Notation

We consider a vocabulary $V := \{v_1, v_2, ..., v_n\}$ together with an embedding matrix $E \in \mathbb{R}^{n \times d}$ where d is the embedding dimension. The ith row of E is the vector e_i.[2] We require an annotation for a specific linguistic feature (e.g., sentiment) and denote this annotation by $l : V \to \{-1, 1\}$. The objective is to find an orthogonal matrix $Q \in \mathbb{R}^{d \times d}$ such that EQ is interpretable, i.e., the values of the first k dimensions correlate well with the linguistic feature. We refer to the first k dimensions as interpretable ultradense word space. We interpret $x \in \mathbb{R}^n$ as a column vector and $x^\intercal$ as a row vector. Further, we normalize all word embeddings with respect to the euclidean norm.

2.2 DensRay

Throughout this section $k = 1$. Given a linguistic signal l (e.g., sentiment), consider $L_= := \{(v, w) \in V \times V |\ l(v) = l(w)\}$, and analogously $L_{\neq}$. We call $d_{vw} := e_v - e_w$ a difference vector.

Densifier (Rothe et al., 2016) solves the following optimization problem,

$$\max_q \sum_{(v,w) \in L_{\neq}} \alpha_{\neq} \left\| q^\intercal d_{vw} \right\|_2 - \sum_{(v,w) \in L_=} \alpha_= \left\| q^\intercal d_{vw} \right\|_2 ,$$

subject to $q^\intercal q = 1$ and $q \in \mathbb{R}^d$. Further $\alpha_{\neq}, \alpha_= \in [0, 1]$ are hyperparameters. We now modify the objective function: we use the squared euclidean norm instead of the euclidean norm, something that is frequently done in optimization to simplify the gradient. The problem becomes then

$$\max_q \sum_{(v,w) \in L_{\neq}} \alpha_{\neq} \left\| q^\intercal d_{vw} \right\|_2^2 - \sum_{(v,w) \in L_=} \alpha_= \left\| q^\intercal d_{vw} \right\|_2^2 . \quad (1)$$

Using $\|x\|_2^2 = x^\intercal x$ together with associativity of the matrix product we can simplify to

$$\max_q q^\intercal \Big(\alpha_{\neq} \sum_{(v,w) \in L_{\neq}} d_{vw} d_{vw}^\intercal - \alpha_= \sum_{(v,w) \in L_=} d_{vw} d_{vw}^\intercal \Big) q \quad (2)$$
$$=: \max_q q^\intercal A q \quad \text{subject to } q^\intercal q = 1.$$

[2] We denote the vector corresponding to a word w by e_w.

Thus we aim to maximize the Rayleigh quotient of A and q. Note that A is a real symmetric matrix. Then it is well known that the eigenvector belonging to the maximal eigenvalue of A solves the above problem (cf. Horn et al. (1990, Section 4.2)). We call this analytical solution **DensRay**.

A second dimension that is orthogonal to the first dimension and encodes the linguistic features second strongest is given by the eigenvector corresponding to the second largest eigenvalue. The matrix of k eigenvectors of A ordered by the corresponding eigenvalues yields the desired matrix Q (cf. Horn et al. (1990, Section 4.2)) for $k > 1$. Due to A being a real symmetric matrix, Q is always orthogonal.

2.3 Comparison to Densifier

We have shown that DensRay is a closed form solution to our new formalization of Densifier. This formalization entails differences.

Case $k > 1$. While both methods – Densifier and DensRay – yield ultradense k dimensional subspaces. While we show that the spaces are comparable for $k = 1$ we leave it to future work to examine how the subspaces differ for $k > 1$.

Multiple linguistic signals. Given multiple linguistic features, Densifier can obtain a single orthogonal transformation simultaneously for all linguistic features with chosen dimensions reserved for different features. DensRay can encode multiple linguistic features in one transformation only by iterative application.

Optimization. Densifier is based on solving an optimization problem using stochastic gradient descent with iterative orthogonalization of Q. DensRay, in contrast, is an analytical solution. Thus we expect DensRay to be more robust, which is confirmed by our experiments.

2.4 Geometric Interpretation

Assuming we normalize the vectors d_{vw} one can interpret Eq. 1 as follows: we search for a unit vector q such that the square of the cosine similarity with d_{vw} is large if $(v, w) \in L_{\neq}$ and small if $(v, w) \in L_=$. Thus, we identify dimensions that are parallel/orthogonal to difference vectors of words belonging to different/same classes. It seems reasonable to consider the average cosine similarity. Thus if $n_=$, $n_{\neq}$ is the number of elements in $L_=$, $L_{\neq}$ one can choose $\alpha_{\neq} = n_{\neq}^{-1}$ and $\alpha_= = n_=^{-1}$.

3 Lexicon Induction

We show that DensRay and Densifier indeed perform comparably using the task of lexicon induction. We adopt Rothe et al. (2016)'s experimental setup. We also use Rothe et al. (2016)'s code for Densifier. Given a word embedding space and a sentiment/concreteness dictionary (binary or continuous scores where we binarize continuous scores using the median), we identify a one-dimensional interpretable subspace. Subsequently we use the values along this dimension to predict a score for unseen words and report Kendall's τ rank correlation with the gold scores.

To ensure comparability across methods we have redone all experiments in the same setting: we deduplicated lexicons, removed a potential train/test overlap and ignored neutral words in the lexicons. We set $\alpha_{\neq} = \alpha_{=} = 0.5$ to ensure comparability between Densifier and DensRay.

Additionally we report results created by linear SVM/SVR inspired be their good performance as demonstrated by Amir et al. (2015). While they did not use linear kernels, we require linear kernels to obtain interpretable dimensions. Naturally the normal vector of the hyperplane in SVMs/SVRs reflects an interpretable dimension. An orthogonal transformation can be computed by considering a random orthogonal basis of the null space of the interpretable dimension.

Table 1 shows results. As expected the performance of Densifier and DensRay is comparable (macro mean deviation of 0.001). We explain slight deviations between the results with the slightly different objective functions of DensRay and Densifier. In addition, the re-orthogonalization used in Densifier can result in an unstable training process. Figure 1 assesses the stability by reporting mean and standard deviation for the concreteness task (BWK lexicon). We varied the size of the training lexicon as depicted on the x-axis and sampled 40 subsets of the lexicon with the prescribed size. For the sizes 512 and 2048 Densifier shows an increased standard deviation. This is because there is at least one sample for which the performance significantly drops. Removing the re-orthogonalization in Densifier prevents the drop and restores performance. Recent work (Zhao and Schütze, 2019) also finds that replacing the orthogonalization with a regularization is reasonable in certain circumstances. Given that DensRay and Densifier yield the same performance and DensRay is a stable closed form solution always yielding a orthogonal transformation we conclude that DensRay is preferable.

Surprisingly, simple linear SVMs perform best in the task of lexicon induction. SVR is slightly better when continuous lexica are used for training (line 8). Note that the eigendecomposition used in DensRay yields a basis with dimensions ordered by their correlation with the linguistic feature. An SVM can achieve this only by iterated application.

4 Removing Gender Bias

Word embeddings are well-known for encoding prevalent biases and stereotypes (cf. Bolukbasi et al. (2016)). We demonstrate qualitatively that by identifying an interpretable gender dimension and subsequently removing this dimension, one can remove parts of gender information that potentially could cause biases in downstream processing. Given the original word space E we consider the interpretable space $E' := EQ$, where Q is computed using DensRay. We denote by $E_{\cdot,-1} \in \mathbb{R}^{n\times(d-1)}$ the word space with removed first dimension and call it the "complement" space. We expect $E_{\cdot,-1}$ to be a word space with less gender bias.

To examine this approach qualitatively we use

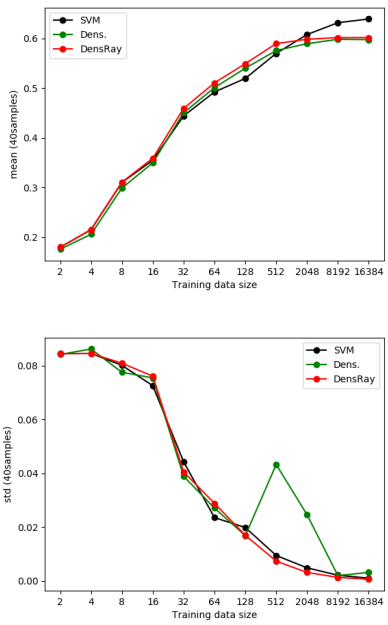

Figure 1: Mean (top) and standard deviation (bottom) of the performance across 40 samples of the training lexicon with varying sizes. Performed on the English concreteness task (line 8 in Table 1). SVR performs similar to SVM and is omitted for clarity.

a list of occupation names[3] by Bolukbasi et al. (2016) and examine the cosine similarities of occupations with the vectors of "man" and "woman". Figure 2 shows the similarities in the original space E and debiased space $E_{\cdot,-1}$. One can see the similarities are closer to the identity (i.e., same distance to "man" and "woman") in the complement space. To identify occupations with the greatest bias, Table 3 lists occupations for which $\text{sim}(e_w, e_{\text{man}}) - \text{sim}(e_w, e_{\text{woman}})$ is largest/smallest. One can clearly see a debiasing effect when considering the complement space. Extending this qualitative study to a more rigorous quantitative evaluation is part of future work.

	Original Space			Complement Space		
		man	woman		man	woman

5 Word Analogy

In this section we use interpretable word spaces for set-based word analogy. Given a list of analogy pairs $[(a, a'), (b, b'), (c, c'), \ldots]$ the task is to predict a' given a. Drozd et al. (2016) provide a detailed overview over different methods, and find that their method LRCos performs best.

LRCos assumes two classes: all left elements of a pair ("left class") and all right elements ("right class"). They train a logistic regression (LR) to differentiate between these two classes. The predicted score of the LR multiplied by the cosine similarity in the word space is their final score. Their prediction for a' is the word with the highest final score.

We train the classifier on all analogy pairs except for a single pair for which we then obtain the predicted score. In addition we ensure that no word belonging to the test analogy is used during training (splitting the data only on word analogy pairs is not sufficient).

Inspired by LRCos we use interpretable word spaces for approaching word analogy: we train DensRay or an SVM to obtain interpretable embeddings $E' = EQ$ using the class information as reasoned above. We use a slightly different notation in this section: for a word w the ith component of its embedding is given by $E_{w,i}$. Therefore we denote as $E_{\cdot,1}$ the first column of E' (i.e., the

most interpretable dimension). We min-max normalize $E_{\cdot,1}$ such that words belonging to the right class have a high value (i.e., we flip the sign if necessary). For a query word a we now want to identify the corresponding a' by solving

$$\hat{a} = \arg\max_{v \in V} \text{norm}(E_{v,1}) \, \text{sim}(E_{a,\cdot}, E_{v,\cdot})$$

where *sim* computes the cosine similarity.

Given the result from §4 we extend the above method by computing the cosine similarity in the orthogonal complement, i.e., $\text{sim}(E_{a,-1}, E_{v,-1})$. We call this method **IntCos** (INTerpretable, COSine). Depending on the space used for computing the cosine similarity add the word "Original" or "Complement".

We evaluate this method across two analogy datasets. These are the Google Analogy Dataset (GA) (Mikolov et al., 2013) and BATS (Drozd et al., 2016). As embeddings spaces we use Google News Embeddings (GN) (Mikolov et al., 2013) and FastText subword embeddings (FT) (Bojanowski et al., 2017). We consider the first 80k word embeddings from each space.

Table 4 shows the results. The first observation is that there is no clear winner. IntCos Original performs comparably to LRCos with slight improvements for GN/BATS: here the classes are widespread and exhibit low cosine similarity (IntraR and IntraL), which makes them harder to solve. IntCos Complement maintains performance for GN/BATS and is beneficial for Derivational analogies on GN. For most other analogies it harms performance.

Within IntCos Original it is favorable to use DensRay as it gives slight performance improvements. Especially for harder analogies, where interclass similarity is high and intraclass similarities are low (e.g., in GN/BATS), DensRay outperforms SVMs. In contrast to SVMs, DensRay considers difference vectors *within* classes as well – this seems to be of advantage here.

6 Related Work

Identifying Interpretable Dimensions. Most relevant to our method is a line of work that uses transformations of existing word spaces to obtain interpretable subspaces. Rothe et al. (2016) compute an orthogonal transformation using shallow neural networks. Park et al. (2017) apply exploratory factor analysis to embedding spaces

to obtain interpretable dimensions in an unsupervised manner. Their approach relies on solving complex optimization problems, while we focus on closed form solutions. Senel et al. (2018) use SEMCAT categories in combination with the Bhattacharya distance to identify interpretable directions. Also, oriented PCA (Diamantaras and Kung, 1996) is closely related to our method. However, both methods yield non-orthogonal transformation. Faruqui et al. (2015a) use semantic lexicons to retrofit embedding spaces. Thus they do not fully maintain the structure of the word space, which is in contrast to this work.

Interpretable Embedding Algorithms. Another line of work modifies embedding algorithms to yield interpretable dimensions (Koç et al., 2018; Luo et al., 2015; Shin et al., 2018; Zhao et al., 2018). There is also much work that generates sparse embeddings that are claimed to be more interpretable (Murphy et al., 2012; Faruqui et al., 2015b; Fyshe et al., 2015; Subramanian et al., 2018). Instead of learning new embeddings, we aim at making dense embeddings interpretable.

7 Conclusion

We investigated analytical methods for obtaining interpretable word embedding spaces. Relevant methods were examined with the tasks of lexicon induction, word analogy and debiasing.

Investigating Meta-Learning Algorithms for Low-Resource Natural Language Understanding Tasks

Zi-Yi Dou, Keyi Yu, Antonios Anastasopoulos
Language Technologies Institute, Carnegie Mellon University
{zdou, keyiy, aanastas}@cs.cmu.edu

Abstract

Learning general representations of text is a fundamental problem for many natural language understanding (NLU) tasks. Previously, researchers have proposed to use language model pre-training and multi-task learning to learn robust representations. However, these methods can achieve sub-optimal performance in low-resource scenarios. Inspired by the recent success of optimization-based meta-learning algorithms, in this paper, we explore the model-agnostic meta-learning algorithm (MAML) and its variants for low-resource NLU tasks. We validate our methods on the GLUE benchmark and show that our proposed models can outperform several strong baselines. We further empirically demonstrate that the learned representations can be adapted to new tasks efficiently and effectively.

1 Introduction

With the ability to learn rich distributed representations of data in an end-to-end fashion, deep neural networks have achieved the state of the arts in a variety of fields (He et al., 2017; Vaswani et al., 2017; Povey et al., 2018; Yu et al., 2018). For natural language understanding (NLU) tasks, robust and flexible language representations can be adapted to new tasks or domains efficiently. Aiming at learning representations that are not exclusively tailored to any specific tasks or domains, researchers have proposed several ways to learn general language representations.

Recently, there is a trend of learning universal language representations via language model pre-training (Dai and Le, 2015; Peters et al., 2018; Radford et al., 2018). In particular, Devlin et al. (2019) present the BERT model which is based on a bidirectional Transformer (Vaswani et al., 2017). BERT is pre-trained with both masked language model and next sentence prediction objectives and exhibits strong performance on several benchmarks, attracting huge attention from researchers. Another line of research tries to apply multi-task learning to representation learning (Liu et al., 2015; Luong et al., 2015). Multi-task learning allows the model to leverage supervision signals from related tasks and prevents the model from overfitting to a single task. By combining the strengths of both language model pre-training and multi-task learning, Liu et al. (2019) improve the BERT model with multi-task learning and their proposed MT-DNN model successfully achieves state-of-the-art results on several NLU tasks.

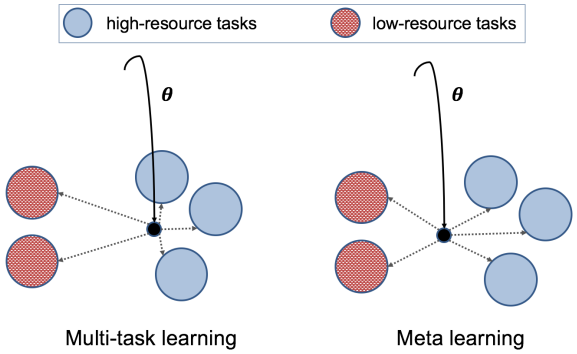

Figure 1: Differences between multi-task learning and meta learning. Multi-task learning may favor high-resource tasks over low-resource ones while meta-learning aims at learning a good initialization that can be adapted to any task with minimal training samples. The figure is adapted from Gu et al. (2018).

Although multi-task learning can achieve promising performance, there still exist some potential problems. As shown in Figure 1, multi-task learning may favor tasks with significantly larger amounts of data than others. Liu et al. (2019) alleviate this problem by adding an additional fine-tuning stage after multi-task learning. In this paper, we propose to apply meta-learning algorithms in general language represen-

tations learning. Meta-learning algorithms aim at learning good initializations that can be useful for fine-tuning on various tasks with minimal training data, which makes them appealing alternatives to multi-task learning. Specifically, we investigate the recently proposed model-agnostic meta-learning algorithm (MAML) (Finn et al., 2017) and its variants, namely first-order MAML and Reptile (Nichol et al., 2018), for NLU tasks.

We evaluate the effectiveness and generalization ability of the proposed approaches on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019). Experimental results demonstrate that our approaches successfully outperform strong baseline models on the four low-resource tasks. In addition, we test generalization capacity of the models by fine-tuning them on a new task, and the results reveal that the representations learned by our models can be adapted to new tasks more effectively compared with baseline models.

2 Proposed Approaches

In this section, we first briefly introduce some key ideas of meta learning, and then illustrate how we apply meta-learning algorithms in language representations learning.

2.1 Background: Meta Learning

Meta-learning, or learning-to-learn, has recently attracted researchers' interests in the machine learning community (Lake et al., 2015). The goal of meta-learning algorithms is to allow fast adaptation on new training data. In this paper, we mainly focus on optimization-based meta-learning algorithms, which achieve the goal by adjusting the optimization algorithm. Specifically, we investigate MAML, one of the most representative algorithms in this category, and its variants for NLU tasks.

MAML and its variants offer a way to learn from a distribution of tasks and adapt to target tasks using few samples. Formally, given a set of tasks $\{T_1, \cdots, T_k\}$, the process of learning model parameters θ can be understood as (Gu et al., 2018):

$$\theta_t^* = \text{Learn}(T_t; \text{MetaLearn}(T_1, \cdots, T_k)),$$

where T_t is the target task.

Hopefully, by exposing models to a variety of tasks, the models can learn new tasks with few steps and minimal amounts of data.

2.2 General Framework

In this part, we introduce the general framework of the MAML approach and its variants, including first-order MAML and Reptile.

Algorithm 1 Training procedure.

Pre-train model parameters θ with unlabeled datasets.
while not done **do**
  Sample batch of tasks $\{T_i\} \sim p(T)$
  for all T_i **do**
    Compute $\theta_i^{(k)}$ with Eqn. 1.
  end for
  Update θ with Eqn. 2.
end while
Fine-tune θ on the target task.

We first describe the meta-learning stage. Suppose we are given a model f_θ with parameters θ and a task distribution $p(T)$ over a set of tasks $\{T_1, T_2, \cdots, T_k\}$, at each step during the meta-learning stage, we first sample a batch of tasks $\{T_i\} \sim p(T)$, and then update the model parameters by k ($k \geq 1$) gradient descent steps for each task T_i according to the equation:

$$\theta_i^{(k)} = \theta_i^{(k-1)} - \alpha \nabla_{\theta_i^{(k-1)}} L_i(f_{\theta_i^{(k-1)}}), \quad (1)$$

where L_i is the loss function for T_i and α is a hyper-parameter.

The model parameters θ are then updated by:

$$\theta = \text{MetaUpdate}(\theta; \{\theta_i^{(k)}\}). \quad (2)$$

We would illustrate the *MetaUpdate* step in the following part. It should be noted that the data used for the MetaUpdate step (Eqn. 2) is different from that used for the first k gradient descent steps (Eqn. 1).

The overall training procedure is shown in Algorithm 1. Basically, the algorithm consists of three stages: the pre-training stage as in BERT, the meta-learning stage and the fine-tuning stage.

2.3 The MetaUpdate Step

As demonstrated in the previous paragraph, MetaUpdate is an important step in the meta-learning stage. In this paper, we investigate three ways to perform MetaUpdate as described in the following parts.

MAML The vanilla MAML algorithm (Finn et al., 2017) updates the model with the meta-objective function:

$$\min_{\theta} \sum_{T_i \sim p(T)} L_i(f_{\theta_i^{(k)}})$$

Therefore, MAML would implement the MetaUpdate step by updating θ according to:

$$\theta = \theta - \beta \sum_{T_i \sim p(T)} \nabla_{\theta} L_i(f_{\theta_i^{(k)}}),$$

where β is a hyper-parameter.

First-Order MAML Suppose $\theta^{(k)}$ is obtained by performing k inner gradient steps starting from the initial parameter $\theta^{(0)}$, we can deduce that:

$$\nabla_{\theta^{(0)}} L(f_{\theta^{(k)}}) = \nabla_{\theta^{(k)}} L(f_{\theta^{(k)}}) \prod_{i=1}^{k} \nabla_{\theta^{(i-1)}} \theta^{(i)}$$

$$= \nabla_{\theta^{(k)}} L(f_{\theta^{(k)}}) \prod_{i=1}^{k} (I - \alpha \nabla^2_{\theta^{(i-1)}} L(f_{\theta^{(i-1)}})).$$

Therefore, MAML requires calculating second derivatives, which can be both computationally and memory intensive. First-Order MAML (FO-MAML) ignores the second derivative part and implement the MetaUpdate as:

$$\theta = \theta - \beta \sum_{T_i \sim p(T)} \nabla_{\theta_i^{(k)}} L_i(\theta_i^{(k)}).$$

Reptile Reptile (Nichol et al., 2018) is another first-order gradient-based meta-learning algorithm that is similar to joint training, as it implements the MetaUpdate step as:

$$\theta = \theta + \beta \frac{1}{|\{T_i\}|} \sum_{T_i \sim p(T)} (\theta_i^{(k)} - \theta).$$

Basically, Reptile moves the model weights towards new parameters obtained by multiple gradient descent steps. Despite the simplicity of Reptile, it has been demonstrated to achieve competitive or superior performance compared to MAML.

2.4 Choosing the Task Distributions

We experiment with three different choices of the task distribution $p(T)$. Specifically, we propose the following options:

- **Uniform**: sample tasks uniformly.

Model	Test Dataset			
	CoLA	MRPC	STS-B	RTE
BERT	52.1	88.9/84.8	87.1/85.8	66.4
MT-DNN	51.7	89.9/86.3	87.6/86.8	75.4
MAML	**53.4**	89.5/85.8	88.0/87.3	76.4
FOMAML	51.6	89.9/86.4	88.6/88.0	74.1
Reptile	53.2	**90.2/86.7**	**88.7/88.1**	**77.0**

Table 1: Results on GLUE test sets. Metrics differ per task (explained in Appendix A) but the best result is **highlighted**.

- **Probability Proportional to Size (PPS)**: the probability of selecting a task is proportional to the size of its dataset.

- **Mixed**: at each epoch, we first sample tasks uniformly and then exclusively select the target task.

3 Experiments

We conduct experiments on the GLUE dataset (Wang et al., 2019) and only on English. Following previous work (Devlin et al., 2019; Liu et al., 2019) we do not train or test models on the WNLI dataset (Levesque et al., 2012). We treat the four high-resource tasks, namely SST-2 (Socher et al., 2013), QQP,[1] MNLI (Williams et al., 2018), and QNLI (Rajpurkar et al., 2016), as auxiliary tasks. The other four tasks, namely CoLA (Warstadt et al., 2018), MRPC (Dolan and Brockett, 2005), STS-B (Cera et al., 2017), and RTE (Dagan et al., 2005) are our target tasks. We also evaluate the generalization ability of our approaches on the SciTail dataset (Khot et al., 2018). The details of all datasets are illustrated in Appendix A.

We compare our models with two strong baselines: the BERT model (Devlin et al., 2019) and the MT-DNN model (Liu et al., 2019). While the former pre-trains the Transformer model on large amounts of unlabeled dataset, the latter further improves it with multi-task learning.

For BERT and MT-DNN, we use their publicly available code to obtain the final results. The setting of MT-DNN is slightly different from the setting of BERT in terms of optimizer choices. We implement our algorithms upon the **BERT$_{\text{BASE}}$**

Model	CoLA	MRPC	STS-B	RTE
Reptile-PPS	**61.6**	**90.0**	**90.3**	**83.0**
Reptile-Uniform	61.5	84.0	**90.3**	75.7
Reptile-Mixed 2:1	60.3	87.8	**90.3**	71.0
Reptile-Mixed 5:1	**61.6**	85.8	90.1	74.7

Table 2: Effect of task distributions. We report the accuracy or Matthews correlation on development sets.

model.[2] We use the Adam optimizer (Kingma and Ba, 2015) with a batch size of 32 and learning rates of 5e-5 to train the models for 5 epochs in the meta-learning stage. We set the update step k to 5, the number of sampled tasks in each step to 8 and α to 1e-3.

3.1 Results

We first use the three meta-learning algorithms with PPS sampling and present in Table 1 the experimental results on the GLUE test set. Generally, the meta-learning algorithms achieve better performance than the strong baseline models, with Reptile performing the best.

Since the MT-DNN also uses PPS sampling, the improvements suggest meta-learning algorithms can indeed learn better representations compared with multi-task learning. Reptile outperforming MAML indicates that reptile is a more effective and efficient algorithm compared with MAML in our setting.

3.2 Ablation Studies

Effect of Task Distributions As we have mentioned above, we propose three different choices of the task distribution $p(T)$ in this paper. Here we train Reptile with these task distributions and test models' performance on the development set as shown in Table 2.

For uniform sampling, we set the number of training steps equal to that of the PPS method. For mixed sampling, we try mix ratios of both 2:1 and 5:1. The results demonstrate that Reptile with PPS sampling achieves the best performance, which suggests that larger amounts of auxiliary task data can generally lead to better performance.

Effect of Hyperparameters for Meta-Gradients In this part, we test the effect of the number of update steps k and the learning rate in the inner learning loop. The experimental results on the development sets are shown in Table 3. We find that setting k to 5 is the optimal strategy and more or fewer update steps may lead to worse performance.

Smaller k would make the algorithms similar to joint training as joint training is an extreme case of Reptile where $k = 1$, and thus cause the model to lose the advantage of using meta-learning algorithms. Similarly, Larger k can make the resulting gradients deviate from the normal ones and become uninformative.

We also vary the inner learning rate α and investigate its impact. The results are listed in Table 3. We can see that larger α may degrade the performance because the resulting gradients deviate a lot from normal ones. The above two ablations studies demonstrate the importance of making the meta-gradient informative.

[2] **BERT$_{\text{BASE}}$** and **BERT$_{\text{LARGE}}$** differ at the number of hidden layers (12 vs. 24), hidden size (768 vs. 1024) and the number of attention heads (12 vs. 16).

Model	#Upt	α	CoLA	MRPC	STS-B	RTE
Reptile	3	1e-3	60.7	89.7	90.2	77.9
	5	1e-4	**62.0**	88.0	90.1	81.2
		1e-3	61.6	**90.0**	**90.3**	**83.0**
		1e-2	60.1	87.8	89.5	73.9
	7	1e-3	57.8	88.7	90.0	81.4

Table 3: Effect of the number of update steps and the inner learning rate α.

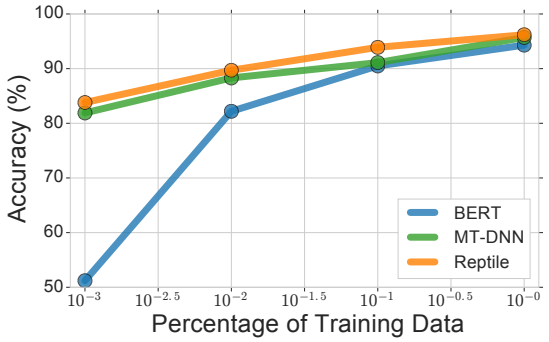

Figure 2: Results on transfer learning. The target task is SciTail which the model does not come across during the meta-learning stage.

3.3 Transferring to New Tasks

In this part, we test whether our learned representations can be adapted to new tasks efficiently. To this end, we perform transfer learning experiments on a new natural language inference dataset, namely SciTail.

We randomly sample 0.1%, 1%, 10% and 100% of the training data and test models' performance on these datasets. Figure 2 reveals that our model consistently outperforms the strong MT-

DNN baseline across different settings, indicating the learned representations are more effective for transfer learning. In particular, the algorithm is more effective when less data are available, especially compared to BERT, suggesting the meta-learning algorithms can indeed be helpful for low-resource tasks.

4 Related Work

There is a long history of learning general language representations. Previous work on learning general language representations focus on learning word (Mikolov et al., 2013; Pennington et al., 2014) or sentence representations (Le and Mikolov, 2014; Kiros et al., 2015) that are helpful for downstream tasks. Recently, there is a trend of learning contextualized word embeddings (Dai and Le, 2015; McCann et al., 2017; Peters et al., 2018; Howard and Ruder, 2018). One representative approach is the BERT model (Devlin et al., 2019) which learns contextualized word embeddings via bidirectional Transformer models.

Another line of research on learning representations focus on multi-task learning (Collobert et al., 2011; Liu et al., 2015). In particular, Liu et al. (2019) propose to combine multi-task learning with language model pre-training and demonstrate the two methods are complementary to each other.

Meta-learning algorithms have received lots of attention recently due to their effectiveness (Finn et al., 2017; Fan et al., 2018). However, the potential of applying meta-learning algorithms in NLU tasks have not been fully investigated yet. Gu et al. (2018) have tried to apply first-order MAML in machine translation and Qian and Yu (2019) propose to address the domain adaptation problem in dialogue generation by using MAML. To the best of our knowledge, the Reptile algorithm, which is simpler than MAML and potentially more useful, has been given less attention.

5 Conclusion

In this paper, we investigate three optimization-based meta-learning algorithms for low-resource NLU tasks. We demonstrate the effectiveness of these algorithms and perform a fair amount of ablation studies. We also show the learned representations can be adapted to new tasks effectively. Our study suggests promising applications of meta-learning algorithms in the field of NLU. Future directions include integrating more sophisticated training strategies of meta-learning algorithms as well as validating our algorithms on other datasets.

Abstract

Contextualized word embedding models, such as ELMo, generate meaningful representations of words and their context. These models have been shown to have a great impact on downstream applications. However, in many cases, the contextualized embedding of a word changes drastically when the context is paraphrased. As a result, the downstream model is not robust to paraphrasing and other linguistic variations. To enhance the stability of contextualized word embedding models, we propose an approach to retrofitting contextualized embedding models with paraphrase contexts. Our method learns an orthogonal transformation on the input space, which seeks to minimize the variance of word representations on paraphrased contexts. Experiments show that the retrofitted model significantly outperforms the original ELMo on various sentence classification and language inference tasks.

1 Introduction

Contextualized word embeddings have shown to be useful for a variety of downstream tasks (Peters et al., 2018, 2017; McCann et al., 2017). Unlike traditional word embeddings that represent words with fixed vectors, these embedding models encode both words and their contexts and generate context-specific representations. While contextualized embeddings are useful, we observe that a language model-based embedding model, ELMo (Peters et al., 2018), cannot accurately capture the semantic equivalence of contexts. Specifically, in cases where the contexts of a word have equivalent or similar meanings but are changed in sentence formation or word order, ELMo may assign very different representations to the word. Table 1 shows two examples, where ELMo generates very different representations for the boldfaced words under semantic equivalent contexts.

Paraphrased contexts	L2	Cosine
How can I make **bigger** my arms? How do I make my arms **bigger**?	6.42	0.27
Some people believe earth is **flat**. Why? Why do people still believe in **flat** earth?	7.59	0.46
It is a very **small** window. I have a **large** suitcase.	5.44	0.26

Table 1: L2 and Cosine distances between embeddings of boldfaced words. The distance between the shared word in the paraphrases is even greater than the distance between *large* and *small* in random contexts.

Quantitatively, 28.3% of the shared words in the paraphrase sentence pairs on the MRPC corpus (Dolan et al., 2004) is larger than the average distance between *good* and *bad* in random contexts, and 41.5% of those exceeds the distance between *large* and *small*. As a result, the downstream model is not robust to paraphrasing and the performance is hindered.

Infusing the model with the ability to capture the semantic equivalence no doubt benefits semantic-oriented downstream tasks. Yet, finding an effective solution presents key challenges. First, the solution inevitably requires the embedding model to effectively identify paraphrased contexts. On top of that, the model needs to minimize the difference of a word's representations on paraphrased contexts, without compromising the varying representations on unrelated contexts. Moreover, the long training time prevents us from redesigning the learning objectives of contextualized embeddings and retraining the model.

To address these challenges, we propose a simple and effective paraphrase-aware retrofitting (PAR) method that is applicable to arbitrary pretrained contextualized embeddings. In particular, PAR prepends an orthogonal transformation layer to a contextualized embedding model. Without retraining the parameters of an existing model, PAR learns the transformation to minimize the differ-

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ence of the contextualized representations of the shared word in paraphrased contexts, while differentiating between those in other contexts. We apply PAR to retrofit ELMo (Peters et al., 2018) and show that the resulted embeddings provide more robust contextualized word representations as desired, which further lead to significant improvements on various sentence classification and inference tasks.

2 Related Work

Contextualized word embedding models have been studied by a series of recent research efforts, where different types of pre-trained language models are employed to capture the context information. CoVe (McCann et al., 2017) trains a neural machine translation model and extracts representations of input sentences from the source language encoder. ELMo (Peters et al., 2018) pre-trains LSTM-based language models from both directions and combines the vectors to construct contextualized word representations. Recent studies substitute LSTMs with Transformers (Radford et al., 2018, 2019; Devlin et al., 2019). As shown in these studies, contextualized word embeddings perform well on downstream tasks at the cost of extensive parameter complexity and the long training process on large corpora (Strubell et al., 2019).

Retrofitting methods have been used to incorporate semantic knowledge from external resources into word embeddings (Faruqui et al., 2015; Yu et al., 2016; Glavaš and Vulić, 2018). These techniques are shown to improve the characterization of word relatedness and the compositionality of word representations. To the best of our knowledge, none of the previous approaches has been applied in contextualized word embeddings.

3 Paraphrase-Aware Retrofitting

Our method, illustrated in Figure 1, integrates the constraint of the paraphrased context into the contextualized word embeddings by learning the orthogonal transformation on the input space.

3.1 Contextualized Word Embeddings

We use $S = (w_1, w_2, \cdots, w_l)$ to denote a sequence of words of length l, where each word w belongs to the vocabulary V. We use boldfaced $\mathbf{w} \in \mathbb{R}^k$ to denote a k-dimensional input word embedding, which can be pre-trained or derived from a character-level encoder (e.g., the character-level

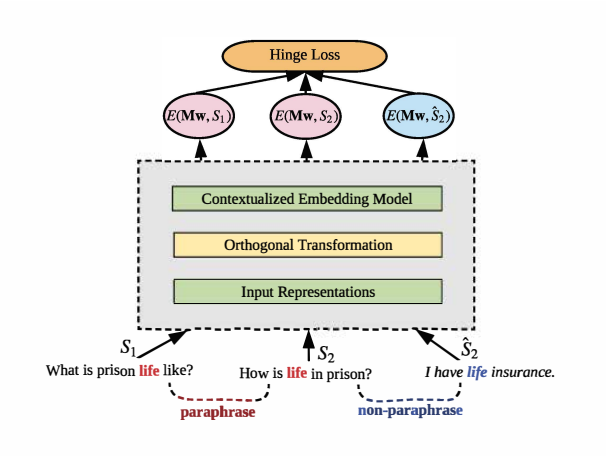

Figure 1: Learning framework of PAR

CNN used in ELMo (Peters et al., 2018)). A contextualized embedding model E takes input vectors of the words in S, and computes the context-specific representation of each word. The representation of word w specific to the context S is denoted as $E(\mathbf{w}, S)$.

3.2 Paraphrase-aware Retrofitting

PAR learns an orthogonal transformation $\mathbf{M} \in \mathbb{R}^{k \times k}$ to reshape the input representation into a specific space, where the contextualized embedding vectors of a word in paraphrased contexts are collocated, while those in unrelated contexts are differentiated. Specifically, given two contexts S_1 and S_2 that both contain a shared word w, the contextual difference of a input representation $\mathbf{w}$ is defined by the $L2$ distance,

$$d_{S_1,S_2}(\mathbf{w}) = \|E(\mathbf{w}, S_1) - E(\mathbf{w}, S_2)\|_2 .$$

Let P be the set of paraphrases on the training corpus, we minimize the following hinge loss (L_H).

$$\sum_{(S_1,S_2)\in P} \sum_{w \in S_1 \cap S_2} \left[d_{S_1,S_2}(\mathbf{Mw}) + \gamma - d_{\hat{S}_1,\hat{S}_2}(\mathbf{Mw}) \right]_+ .$$

$(S_1, S_2) \in P$ thereof is a pair of paraphrases in P. $(\hat{S}_1, \hat{S}_2) \notin P$ is a negative sample generated by randomly substituting either S_1 or S_2 with another sentence in the dataset that contains w. $\gamma > 0$ is a hyper-parameter representing the margin. The operator $[x]_+$ denotes $\max(x, 0)$.

The orthogonalization is realized by the following regularization term.

$$L_O = \left\| \mathbf{I} - \mathbf{M}^\top \mathbf{M} \right\|_F ,$$

where $\|\cdot\|_F$ denotes the Frobenius norm, and $\mathbf{I}$ is an identity matrix. The learning objective of PAR is then denoted as $L = L_H + \lambda L_O$ with a positive hyperparameter λ.

Orthogonalizing $\mathbf{M}$ has two important effects: (i) It preserves the word similarity captured by the original input word representation (Rothe et al., 2016); (ii) It prevents the model from converging to a trivial solution where all word representations collapse to the same embedding vector.

4 Experiment

Our method can be integrated with any contextualized word embedding models. In our experiment, we apply PAR on ELMo (Peters et al., 2018) and evaluate the quality of the retrofitted ELMo on a broad range of sentence-level tasks and the adversarial SQuAD corpus.

4.1 Experimental Configuration

We use the officially released 3-layer ELMo (original), which is trained on the 1 Billion Word Benchmark with 93.6 million parameters. We retrofit ELMo with PAR on the training sets of three paraphrase datasets: (i) *MRPC* contains 2,753 paraphrase pairs; (ii) *Sampled Quora* contains randomly sampled 20,000 paraphrased question pairs (Iyer et al., 2017); and (iii) *PAN* training set (Madnani et al., 2012) contains 5,000 paraphrase pairs.

The orthogonal transformation $\mathbf{M}$ is initialized as an identity matrix. In our preliminary experiments, we observed that SGD optimizer is more stable and less likely to quickly overfit the training set than other optimizers with adaptive learning rates (Reddi et al., 2018; Kingma and Ba, 2015). Therefore, we use SGD with the learning rate of 0.005 and a batch size of 128. To determine the terminating condition, we train a Multi-Layer Perceptron (MLP) classifier on the same paraphrase training set and terminate training based on the paraphrase identification performance on a set of held-out paraphrases. The sentence in the dataset is represented by the average of the word embeddings. λ is selected from $\{0.1, 0.5, 1, 2\}$ and γ from $\{1, 2, 3, 4\}$ based on validation set. The best margin γ and epochs ζ by early stopping are $\{\gamma = 3, \zeta = 20\}$ on MRPC, $\{\gamma = 2, \zeta = 14\}$ on PAN, and $\{\gamma = 3, \zeta = 10\}$ on Sampled Quora, with $\lambda = 1$ in all settings.

4.2 Evaluation

We use the SentEval framework (Conneau and Kiela, 2018) to evaluate the sentence embeddings on a wide range of sentence-level tasks. We consider two baselines models: (1) ELMo (all layers) constructs a 3,074-dimensional sentence embedding by averaging the hidden states of all the language model layers. (2) ELMo (top layers) encodes a sentence to a 1,024 dimensional vector by averaging the representations of the top layer. We compare these baselines with four variants of PAR built upon ELMo (all layers) that trained on different paraphrase corpora.

4.3 Task Descriptions

Sentence classification tasks. We evaluate the sentence embedding on four sentence classification tasks including two sentiment analysis (MR (Pang and Lee, 2004), SST-2 (Socher et al., 2013)), product reviews (CR (Hu and Liu, 2004)), and opinion polarity (MPQA (Wiebe et al., 2005)). These tasks are all binary classification tasks. We employ a MLP with a single hidden layer of 50 neurons to train the classifer, using a batch size of 64 and Adam optimizer.

Sentence inference tasks We consider two sentence inference tasks: paraphrase identification on MRPC (Dolan et al., 2004) and the textual entailment on SICK-E (Marelli et al., 2014). MRPC consists of pairs of sentences, where the model aims to classify if two sentences are semantically equivalent. The SICK dataset contains 10,000 English sentence pairs annotated for relatedness in meaning and entailment. The aim of SICK-E is to detect discourse relations of entailment, contradiction and neutral between the two sentences. Similar to the sentence classification tasks, we apply a MLP with the same hyperparameters to conduct the classification.

Semantic textual similarity tasks. Semantic Textual Similarity (STS-15 (Agirre et al., 2015) and STS-16 (Agirre et al., 2016)) measures the degree of semantic relatedness of two sentences based on human-labeled scores from 0 to 5. We report the Pearson correlation between cosine similarity of two sentence representations and normalized human-label scores.

Semantic relatedness tasks The semantic relatedness tasks include SICK-R (Marelli et al., 2014) and the STS Benchmark dataset (Cer et al., 2017), which comprise pairs of sentences annotated with

Method	Classification (Acc %)				Relatedness \ Similarity (ρ)				Inference (Acc %)	
	MPQA	MR	CR	SST-2	SICK-R	STS-15	STS-16	STS-Benchmark	MRPC	SICK-E
ELMo (all layers)	89.55	79.72	85.11	86.33	0.84	0.69	0.64	0.65	71.65	81.86
ELMo (top layer)	89.30	79.36	84.13	85.28	0.81	0.67	0.63	0.62	70.20	79.64
ELMo-PAR (*MRPC*)	92.61	**83.40**	**87.01**	86.83	**0.87**	0.70	0.66	0.64	-	82.89
ELMo-PAR (*Sampled Quora*)	**93.76**	81.14	85.52	88.71	0.83	0.71	0.66	0.69	73.22	81.51
ELMo-PAR (*PAN*)	92.13	83.11	85.73	88.56	0.85	**0.73**	0.67	**0.70**	**74.86**	83.37
ELMo-PAR (*PAN+MRPC+Quora*)	93.40	82.26	86.39	**89.26**	0.86	**0.73**	**0.68**	0.67	-	**84.46**

Table 2: Performance on downstream applications. We report accuracy for classification and inference tasks, and Pearson correlation for relatedness and similarity tasks. We do not report results of ELMo-PAR on MRPC when MRPC is used in training the model. The baseline results are from (Perone et al., 2018).

Model	AddOneSent		AddSent	
	EM	F1	EM	F1
BiSAE	47.7	53.7	36.1	41.7
BiSAE-PAR(MRPC)	**51.6**	**57.9**	**40.8**	**47.1**

Table 3: Exact Match and F1 on Adversarial SQuAD.

semantic scores between 0 and 5. The goal of the tasks is to measure the degree of semantic relatedness between two sentences. We learn tree-structured LSTM (Tai et al., 2015) to predict the probability distribution of relatedness scores.

Adversarial SQuAD The Stanford Question Answering Datasets (SQuAD) (Rajpurkar et al., 2016) is a machine comprehension dataset containing 107,785 human-generated reading comprehension questions annotated on Wikipedia articles. Adversarial SQuAD (Jia and Liang, 2017) appends adversarial sentences to the passage in the SQuAD dataset to study the robustness of the model. We conduct evaluations on two Adversarial SQuAD datasets: AddOneSent which adds a random human-approved sentence, and AddSent which adds grammatical sentences that look similar to the question. We train the Bi-Directional Attention Flow (BiDAF) network (Seo et al., 2017) with self-attention and ELMo embeddings on the SQuAD dataset and test it on the adversarial SQuAD datasets.

4.4 Result Analysis

The results reported in Table 2 show that PAR leads to 2% $\sim$ 4% improvement in accuracy on sentence classification tasks and sentence inference tasks. It leads to 0.03 $\sim$ 0.04 improvement in Pearson correlation (ρ) on semantic relatedness and textual similarity tasks. The improvements on sentence similarity and semantic relatedness tasks shows that ELMo-PAR is more stable to the semantic-preserving modifications but more sensitive to subtle yet semantic-changing perturbations. PAR model trained on the combined corpus (*PAN+MRPC+Sampled Quora*) achieves the best improvement across all these tasks, showing the model benefits from a larger paraphrase corpus. Besides sentence-level tasks, Table 3 shows that the proposed PAR method notably improves the performance of a downstream question-answering task. For AddSent, ELMo-PAR achieves 40.8% in EM and 47.1% in F1. For AddOneSent, it boosts EM to 51.6% and F1 to 57.9%, which clearly shows that the proposed PAR method enhances the robustness of the downstream model combined with ELMo.

4.5 Case Study

Shared word distances We compute the average embedding distance of shared words in paraphrase and non-paraphrase sentence pairs from test sets of MRPC, PAN, and Quora. Results are listed in Table 4. Table 5 shows the ELMo-PAR embedding distance for the shared words in the examples in Table 1. Our model effectively minimizes the embedding distance of the shared words in the paraphrased contexts and maximize such distance in the non-paraphrased contexts.

5 Conclusion

We propose a method for retrofitting contextualized word embeddings, which leverages semantic equivalence information from paraphrases. PAR learns an orthogonal transformation on the input space of an existing model by minimizing the contextualized representations of shared words on paraphrased contexts without compromising the varying representations on non-paraphrased contexts. We demonstrate the effectiveness of this method applied to ELMo by a wide selection of semantic tasks. We seek to extend the use of PAR to other contextualized embeddings (Devlin et al., 2019; McCann et al., 2017) in future work.

Model	Paraphrase			Non-paraphrase		
	MRPC	Quora	PAN	MRPC	Quora	PAN
ELMo(all layers)	3.35	3.17	4.03	3.97	4.42	6.26
ELMo-PAR(*PAN+MRPC+Quora*)	1.80	1.34	1.21	4.73	5.49	6.54

Table 4: Averaging L2 distance for the shared word in paraphrased and non-paraphrased contexts.

Incorporating Contextual and Syntactic Structures Improves Semantic Similarity Modeling

Abstract

Semantic similarity modeling is central to many NLP problems such as natural language inference and question answering. Syntactic structures interact closely with semantics in learning compositional representations and alleviating long-range dependency issues. However, such structure priors have not been well exploited in previous work for semantic modeling. To examine their effectiveness, we start with the Pairwise Word Interaction Model, one of the best models according to a recent reproducibility study, then introduce components for modeling context and structure using multi-layer BiLSTMs and TreeLSTMs. In addition, we introduce residual connections to the deep convolutional neural network component of the model. Extensive evaluations on eight benchmark datasets show that incorporating structural information contributes to consistent improvements over strong baselines.

1 Introduction

Modeling the semantic similarity between a pair of sentences is a fundamental task in natural language processing. It is the core problem of many tasks such as question answering (He et al., 2015; Rao et al., 2017; Wang et al., 2018) and query ranking (Mitra and Craswell, 2019). Recently, various neural networks have been proposed for textual similarity modeling. These models share three main components: (1) sequential sentence encoders, which incorporate word context and sentence order for better sentence representations, e.g., by using recurrent neural networks (RNNs; Mikolov et al., 2010; Seo et al., 2016), (2) interaction and attention mechanisms, which use the encoding outputs of sentences to calculate or reweight salient word pair interactions (He and Lin, 2016; Chen et al., 2017), and (3) incorporating syntactic parsing information as an intuitive structure prior for sentence modeling (Chen and Manning, 2014; Zhao et al., 2016; Chen et al., 2017).

Our work is inspired by the recent reproducibility study by Lan and Xu (2018), which examines many neural network architectures for semantic similarity modeling through extensive evaluations on multiple benchmark datasets. Their results suggest that syntactic structure information captured by a TreeLSTM encoder either provides few benefits or even hurts performance. Structure information has often been overlooked in recent semantic modeling methods, such as InferSent (Conneau et al., 2017), DecAtt (Parikh et al., 2016), and BiMPM (Wang et al., 2017). It is not yet clear whether the syntactic structures implicitly captured by sequential modeling of texts from large annotated data or existing structure modeling techniques (Tai et al., 2015; Kipf and Welling, 2017) are effective in learning tree representations.

To further explore the effects of tree structures in sentence modeling, we start with the Pairwise Word Interaction Model (PWIM) of He and Lin (2016) as our base architecture, which has shown strong performance on various datasets from Lan and Xu (2018). In summary, PWIM uses a BiLSTM to learn word-level context vectors from both input sentences and builds a novel similarity focus layer with pairwise metrics to identify important word pairs. It then converts the similarity measurement problem to a pattern recognition problem for the final classification. We argue that PWIM approaches semantic modeling from a word-level matching perspective, and hence fails to capture syntactic and contextual semantics. To this end, we add multi-layer BiLSTMs with shortcut connections to capture long-range context, as well as TreeLSTM encoders to capture the syntactic structure of sentences.

We conduct thorough evaluations across eight

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1204–1209, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

datasets in four NLP tasks: paraphrase identification, semantic textual similarity, natural language inference, and answer sentence selection. Extensive experiments show that our proposed components lead to consistent improvements against PWIM and other strong baselines, suggesting that incorporating contextual and syntactic structures can help semantic modeling. Our improved model achieves competitive numbers on eight datasets, and we open-source our code to improve reproducibility and to facilitate future research.[1]

2 Methods

2.1 The Pairwise Word Interaction Model

The Pairwise Word Interaction model (He and Lin, 2016) captures fine-grained word-level information to measure textual similarity. They use a Bi-LSTM for context modeling, where the word at time step t is encoded as a forward hidden state h_t^{for} and a backward hidden state h_t^{back}. Pairwise word interactions are modeled through a multi-metric comparison unit coU, which computes cosine distance, L_2 distance, and dot-product distance over two hidden states. This comparison unit is applied to not only the forward and backward hidden states h_t^{for} and h_t^{back}, but also their concatenation $\overleftrightarrow{h_t} = [h_t^{\text{for}}, h_t^{\text{back}}]$ and summation $h_t^{+} = h_t^{\text{for}} + h_t^{\text{back}}$.

The output is a similarity tensor of size $R^{13\times|sent1|\times|sent2|}$ with one extra dimension for the padding indicator. Instead of using attention weight vectors or weighted representations, He and Lin apply a focus layer on the similarity tensor to decrease the weights of unimportant word interactions by a factor of ten. They then consider the tensor as an "image" with 13 channels and use a 19-layer-deep convolutional neural network to predict the final classification.

2.2 Residual Connections

Since He and Lin (2016) phrase the similarity measurement problem as a pattern recognition (image processing) problem and apply deep convolutional neural networks, we explore the addition of residual connections (He et al., 2016) to deal with the potential vanishing gradient problems in deep networks. A building block is defined as $y = f(x, W_i) + x$, where x, y are the input and output of the layer considered, and $f(x, W_i)$ is the learned residual mapping.

[1] https://github.com/likicode/spwim

2.3 Multi-layer BiLSTM Sentence Encoders

We use multiple stacked, bi-directional LSTM layers with shortcut connections, similar to Nie and Bansal (2017). In this architecture, the input sequences of the i^{th} BiLSTM layer are the concatenated outputs of all the previous layers and the initial word embedding sequences. Let $W = \{w_1, w_2, ..., w_n\}$ represent the word embeddings associated with each word in the source sentence. Define the output of the i^{th} BiLSTM layer at time t as $h_t^i = \text{BiLSTM}^i(x_t^i)$. Then, the input of the i^{th} BiLSTM layer at time t is:

$$x_t^1 = w_t, \;\; x_t^i = [w_t, h_t^1, ..., h_t^{i-2}, h_t^{i-1}](i > 1)$$

Differing from the original paper, we directly use the output of the last BiLSTM layer to encode the sentence $v = (h_1^m, h_2^m, ...h_n^m)$, where n denotes the length of the sentence and m the number of BiLSTM layers. In our experiments we set $m = 3$.

2.4 Hybrid Inference Model with Parse Trees

While stacked BiLSTMs capture long-term dependency and contextual information over each sentence, we are also interested in investigating explicit hierarchical relationships among linguistic phrases and clauses. To incorporate this domain-specific information, we use the Dependency TreeLSTM (Tai et al., 2015), whose nodes condition their components on the sum of the hidden states of their children. Suppose h_L and h_R are the sentence representations in the pair over the parse tree of each sentence: to model similarity, we compute the element-wise product $h_L \odot h_R$ and absolute difference $|h_L - h_R|$. Then, we feed the two similarity vectors to a fully-connected layer with softmax whose output is the probability distribution over labels. To compute the final label for the sentence pair, we interpolate between the output probabilities of this model and those of PWIM. Chen et al. (2017) also incorporate tree structures produced by a constituency parser into the ESIM model, then average the predicted probabilities.

3 Experimental Setup

We conducted experiments on eight separate datasets—one natural language inference dataset, two paraphrase identification datasets, three SemEval competition datasets, and two QA datasets—which are as follows:

- SNLI (Bowman et al., 2015) is a collection of 570k manually-labeled sentence pairs for

Dataset	SNLI	Quora	Twitter	PIT-2015	STS-2014	WikiQA	TrecQA	SICK

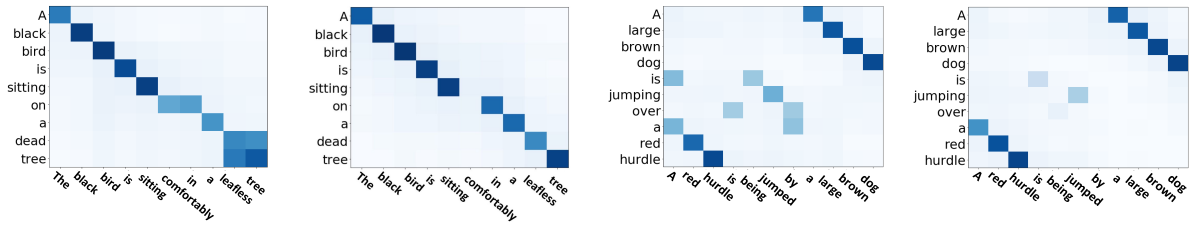
Table 1: Test results on different datasets.

the task of natural language inference. The relationship between two sentences includes entailment, contradiction, and neutral.



- Quora (Iyer et al., 2017) consists of 400k question pairs collected from the Quora website, with binary labels indicating if they are duplicates of each other.
- Twitter-URL (Lan et al., 2017) is a paraphrase corpus with 50k sentence pairs.
- PIT-2015 (Xu et al., 2015) is a paraphrase dataset that comes from SemEval-2015 Task 1.
- STS-2014 (Agirre et al., 2014) comes from SemEval-2014 Task 10 and each pair of sentences has a similarity score $\in [0, 5]$.
- WikiQA (Yang et al., 2015) is an open-domain question-answering dataset. After applying the same pre-processing methods in He and Lin (2016), it contains 12k question-answer pairs with binary labels.
- TrecQA (Wang et al., 2007) is from the Text Retrieval Conferences and consists of 56k question-answer pairs.
- SICK (Marelli et al., 2014) comes from SemEval-2014 Task 1 with 10k annotated sentence pairs. Each pair has a similarity score $\in [1, 5]$.

The first seven datasets are the same as the ones examined in Lan and Xu (2018), except for MNLI (Williams et al., 2018), since SNLI is much larger than MNLI for the task of natural language inference. We also add the SICK dataset (Marelli et al., 2014), which is unexplored in Lan and Xu (2018). Across multiple tasks and domains, we systematically compare our proposed models with state-of-the-art neural models: InferSent (Conneau et al., 2017), Shortcut-stacked Sentence Encoder (SSE; Nie and Bansal, 2017), Decomposable Attention Model (DecAtt; Parikh et al., 2016), and Enhanced Sequential Inference Model (ESIM; Chen et al., 2017).

For our experiments on SNLI, Quora, Twitter-URL, PIT-2015, WikiQA and TrecQA, the training objective is to minimize the NLL loss. For STS-2014 and SICK datasets, we use the KL divergence loss. Following He and Lin (2016), for all cases, we use the RMSProp optimizer (Tieleman and Hinton, 2012). Our word representations use 300-dimensional GloVe word vectors (Pennington et al., 2014), which we make static in all experiments. We produce dependency parse trees for each sentence using the Stanford Neural Network Dependency Parser (Chen and Manning, 2014). The TreeLSTM then models sentence representations over each sentence's parse tree.

4 Results and Analysis

Table 1 shows the results of our models on different datasets. The first block of the table contains figures copied directly from Lan and Xu (2018); note that they do not use SICK. PWIM$_{our}$ refers to our own implementation. Note that there are at least three independent open-source implementations of the PWIM base model that we are aware of, which confirms the robustness and reproducibility of the model. Most results from these implementations are consistent; however, for

(a) mPWIM$_{seq}$ (b) mPWIM$_{seq+tree}$ (c) mPWIM$_{seq}$ (d) mPWIM$_{seq+tree}$

Figure 1: Visualization of cosine values in the focusCube of two sentence pairs in the SICK test set.

PIT-2015 and STS-2014, we observe some differences, which we were unable to reconcile even after contacting the previous authors. Thus, for comparison purposes, we report results from our base PWIM$_{our}$ implementation.

4.1 Effects of the Multi-Layer BiLSTM

The entry mPWIM$_{seq}$ denotes PWIM using multi-layer BiLSTMs for modeling the context of the input sentences and also incorporating residual connections in the final classification. On all datasets listed in the table, adding multi-layer BiLSTMs leads to a higher performance than that of the original model PWIM$_{our}$.

SSE (Nie and Bansal, 2017) is a stacked BiLSTM model with shortcut connections and fine-tuning of word embeddings. Unlike our setting, where each word is represented by its own hidden state in the final output layer, SSE applies max-pooling over time to the output of the last BiLSTM layer to extract the final sentence feature vector. Based on Table 1, mPWIM$_{seq}$ clearly outperforms SSE on Twitter, PIT-2015, STS-2014, WikiQA, and TrecQA. However, for the SNLI and Quora datasets, SSE slightly exceeds mPWIM by 0.4% and 1.6%, respectively. SNLI and Quora have the largest training data among all the datasets with 550k and 393k training sentence pairs, respectively, which suggests that SSE performs better on larger data beyond a certain threshold. We surmise that as the dataset increases in size, the simplicity of SSE will have more performance advantages.

4.2 Effects of TreeLSTM

The mPWIM$_{seq+tree}$ further enhances mPWIM$_{seq}$ by incorporating syntactic TreeLSTMs based on syntactic parse trees of each sentence. It averages the prediction probabilities of the PWIM using multi-layer BiLSTMs and TreeLSTMs separately to arrive at the final label. ESIM$_{seq+tree}$ also computes its final predictions by averaging prediction probabilities of two ESIM variants that use BiLSTMs and TreeLSTMs as sentence encoders, respectively.

From the table, we observe that adding TreeLSTMs to the ESIM model only marginally helps or has no effect for most datasets. On the other hand, TreeLSTM complements PWIM well: for WikiQA, it increases mean average precision (MAP) by 1.8% and mean reciprocal rank (MRR) by 2.3%. TreeLSTM also contributes to an 1.1% increase in the F1-measure for PIT-2015, 0.9% Pearson's r for SICK, and 0.7% MAP for TrecQA.

We hypothesize that these observed differences can be attributed to the model architectures. The inference model of ESIM is based on chain LSTMs, which might encode overlapping information with TreeLSTMs. For PWIM, the sentence context information is transformed into pairwise word interaction similarity units, and then a 19-layer-deep CNN exploits the spatially localized patterns. During this process, its focus is word-level similarities in sentences. The syntactic parsing structure introduced by TreeLSTM compensates for some of the information deficiencies. Notably, TreeLSTM does not help PWIM on the Twitter dataset; this makes sense, as Kong et al. (2014) note that many elements in tweets have no syntactic function, including hashtags and URLs. Furthermore, tweets often contain multiple fragments, each with its own syntactic span. Both of these issues may degrade the quality of the syntactic modeling of tweets.

4.3 Sample Visualization and Analysis

To better understand *why* our models achieve improved effectiveness, we visualize the cosine values of the focusCube (the final output of the similarity layer) for pairwise word interactions in mPWIM$_{seq}$ and mPWIM$_{seq+tree}$, using the same method as Chen et al. (2017), where darker colors indicate stronger pairwise word interactions.

In Figure 1, we show visualizations from two pairs of sentences from SICK: 1a and 1b form a contrastive pair, as do 1c and 1d. We see that, in both cases, the TreeLSTM helps the model find syntactically important pairwise word interactions. For example, in Figure 1a, for the mPWIM$_{seq}$ model, the cluster of dark patches near the top shows obviously irrelevant correspondences, e.g., "on" with "comfortably", "dead" with "tree", and several of the articles are misaligned with respect to their positions in phrase structure. With the incorporation of syntactic information in Figure 1b, the correspondences are much more accurate.

We see that this is similarly the case when comparing Figures 1c and 1d, where the TreeLSTM yields more accurate correspondences. With the TreeLSTM, the model has learned the correct correspondence between "is being jumped" and "is jumping over", whereas without the syntactic structure, the correspondences are quite muddled. In both cases, we observe that mPWIM$_{seq+tree}$ is able to capture the passive construction for paraphrase detection.

5 Conclusion

We examine the hypothesis of whether incorporating contextual and syntactic structures can improve semantic similarity modeling. We extend the strong PWIM model and add additional components comprised of TreeLSTMs and multi-layer BiLSTMs to capture syntax and context information. Thorough experiments on eight datasets show that our improved models achieve consistent gains in effectiveness.

Neural Linguistic Steganography

Abstract

Whereas traditional cryptography encrypts a secret message into an unintelligible form, steganography conceals that communication is taking place by encoding a secret message into a cover signal. Language is a particularly pragmatic cover signal due to its benign occurrence and independence from any one medium. Traditionally, linguistic steganography systems encode secret messages in existing text via synonym substitution or word order rearrangements. Advances in neural language models enable previously impractical generation-based techniques. We propose a steganography technique based on arithmetic coding with large-scale neural language models. We find that our approach can generate realistic looking cover sentences as evaluated by humans, while at the same time preserving security by matching the cover message distribution with the language model distribution.

1 Introduction

Cryptography is central to modern communication, but while it effectively conceals the content of a message it reveals that meaningful communication is taking place. Steganography answers an alternative question: how to conceal a message in some cover signal (an image, text etc.) such that an eavesdropper is not even aware any meaningful communication has taken place (Amin et al., 2003; Shirali-Shahreza and Shirali-Shahreza, 2007; Kumar and Pooja, 2010)? Different from cryptography, in steganography security is derived from the inability to detect that a message exists within the cover signal, rather than the inability of an eavesdropper to determine the content of the message (Westfeld and Pfitzmann, 1999).

Natural language is an especially useful cover signal for steganography because it is prevalent and innocuous in everyday life. Furthermore, unlike images or audio in which encoded information depends on exact pixel values, linguistic steganography (hiding information in choices of words) is untethered from any one medium. For example, the sender could encode a message on a computer, read off the cover text in person, and then the receiver could separately enter the cover text into her decoder and retrieve the message.

Linguistic steganography methods can be classified as either edit-based or generation-based (Bennett, 2004). In edit-based methods, such as synonym substitution, the content of the cover text is selected by a human and slightly modified to encode information (Xiang et al., 2017; Hefei, 2009; Xiang et al., 2018). In generative methods an entire block of text is generated while encoding the message reversibly in the choice of tokens. Traditionally, most practical stenography systems are edit-based. These methods only encode a small amount of information (for example, 2 bits per tweet (Wilson and Ker, 2016)), whereas generation-based systems can encode an order of magnitude more information (Fang et al., 2017).

Generation-based steganography has a well-established foundation in information theory (Cox et al., 2005) with the aim of provably fooling any machine steganalysis. Due to weak language models practical performance at the scale of modern neural network-based models has not been considered or developed. One recent exception is a neural network-based approach using heuristic-based methods with the goal of fooling human eavesdroppers. These methods are theoretically sub-optimal, however, and while they demonstrate some fluency in generations the underlying language models are much worse than current state-of-the-art large models (Fang et al., 2017).

In this paper we aim to get the best of both approaches with a linguistic steganography

* Equal contribution.

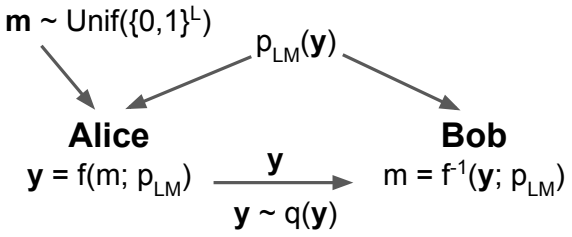

Figure 1: Problem setup. $\boldsymbol{m} \sim \text{Unif}(\{0,1\}^L)$ is the secret message, $\boldsymbol{y}$ is the cover text, $p(\boldsymbol{y})$ is the language model and f is a deterministic invertible function. f and the distribution of m implicitly defines q.

method based on arithmetic coding and modern language models. Our contribution is two-fold: 1) we show that a linguistic steganography approach combining arithmetic coding with state-of-the-art language models can achieve near-optimal statistical security; 2) human evaluations show that the cover text from our approach is able to fool humans even in the presence of context. Our code is available at https://github.com/harvardnlp/NeuralSteganography. A demo is available at http://steganography.live/

2 Background & Related work

Linguistic steganography We briefly give an overview of steganography as outlined in (Cox et al., 2005) and diagrammed in Figure 1: Alice wants to communicate a hidden message $\boldsymbol{m} \sim \text{Unif}(\{0,1\}^L)$ with Bob by encoding it into a choice of natural language cover text $\boldsymbol{y}$. The uniform distribution is chosen for $\boldsymbol{m}$ without loss of generality: if $\boldsymbol{m}$ has additional structure it can be further compressed to a uniformly distributed random variable (Han, 2005). Alice and Bob have both agreed on an invertible mapping f which performs the steganography. Alice and Bob also both have access to the exact same language model, $p_{LM}(\boldsymbol{y})$, which f can use during encoding and decoding. The steganography mapping f and the language model $p_{LM}(\boldsymbol{y})$ form the key.

The combination of the distribution of $\boldsymbol{m}$ and deterministic function $\boldsymbol{y} = f(\boldsymbol{m})$ implicitly defines a distribution for $\boldsymbol{y}$ which we denote q. This is the cover distribution of natural language that an eavesdropper would observe. As described in (Cox et al., 2005), the security of the system is determined by $D_{KL}(q||P_{true})$ where P_{true} is the true distribution of natural language. For example, if $D_{KL} = 0$ then the system is perfectly secure

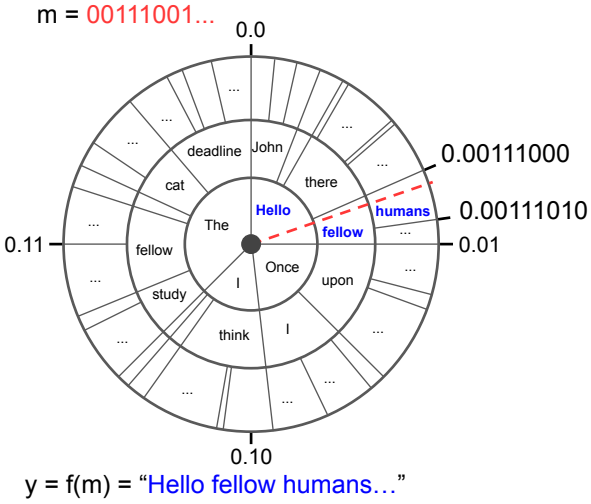

Figure 2: Diagram of arithmetic coding for steganography. See Section 3 for details.

because an eavesdropper could not distinguish the encoded messages from normal language. From an information theoretic perspective the security objective of steganography is therefore to ensure a small D_{KL}. At the same time, because f is invertible the average number of bits that can be encoded is given by the entropy $H(q)$. Thus, the compression objective is to maximize $H(q)$.

Generative coding techniques Recent work studying generative approaches for linguistic steganography have considered heuristic approaches to map uniform messages into similar distributions as natural language. Fang et al. (2017) considers a block-based approach (**Block**), where the vocabulary is randomly split into $2^{|B|}$ bins and each bin is indexed by a $|B|$-bit string. Encoding is performed by splitting the message up into chunks B_t and taking the maximum likelihood token as determined by the language model $p(y_t|y_{<t})$ that falls in bin B_t. Yang et al. (2019) proposes a related method based on constructing a Huffman coding (**Huffman**) at each step t based on $p(y_t|y_{<t})$ and encoding the message in variable length chunks via the Huffman tree. Both objectives provide a "quality" parameter that trades off quality at the expense of encoding fewer bits.

These approaches target a different security objective than the information-theoretic view in Cox et al. (2005). Instead of aiming to minimize the KL at maximal compression they aim to maximize generated quality at maximal compression (Yang et al., 2019; Fang et al., 2017). The issue with these approaches is that they aim to fool human eavesdroppers for whom generation quality

Context	kim jong il was the enigmatic leader of the most enigmatic country on earth. much about kim's life was, and is, shrouded in mystery. even the year of his birth – 1942 – has been contested by knowledgeable sources in south korea and russia, who claim kim was born a few years earlier but that his official birth date was pushed back to make him exactly 30 years younger than his father, north korea's founding leader, kim il sung.
Message 1	Bob, I have something very important to tell you. Eve is not who she says she is. I know that you think she's your friend, but really she's a creepy stalker who wants to read all of your messages for some unknown reason.
Cover text 1	That kim's birthdate was not even known to the people of south korea is even more baffling. however, there is another contradiction. bak tae-jung, the ruler of north korea at the time, claimed to have inherited kim's kim ju-ha-teh, his so-called golden heritage, from his father, the last kim Yun-jong. and he also
Message 2	The secret code is X3SJ83F. Once you open the door you will see a staircase on your left and a hallway to your right. Go down the hallway and enter the code in the safe at the end of the hallway.
Cover text 2	kim il sang, by the way, was not the first leader of north korea, but the first for nearly a thousand years. his leader was kim jong il, the same person the people voted in to power to start with, without their knowledge or consent. though it's been claimed by others that kim il sang fled north korea in 1940 to escape the reprisals, even that is disputed by k

Table 1: Steganography example. Two different encoded messages are produced given the same introductory context. The messages are first converted into bit strings and then mapped to cover text using the arithmetic steganography approach described in Section 4.4.

is most important; but are susceptible to machine-based eavesdroppers which can in principle identify statistical patterns in generations.

Concurrent with this work, Dai and Cai (2019) conduct a related analysis in terms of KL with a modified Huffman algorithm. Experiments consider the distribution of KL values, although no human evaluation is performed.

3 Arithmetic coding

Arithmetic coding is a data compression method designed specifically to code strings of elements with a known probability distribution (Rissanen and Langdon, 1979; Zoph et al., 2015). For long strings the coding is optimal; it compresses information to its entropy (Rissanen and Langdon, 1979). In practice, it is often more efficient than Huffman coding because it does not require blocking. Arithmetic coding traditionally maps a string of elements to a uniformly distributed binary string. To use such a coding for steganography we reverse the order: first a (uniformly sampled) message is selected, then the message is mapped to a sequence (words).

The coding scheme is demonstrated in Figure 2. In this work the probability distribution comes from the conditional distributions of a pretrained language model, but for illustration purposes a hand-crafted example distribution is used in the diagram. Concentric circles represent timesteps; the innermost represents $t = 1$, the middle $t = 2$, and the outer $t = 3$. Each circle represents the conditional distribution $p(y_t|y_{<t})$. For example, given that y_1 = "Once", $p(y_2|y_1)$ has "upon" and "I" as the only possible tokens with equal probability. The circle diagram spans [0,1) from 0 at the top, clockwise around to 1.

To encode the message into text, the secret message m is viewed as a binary representation of a fraction in the range $[0, 1)$. This fraction uniquely marks a point on the edge of the circle, as well as a line from the origin to the point. Encoding is performed by simply reading off the tokens corresponding to the bins. Encoding stops when the list of tokens unambiguously defines the message.

Decoding is performed via the reverse operation: the sequence of natural language tokens progressively narrows the range of possible messages. Assuming that the original message is encoded with a predetermined end token, decoding terminates once both sides of the range of possible messages includes the end token.

Sallee (2004) show that just as arithmetic coding is optimal for data compression, it is also optimal for steganography. Specifically, given any goal distribution $p_s(\boldsymbol{y})$ that one wants to sample from, starting with a uniform $\boldsymbol{m}$ and applying the deterministic steganography procedures yields a distribution $q = p_s$ or equivalently $D_{KL}(q||p_s) = 0$ for long sequences. This further ensures that $H(q) = H(p_s)$ and therefore the number of bits encoded on average is equal to the entropy of p_s. Intuitively, this works because higher probability sequences map to larger "chunks" of the pie and therefore require fewer bits to uniquely determine.

In this work we apply arithmetic coding to lin-

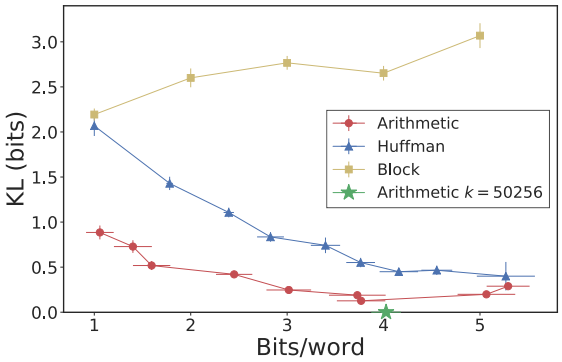

Figure 3: Information theoretic evaluation. KL and bits/word are evaluated for each algorithm at different values of the tuning parameter; each datapoint gives the mean and standard error for repeated samples with a fixed value of the tuning parameter. We show the standard error bars for both bits/word and KL.

guistic steganography. Given a pretrained language model, this approach can be directly applied to produce cover texts given some preliminary context. To ensure that these texts seem more natural to human eavesdroppers we introduce two parameters to trade off quality for compression: we modulate the LM distribution by a temperature τ, and we truncate the distribution to a top-k tokens at each position to ensure generations do not include tokens from the long tail.

In practice, a naive implementation of arithmetic coding quickly runs into precision limitations. We use a common equivalent variant based on fixed precision binary fractions (Rubin, 1979).

4 Experiments and results

4.1 Experimental Setup

We use the 345M parameter GPT-2 model as our language model p_{LM} (Radford et al., 2019). We run our experiments on the CNN/Dailymail (CNNDM) dataset (Hermann et al., 2015; Nallapati et al., 2016), which is used to provide context for generation[1]. We take the first three sentences of each news article as the context on which to condition our language model, and use the indicated steganography algorithm to generate an entire sentence for estimation or evaluation given a uniform random message. We compare the proposed arithmetic coding-based algorithm with the Block (Fang et al., 2017) and Huffman (Yang et al., 2019) methods as baselines. The baselines are re-implemented to allow for a fair comparison using the strong GPT-2 language model. Each method has a parameter that controls the various tradeoffs: for arithmetic encoding we vary the temperature from 0.4 to 1.2 with $k = 300$, for Huffman encoding we vary the truncation length from 2^1 to 2^8, for block encoding we vary the block size from 2^1 to 2^5. For the KL analysis we also evaluate arithmetic coding with $\tau = 1$ and $k = 50256$, i.e. the unmodulated language model.

[1]Conditional generation makes it more challenging to fool humans and is thus better for comparisons. CNNDM presents an additional challenge as poor generations may have clear factual errors.

4.2 Metrics

We consider several different metrics to assess performance. In all cases, it is important that the algorithms encode information efficiently. The metric **Bits/word** is the ratio of message bits encoded to sentence length.

Another key aspect of the system is being able to fool a statistical adversary in a *distributional* sense, i.e. when the adversary gets multiple samples from q. This can be quantified by the **KL** divergence between q and P_{true}. Since we do not have access to P_{true} we resort to $D_{KL}(q||p_{LM})$. p_{LM} might not match the distribution of natural language, but it allows for relative comparisons of steganography algorithms. The remaining gap is a function of language model performance, which is not the focus of this work. For each model the KL is estimated via MC sampling on the news data.

Finally it is important to be able to convince a **human adversary** that the text is natural. This differs from statistical considerations because a human will only see a single sample from q at a time. To this end, we conduct a human study aligned with the information theoretic evaluation above, using Amazon Mechanical Turk. For each of the three methods we generate sentences with randomly sampled messages conditioned on a news article context, and ask participants to indicate if the sentence is a likely next sentence in context. We repeat this experiment with the true next sentence as well. See the Supplementary Materials for more details.

4.3 Quantitative results

Figure 3 shows the information theoretic evaluation. For any bits/word in the range of (1, 5), arithmetic coding achieves the lowest KL, i.e. the distribution of the encoded texts is the most similar to the language model distribution, providing the best defensive against algorithmic detections. Most striking, arithmetic coding with the unmodu-

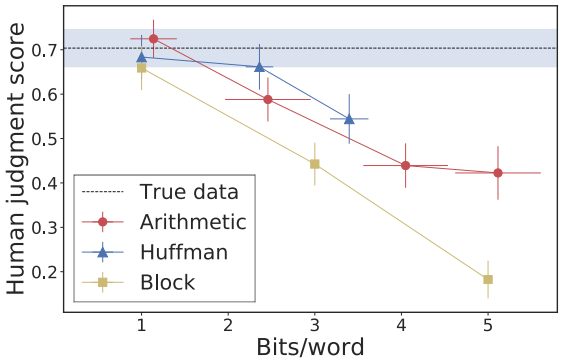

Figure 4: Human evaluation. Y axis shows the percentage of humans considering the generation to be a proper continuation of the context. Huffman coding achieves the best generation quality as judged by humans, while arithmetic coding is comparable (the difference is not statistically significant).

lated language model induces a q distribution with a KL of 4e-8 nats. This indicates that, consistent with theory (Sallee, 2004), arithmetic coding enables generative steganography matching the *exact* distribution of the language model used. The small but positive KL value for arithmetic coding with $k = 300$ comes from the slight distributional difference when the long tail is truncated.

Figure 4 shows the human evaluation results. Within 3 bits/word both Huffman and arithmetic coding give plausible next sentences over 50% of the time, and at 1 bit/word both methods lead to cover texts statistically indistinguishable from human-written sentences. Although Huffman coding reaches slightly better performance than arithmetic coding, the transferred cover text distribution is statistically different from natural text (see Figure 3), which can be potentially discovered by automatic systems. Compared to the KL analysis which focuses on the relative performance of the algorithms, the human evaluation highlights the realizable generation quality enabled specifically by large pretrained language models. Still, there is room for improvement in terms of language modeling capabilities: whereas the arithmetic approach reaches minimum KL around 4 bits/word with $\tau = 1.0$, only at 1 bit/word with $\tau = 0.4$ do the generations fool humans.

4.4 Qualitative results

Steganography fundamentally deals with hiding uniformly random message bits in cover text. In many cases, however, the message may itself be natural language. In these cases we have an additional choice of how the text is converted to bits. One option is simply the unicode encoding (i.e. UTF-8), though this is highly inefficient. Instead, we can use the same arithmetic coding algorithm in reverse, with an empty context, to compress the message text into near-uniformly distributed bits (Han, 2005). The full procedure is as follows:

1. Alice decodes message text into bits via arithmetic coding with an empty context.
2. Alice encodes bits into cover text via arithmetic coding with a predetermined context.
3. Alice sends cover text over public channel.
4. Bob decodes cover text into bits via arithmetic coding with the predetermined context.
5. Bob encodes bits into message text via arithmetic coding with empty context.

Because the same strong LM is used with different contexts for the two applications of arithmetic coding, the message text length and cover text length will be comparable (modulo a small overhead) but the content of the text can be completely different. This is demonstrated in Table 1, which shows two examples of natural language messages (Step 1) encoded in unrelated and innocuous cover text (Step 3). In both cases the message is encoded efficiently into cover text which is largely fluent and coherent, and follows from the given context.

5 Conclusion

We demonstrate how the combination of large pretrained language models and an arithmetic coding-based steganography algorithm allows for a steganography system that can fool both statistical adversaries who analyze the full generative distribution, and human adversaries who analyze a single sample. While our work shows the potential for high-quality efficient steganography and the realizable optimality of arithmetic coding, future advancements in language modeling can push steganographic performance even further. With current state-of-the-art language models the steganography algorithms studied generate most convincing cover texts at low compression, where the KL is moderate. As language models continue to improve, they can be directly plugged into our arithmetic approach to maximize steganographic performance.

The Feasibility of Embedding Based Automatic Evaluation for Single Document Summarization

Abstract

ROUGE is widely used to automatically evaluate summarization systems. However, ROUGE measures semantic overlap between a system summary and a human reference on word-string level, much at odds with the contemporary treatment of semantic meaning. Here we present a suite of experiments on using distributed representations for evaluating summarizers, both in reference-based and in reference-free setting. Our experimental results show that the max value over each dimension of the summary ELMo word embeddings is a good representation that results in high correlation with human ratings. Averaging the cosine similarity of all encoders we tested yields high correlation with manual scores in reference-free setting. The distributed representations outperform ROUGE in recent corpora for abstractive news summarization but are less good on older test data and systems.

1 Introduction

The widely used ROUGE (Lin, 2004) automatic evaluation for summarization relies on token overlap between reference and system summary. This limited view of meaning has motivated numerous studies on summarization evaluation (Zhou et al., 2006; Ganesan, 2018; ShafieiBavani et al., 2018), and the related areas of translation and dialog, to explore more compelling semantic matching (Kauchak and Barzilay, 2006; Lavie and Denkowski, 2009; Lo and Wu, 2011; Chen and Guo, 2015; Liu et al., 2016; Tao et al., 2018). Most recently, incorporating word embeddings in ROUGE pairwise comparison of n-grams has proven beneficial (Ng and Abrecht, 2015), as well as representing sentences using universal sentence representation to predict the quality of translation (Shimanaka et al., 2018).

We build upon this line of work and show that cosine similarity between the reference and summary embedding works well, and better than ROUGE on recent datasets, for comparing single document summarization systems. Unlike prior work (Ng and Abrecht, 2015), we thoroughly abandon ROUGE and n-gram co-occurrences in the computation of semantic similarity. To give a sense of the generalizability of our findings, we validate the method on three different test sets with human evaluation. We compare several popular representation including sentence embedding, un-contextualized word embedding and contextualized word embedding. Finally, we present experiments on evaluating single document summaries without reference summaries which was originally proposed for multi-document summarization (Louis and Nenkova, 2013) and explored a variety of word-string similarity techniques. Here we study reference-free evaluations via embedding similarity between the full document to be summarized and the system summaries.

2 Embeddings

To get a dense low-dimenional representation of texts, we test seven representations covering sentence embedding, variants of un-contextualized word embedding and variants of contextualized word embedding. Specifically: *(i)* Two Google universal sentence encoders: (Cer et al., 2018), an encoder (*enc-2*) based on deep averaging net (Iyyer et al., 2015) and an encoder (*enc-3*) based on transformer (Vaswani et al., 2017). Both encoders encode input text to 512-dimensional vector. *(ii)* Average (*ELMo-a*) and max (*ELMo-m*) over each dimension of all ELMo (Peters et al., 2018) word embeddings of an input text. For each token in the input, three layers of 1,024-dimensional vectors were concatenated to form a 3,072-dimensional vector. *(iii)* Average (*avg*) and max (*max*) over GoogleNews 300-d word2vec.

Table 1: Correlation results on DUC2001/2002. P is shorthand for Pearson correlation, S for Spearman correlation. Detailed description of encoders can be found in §2. (ref / doc) shows the correlation between summary embedding with either reference embedding or document embedding. Entries with p-value lower than 0.05 are marked with *. ROUGE F1 scores, the commonly reported metric, are underlined for better comparison.

(iv) InferSent (Conneau et al., 2017) (*InferSent*), a BiLSTM encoder producing representation of 4,096 dimensions. We compute cosine similarity between summary and reference embedding to capture semantic similarity. To test the robustness of this evaluation approach, we check correlations on old single document summarization evaluations of somewhat obsolete systems and modern corpora for summarization with a mix of extractive and neural abstractive systems.

3 Evaluation on DUC2001/2002

Document Understanding Conferences (DUC) 2001/2002 provide benchmark datasets along with human evaluation over multiple submitted systems. Human evaluation (*coverage score*) reflects the degree to which semantic units, roughly clauses, in the reference summary are expressed in the system summary (Lin and Hovy, 2003).

To evaluate the newly proposed automatic evaluations, we follow the conventional methodology of computing correlation between the automatic metric and human evaluations of summary content. The results are shown in Table 1[1]. R1-F correlates better with human ratings on DUC'01, while R2-R works extremely well on DUC'02. Both uni- and bi-gram ROUGE F-measure also correlate well with human evaluation, which is an important finding given that ROUGE-F has become the de facto standard for evaluation of neural summarization systems (Nallapati et al., 2016; See et al., 2017; Gehrmann et al., 2018; Zhang et al., 2018; Celikyilmaz et al., 2018).

[1]There are total 14 systems in DUC'02. We discard two poorly performing systems, 17 and 30. Including them in the analysis results in high correlation (> 0.9) for both ROUGE and embedding similarity but the results we present are more convincing without the presence of clearly inferior systems.

We find that there is no single optimal representation that gives the best correlation on both data sets. There is a clear increase of performance from DUC'01 to DUC'02. In DUC'02, embedding similarity can achieve the same level or even higher correlation with human evaluation than ROUGE F-measure, but it performs worse on DUC'01. The correlations using *avg*, *max* and *InferSent* in reference-free setting on DUC'01 are lower.

Statistics	**DUC2001**	**DUC2002**
# of systems	12	12
Avg. reference length	116.595	113.607
Avg. summarry length	114.598	114.184
Avg. document length	841.000	650.053
Min coverage score	0.320	0.346
Max coverage range	0.453	0.4975
Std sys coverage score	0.048	0.049
Avg. annotated article per sys	148.000	293.250

Table 2: DUC2001 and DUC2002 dataset statistics

To understand what causes the low performance on DUC'01, we examined statistics for both datasets, shown in Table 2. Systems in DUC'01 are, on average, inferior to DUC'02 systems (lines 5 and 6) and systems in DUC'01 are more similar to each other than in DUC'02 (line 7), which leaves less room to rank the systems and thus achieve high correlation. Another difference between DUC'01 and DUC'02 is that the number of evaluated articles for each system is considerably larger than that in DUC'01. One might ask if enough articles are provided for each system on DUC'01 data. We show in Figure 1 that 140 is a large enough number for eliciting stable system-level correlation. Another possible problem is that the number of systems is not enough, so a minor change in either human or embedding similarity score can lead to large oscillation of correlation. Scatter plots of these systems are shown in Figure

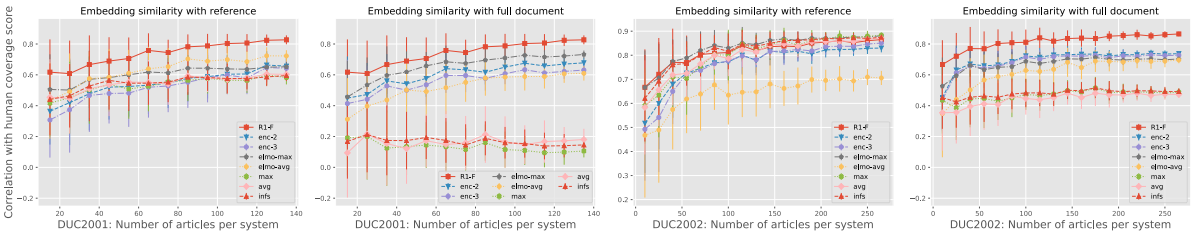

Figure 1: For each number of articles, we sample and compute the correlation for 50 times and plot the average as well as standard deviation. The decreasing size of error bar shows that enough articles are provided for each system and it is not the reason of the performance discrepancy between DUC2001 and DUC2002.

3. As we can see, similarity of all kinds of embeddings indeed correlate with coverage score, however they also generate more extreme values when pairs of systems are examined. For example, two systems may be close in terms of R1-F, but can be relatively distant when comparing the embedding similarities. This problem, possibly due to different architectures and different data each encoder is trained on, may be alleviated by averaging the cosine similarities computed from all the representations. Overall, given the stable results on DUC'02, embedding similarity is a good metric which does not depend on lexical overlap and can be computed quickly immediately after inference without the need of running ROUGE.

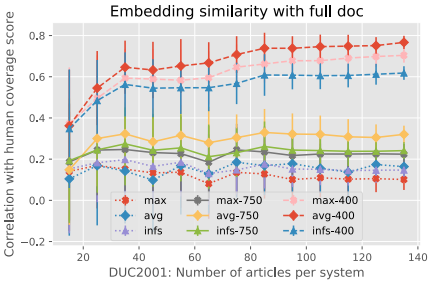

Figure 2: Truncated articles lead to performance improvement for *max*, *avg* and *InferSent* representation.

DUC'01 — where reference-free results are weaker — contains longer articles. To check if representations are sensitive to input length, we truncated the articles to the first 400 or 750 tokens when the length exceeds that limit. We plot the correlations in this setting for the three encoders which have worse results on DUC'01. Figure 2 shows a clear and consistent improvement of correlation when the document size is smaller. In fact, when only the lead 400 tokens are included, the average word embedding is only slightly worse than R1-F. This finding suggests that the embedding of the document lead sentences serves as a better reference than the full document and that the three representations are sensitive to input length.

Another noticeable difference between DUC'01 and DUC'02 is the performance of *ELMo-a* word embeddings. Both ELMo embedding variants are capable of dealing with long texts. For the four settings we tested, *ELMo-m* has better Spearman correlation than averaging ELMo embeddings. On DUC'02, *ELMo-a* leads to lower correlations than other encoders. Unlike *max* and *avg* where word embeddings are fixed, contextualized word embeddings are more flexible, thus the average ELMo embeddings for reference and summary can be far away from each other, in this case *ELMo-m* reflects more salient information about the input than *ELMo-a*.

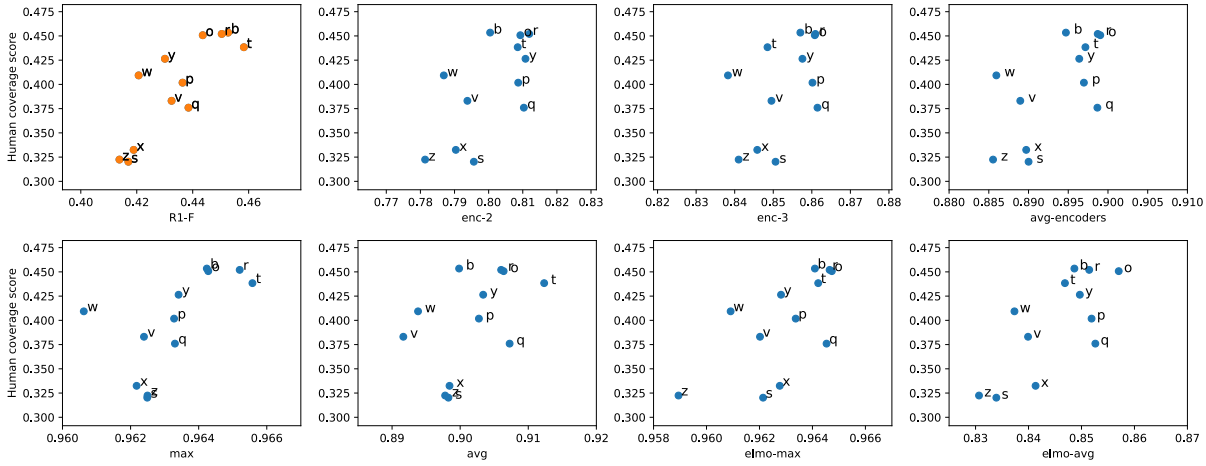

Figure 3: This scatter plot shows the human coverage score and embedding similarity on DUC2001. The baseline system is shortened to 'b'.

4 Evaluation on Newsroom 60

In this section, we use contemporary data and systems and explore other factors that embedding similarity could potentially capture. We employ the human evaluation set from newsroom data introduced in (Grusky et al., 2018). The evaluation data includes 7 systems, each producing summaries for 60 articles. The 7 systems are: (1) lead3 sentences of the article (2) textrank with word limit of 50 (3) extractive oracle 'fragments' system, representing the best possible performance of an extractive system (4) abstractive model (Rush et al., 2015) trained on Newsroom training data (5) Pointer-Generator (See et al., 2017) trained on CNN/DailyMail data set (Nallapati et al., 2016), on complete and a subset of Newsroom training set respectively.

We collected crowdsourced evaluations of relevance *(RL)* and informativeness *(IN)* as introduced in the original paper, closely reproducing the earlier findings. We introduce four more dimensions: verbosity *(VE)*, unnecessary content *(UC)*, perfect surrogate *(SR)* and continue reading *(CN)*. Higher rating corresponds to assessment that the summary is not unnecessarily verbose, it has no unnecessary content, it is a good surrogate for the input and that much additional information can be obtained from the article after reading the summary. The exact questions are presented in the supplementary material. We asked workers to rate in the range of 1 to 7 instead of 1 to 5 in the original paper. We excluded from the analysis the 'fragments' oracle system which maximizes ROUGE by selecting word n-grams but receives very low human ratings because the resulting summary is incomprehensible. Each summary is scored by three crowdworkers whose scores we average. Table 3 shows Spearman correlations and Pearson correlations are in the Appendix.

Eval by rank	**P**(ref)	**S**(ref)	**P**(doc)	**S**(doc)
enc-2	6.667	5.000	5.667	4.667
enc-3	8.000	6.667	6.333	4.667
max	4.333	5.667	7.333	7.000
avg	5.667	6.000	8.333	8.667
InferSent	6.333	5.333	7.000	6.000
ELMo-m	**4.000**	**3.000**	3.667	**2.333**
ELMo-a	4.667	6.000	6.000	3.667
enc-avg	4.333	6.000	**2.667**	3.333
R1-F	5.667	4.667	3.667	4.000
R2-F	5.333	4.000	4.667	4.667

Table 4: Average correlation rank of each system on DUC2001, DUC2002 and Newsroom 60 data. P is shorthand for Pearson correlation and S for Spearman.

The table shows that embedding similarity correlates better or the same as ROUGE with human ratings on informativeness, relevance and surrogate. However, ROUGE precision is a more suitable metric for evaluating the extent of unnecessary content and verbosity. This implies that the examined representations capture well the meaning of the input but store repetitive information without enough penalty. For the dimension *CN*, showing that the input contains considerably more important details than in the summary, neither embedding similarity nor ROUGE is good enough to show a correlation with small p-value.

To establish which representation correlates

best with human ratings, we sort the representations by correlations in descending order on the three data sets we examined and compute the average rank for each. We used informativeness ratings on Newsroom data. Smaller value means overall better performance on all three data sets. The results are shown in Table 4. The max value over each dimension of ELMo word embedding of input text performs the best when reference summaries are given. When we compare the embedding between system summary and document, the averaged cosine similarities of all seven representation also gives good results. Most importantly, the *ELMo-m* evaluation ranks consistently better than ROUGE-F for all evaluation settings.

5 Conclusion

In this paper we systematically study embedding cosine similarity as a measure of the quality of summarizers on three data sets. We verify the feasibility of the embedding similarity for system comparison on DUC'01, DUC'02 and Newsroom human evaluation data. The worse results on DUC'01 can be explained by the fact that systems being evaluated are too similar and not that well-performing. On DUC'02 and Newsroom data, embedding similarity can achieve the same level or even higher correlation with human ratings compared to ROUGE. Overall, when references are given, max ELMo word embeddings have highest correlation and the averaged cosine similarities of the examined representations gives high correlation in reference-free setting.

Abstract

Attention plays a key role in the improvement of sequence-to-sequence-based document summarization models. To obtain a powerful attention helping with reproducing the most salient information and avoiding repetitions, we augment the vanilla attention model from both local and global aspects. We propose an attention refinement unit paired with local variance loss to impose supervision on the attention model at each decoding step, and a global variance loss to optimize the attention distributions of all decoding steps from the global perspective. The performances on the CNN/Daily Mail dataset verify the effectiveness of our methods.

1 Introduction

Abstractive document summarization (Rush et al., 2015; Nallapati et al., 2016; Tan et al., 2017; Chen and Bansal, 2018; Celikyilmaz et al., 2018) attempts to produce a condensed representation of the most salient information of the document, aspects of which may not appear as parts of the original input text. One popular framework used in abstractive summarization is the sequence-to-sequence model introduced by Sutskever et al. (2014). The *attention* mechanism (Bahdanau et al., 2014) is proposed to enhance the sequence-to-sequence model by allowing salient features to dynamically come to the forefront as needed to make up for the incapability of memorizing the long input source.

However, when it comes to longer documents, basic attention mechanism may lead to distraction and fail to attend to the relatively salient parts. Therefore, some works focus on designing various attentions to tackle this issue (Tan et al., 2017; Gehrmann et al., 2018). We follow this line of research and propose an effective attention refinement unit (ARU). Consider the following case. Even with a preliminary idea of which parts of source document should be focused on (attention), sometimes people may still have trouble in deciding which exact part should be emphasized for the next word (the output of the decoder). To make a more correct decision on what to write next, people always adjust the concentrated content by reconsidering the current state of what has been summarized already. Thus, ARU is designed as an update unit based on current decoding state, aiming to retain the attention on salient parts but weaken the attention on irrelevant parts of input.

The de facto standard attention mechanism is a soft attention that assigns attention weights to all input encoder states, while according to previous work (Xu et al., 2015; Shankar et al., 2018), a well-trained hard attention on exact one input state is conducive to more accurate results compared to the soft attention. To maintain good performance of hard attention as well as the advantage of end-to-end trainability of soft attention, we introduce a local variance loss to encourage the model to put most of the attention on just a few parts of input states at each decoding step. Additionally, we propose a global variance loss to directly optimize the attention from the global perspective by preventing assigning high weights to the same locations multiple times. The global variance loss is somewhat similar with the coverage mechanism (Tu et al., 2016; See et al., 2017), which is also designed for solving the repetition problem. The coverage mechanism introduces a coverage vector to keep track of previous decisions at each decoding step and adds it into the attention calculation. However, when the high attention on certain position is wrongly assigned during previous timesteps, the coverage mechanism hinders the correct assignment of attention in later steps.

We conduct our experiments on the CNN/Daily Mail dataset and achieve comparable results on ROUGE (Lin, 2004) and METEOR (Denkowski and Lavie, 2014) with the state-of-the-art models.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1222–1228, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Our model surpasses the strong pointer-generator baseline (w/o coverage) (See et al., 2017) on all ROUGE metrics by a large margin. As far as we know, we are the first to introduce explicit loss functions to optimize the attention. More importantly, the idea behind our model is simple but effective. Our proposal could be applied to improve other attention-based models, which we leave these explorations for the future work.

2 Proposed model

2.1 Model Architecture

We adopt the Pointer-Generator Network (PGN) (See et al., 2017) as our baseline model, which augments the standard attention-based seq2seq model with a hybrid pointer network (Vinyals et al., 2015). An input document is firstly fed into a Bi-LSTM encoder, then an uni-directional LSTM is used as the decoder to generate the summary word by word. At each decoding step, the attention distribution a_t and the context vector c_t are calculated as follows:

$$e_{ti} = v^T \tanh(W_h h_i + W_s s_t + b_{attn}) \quad (1)$$

$$a_t = \text{softmax}(e_t) \quad (2)$$

$$c_t = \sum_{i=1} a_{ti} h_i \quad (3)$$

where h_i and s_t are the hidden states of the encoder and decoder, respectively. Then, the token-generation softmax layer reads the context vector c_t and current hidden state s_t as inputs to compute the vocabulary distribution. To handle OOVs, we inherit the pointer mechanism to copy rare or unseen words from the input document (refer to See et al. (2017) for more details).

To augment the vanilla attention model, we propose the Attention Refinement Unit (ARU) module to retain the attention on the salient parts while weakening the attention on the irrelevant parts of input. As illustrated in Figure 1, the attention weight distribution a_t at timestep t (the first red histogram) is fed through the ARU module. In the ARU module, current decoding state s_t and attention distribution a_t are combined to calculate a refinement gate r_t:

$$r_t = \sigma(W_s^r s_t + W_a^r a_t + b_r) \quad (4)$$

where σ is the sigmoid activation function, W_s^r, W_a^r and b_r are learnable parameters. r_t represents how much degree of the current attention should be updated. Small value of r_{ti} indicates that the content of i-th position is not much relevant to current decoding state s_t, and the attention on i-th position should be weakened to avoid confusing the model. The attention distribution is updated as follows (the symbol $\odot$ means element-wise product):

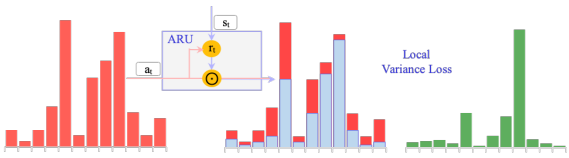

Figure 1: The process of attention optimization (better view in color). The original attention distribution (red bar on the left) is updated by the refinement gate r_t and attention on some irrelevant parts are lowered. Then the updated attention distribution (blue bar in the middle) is further supervised by a local variance loss and get a final distribution (green bar on the right).

$$a_t^r = r_t \odot a_t \quad (5)$$

2.2 Local Variance Loss

As discussed in section 1, the attention model putting most of attention weight on just a few parts of the input tends to achieve good performance. Mathematically, when only a small number of values are large, the shape of the distribution is sharp and the variance of the attention distribution is large. Drawing on the concept of variance in mathematics, local variance loss is defined as the reciprocal of its variance expecting the attention model to be able to focus on more salient parts. The standard variance calculation is based on the mean of the distribution. However, as previous work (Huang et al., 1979; Jung et al., 2018) mentioned that the median value is more robust to outliers than the mean value, we use the median value to calculate the variance of the attention distribution. Thus, local variance loss can be calculated as:

$$var(a_t^r) = \frac{1}{|D|} \sum_{i=1}^{|D|} (a_{ti}^r - \hat{a_t^r})^2 \quad (6)$$

$$\mathcal{L}_L = \frac{1}{T} \sum_{t}^{T} \frac{1}{var(a_t^r) + \epsilon} \quad (7)$$

where $\hat{\cdot}$ is a median operator and ϵ is utilized to avoid zero in the denominator.

2.3 Global Variance Loss

To avoid the model attending to the same parts of the input states repeatedly, we propose another variance loss to adjust the attention distribution globally. Ideally, the same locations should be assigned a relatively high attention weight once at most. Different from the coverage mechanism (See et al., 2017; Tu et al., 2016) tracking attention distributions of previous timesteps, we maintain the sum of attention distributions over all decoder timesteps, denoted as A. The i-th value of A represents the accumulated attention that the input state at i-th position has received throughout the whole decoding process. Without repeated high attention being paid to the same location, the difference between the sum of attention weight and maximum attention weight of i-th input state among all timesteps should be small. Moreover, the whole distribution of the difference over all input positions should have a flat shape. Similar to the definition of local variance loss, the global variance loss is formulated as:

$$g_i = \sum_t (a^r_{ti}) - \max_t (a^r_{ti}) \tag{8}$$

$$\mathcal{L}_G = \frac{1}{|D|} \sum_{i=1}^{|D|} (g_i - \hat{g})^2 \tag{9}$$

where g_i represents the difference between the accumulated attention weight and maximum attention weight at i-th position.

2.4 Model Training

The model is firstly pre-trained to minimize the maximum-likelihood loss, which is widely used in sequence generation tasks. We define $y^* = \{y^*_1, \cdots, y^*_T\}$ as the ground-truth output sequence for a given input sequence x, then the loss function is formulated as:

$$\mathcal{L}_{MLE} = -\frac{1}{T} \sum_{t=1}^{T} \log(p(y^*_t|x) \tag{10}$$

After converging, the model is further optimized with local variance loss and global variance loss. The mix of loss functions is:

$$\mathcal{L} = \mathcal{L}_{MLE} + \lambda_1 \mathcal{L}_L + \lambda_2 \mathcal{L}_G \tag{11}$$

where λ_1 and λ_2 are hyper-parameters.

3 Experiments

3.1 Preliminaries

Dataset and Metrics. We conduct our model on the large-scale dataset CNN/Daily Mail (Hermann et al., 2015; Nallapati et al., 2016), which is widely used in the task of abstractive document summarization with multi-sentences summaries. We use the scripts provided by See et al. (2017) to obtain the non-anonymized version of the dataset without preprocessing to replace named entities. The dataset contains 287,226 training pairs, 13,368 validation pairs and 11,490 test pairs in total. We use the full-length ROUGE F1[1] and METEOR[2] as our main evaluation metrics.

Implementation Details. The data preprocessing is the same as PGN (See et al., 2017), and we randomly initialize the word embeddings. The hidden states of the encoder and the decoder are both 256-dimensional and the embedding size is also 256. Adagrad with learning rate 0.15 and an accumulator with initial value 0.1 are used to train the model. We conduct experiments on a single Tesla P100 GPU with a batch size of 64 and it takes about 50000 iterations for pre-training and 10000 iterations for fine-tuning. Beam search size is set to 4 and trigram avoidance (Paulus et al., 2018) is used to avoid trigram-level repetition. Tuned on validation set, λ_1 and λ_2 in the loss function (Equation. 11) is set to 0.3 and 0.1, respectively.

3.2 Automatic Evaluation Result

As shown in Table 1 (the performance of other models is collected from their papers), our model exceeds the PGN baseline by 3.85, 2.1 and 3.37 in terms of R-1, R-2 and R-L respectively and receives over 3.23 point boost on METEOR. FastAbs (Chen and Bansal, 2018) regards ROUGE scores as reward signals with reinforcement learning, which brings a great performance gain. DCA (Celikyilmaz et al., 2018) proposes deep communicating agents with reinforcement setting and achieves the best results on CNN/Daily Mail. Although our experimental results have not outperformed the state-of-the-art models, our model has a much simpler structure with fewer parameters. Besides, these simple methods do yield a boost

in performance compared with PGN baseline and may be applied on other models with attention mechanism.

We further evaluate how these optimization approaches work. The results at the bottom of Table 1 verify the effectiveness of our proposed methods. The ARU module has achieved a gain of 0.97 ROUGE-1, 0.35 ROUGE-2, and 0.64 ROUGE-L points; the local variance loss boosts the model by 3.01 ROUGE-1, 1.6 ROUGE-2, and 2.58 ROUGE-L. As shown in Figure 2, the global variance loss helps with eliminating n-gram repetitions, which verifies its effectiveness.

3.3 Human Evaluation and Case Study

We also conduct human evaluation on the generated summaries. Similar to the previous work (Chen and Bansal, 2018; Nallapati et al., 2017), we randomly select 100 samples from the test set of CNN/Daily Mail dataset and ask 3 human testers to measure *relevance* and *readability* of each summary. Relevance is based on how much salient information does the summary contain, and readability is based on how fluent and grammatical the summary is. Given an article, different people may have different understandings of the main content of the article, the ideal situation is that more than one reference is paired with the articles. However, most of summarization datasets contain the pairs of article with a single reference summary due to the cost of annotating multi-references. Since we use the reference summaries as target sequences to train the model and assume that they are the gold standard, we give both articles and reference summaries to the annotator to score the generated summaries. In other words, we compare the generated summaries against the reference ones and the original article to obtain the (relative) scores in Table 3. Each perspective is assessed with a score from 1 (worst) to 5 (best). The result in Table 2 demonstrate that our model performs better under both criteria w.r.t. See et al. (2017). Additionally, we show the example of summaries generated by our model and baseline model in Table 3. As can be seen from the table, PGN suffers from repetition and fails to obtain the salient information. Though with coverage mechanism solving saliency and repetition problem, it generates many trivial facts. With ARU, the model successfully concentrates on the salient information, however, it also suffers from serious repetition problem. Further optimized by the variance loss, our model can avoid repetition and generate summary with salient information. Besides, our generated summary contains fewer trivial facts compared to the PGN+Coverage model.

Models	Relevance	Readability
Reference	5.00	5.00
PGN	2.27	4.30
PGN+Coverage	2.46	4.88
Our model	2.74	4.92

et al., 2018) select salient sentences from original document as a summary. In contrast, abstractive summarization (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017; Chen and Bansal, 2018) generates summaries word-by-word after digesting the main content of the document. Out-of-vocabulary(OOV), repetition, and saliency are three conspicuous problems need to be well solved in abstractive document summarization. Some works (Nallapati et al., 2016; See et al., 2017; Paulus et al., 2018) handle the OOV problem by introducing the pointer network. See et al. (2017) introduces a coverage mechanism, which is a variant of the coverage vector (Tu et al., 2016) from Neural Machine Translation, to eliminate repetitions. However, there are just a few studies on saliency problem (Tan et al., 2017; Shi et al., 2018; Gehrmann et al., 2018). To obtain more salient information, Chen et al. (2016) proposes a new attention mechanism to distract them in the decoding step to better grasp the overall meaning of input documents. We optimize attention using an attention refinement unit under the novel variance loss supervision. As far as we know, we are the first to propose explicit losses to refine the attention model in abstractive document summarization tasks. Recently many models (Paulus et al., 2018; Celikyilmaz et al., 2018; Chen and Bansal, 2018; Zhou et al., 2018; Jiang and Bansal, 2018) have emerged taking advantage of reinforcement learning (RL) to solve the discrepancy issue in seq2seq model and have yielded the state-of-the-art performance.

5 Conclusion

In this paper, we propose simple but effective methods to optimize the vanilla attention mechanism in abstarctive document summarization. The results on CNN/Daily Mail dataset demonstrate the effectiveness of our methods. We argue that these simple methods are also adaptable to other summarization models with attention. Further exploration on this and combination with other approaches like RL remains as our future exploration. Besides, we will also conduct experiments on several other current summarization datasets like New York Times (NYT) (Paulus et al., 2018) and Newsroom (Grusky et al., 2018).

Abstract

Unresolved coreference is a bottleneck for relation extraction, and high-quality coreference resolvers may produce an output that makes it a lot easier to extract knowledge triples. We show how to improve coreference resolvers by forwarding their input to a relation extraction system and reward the resolvers for producing triples that are found in knowledge bases. Since relation extraction systems can rely on different forms of supervision and be biased in different ways, we obtain the best performance, improving over the state of the art, using multi-task reinforcement learning.

1 Introduction

Coreference annotations are costly and difficult to obtain, since trained annotators with sufficient world knowledge are necessary for reliable annotations. This paper presents a way to *simulate* annotators using reinforcement learning. To motivate our approach, we rely on the following example from Martschat and Strube (2014, colors added to mark entity mentions):

(1) [**Lynyrd Skynyrd**]$_1$ was formed in **Florida**$_2$. Other bands from [**the Sunshine State**]$_2$ include **Fireflight** and **Marilyn Manson**.

Martschat and Strube (2014) cite the association between Florida and the Sunshine State as an example of a common source of name-name recall error for state-of-the-art coreference resolution systems. The challenge is that the two names co-occur relatively infrequently and are unlikely to do so in a moderate-sized, manually annotated training corpus. A state-of-the-art system may be able to infer the relation using distributional information about the phrase the Sunshine State, but is likely to have limited evidence for the decision that it is coreferential with Florida rather than Lynyrd Skynyrd.

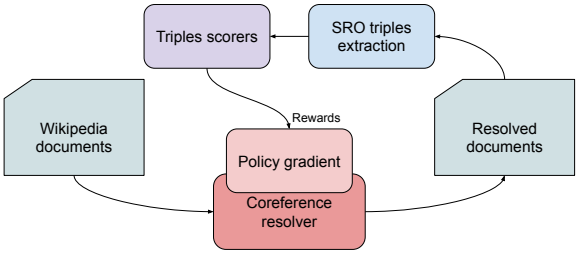

Figure 1: Our strategy for training a coreference resolver using reward from relation extraction.

While coreference-annotated data is scarce, knowledge bases including factual information (such as that Fireflight is from Florida) are increasingly available. For a human annotator unaware that Florida is sometimes referred to as the Sunshine State, the information that Fireflight is from Florida is sufficient to establish that Florida and the Sunshine State are (with high probability) coreferential. This paper explores a novel architecture for making use of such information from knowledge bases by tying a coreference resolution system to a relation extraction system, enabling us to reward the coreference system for making predictions that lead us to infer facts that are consistent with such knowledge bases. This potentially provides us with more evidence for resolving coreference such as (1).

We propose a training strategy (Figure 1) in which we pass on the predictions of a neural coreference resolver to an open relation extraction (OpenRE) system, matching relations extracted from resolved sentences with a knowledge base. We show how checking the produced relationships for consistency against the knowledge base produces a reward that is, indirectly, a signal about the quality of the coreference resolution. In order to generalize this signal beyond the coverage of the knowledge base, we train a Universal Schema model (Riedel et al., 2013) and use its confidence as our reward function. With this reward function,

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1229–1235, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

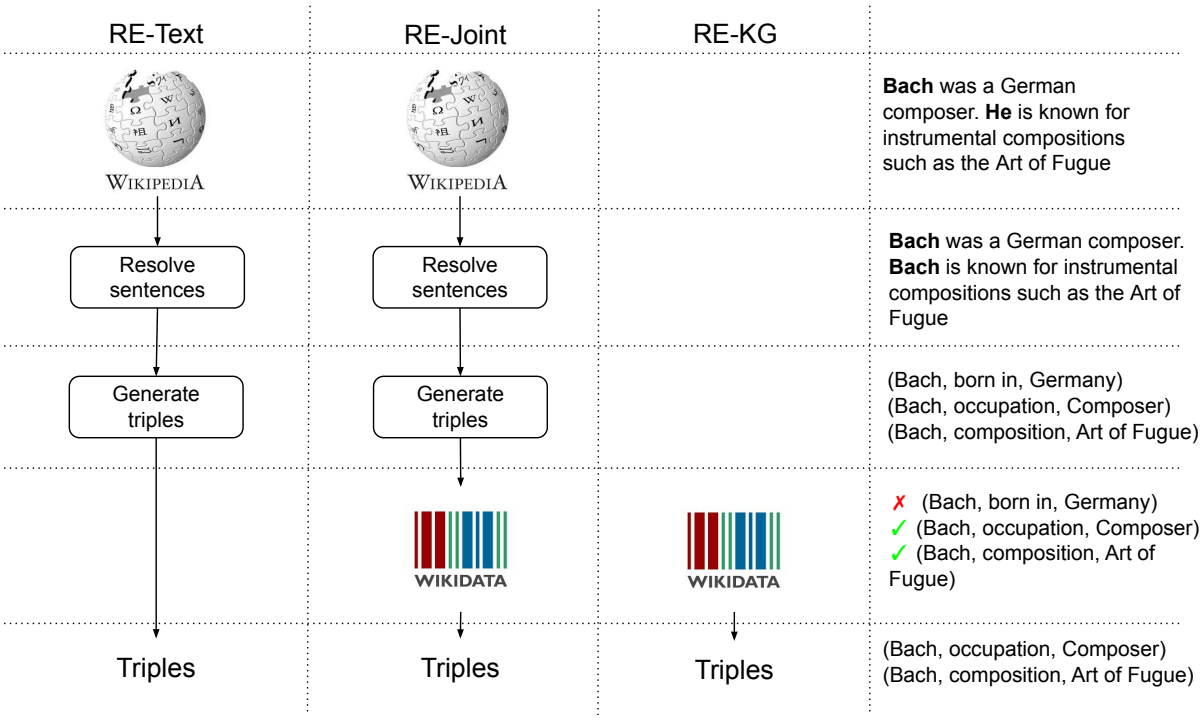

Figure 2: The three left columns show the pipelines for extracting data in different settings to train the reward models. The right column gives an example of the process: original text, coreference resolved text, extracted triples, pruning triples (the first triple is discarded as it is not present in Wikidata) and final training data.

we do policy-gradient fine-tuning of our coreference resolver, effectively optimizing its predictions' consistency with world knowledge.

Contributions We demonstrate that training a coreference resolver by reinforcement learning with rewards from a relation extraction system, results in improvements for coreference resolution. Our code is made publicly available at https://github.com/rahular/coref-rl

2 Consistency Reward for Coreference Resolution

In order to reward a coreference resolver for being consistent with world knowledge, we propose a simple training strategy based on relation extraction: (i) Sample a Wikipedia[1] document at random, (ii) Replace mentions with their antecedents using a coreference resolver, (iii) Apply an off-the-shelf openRE system to each rewritten document, (iv) Score relationships that include coreferent mentions using Universal Schema, and (v) Use the score as a reward for training the coreference resolvers.

Reward functions To model consistency with world knowledge, we train different Universal Schema models (Riedel et al., 2013; Verga and McCallum, 2016), resulting in three reward functions (Figure 2): **RE-KG** (Knowledge Graph Universal Schema) is trained to predict whether two entities are linked in Wikidata[2]; **RE-Text** (Text-based Universal Schema) is trained to predict whether two entities co-occur in Wikipedia; and **RE-Joint** (Joint Universal Schema) is trained to predict whether two entities are linked *and* co-occur. The three rewards focus on different aspects of relationships between entities, giving complimentary views of what entities are related.

Similar to Verga et al. (2016), we parameterize candidate relation phrases with a BiLSTM (Graves and Schmidhuber, 2005), and use pre-trained Wikidata BigGraph embeddings (Lerer et al., 2019) as the entity representations. We apply a one-layer MLP on the concatenated representations to get the reward value.

Updating the coreference resolver Each resolved document is converted into n subject-relation-object (SRO) triples by an open information retrieval system (Angeli et al., 2015). Each

[1] https://www.wikipedia.org

[2] https://www.wikidata.org

triple t_i is then scored using a reward function to obtain a reward r_i for $i \in \{1, \ldots, n\}$. The final document-level reward is the normalized sum of the individual rewards as shown in Equation 1, where R_h is a moving window containing the previous $h = 100$ normalized reward values.

$$R = \frac{\sum_i r_i - mean(R_h)}{stddev(R_h)} \quad (1)$$

Since R is not differentiable with respect to the coreference resolver's parameters, we use policy gradient training to update the coreference resolver. We select the best action according to the current policy, using random exploration of the alternative solutions with $p = \frac{1}{10}$.

Multi-task reinforcement learning Our overall training procedure is presented in Algorithm 1. After training the three aforementioned reward models, we create **RE-Distill** by interpolating their trained weights. Next, we pre-train a coreference resolver using supervised learning, and fine-tune it using each of the three reward functions to get three different coreference policies: **Coref-KG**, **Coref-Text** and **Coref-Joint**, respectively. We then use multi-task reinforcement learning to combine these three policies to get **Coref-Distill**. Our approach is a particular instance of DisTraL (Teh et al., 2017), using policy gradient and model interpolation. Finally, **Coref-Distill** is fine-tuned with rewards from **RE-Distill**.

Algorithm 1 Multi-task Reinforcement Learning

return Distilled policy θ_*

3 Experiments

We use a state-of-the-art neural coreference resolution model (Lee et al., 2018) as our baseline coreference resolver.[3] This model extends Lee et al. (2017) with coarse-to-fine inference and ELMo pretrained embeddings (Peters et al., 2018).

Data We use the standard training, validation, and test splits from the English OntoNotes.[4] We also evaluate on the English WikiCoref (Ghaddar and Langlais, 2016), with a validation and test split of 10 and 20 documents respectively.

Reward model training We use data from English Wikipedia and Wikidata to train our three reward models. For training **RE-KG**, we sample 1 million Wikidata triples, and expand them to 12 million triples by replacing relation phrases with their aliases. For **RE-Text**, we pass the summary paragraphs from 50,000 random Wikipedia pages to Stanford's OpenIE extractor (Manning et al., 2014), creating 2 million triples. For **RE-Joint**, we only use Wikipedia triples that are grounded in Wikidata, resulting in 60,000 triples.[5] We further sample 200,000 triples from Wikidata and Wikipedia for validation, and train the reward models with early stopping based on the F_1 score of their predictions.

Evaluation All models are evaluated using the standard CoNLL metric, which is the average F_1 score over MUC, CEAFe, and B^3 (Denis and Baldridge, 2009).

4 Results

Since the quality of our reward models is essential to the performance of the coreference resolver adaptations, we first report the validation accuracy and F_1 scores of the four reward models used, in Table 1. We clearly see the advantage of distillation, with a 5% absolute difference between the best single model (**RE-Text**) and **RE-Distill**.

Table 2 presents the downstream effects of applying these reward functions to our baseline coreference policy.[6]

[3] https://github.com/kentonl/e2e-coref

[4] https://catalog.ldc.upenn.edu/LDC2013T19

[5] That is, we retain only those triples whose subject and object can be linked to an entity in Wikidata.

[6] The models were re-trained from scratch, and the scores

System	Data	Accuracy	F_1 score
RE-KG	12M	0.64	0.78
RE-Text	2M	0.71	0.83
RE-Joint	60K	0.58	0.73
RE-Distill	—	**0.78**	**0.88**

Table 1: Training data size, accuracy and F_1 scores of the reward models on the 200,000 validation triples.

System	OntoNotes	WikiCoref
Lee et al. (2018)	72.60	57.49
Coref-KG	72.96	57.84
Coref-Text	72.99	57.54
Coref-Joint	72.77	57.51
Coref-Distill	**73.10**	**58.14**

Table 2: Coreference results: average F_1 scores on the OntoNotes and WikiCoref test sets. Differences are significant w.r.t. B^3 (bootstrap test, $p < 0.05$).

The coreference resolution results are similar to the relation extraction results: using a distilled policy, learned through multi-task reinforcement learning, leads to better results on both datasets.[7]

While improvements over the current state of the art are relatively small, they reflect significant progress, as they demonstrate the ability to successfully augment coreference resolvers with "free" data from large-scale KB like Wikidata. For relation extraction, this could have positive downstream effects, and also ensure that relations are consistent with real world knowledge. Moreover, this approach has the potential to also be beneficial for coreference resolution in low resource languages, where less annotated data is available, as Wikidata triples are abundant for many languages.

5 Analysis

Empirically, we find that fine-tuning the coreference resolver on Wikidata results in two kinds of improvements:

Better mention detection Since the model is rewarded if the SRO triples produced from the resolved document are present in Wikidata, the model can do well only if it correctly resolves the subject and object, which are usually named entities (more generally, noun phrases). Indeed, we see an improvement in mention detection as exemplified in the first example of Figure 3. Compared to the baseline, the fine-tuned model identifies a larger number of entities, including "southern hemisphere", "Cambridge" and "Oxford", which are missed by the baseline model.

Better linking As a direct consequence of the above, the model is inclined to also link noun phrases that are not entities. In the second example of Figure 3, we see that "This attempt" is linked to "releasing" by the fine-tuned model. Interestingly, we do not see this type of *eventive* noun phrase linking either in OntoNotes or in the predictions of the baseline model.

This phenomenon, however, also has a side-effect of producing singleton clusters and spurious linking, which adversely affect the recall. On the OntoNotes test data, while the average precision of the best performing fine-tuned model is higher than the baseline (75.62 vs. 73.80), a drop in recall (70.75 vs. 71.34) causes the final F_1 score to only marginally improve.

6 Related Work

Coreference resolution Among neural coreference resolvers (Wu and Ma, 2017; Meng and Rumshisky, 2018), Lee et al. (2017) were the first to propose an end-to-end resolver which did not rely on hand-crafted rules or a syntactic parser. Extending this work, Lee et al. (2018) introduced a novel attention mechanism for iteratively ranking spans of candidate coreferent mentions, thereby improving the identification of long distance coreference chains. Zhang et al. (2019) improve pronoun coreference resolution by 2.2 F1 using linguistic features (gender, animacy and plurality) and a frequency based predicate-argument selection preference as external knowledge. Emami et al. (2018) incorporate knowledge into coreference resolution by means of information retrieval, finding sentences that are syntactically similar to a given instance, and improving F1 by 0.16.

Reinforcement learning RL has been used for many NLP tasks, including coreference resolution (Clark and Manning, 2016) and relation extraction (Zeng et al., 2018). Clark and Manning (2016) use RL to improve coreference resolution by op-

are slightly different from those reported in Lee et al. (2018).

[7] We repeat this experiment three times with different random seeds and observed the same pattern and very robust performance across the board.

timizing their mention ranking model and directly use the standard evaluation metrics as the rewards. We, on the other hand, perform end-to-end optimization by rewarding the model's consistency with real world knowledge using relation extraction. To our knowledge, we are the first to use consistency with world knowledge as a reward for tasks other than knowledge base construction.[8]

Knowledge bases Knowledge bases have been leveraged across multiple tasks across NLP (Bordes et al., 2011; Chang et al., 2014; Lin et al., 2015; Toutanova et al., 2015; Yang and Mitchell, 2017). Specifically for coreference resolution, Prokofyev et al. (2015) implement a resolver that ensures semantic relatedness of resulting coreference clusters by leveraging Semantic Web annotations. Their work incorporates knowledge graph information only in the final stage of the resolver's pipeline, and not during training. In contrast, our work augments information from the knowledge base directly into the training pipeline. Also, they use DBpedia (Auer et al., 2007) as the ontology. Although both Wikidata and DBpedia are designed to support working with Wikipedia articles, DBpedia can be considered as a subset of Wikidata as Wikipedia infoboxes are its main data source. The advantage of Wikidata over DBpedia is its size, and the fact that it is multilingual, which will allow applying our method to other languages in the future.

[8] Mao et al. (2018), for example, use reinforcement learning with consistency-like reward to induce lexical taxonomies.

7 Conclusion

We presented an architecture for adapting coreference resolvers by rewarding them for being consistent with world knowledge. Using simple multi-task reinforcement learning and a knowledge extraction pipeline, we achieved improvements over the state of the art across two datasets. We believe this is an important first step in exploring the usefulness of knowledge bases in the context of coreference resolution and other discourse-level phenomena. In this area, manually annotated data is particularly expensive, and we believe leveraging knowledge bases will eventually reduce the need for manual annotation.

Abstract

The incorporation of pseudo data in the training of grammatical error correction models has been one of the main factors in improving the performance of such models. However, consensus is lacking on experimental configurations, namely, choosing how the pseudo data should be generated or used. In this study, these choices are investigated through extensive experiments, and state-of-the-art performance is achieved on the CoNLL-2014 test set ($F_{0.5} = 65.0$) and the official test set of the BEA-2019 shared task ($F_{0.5} = 70.2$) without making any modifications to the model architecture.

1 Introduction

To date, many studies have tackled grammatical error correction (GEC) as a machine translation (MT) task, in which ungrammatical sentences are regarded as the source language and grammatical sentences are regarded as the target language. This approach allows cutting-edge neural MT models to be adopted. For example, the encoder-decoder (EncDec) model (Sutskever et al., 2014; Bahdanau et al., 2015), which was originally proposed for MT, has been applied widely to GEC and has achieved remarkable results in the GEC research field (Ji et al., 2017; Chollampatt and Ng, 2018; Junczys-Dowmunt et al., 2018).

However, a challenge in applying EncDec to GEC is that EncDec requires a large amount of training data (Koehn and Knowles, 2017), but the largest set of publicly available parallel data (Lang-8) in GEC has only two million sentence pairs (Mizumoto et al., 2011). Consequently, the method of augmenting the data by incorporating pseudo training data has been studied intensively (Xie et al., 2018; Ge et al., 2018; Lichtarge et al., 2019; Zhao et al., 2019).

When incorporating pseudo data, several decisions must be made about the experimental configurations, namely, (i) the method of generating the pseudo data, (ii) the seed corpus for the pseudo data, and (iii) the optimization setting (Section 2). However, consensus on these decisions in the GEC research field is yet to be formulated. For example, Xie et al. (2018) found that a variant of the backtranslation (Sennrich et al., 2016b) method (BACKTRANS (NOISY)) outperforms the generation of pseudo data from raw grammatical sentences (DIRECTNOISE). By contrast, the current state of the art model (Zhao et al., 2019) uses the DIRECTNOISE method.

In this study, we investigate these decisions regarding pseudo data, our goal being to provide the research community with an improved understanding of the incorporation of pseudo data. Through extensive experiments, we determine suitable settings for GEC. We justify the reliability of the proposed settings by demonstrating their strong performance on benchmark datasets. Specifically, without any task-specific techniques or architecture, our model outperforms not only all previous single-model results but also all ensemble results except for the ensemble result by Grundkiewicz et al. (2019)[1]. By applying task-specific techniques, we further improve the performance and achieve state-of-the-art performance on the CoNLL-2014 test set and the official test set of the BEA-2019 shared task.

2 Problem Formulation and Notation

In this section, we formally define the GEC task discussed in this paper. Let $\mathcal{D}$ be the GEC training data that comprise pairs of an ungrammatical source sentence $\boldsymbol{X}$ and grammatical target sentence

[*] Current affiliation: Future Corporation

[1] The paper (Grundkiewicz et al. 2019) has not been published yet at the time of submission.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1236–1242,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

$\boldsymbol{Y}$, i.e., $\mathcal{D} = \{(\boldsymbol{X}_n, \boldsymbol{Y}_n)\}_n$. Here, $|\mathcal{D}|$ denotes the number of sentence pairs in the dataset $\mathcal{D}$.

Let $\boldsymbol{\Theta}$ represent all trainable parameters of the model. Our objective is to find the optimal parameter set $\widehat{\boldsymbol{\Theta}}$ that minimizes the following objective function $\mathcal{L}(\mathcal{D}, \boldsymbol{\Theta})$ for the given training data $\mathcal{D}$:

$$\mathcal{L}(\mathcal{D}, \boldsymbol{\Theta}) = -\frac{1}{|\mathcal{D}|} \sum_{(\boldsymbol{X},\boldsymbol{Y})\in\mathcal{D}} \log(p(\boldsymbol{Y}|\boldsymbol{X}, \boldsymbol{\Theta})), \quad (1)$$

where $p(\boldsymbol{Y}|\boldsymbol{X}, \boldsymbol{\Theta})$ denotes the conditional probability of $\boldsymbol{Y}$ given $\boldsymbol{X}$.

In the standard supervised learning setting, the parallel data $\mathcal{D}$ comprise only "genuine" parallel data $\mathcal{D}_g$ (i.e., $\mathcal{D} = \mathcal{D}_g$). However, in GEC, incorporating pseudo data $\mathcal{D}_p$ that are generated from grammatical sentences $\boldsymbol{Y} \in \mathcal{T}$, where $\mathcal{T}$ represents *seed corpus* (i.e., a set of grammatical sentences), is common (Xie et al., 2018; Zhao et al., 2019; Grundkiewicz et al., 2019).

Our interest lies in the following three nontrivial aspects of Equation 1. **Aspect (i)**: multiple methods for generating pseudo data $\mathcal{D}_p$ are available (Section 3). **Aspect (ii)**: options for the seed corpus $\mathcal{T}$ are numerous. To the best of our knowledge, how the seed corpus domain affects the model performance is yet to be shown. We compare three corpora, namely, Wikipedia, Simple Wikipedia (SimpleWiki) and English Gigaword, as a first trial. Wikipedia and SimpleWiki have similar domains, but different grammatical complexities. Therefore, we can investigate how grammatical complexity affects model performance by comparing these two corpora. We assume that Gigaword contains the smallest amount of noise among the three corpora. We can therefore use Gigaword to investigate whether clean text improves model performance. **Aspect (iii)**: at least two major settings for incorporating $\mathcal{D}_p$ into the optimization of Equation 1 are available. One is to use the two datasets jointly by concatenating them as $\mathcal{D} = \mathcal{D}_g \cup \mathcal{D}_p$, which hereinafter we refer to as JOINT. The other is to use $\mathcal{D}_p$ for pretraining, namely, minimizing $\mathcal{L}(\mathcal{D}_p, \boldsymbol{\Theta})$ to acquire $\boldsymbol{\Theta}'$, and then fine-tuning the model by minimizing $\mathcal{L}(\mathcal{D}_g, \boldsymbol{\Theta}')$; hereinafter, we refer to this setting as PRETRAIN. We investigate these aspects through our extensive experiments (Section 4).

3 Methods for Generating Pseudo Data

In this section, we describe three methods for generating pseudo data. In Section 4, we experimentally compare these methods.

BACKTRANS (NOISY) and BACKTRANS (SAMPLE) Backtranslation for the EncDec model was proposed originally by Sennrich et al. (2016b). In backtranslation, a reverse model, which generates an ungrammatical sentence from a given grammatical sentence, is trained. The output of the reverse model is paired with the input and then used as pseudo data.

BACKTRANS (NOISY) is a variant of backtranslation that was proposed by Xie et al. (2018)[2]. This method adds $r\beta_{\text{random}}$ to the score of each hypothesis in the beam for every time step. Here, noise r is sampled uniformly from the interval $[0, 1]$, and $\beta_{\text{random}} \in \mathbb{R}_{\geq 0}$ is a hyper-parameter that controls the noise scale. If we set $\beta_{\text{random}} = 0$, then BACKTRANS (NOISY) is identical to standard backtranslation.

BACKTRANS (SAMPLE) is another variant of backtranslation, which was proposed by Edunov et al. (2018) for MT. In BACKTRANS (SAMPLE), sentences are decoded by sampling from the distribution of the reverse model.

DIRECTNOISE Whereas BACKTRANS (NOISY) and BACKTRANS (SAMPLE) generate ungrammatical sentences with a reverse model, DIRECTNOISE injects noise "directly" into grammatical sentences (Edunov et al., 2018; Zhao et al., 2019). Specifically, for each token in the given sentence, this method probabilistically chooses one of the following operations: (i) masking with a placeholder token $\langle mask \rangle$, (ii) deletion, (iii) insertion of a random token, and (iv) keeping the original[3]. For each token, the choice is made based on the categorical distribution $(\mu_{\text{mask}}, \mu_{\text{deletion}}, \mu_{\text{insertion}}, \mu_{\text{keep}})$.

4 Experiments

The goal of our experiments is to investigate **aspect (i)–(iii)** introduced in Section 2. To ensure that the experimental findings are applicable to GEC in general, we design our experiments by using the following two strategies: (i) we use an off-the-shelf EncDec model without any task-specific architecture or techniques; (ii) we conduct hyper-parameter tuning, evaluation and comparison of each method or setting on the validation set. At the end of experiments (Section 4.5), we summarize our findings and propose suitable settings. We then perform a single-shot evaluation of their performance on the test set.

[2] referred as "random noising" in Xie et al. (2018)

[3] The detailed algorithm is described in Appendix A.

Dataset	#sent (pairs)	#refs.	Split	Scorer

DIRECTNOISE	**48.9**	25.7	**41.4**

Table 2: Performance of models on BEA-valid: a value in **bold** indicates the best result within the column. The seed corpus $\mathcal{T}$ is SimpleWiki.

4.1 Experimental Configurations

Dataset The BEA-2019 workshop official dataset[4] is the origin of the training and validation data of our experiments. Hereinafter, we refer to the training data as BEA-train. We create validation data (BEA-valid) by randomly sampling sentence pairs from the official validation split[5].

As a seed corpus $\mathcal{T}$, we use SimpleWiki[6], Wikipedia[7] or Gigaword[8]. We apply the noizing methods described in Section 3 to each corpus and generate pseudo data $\mathcal{D}_p$. The characteristics of each dataset are summarized in Table 1.

Evaluation We report results on BEA-valid, the official test set of the BEA-2019 shared task (BEA-test), the CoNLL-2014 test set (CoNLL-2014) (Ng et al., 2014), and the JFLEG test set (JFLEG) (Napoles et al., 2017). All reported results (except ensemble) are the average of five distinct trials using five different random seeds. We report the scores measured by ERRANT (Bryant et al., 2017; Felice et al., 2016) for BEA-valid, BEA-test, and CoNLL-2014. As the reference sentences of BEA-test are publicly unavailable, we evaluate the model outputs on `CodaLab`[9] for BEA-test. We also report results measured by the M^2 scorer (Dahlmeier and Ng, 2012) on CoNLL-2014 to compare them with those of previous studies. We use the GLEU metric (Napoles et al., 2015, 2016) for JFLEG.

Model We adopt the *Transformer* EncDec model (Vaswani et al., 2017) using the `fairseq` toolkit (Ott et al., 2019) and use the "Transformer (big)" settings of Vaswani et al. (2017).

Optimization For the JOINT setting, we optimize the model with Adam (Kingma and Ba, 2015). For the PRETRAIN setting, we pretrain the model with Adam and then fine-tune it on BEA-train using Adafactor (Shazeer and Stern, 2018)[10].

4.2 Aspect (i): Pseudo Data Generation

We compare the effectiveness of the BACKTRANS (NOISY), BACKTRANS (SAMPLE), and DIRECTNOISE methods for generating pseudo data. In DIRECTNOISE, we set $(\mu_{\text{mask}}, \mu_{\text{deletion}}, \mu_{\text{insertion}}, \mu_{\text{keep}}) = (0.5, 0.15, 0.15, 0.2)$[11]. We use $\beta_{\text{random}} = 6$ for BACKTRANS (NOISY)[12]. In addition, we use (i) the JOINT setting and (ii) all of SimpleWiki as the seed corpus $\mathcal{T}$ throughout this section.

The results are summarized in Table 2. BACKTRANS (NOISY) and BACKTRANS (SAMPLE) show competitive values of $F_{0.5}$. Given this result, we exclusively use BACKTRANS (NOISY) and discard BACKTRANS (SAMPLE) for the rest of the experiments. The advantage of BACKTRANS (NOISY) is that its effectiveness in GEC has already been demonstrated by Xie et al. (2018). In addition, in our preliminary experiment, BACKTRANS (NOISY) decoded ungrammatical sentence 1.2 times faster than BACKTRANS (SAMPLE) did. We also use DIRECTNOISE because it achieved the best value of $F_{0.5}$ among all the methods.

4.3 Aspect (ii): Seed Corpus $\mathcal{T}$

We investigate the effectiveness of the seed corpus $\mathcal{T}$ for generating pseudo data $\mathcal{D}_p$. The three corpora (Wikipedia, SimpleWiki and Gigaword) are compared in Table 3. We set $|\mathcal{D}_p| = 1.4\text{M}$. The difference in $F_{0.5}$ is small, which implies that the seed corpus $\mathcal{T}$ has only a minor effect on the model performance. Nevertheless, Gigaword consistently outperforms the other two corpora. In particular,

[4] Details of the dataset is in Appendix B.

[5] The detailed data preparation process is in Appendix C.

[6] https://simple.wikipedia.org

[7] We used `2019-02-25` dump file at https://dumps.wikimedia.org/other/cirrussearch/.

[8] We used the English Gigaword Fifth Edition (LDC Catalog No.: LDC2011T07).

[9] https://competitions.codalab.org/competitions/20228

[10] The detailed hyper-parameters are listed in Appendix D.

[11] These values are derived from preliminary experiments (Appendix E).

[12] $\beta_{\text{random}} = 6$ achieved the best $F_{0.5}$ in our preliminary experiments (Appendix F).

Method	Seed Corpus $\mathcal{T}$	Prec.	Rec.	$F_{0.5}$
Baseline	N/A	46.6	23.1	38.8
BACKTRANS (NOISY)	Wikipedia	43.8	30.8	40.4
BACKTRANS (NOISY)	SimpleWiki	42.5	31.3	39.7
BACKTRANS (NOISY)	Gigaword	43.1	33.1	40.6
DIRECTNOISE	Wikipedia	48.3	25.5	41.0
DIRECTNOISE	SimpleWiki	48.9	25.7	41.4
DIRECTNOISE	Gigaword	48.3	26.9	41.7

Table 3: Performance on BEA-valid when changing the seed corpus $\mathcal{T}$ used for generating pseudo data ($|\mathcal{D}_p| = 1.4$M).

DIRECTNOISE with Gigaword achieves the best value of $F_{0.5}$ among all the configurations.

4.4 Aspect (iii): Optimization Setting

We compare the JOINT and PRETRAIN optimization settings. We are interested in how each setting performs when the scale of the pseudo data $\mathcal{D}_p$ compared with that of the genuine parallel data $\mathcal{D}_g$ is (i) approximately the same ($|\mathcal{D}_p| = 1.4$M) and (ii) substantially bigger ($|\mathcal{D}_p| = 14$M). Here, we use Wikipedia as the seed corpus $\mathcal{T}$ instead of SimpleWiki or Gigaword for two reasons. First, SimpleWiki is too small for the experiment **(b)** (see Table 1). Second, the fact that Gigaword is not freely available makes it difficult for other researchers to replicate our results.

(a) Joint Training or Pretraining Table 4 presents the results. The most notable result here is that PRETRAIN demonstrates the properties of *more pseudo data and better performance*, whereas JOINT does not. For example, in BACKTRANS (NOISY), increasing $|\mathcal{D}_p|$ (1.4M $\rightarrow$ 14M) improves $F_{0.5}$ on PRETRAIN (41.1 $\rightarrow$ 44.5). By contrast, $F_{0.5}$ does not improve on JOINT (40.4 $\rightarrow$ 40.3). An intuitive explanation for this case is that when pseudo data $\mathcal{D}_p$ are substantially more than genuine data $\mathcal{D}_g$, the teaching signal from $\mathcal{D}_p$ becomes dominant in JOINT. PRETRAIN alleviates this problem because the model is trained with only $\mathcal{D}_g$ during fine-tuning. We therefore suppose that PRETRAIN is crucial for utilizing extensive pseudo data.

(b) Amount of Pseudo Data We investigate how increasing the amount of pseudo data affects the PRETRAIN setting. We pretrain the model with different amounts of pseudo data {1.4M, 7M, 14M, 30M, 70M}. The results in Figure 1 show that BACKTRANS (NOISY) has superior sample efficiency to DIRECTNOISE. The best model (pretrained with 70M BACKTRANS (NOISY)) achieves $F_{0.5} = 45.9$.

Optimization	Method	$|\mathcal{D}_p|$	Prec.	Rec.	$F_{0.5}$
N/A	Baseline	0	46.6	23.1	38.8
PRETRAIN	BACKTRANS (NOISY)	1.4M	49.6	24.3	41.1
PRETRAIN	DIRECTNOISE	1.4M	48.4	21.2	38.5
JOINT	BACKTRANS (NOISY)	1.4M	43.8	30.8	40.4
JOINT	DIRECTNOISE	1.4M	48.3	25.5	41.0
PRETRAIN	BACKTRANS (NOISY)	14M	50.6	30.1	44.5
PRETRAIN	DIRECTNOISE	14M	49.8	25.8	42.0
JOINT	BACKTRANS (NOISY)	14M	43.0	32.3	40.3
JOINT	DIRECTNOISE	14M	48.7	23.5	40.1

Table 4: Performance of the model with different optimization settings on BEA-valid. The seed corpus $\mathcal{T}$ is Wikipedia.

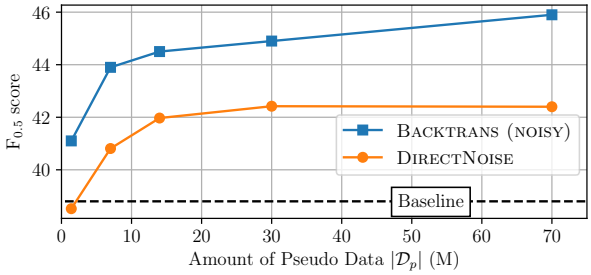

Figure 1: Performance on BEA-valid for different amounts of pseudo data ($|\mathcal{D}_p|$). The seed corpus $\mathcal{T}$ is Wikipedia.

4.5 Comparison with Current Top Models

The present experimental results show that the following configurations are effective for improving the model performance: (i) the combination of JOINT and Gigaword (Section 4.3), (ii) the amount of pseudo data $\mathcal{D}_p$ not being too large in JOINT (Section 4.4(a)), and (iii) PRETRAIN with BACKTRANS (NOISY) using large pseudo data $\mathcal{D}_p$ (Section 4.4(b)). We summarize these findings and attempt to combine PRETRAIN and JOINT. Specifically, we pretrain the model using 70M pseudo data of BACKTRANS (NOISY). We then fine-tune the model by combining BEA-train and relatively small DIRECTNOISE pseudo data generated from Gigaword (we set $|\mathcal{D}_p| = 250$K). However, the performance does not improve on BEA-valid. Therefore, the best approach available is simply to pretrain the model with large (70M) BACKTRANS (NOISY) pseudo data and then fine-tune using BEA-train, which hereinafter we refer to as PRETLARGE. We use Gigaword for the seed corpus $\mathcal{T}$ because it has the best performance in Table 3.

We evaluate the performance of PRETLARGE on test sets and compare the scores with the current top models. Table 5 shows a remarkable result, that is,

Model	Ensemble	CoNLL-2014 (M^2 scorer)			CoNLL-2014 (ERRANT)			JFLEG	BEA-test (ERRANT)

PRETLARGE+SSE+R2L+SED	✓	**73.3**	44.2	64.7	**68.1**	42.1	60.6	61.2	**74.7**	56.7	**70.2**

Table 5: Comparison of our best model and current top models: a **bold** value indicates the best result within the column.

our PRETLARGE achieves $F_{0.5} = 61.3$ on CoNLL-2014. This result outperforms not only all previous single-model results but also all ensemble results except for that by Grundkiewicz et al. (2019).

To further improve the performance, we incorporate the following techniques that are widely used in shared tasks such as BEA-2019 and WMT[13]:

Synthetic Spelling Error (SSE) Lichtarge et al. (2019) proposed the method of probabilistically injecting character-level noise into the source sentence of pseudo data $\mathcal{D}_p$. Specifically, one of the following operations is applied randomly at a rate of 0.003 per character: deletion, insertion, replacement, or transposition of adjacent characters.

Right-to-left Re-ranking (R2L) Following Sennrich et al. (2016a, 2017); Grundkiewicz et al. (2019), we train four right-to-left models. The ensemble of four left-to-right models generate n-best candidates and their corresponding scores (i.e., conditional probabilities). We then pass each candidate to the ensemble of the four right-to-left models and compute the score. Finally, we re-rank the n-best candidates based on the sum of the two scores.

Sentence-level Error Detection (SED) SED classifies whether a given sentence contains a grammatical error. Asano et al. (2019) proposed incorporating SED into the evaluation pipeline and reported improved precision. Here, the GEC model is applied only if SED detects a grammatical error in the given source sentence. The motivation is that SED could potentially reduce the number of false-positive errors of the GEC model. We use the re-implementation of the BERT-based SED model (Asano et al., 2019).

Table 5 presents the results of applying SSE, R2L, and SED. It is noteworthy that PRETLARGE+SSE+R2L achieves state-of-the-art performance on both CoNLL-2014 ($F_{0.5} = 65.0$) and BEA-test ($F_{0.5} = 69.8$), which are better than those of the best system of the BEA-2019 shared task (Grundkiewicz et al., 2019). In addition, PRETLARGE+SSE+R2L+SED can further improve the performance on BEA-test ($F_{0.5} = 70.2$). However, unfortunately, incorporating SED decreased the performance on CoNLL-2014 and JFLEG. This fact implies that SED is sensitive to the domain of the test set since the SED model is fine-tuned with the official validation split of BEA dataset. We leave this sensitivity issue as our future work.

5 Conclusion

In this study, we investigated several aspects of incorporating pseudo data for GEC. Through extensive experiments, we found the following to be effective: (i) utilizing Gigaword as the seed corpus, and (ii) pretraining the model with BACKTRANS (NOISY) data. Based on these findings, we proposed suitable settings for GEC. We demonstrated the effectiveness of our proposal by achieving state-of-the-art performance on the CoNLL-2014 test set and the BEA-2019 test set.

Acknowledgements

We thank the three anonymous reviewers for their insightful comments. We are deeply grateful to Takumi Ito and Tatsuki Kuribayashi for kindly sharing the re-implementation of BACKTRANS (NOISY). Abstract

Multilingual topic models (MTMs) learn topics on documents in multiple languages. Past models align topics across languages by implicitly assuming the documents in different languages are highly comparable, often a false assumption. We introduce a new model that does not rely on this assumption, particularly useful in important low-resource language scenarios. Our MTM learns weighted topic links and connects cross-lingual topics only when the dominant words defining them are similar, outperforming LDA and previous MTMs in classification tasks using documents' topic posteriors as features. It also learns coherent topics on documents with low comparability.

1 Introduction

Topic models explain document collections at a high level (Boyd-Graber et al., 2017). Multilingual topic models (MTMs) uncover latent topics *across* languages and reveal commonalities and differences across languages and cultures (Ni et al., 2009; Shi et al., 2016; Gutiérrez et al., 2016). Existing models extend latent Dirichlet allocation (Blei et al., 2003, LDA) and learn *aligned* topics across languages (Mimno et al., 2009).

Prior models work well because they implicitly assume—even if not part of the model—parallel or highly comparable data with well-aligned topics. However, this assumption does not always comport with reality. Even documents from the same place and time can discuss very different things across languages: in multicultural London, Hindi tweets focus on a Bollywood actor's BBC appearance, French blogs fret about Brexit, and English articles focus on Tottenham's lineup. Generally, corpora have a range of "nonparallelness" (Fung, 2000). In less comparable settings, while some topics are shared, languages' emphasis may diverge and some topics may lack analogs.

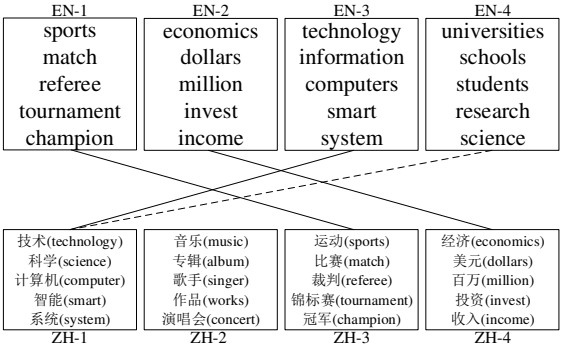

Figure 1: Topic pairs with many word translation pairs have high link weights, e.g., (EN-1, ZH-3) and (EN-2, ZH-4); topic pairs with partial overlap receive lower weights, e.g., (EN-4, ZH-1); a topic is unlinked if there is no corresponding topic in the other language (ZH-2).

We therefore introduce a new multilingual topic model that assumes each language has its own topic sets and jointly learns all topics, but does not force one-to-one alignment across languages. Instead, our MTM learns *weighted* topic links across languages and only assigns a high link weight to a topic pair whose top words have many direct translation pairs (Figure 1). Moreover, it allows unlinked topics if there is no matching topic in the other language. This makes the model robust for (more common) less-comparable data with topic misalignment. Joint inference also allows insights from high-resource languages to uncover low-resource language patterns. It is particularly useful in scenarios that involve modeling topics on low-resource languages in humanitarian assistance, peacekeeping, and/or infectious disease response, while limiting the additional cost to other steps that will also need to be taken, such as finding or creating a word translation dictionary.

We validate the MTM in two classification tasks using inferred topic posteriors as features. Our

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1243–1248, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

MTM has higher F1 than other models in both intra- and cross-lingual evaluations, while discovering coherent topics and meaningful topic links.

2 Multilingual Topic Model for Connecting Cross-Lingual Topics

Yang et al. (2015) present a flexible framework for adding regularization to topic models. We extend this model to the multilingual setting by adding a potential function that links topics across languages. For simplicity of exposition, we focus on the bilingual case with languages S and T.

Unlike Yang et al. (2015) that encode monolingual information only, our potential function encodes multilingual knowledge parameterized by two matrices, $\boldsymbol{\rho_{S\to T}}$ and $\boldsymbol{\rho_{T\to S}}$, that transform topics between the two languages. Cells' values are between 0 and 1 and a cell $\rho_{S\to T,k_T,k_S}$ close to one is a strong connection of topics k_T and k_S in language T and S. Transformations $\boldsymbol{\rho}$ are learned from translation pairs' topic distributions.

These topic distributions come from the assignments of Gibbs sampling (Griffiths and Steyvers, 2004). Fortunately adding the potential function is equivalent to adding an additional term to Gibbs sampling for topic models (Yang et al., 2015). During sampling, each token is assigned to a topic, so we can compute a *post hoc* word distribution over topics. The probability of a topic k given a word w is $\Pr(k \mid w) \equiv \Omega_{w,k} \equiv N_{k,w}/N_w$, where $N_{k,w}$ is the number of times that word w is assigned to topic k and N_w is w's term frequency.

To find good topic links $\boldsymbol{\rho_{S\to T}}$, we use a dictionary. For instance, given the translation pair of "sports" and "运 动 (yùn dòng)", they should have similar topic distributions, so we want $\boldsymbol{\rho}_{\text{EN}\to\text{ZH}}\boldsymbol{\Omega}_{\text{sports}}$ to be close to $\boldsymbol{\Omega}_{\text{运动}}$ and vice versa. Moreover, the transformations should be symmetric: $\boldsymbol{\rho_{S\to T}\Omega_{w_S}}$ close to $\boldsymbol{\Omega_{w_T}}$, and vice versa. We encode this cross-lingual knowledge of topic transformations into the potential function Ψ which measures the difference of translation pairs' topic distributions after transformation:

$$\left(\prod_{c=1}^{C} \|\boldsymbol{\Omega_{S,c}} - \boldsymbol{\rho_{T\to S}\Omega_{T,c}}\|_2^{\eta_c} \, \|\boldsymbol{\rho_{S\to T}\Omega_{S,c}} - \boldsymbol{\Omega_{T,c}}\|_2^{\eta_c}\right)^{-1}, \tag{1}$$

where η_c is the statistical importance of the c-th translation pair to the corpus (Figure 2, full details in the Supplement).

While Yang et al. (2015) provide a blueprint for Gibbs sampling with potential functions without additional parameters, our model has additional parameters of $\boldsymbol{\rho_{S\to T}}$ and $\boldsymbol{\rho_{T\to S}}$ so we need to optimize them. Thus, we use stochastic EM (Celeux, 1985). The E-step updates tokens' topic assignments using Gibbs sampling, while holding the parameters of the topic link weight matrices $\boldsymbol{\rho}$ fixed. The M-step optimizes $\boldsymbol{\rho}$ while holding the topic assignments fixed. We optimize Ψ in log space using the objective function $J(\boldsymbol{\rho_{S\to T}})$ as

$$\sum_{c=1}^{C} \eta_c \log \|\boldsymbol{\Omega_{T,c}} - \boldsymbol{\rho_{S\to T,i_T}\Omega_{S,c}}\|_2 , \tag{2}$$

which is minimized by using L-BFGS (Liu and Nocedal, 1989), with the partial derivatives with respect to $\rho_{S\to T,k_T,k_S}$

$$-\sum_{c=1}^{C} \frac{\eta_c \Omega_{S,c,k_S} \left(\Omega_{T,c,k_T} - \boldsymbol{\rho_{S\to T,k_T}\Omega_{S,c}}\right)}{\|\boldsymbol{\Omega_{T,c}} - \boldsymbol{\rho_{S\to T,i_T}\Omega_{S,c}}\|_2^2}. \tag{3}$$

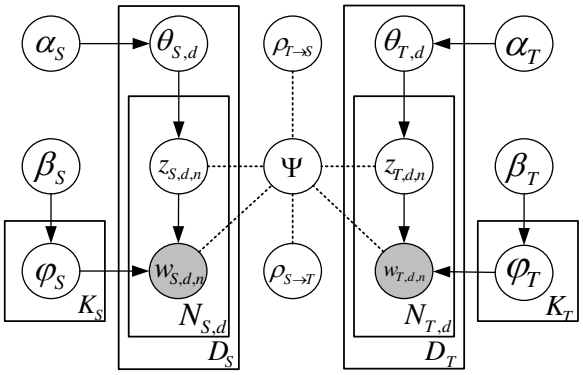

Figure 2: The graphical model of our multilingual topic model. The topic links $\boldsymbol{\rho}$, as instantiated by the function Ψ, encourage topics to encourage word translations to have consistent topics.

3 Experiments

We evaluate our model extrinsically on classification tasks, followed by intrinsic topic coherence.

3.1 Classification with Topic Posteriors

We use two datasets for classification: Wikipedia documents in English (EN) and Chinese (ZH) (Yuan et al., 2018) and an English-Sinhalese (SI) disaster response dataset (Strassel and Tracey, 2016).[1] Each dataset provides labeled documents and a dictionary. Yuan et al. (2018) extract the EN-ZH dictionary from MDBG, while Strassel and Tracey (2016) construct the EN-SI dictionary from online resources and manual annotation.[2] Each

[1] More dataset details in the Supplement.

[2] MDBG: https://www.mdbg.net/chinese/dictionary?page=cc-cedict

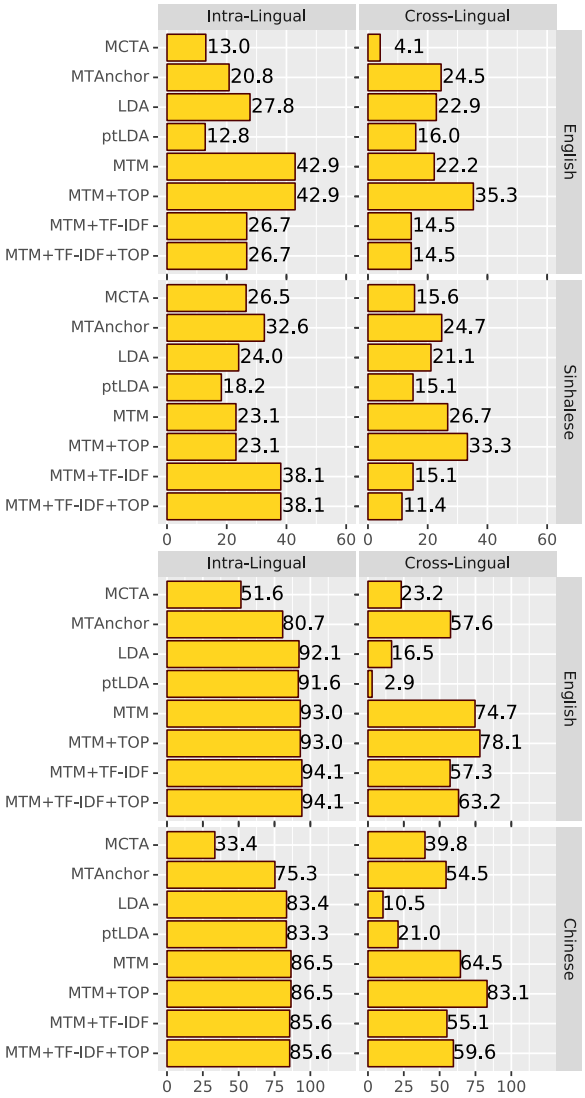

Figure 3: The F1 scores on disaster response (upper) and Wikipedia (lower) datasets. Our MTM outperforms all the baselines in intra- and cross-lingual evaluations.

Wikipedia document is labeled with one of the topics of *film*, *music*, *animals*, *politics*, *religion*, and *food*. A portion of the disaster response documents are labeled with one of eight types of needed rescue resources: *evacuation*, *food supply*, *search/rescue*, *utilities*, *infrastructure*, *medical assistance*, *shelter*, and *water supply*.

We follow Yuan et al. (2018) for preprocessing (such as lemmatization for English and segmentation for Chinese) and use a linear SVM for classification. For the Wikipedia dataset, we report micro-F1 scores on a six-way classification. For the disaster response dataset, our goal is binary classification of the need for *evacuation* versus other assistance. The classification uses features of topic posteriors: $\Pr(k \mid d) \equiv N_{d,k}/N_d$ which is the proportion of the tokens assigned to topic k in document d.

The baselines include polylingual tree LDA (Hu et al., 2014, ptLDA) which encodes the dictionary as a tree prior (Andrzejewski et al., 2009), Multilingual Topic Anchoring (Yuan et al., 2018, MTAnchor), and Multilingual Cultural-common Topic Analysis (Shi et al., 2016, MCTA). We also include LDA, which runs monolingually in each language. We use 20 topics and set hyperparameters $\alpha = 0.1$ and $\beta = 0.01$ (if applicable).

Our evaluations are both intra- and cross-lingual. The intra-lingual evaluation trains and tests classifiers on the same language, while the cross-lingual evaluation trains classifiers on one language and tests on another. In cross-lingual evaluations, MTAnchor, MCTA, and ptLDA align topic spaces, so topic posterior transformation is not necessary. LDA cannot transform topic spaces, so we do not apply any transformation. For our MTM, we explore two transformation methods with $\boldsymbol{\rho}$. The first multiplies $\boldsymbol{\rho}$ with a language's document topic distributions, i.e., $\boldsymbol{\rho}_{\text{ZH}\to\text{EN}}\boldsymbol{\theta}_{\text{ZH}}$ and vice versa. The second (TOP), transfers each document topic's probability mass to the topic in the other language with the highest link weight.[3]

Our MTM has higher F1 both intra- and cross-lingually (Figure 3). TF-IDF weighting on translation pairs sometimes improves the intra-lingual F1, although it hurts the cross-lingual F1. Connecting the top linked topics (TOP) is better than directly using the topic link weight matrices. This indicates that $\boldsymbol{\rho}$'s values have some noise.

3.2 Looking at Learned Topics

Past MTMs align topics across languages but our MTM does not, so we compare the topics across models to see how they differ. We look at the Movies topics from the Wikipedia dataset (Table 1). For the Chinese MTM topics, we show the three English topics with the highest link weights.

The topics are about Movies, but the MCTA and MTAnchor topics do not rank "movie" or "电影 (diàn yǐng)" at the top. The ptLDA topics, although aligned well, incorrectly align some Chinese words. "胶片 (jiāo piàn)" means "*photographic* film", while "释放 (shì fàng)" means *release* as in "let something go", not movie distribution. ptLDA links words based on translations

[3] An example of TOP is available in the Supplement.

[4] In Tables 1 and 2, "[Q]" denotes the Chinese word is a counter for the following English word.

Lang.	Words
	MCTA
ZH	主演 (starring), 改编 (adapt), 本 (this), 小说 (novel), 拍摄 (shoot), 角色 (role)
EN	dog, san, movie, mexican, fighter, novel
	MTAnchor
ZH	主演 (starring), 改编 (adapt), 饰演 (act), 本片 (the movie), 演员 (actor), 编剧 (playwright)
EN	kong, hong, movie, official, martial, box
	LDA
ZH	电影 (movie), 部 ([Q] movie),[4] 美国 (USA), 上映 (release), 英语 (English), 剧情 (plot)
EN	film, star, direct, release, action, plot
	ptLDA
ZH	电影 (movie), 胶片 (film), 星 (star), 动作 (action), 释放 (release), 影片 (movie)
EN	film, star, direct, action, release, plot
	MTM
ZH	电影 (movie), 部 ([Q] movie), 上映 (release), 动画 (animation), 故事 (story), 作品 (works),
EN (.20)	film, direct, star, release, action, plot
EN (.12)	kill, find, death, attack, escape, return
EN (.11)	shrine, japanese, temple, japan, shinto, kami
	MTM + TF-IDF
ZH	电影 (movie), 部 ([Q] movie), 上映 (release), 美国 (USA), 英语 (English), 导演 (director)
EN (.32)	film, direct, star, action, release, plot
EN (.24)	film, kill, find, escape, attack, return
EN (.09)	character, series, star, game, trek, create

Table 1: The Movies topics given by models. For the Chinese (ZH) topics given by MTM, the top three English (EN) topics and their link weights are also given.

without looking at the context, which causes problems with multiple-sense words. The LDA and MTM topics are generally coherent.

The MTM's unique joint modeling of weighted topic links also recovers additional topical structure: after linking respective EN-ZH Movies topics, the next linked topics are Action Movies ("kill", "death", "attack", and "escape"). Further, the models capture a degree of connection between Movies and Computer Games (MTM + TF-IDF) and Japanese Animations (MTM).

3.3 Looking at Learned Topic Links

We give more examples of weighted MTM topic links in Table 2. High-weighted Biology (ZH-0, EN-12, and EN-19) and Music topics (EN-10, ZH-9, and ZH-17) are characterized by cross-lingual words in common. The model can also infer topic links beyond words, linking topics when the topical words have few direct translations but are related in senses. For instance, ZH-14 is about the "campaigns" against "government". Only "government" overlaps with EN-16 and EN-11, but

Lang.	Words
ZH-0	学名 (scientific name), 它们 (they), 呈 (show), 白色 (white), 长 (long), 黑色 (black)
EN-12 (.57)	specie, bird, eagle, genus, white, owl
EN-19 (.13)	breed, chicken, white, goose, bird, black
ZH-14	主义 (-ism), 组织 (organization), 美国 (USA), 革命 (revolution), 运动 (campaign), 政府 (government)
EN-16 (.32)	sex, law, act, sexual, marriage, court
EN-11 (.17)	traffic, victim, government, trafficking, child, force
EN-10	album, release, record, music, song, single
ZH-9 (.30)	专辑 (album), 张 ([Q] album), 发行 (release), 音乐 (music), 首 ([Q] song), 唱片 (record)
ZH-17 (.20)	音乐 (music), 乐团 (musical group), 艺术 (art), 创作 (create), 奖 (award), 演出 (perform)

Table 2: Topics are linked because they have overlap in topical words. Our MTM can also infer the topic relations beyond words, e.g., ZH-14 and EN-16.

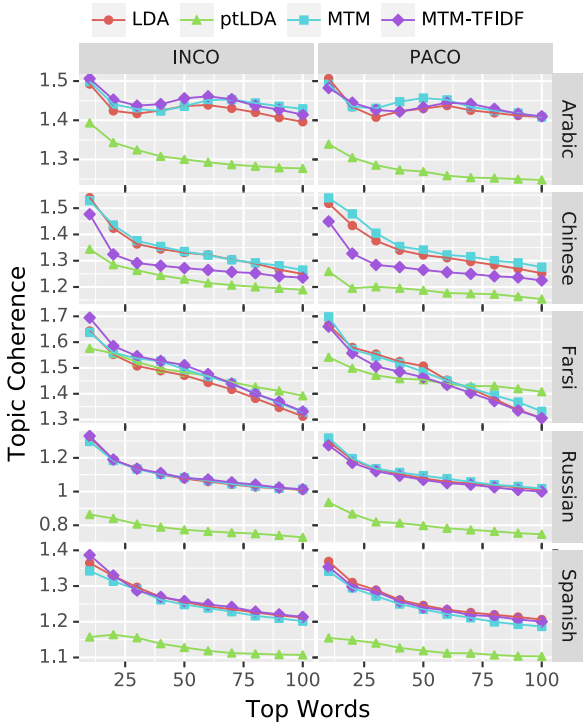

Figure 4: Topic coherence on INCO and PACO datasets with the number of top words in each topic.

MTM identifies the two English topics as the top linked topics for ZH-14: EN-16 is about the "campaign" in Sexual Rights, while EN-11 is about the Crime of human trafficking. This shows that our MTM can incorporate word translations and infer more cross-lingual word and topic relationships.

3.4 Evaluating Topic Coherence

We intrinsically evaluate models' topic coherence on two sets of preprocessed bilingual Wikipedia corpora (Hao and Paul, 2018) that vary in "non-

parallelness". Both pair English with Arabic, Chinese, Spanish, Farsi, and Russian. In PACO, 30% of documents have direct translations across languages, and in INCO none has direct translations. Dictionaries are extracted fromn Wiktionary.[5] Standard preprocessing has already been applied to the datasets, including stemming, stop word removal, and high-frequency word removal.

We use an intra-lingual metric to evaluate topic coherence (Lau et al., 2014): for every topic, we compute its top N words' average pairwise PMI score on a disjoint subset of Wikipedia documents (Hao and Paul, 2018). We report average coherence with N from 10 to 100 with a step size of 10 (five-fold cross-validation). We use the same translation pair weighting options as in our classification tasks and also compare against monolingual LDA and ptLDA (Hu et al., 2014).

MTM is no worse than LDA and sometimes slightly better (Figure 4). TF-IDF weighting on translation pairs sometimes further improves coherence (e.g., Arabic, Farsi, Russian, and Spanish on INCO) but occasionally hurts (e.g., Chinese). ptLDA mostly works poorly, except on Farsi with a high number of top words. ptLDA aligns topic spaces, which is hard for low-comparability data, thus sacrificing coherence for alignment; in contrast MTM only connects topics when they align well in senses.

3.5 Topic Coherence vs. Target Language Corpora Sizes

We next vary the size of target language (non-English languages in PACO and INCO) corpora: how much can MTM help topic coherence for low-resource languages? We start from 10% of the randomly-selected documents in target languages and incrementally add more target language documents at a step size of 10% until it reaches 100%. Meanwhile, we always use 100% of the English documents. We train monolingual LDA, ptLDA, and MTMs with and without TF-IDF weighting on translation pairs on each setting and evaluate the topic coherence on the same reference corpora using the top thirty words of each topic (Figure 5).

In most cases, the topic coherence improves with larger target corpora, except Arabic and Russian on PACO. This confirms our intuition that more data yield a better topic model. MTM is helpful in cases when the target language corpora sizes are small, e.g., Chinese and Russian with 10% or 20% of the corpora. TF-IDF weighting is not consistently better or worse than equal weights.

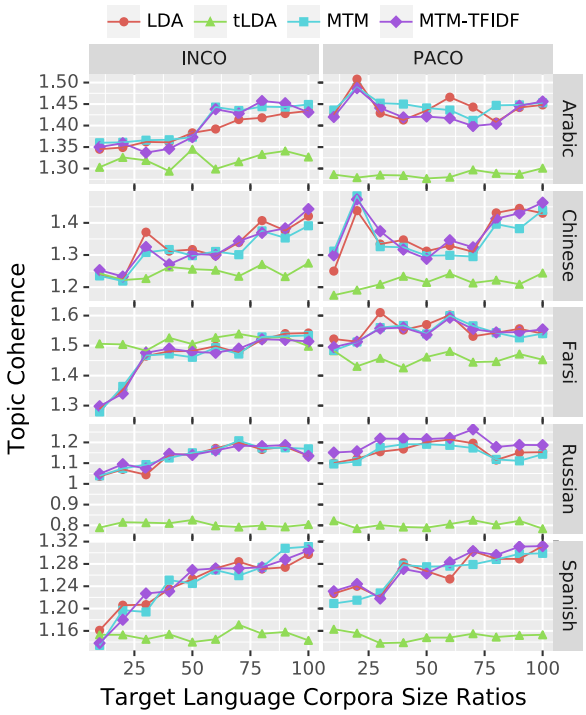

Figure 5: The models' topic coherence on INCO and PACO datasets when the sizes of target language corpora grow from 10% to 100%, with a step size of 10%.

The ptLDA with tree priors based on dictionaries performs poorly in topic coherence, except Farsi in INCO. In most cases, its topic coherence is substantially below others' and improves little when the target corpora grow.

4 Conclusions and Future Work

We introduce a novel multilingual topic model (MTM) that learns weighted topic links across languages by minimizing the Euclidean distances of translation pairs' (transformed) topic distributions, where translation pairs can be weighted, e.g., by TF-IDF. This connects topics in different languages *only* when necessary and is more robust on low-comparability corpora. The MTM outperforms baselines substantially in both intra- and cross-lingual classification tasks, while achieving no worse or slightly better topic coherence than monolingual LDA on low-comparability data.

We plan to explore weighting methods to better evaluate the importance of translation pairs. We will also study how to improve topic transformation with the topic link weight matrices.

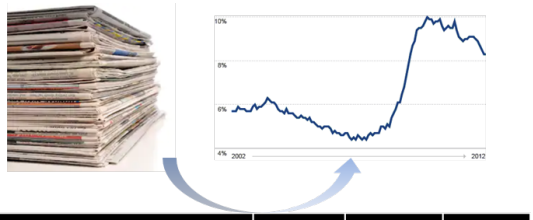
Measure Country-Level Socio-Economic Indicators with Streaming News: An Empirical Study

Bonan Min
Raytheon BBN Technologies
bonan.min@raytheon.com

Xiaoxi Zhao
Department of Economics, Boston University
xiaoxiz@bu.edu



Abstract

Socio-economic conditions are difficult to measure. For example, the U.S. Bureau of Labor Statistics needs to conduct large-scale household surveys regularly to track the unemployment rate, an indicator widely used by economists and policy makers. We argue that events reported in streaming news can be used as "micro-sensors" for measuring socio-economic conditions. Similar to collecting surveys and then counting answers, it is possible to measure a socio-economic indicator by counting related events. In this paper, we propose Event-Centric Indicator Measure (ECIM), a novel approach to measure socio-economic indicators with events. We empirically demonstrate strong correlations between ECIM values to several representative indicators in socio-economic research.

1 Introduction

Socio-economic indicators are powerful instruments for measuring economic conditions and the sociocultural environment that people live in. They are widely used to inform policy makers, and help them to measure outcome of policy interventions. They are often difficult, if not impossible, to measure. Take unemployment rate as an example, the U.S. Bureau of Labor Statistics conducts large-scale household surveys in order to track it. More abstract indicators (e.g. economic uncertainty), which involve vague or complex social interactions, are very difficult to measure accurately.

We hypothesize that streaming news, reporting a vast amount of real-world events, can be used for measuring socio-economic indicators. We propose Event-Centric Indicator Measure (ECIM), a novel approach to measure socio-economic indicators using events extracted from streaming news. We demonstrated that ECIM is effective; ECIM values are strongly correlated with representative socio-economic indicators.

Event triggers	Location	Time	Related*
the U.S. **recession** began in December 2007	U.S. (USA)	December 2007 (2007-12)	Y
SEPT. 1, 2011 The **bankruptcies** of three American solar power companies in the last month	American (USA)	Last month (2011-08)	Y
The man accused of fatally **shooting** his estranged wife inside a New Jersey church last Tuesday	New Jersey (USA)	Last Tuesday (2009-07)	N
…	…	…	

Figure 1: The ECIM workflow. Words in bold are event triggers. Text in parentheses shows normalized locations (countries) and time. "Related" shows whether an event trigger is related to the target indicator (e.g., "unemployment rate") based on keyword matching.

We will first present an overview of the ECIM approach, and then describe how we extract events from text and aggregate them to calculate ECIMs for each socio-economic indicator. We will then present large-scale experiments to demonstrate that ECIM is effective, using several widely used socio-economic indicators.

2 Event-Centric Indicator Measure

The ECIM workflow is summarized in Figure 1. Given a large-scale streaming news collection, the system first extracts event mentions (event trigger words or phrases) along with their locations and time. For each socio-economic indicator, the system will then aggregate relevant events per each time step to produce ECIM, a time series measuring the corresponding socio-economic condition.

2.1 Extract Events from Text

We extract event frames from predicate-argument structures that are automatically generated from

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1249–1254, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

text. Then we extract an event trigger, a location and a time, if available, from each event frame. To attach a location or time that is further away from the trigger (or based on the publishing date), we apply a few inference rules.

Extract Events Syntactic-semantic representations such as Abstract Meaning Representation (Huang et al., 2016) and Semantic Role Labeling (SRL) (Peng et al., 2016; Surdeanu et al., 2003), have been shown to be effective for event extraction. Following (Peng et al., 2016; Surdeanu et al., 2003), our event extractor is based on tagging predicates (verbs and eventive nouns) and their locations and temporal arguments.

We first apply SRL (Punyakanok et al., 2004; He et al., 2017) over each sentence. An example SRL representation on a sentence is shown in Figure 2. From the predicate-argument structure, the system then extracts the predicate as an event trigger [1], the entity mention and time mention attached to the predicate through AM-LOC and AM-TMP as the location and time for the event respectively. The location is resolved to a country-level GPE by looking up part-of relations in GeoNames [2] (e.g., convert "Boston" into "U.S."). Our system also normalizes time mentions into Timex2 (Ferro et al., 2001) and resolves relative time (e.g., *last Tuesday*) into Timex2, based on the document publishing date. This process extracts an event mention in the form of a triple <trigger: *clashed*, location: Syria, time: 2018-11-23> from the sentence in Figure 2.

Figure 2: An SRL representation of a sentence.

Find relevant event triggers Given an indicator, we use the following approach to find a set of relevant event trigger words/phrases:

- We process a development corpus (500 documents from the English Gigaword [3]) with the above-mentioned approach to extract all event triggers, and then ask an annotator to find trigger words for the target indicator, starting with the most frequent trigger.
- We then use WordNet (Miller, 1995) synsets to automatically expand the trigger word list. We also use word embedding similarities to search for new trigger words that are most similar (e.g., using cosine similarity) to the centroid of existing triggers.

An annotator then reviews the expanded triggers and removes incorrect ones. The whole process [4] takes less than 10 minutes per indicator. Example triggers for three representative indicators are listed in Table 1.

To tag event mentions, we match the predicate to the relevant keyword list [5], constructed using the processed described above.

Infer location and time Locations are crucial for identifying whether events are related to the country of interests. Time is necessary for binning events by time steps for counting. Extracting time and locations for event triggers can be challenging if they are further apart from the trigger. Oftentimes no location or time is mentioned in the same sentence where the event is stated.

To increase the coverage of location and time for events, we apply the following inference rules:

- *Same-sentence*: if the event extractor doesn't find a location or a time, but there is one and only one location (an entity mention with type GPE or Location), and/or one and only one time mention in the same sentence, it will attach the location and/or time to the event.
- *Document metadata*: A news article often come with a publishing date and a location. When neither the extractor nor the *same-sentence* rule found a location or a time for an event, we will attach the publishing location and/or date to the event.

2.2 Measure Socio-economic Indicators

We filter events by location (target country) and then use the following steps to calculate ECIM:

- *Aggregation and counting*: We bin events by time step [7]. For each time step t and event $e \in$

[1] We expand nouns into their base noun phrases.
[2] https://www.geonames.org/
[3] https://catalog.ldc.upenn.edu/LDC2011T07
[4] We used the UI described in (Chan et al., 2019) to facilitate this process.
[5] The keyword list is available at https://github.com/BBN-E/ecim.
[6] https://en.wikipedia.org/wiki/VIX
[7] One month is used as the time step, since not all numeric indices come with higher-frequency data for validating our approach.

Indicator	Event triggers	Text
Unemployment rate	*unemploy, layoff, dismissal, lay off, economic crisis, bankrupt*	*Apple to* **lay off** *190 employees from self-driving car unit.*
CBOE Volatility Index (VIX) [6]	*sell share, liquidate, scandal, debt, loan* & (events for EPU)	*Humana executives* **sell** *nearly 74000 shares worth $22.7 million.*
Economic Policy Uncertainty (EPU)	*economic slowdown, institutional weaknesses, war, crisis, terrorist attack*	*These policies and other* **institutional weaknesses** *continue to undermine prospects for sustained economic development*

Table 1: Indicators, examples of event triggers (words or phrases) and sentences

$\mathbb{E}_i$ ($\mathbb{E}_i$ is the set of events for indicator i), we then generate count $N_{e,t}$. For each indicator i, we aggregate the counts: $\sum_{e \in \mathbb{E}_i} N_{e,t'}$.

- *Normalizing counts*: Those counts are not normalized and can be inflated due to the increasing level of media activity. To normalize, we divide them by the total number of articles published in each month M_t.

- *Smoothing*: To remove noise, we smooth the normalized counts by calculating moving averages [8] centered around each t with a window of $T = 7$ time steps [9].

In summary, ECIM for indicator i at time t is defined as

$$ECIM_{i,t} = \frac{1}{T} \sum_{t' \in [t-\frac{T}{2}, t+\frac{T}{2}]} \frac{\sum_{e \in \mathbb{E}_i} N_{e,t'}}{M_{t'}}$$

3 Experiments

We use the English Gigaword corpus [10], which consists of 5.7 million articles published from 1994 to 2010, from a wide range of sources including the New York Times, the Associated Press, Los Angeles Times, Washington Post, Agence France-Presse, Central News Agency of Taiwan, and Xinhua News Agency.

We run event extractors on this corpus to extract over 10 million event mentions that happen in the U.S. from 1994 to 2010. We then generate ECIMs for 3 representative socio-economic indicators: (1) Unemployment rate—a crucial index of economy and for policy making, (2) Chicago Board Options Exchange (CBOE) Volatility Index (VIX) —a widely-used market volatility measurement, and (3) Economic Policy Uncertainty (EPU) (Baker et al., 2016)—a policy uncertainty index. We focus on these 3 indicators because (1) they are widely used in economics and social science research, and (2) their data are publicly available [11].

Figure 3 shows the time series of ECIMs (blue solid lines) and that of the 3 corresponding indicators (red dash lines):

Unemployment rate: The downward/upward trends and the peaks of the two lines match each other quite well. This shows the ECIM is correlated with unemployment rate. There are some delay between peaks and downward trends shown in the line for unemployment rate: not surprisingly, unemployment rate reacts to events such as "economic downturn" with delay, and its recovery takes longer time than media coverage on "economic downturn" events. Among the events detected, our system found many events that can be labeled as "economic downturn" (e.g., "recession", "depression", "financial crisis") or "bankruptcy" (e.g., "bankrupt"). This matches our intuition that economic downturn and more bankruptcies are often correlated with higher unemployment rate (Reinhart and Rogoff, 2009).

VIX: Figure 3 shows that the ECIM matches very well with VIX over time. We found that high market volatility is strongly correlated with unfavorable macroeconomic events such as "economic crisis", firm-level events such as "bankruptcy", as well as its after effects such as "loan".

EPU: The ECIM strongly correlates with EPU. Similarly, economic crisis, which often led to high economic policy uncertainty, is found to be among events the most frequently detected. In addition, our system found extreme events such as "attack", "conflict", and "terrorism" which may trigger major changes of economic policy. The slight deviation in 2003-2004 is caused by low-coverage of

[8] https://en.wikipedia.org/wiki/Moving_average

[9] Other window sizes generate similar results. Due to space limitation, we only present results using 7 time steps.

[10] https://catalog.ldc.upenn.edu/LDC2011T07.

[11] We downloaded these three datasets from Federal Reserve Economic Data, CBOE, and EPU websites, respectively. For VIX which is available daily, we generated monthly averages. The cleaned version of the time-series data is available at https://github.com/BBN-E/ecim.

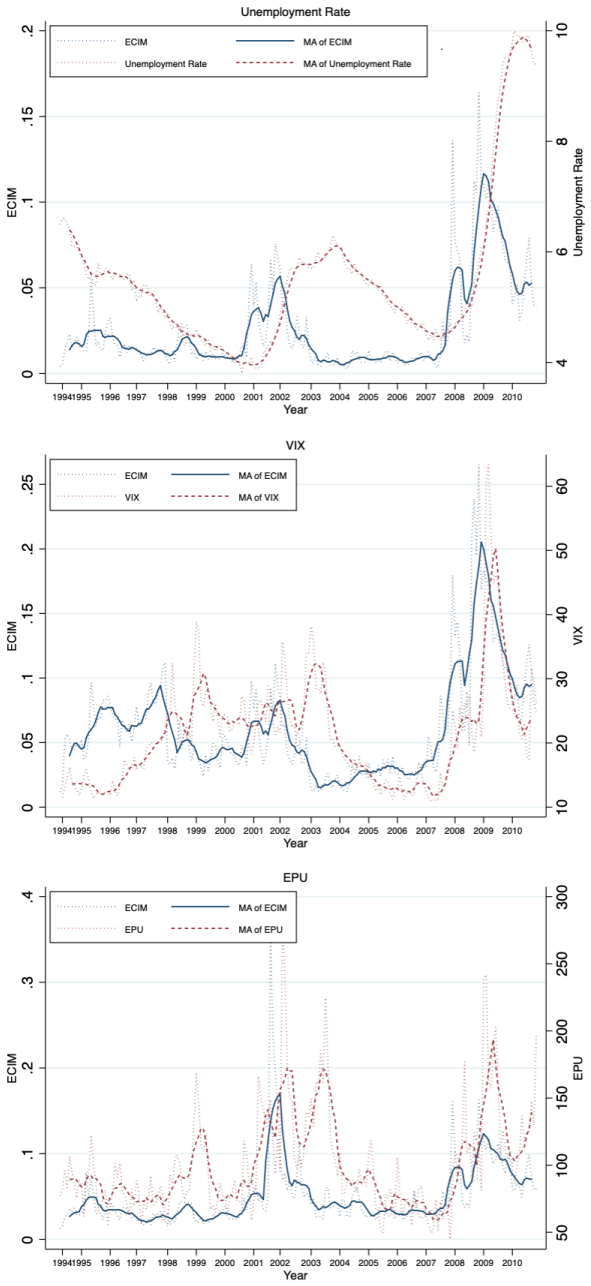


Figure 3: Values of ECIMs (blue solid lines) and the 3 corresponding socio-economic indicators (red dash lines) unemployment rate, VIX and EPU through time. Blue solid lines show ECIMs. Dotted lines show unsmoothed values. Solid and dash lines show the moving average (MA) which are smoothed values. X-axis is the year. Left Y-axis is for the ECIM value. Right Y-axis is for the indicator.

the Iraq War in Gigaword.

Table 2 shows quantitative correlation analysis between ECIMs and their corresponding indicators. Pearson correlation coefficients[12] show strong correlation between these two for each indicator. We also test the hypothesis that ECIMs and their corresponding indicators are independent (p-value is shown in the third column). For all three indicators, we are 99.99% confident to reject the hypothesis of independence.

[12] en.wikipedia.org/wiki/Pearson_correlation_coefficient

Indicator	Pearson	P-value
Unemployment rate ($1/\mathbb{M}_{comp}$)	0.4286 (0.4877)	0.0000 (0.0000)
EPU News	0.5136	0.0000
VIX	0.4115	0.0000

Table 2: Correlation coefficients between ECIMs and indicators. For unemployment rate, we also show its correlation with $1/\mathbb{M}_{comp}$ (in parentheses).

On negative correlation We further study negative correlation between some events and indicators. We hypothesize that "Competition" is positively correlated with more participants in a market, therefore a higher demand for labor which means lower unemployment rate. We construct an ECIM $\mathbb{M}_{comp}$ for "Competition" and then plot $1/\mathbb{M}_{comp}$ over time against unemployment rate. It is important to note that we use $1/\mathbb{M}_{comp}$ to flip the line for "Competition" upside down, so that the better the two lines aligns with each other, the more these two are negatively correlated.

Figure 4 shows a strikingly high negative correlation between "Competition" and unemployment rate. The correlation coefficients between unemployment rate and $1/\mathbb{M}_{comp}$ are also very high as shown in the parentheses in the first row of Table 2. This points to a promising future direction: it is possible to measure an indicator using an event that occurs more frequently when the value of the indicator is low.

4 Related Work

Most prior work on constructing or measuring indicators(Bansal et al., 2005; Jurado et al., 2015; Bachmann et al., 2013) is in social or economic science research. Recent work (Dzielinski, 2012; Alexopoulos and Cohen, 2015; Baker et al., 2016) tries to incorporate text into economic research with keyword-based approaches. Similar to ECIM, EPU (Baker et al., 2016) applies a keyword-counting approach (with keywords "economic", "policy" and "uncertainty") to measure economic policy uncertainty. In contrast, this paper uses the richer information from syntactic-semantic analysis of text. Furthermore, EPU uses

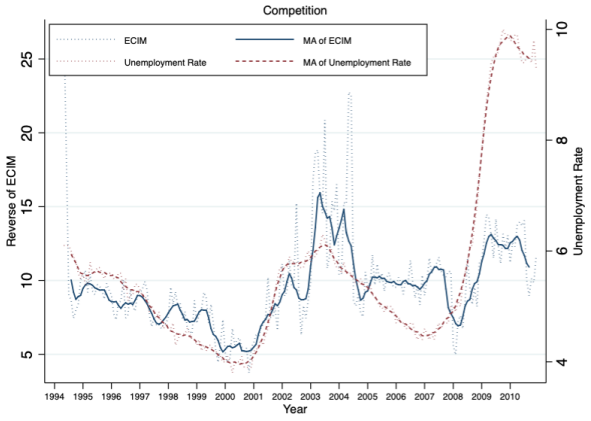

Figure 4: Values of $1/\mathbb{M}_{comp}$ (blue solid line), in which $\mathbb{M}_{comp}$ is the ECIM for "Competition", and unemployment rate (red dash line), through time.

the aggregated sentiment (by counting the number of times people expressed their views on economic policy uncertainty) as the measure, but we use a more objective approach which measures events that are correlated to the uncertainty.

(Rohlfs et al., 2016) applied supervised topic modeling to measure the effects of Federal Open Market Committee text content on the direction of short- and medium-term interest rate movements.

5 Conclusion and Future Work

This paper presents ECIM, a novel approach to measure socio-economic indicators with news events. Experiments show strong correlations between ECIM values and representative indicators in socio-economic research.

Our next steps are to further study the correlation with time lags, and to incorporate more sophisticated event extraction techniques.

Abstract

We introduce a new dataset consisting of natural language interactions annotated with medical family histories, obtained during interactions with a genetic counselor and through crowdsourcing, following a questionnaire created by experts in the domain. We describe the data collection process and the annotations performed by medical professionals, including illness and personal attributes (name, age, gender, family relationships) for the patient and their family members. An initial system that performs argument identification and relation extraction shows promising results – average F-score of 0.87 on complex sentences on the targeted relations.

1 Introduction

Individual family history is an important medical tool for diagnosis, disease prevention and treatment. Macro analyses of family histories provide useful and important information for determining disease susceptibility by researching genetic influences between family histories and diseases. This can be used to determine levels of risk for certain illnesses for a given family member, and potentially develop a protocol of preventative screening. In-person appointments with genetic counselors are time-consuming and suffer from limitations such as long wait times and small number of genetic counseling centers (Sutphen et al., 2010; Nathan et al., 2016). Moreover, collecting a patient's family history away from pressured consultation environment results in more accurate and complete information (Nathan et al., 2016).

An interesting solution would be the deployment of a dialog agent to collect such data. The interaction between the agent and the patient can vary between two extremes: (a) pose very specific questions about each member of the family and their history – difficult because of the need to identify very clearly the family relations in real time during the interaction, but easier because the answers will be short and focused; (b) a system that asks more generic questions, and elicits more narrative answers from the patients – easier because the interaction with the patient is more generic and does not have to be adjusted in real time, but harder because the elicited answers are longer and more free-form. To support research in this area, we choose to explore the second end of the spectrum, which favours a simpler interaction and more intense processing for relation extraction. We introduce a dataset consisting of free-form natural language responses to a medical cancer family history questionnaire created by experts in the domain. The dataset consists of 20,774 annotated relations (illness, name, age, gender, family relationships) in 228 family histories answering 159 questions each, collected through crowdsourcing or as test cases of genetic counseling sessions. The collected questionnaires were extensively annotated by genetic counseling professionals – medical staff and students from the University of Michigan – by identifying family relations, illnesses and person attributes (name, age, gender, family relationships) for family members, to construct complete family history records.

Due to its potentially high impact, extracting family history from clinical notes, admission reports, or questionnaires specifically designed to elicit this type of information is an important area of research (Lewis et al., 2011; Bill et al., 2014; Goryachev et al., 2008). The specific data used in previous studies focused on different types of attributes/relations, and were not made available for further research, even though some used synthetically produced clinical notes.

The dataset we collected and the annotations

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1255–1260, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

are publicly available[1]. We also provide a baseline system for relation extraction, which identifies relation arguments and the relation between them using a neural network with a CRF layer to produce attribute annotations, and then a simple neural network for binary classification of relations. The system achieves 0.87 average F-score when trained on data form both crowd-sourcing and genetic counseling sessions.

2 Related Work

The scope and approach to extracting relations related to family illness history from clinical notes is varied, and relied on small annotated datasets which have not been shared.

From a corpus of synthetically produced clinical notes (MTSamples), Bill et al. (2014) identify 284 sentences as containing family history. Attributes (vital status, negation, etc.) are annotated by medical and informatics experts. Identifying the relation and its arguments relies on a combination of heuristics and learning based on lexicalized features. Goryachev et al. (2008) use association rules to find family members and their illness history (a pre-specified set of 8 illnesses) in discharge summaries and outpatient visit notes. The system is run on 2000 reports randomly selected from 4 different hospitals' clinical notes. 1000 of the relations detected by the system were manually inspected for evaluation. Lewis et al. (2011) rely on grammatical dependencies and patterns of dependency sequences to detect family history information, constraining one of the arguments of a relation to express a family member (e.g. mother, brother). The system is trained on 299 sentences, 77 of which contained 167 person-diagnosis pairs. Rama et al. (2018) iteratively develop an annotation schema and a synthetic corpus of clinical notes in Norwegian for family history annotation and extraction. They produce a corpus of 477 sentences, with 4154 entities and 2078 relations. Entity detection and relation extraction are performed separately, using an SVM with lexical, POS and dependency features.

These approaches rely on heuristics to detect the arguments of relations: use a predefined list of family relationships and diseases, or use as arguments the noun phrases that are detected close to the suspected relationship markers. Finding relation arguments is difficult because of their variable length. Sequence labelling approaches have proved successful for such problems (Ramshaw and Marcus, 1995; Lample et al., 2016; Ma and Hovy, 2016; Chiu and Nichols, 2016). On the relation extraction side, the recently developed deep learning approaches have also proved useful, by successfully combining information about the meaning of the arguments, their context and their grammatical connections (Zeng et al., 2014; Liu et al., 2015; dos Santos et al., 2015). Determining the relation arguments and the relation itself depend on each other, so it would be beneficial to have an approach that performs these two tasks jointly (Miwa and Bansal, 2016).

Zheng et al. (2017) propose a new tagging scheme for relations in a text, and use an encoder-decoder LSTM-based model to predict for an input sentence the tags that combine relation and argument information. We will use a similar tag set, but in a two step approach.

3 Dataset

Our dataset consists of answers to a family history questionnaire collected from volunteers through Amazon Mechanical Turk (AMT) and from test cases of genetic counseling sessions (GCS).[2] This questionnaire has been developed by cancer genetic counseling experts to construct a patient's medical history (Wattendorf and Hadley, 2005). It consists of 159 questions targeting the medical history of the patient and their relatives up to third degree (including the patient's great-grandparents and cousins). Some questions require a brief and precise answer ("what is your age?"), while the majority are open-ended ("Please describe each of your health issues or problems.") Our final dataset contains 228 questionnaire responses, 156 from AMT and 72 from GCS. In the next step the dataset will be annotated by experts with information relevant to medical histories.

	AMT	GCS	Total
# questionnaires	156	72	228
# sentences	2,993	1,311	4,304
# tokens	30,700	11,131	41,831

Table 1: Dataset size statistics

[1] http://lit.eecs.umich.edu/downloads.html

[2] Our study was exempt from IRB because the contributors were anonymous. Moreover, the family histories reported do not necessarily reveal real patient information.

My brother is named Michael, he is 42. I have two sisters, Lydia who is 38 and July who is 36.

```
My <ft id=1 rel=brother gender=male>brother</ft> is named <ft id=1 name=Michael
    >Michael</ft>, he is <ft id=1 age=42>42</ft>. I have two <ft id=2,3 rel=
    sister gender=female source=self>sisters</ft>, <ft id=2 name=Lydia>Lydia</
    ft> who is <ft id=2 age=38>38</ft> and <ft id=3 name=July>July</ft> who is
    <ft id=3 age=36>36</ft>.
```

My niece Alicia has Asthma.

```
My <ft id=1 rel=niece gender=female>niece</ft> <ft id=1 name=Alicia>Alicia</ft>
     has <ft id=1 illness=asthma>Asthma</ft>.
```

Figure 1: Sample annotations

Annotations. We worked with genetic counseling experts to define the set of annotations that would enable them to construct a patient's medical history: (i) all the persons in one's family tree; and (ii) the attributes associated with a person. We target the following five annotation types: *FT* (family tree member), *name, age, gender, illness* along with their attributes, shown in Table 2. Every family member is assigned a unique *ft_id*, which is used to connect all their information throughout the questionnaire. A person can have several health issues, so each illness is assigned an *ill_id*, which is unique when combined with *ft_id*. If an illness is a cancer, a cancer flag is set to true and a cancer type is selected from a list of 23 cancer types. To handle complex cases as in the phrase *both cousins suffered from high blood pressure*, every annotation can refer to multiple *ft_ids* and *ill_ids*.

Type	attributes
FT	ft_id, parent_id_1, parent_id_2, deceased {T/F}
Name	ft_id
Gender	ft_id, sex: {male/female/unknown}
Age	ft_id, age_at_diagnosis {T/F}, age_at_death {T/F}
Illness	ft_id, ill_id, cause_of_death {T/F}, cancer {T/F}, cancer_type {23 types}

Table 2: The annotation types included in our dataset with their corresponding attributes.

Each questionnaire response is manually annotated by a genetic counseling expert, using Brat to facilitate the annotation process (Stenetorp et al., 2012).[3] Figure 1 shows an annotation example.

[3]To ensure the quality of our questionnaires, we discard questionnaires that contain spam responses and the ones in which the patients did not use proper natural language to answer such as (e.g. "Mary/f/20").

To evaluate the quality of the annotations, four full questionnaires were annotated by two judges. The Cohens Kappa inter-annotator agreement score for these questionnaires for annotation types and their corresponding attributes is 0.8908, showing high agreement.

The final dataset consists of 4,304 sentences of various complexity w.r.t. the relations included – "simple sentences" containing information about a single family member, and "complex sentences" containing information about two or more family members. (Table 3).

	Simple sentences		Complex sentences	
	#sent	#rels	#sent	#rels
AMT	2413	7069	520	7374
GCS	453	1409	803	4923
Total	3214	8477	973	12,297

Table 3: Sentence and relations statistics

The two data subsets (AMT, GCS) were obtained using the same questionnaire, but they are slightly different. Compared to the GCS data which contains about twice as many complex sentences as simple ones, the AMT data contains approx. five times more simple sentences than complex ones. However, AMT's complex sentences are much denser in information than the complex sentences in the GCS data – 14.2 vs 6.1 relations per sentence.

Table 4 shows the overall annotation statistics.

4 Relation Extraction

To evaluate the viability of our annotations, we develop a pipeline for relation extraction, illustrated in Figure 2. It works in two steps: (i) argument (entity/attributes) identification and (ii) relation classification. We split our dataset into

Annotation type	AMT	GCS	Total
# FT	2,633	1,128	3,761
# Name	1,640	1,225	2,865
# Gender	879	601	1,480
# Age	1,094	914	2,008
# Illness	1,636	441	2,077
# cancer	428	346	774
# age at diagnosis	645	179	824
# age at death	206	156	362
# cause of death	478	227	705
# relations	14,443	6,322	20,774

Table 4: Annotation types, attributes, and relations statistics.

train, validation, and test based on the questionnaire identifier (Table 5). Every sentence in our data is tokenized and part-of-speech tagged using Stanford CoreNLP (Manning et al., 2014). Our pipeline processes an input sentence in two steps. First, we tag every token with its corresponding annotation type, including entities and attributes, using the IOB (Inside, Outside, Beginning) tagging scheme. The tagged sentence is then passed to a binary relation classifier to classify the relations between every pair of entities in this sentence. Figure 2 shows an overview and an example of our model. The two steps of the pipeline are detailed below.

	AMT			GCS		
	train	val	test	train	val	test
#questionnaires	91	15	50	45	7	20
#sentences	1574	372	1047	893	151	267

Table 5: Data distribution in each split.

Entity Identification. We model entity identification as a sequence labeling problem using a conditional random field (CRF) classifier.[4] [5] The set of labels used consist of the annotation labels (Table 2) combined with the IOB markers (Inside, Outside, Beginning).

The model is trained using the following features:

Lexical: current word and words in context window of size 3

Part-of-speech: POS tags of current word and words context window of size 3

Binary features: is beginning of sentence, starts with capital letter, is digit

[4] sklear-crfsuite (Okazaki, 2007)

[5] Only the results of the best classifier are reported, but we experimented with other classifiers including logistic regression and BiLSTM-CRF.

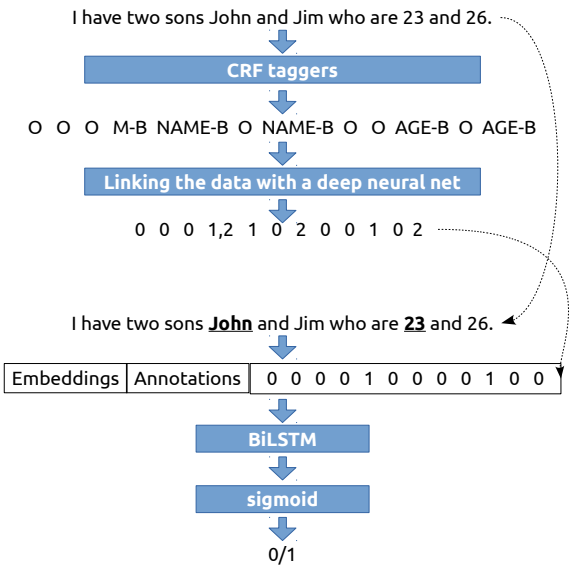

Figure 2: Method pipeline

Relation Classification The entity identification step outputs entity type tags for every token of a given sentence, as illustrated in Figure 2. We model the relation classification between entities as a binary classification task. Each sentence is used to produce positive and negative instances for the relations it contains. For example, the sentence `I have two sons John and Jim who are 23 and 26.` will produce two positive instances: *(John, age, 23)* and *(Jim, age, 26)*. Negative instances are produced by pairing up unrelated arguments (e.g. *(John, age, 26)*).

We train a bi-directional LSTM classifier for this task and fine-tune the parameters using the validation set. The model is trained using the following feature representation:

Word embeddings: we use pretrained 300 dimensional Glove embeddings (Pennington et al., 2014)

Position features: binary flag representing the position of the target entities

Annotation: the tag of the token from the entity identification step.

5 Results

The system is trained on training data from both sources (AMT and GCS), and is evaluated on the test data. Since the relation classification model relies on the output of the entity identification model, we evaluate it using the automatically detected entities. Table 6 shows the performance of

the tagger and relation classifier on the test set. We further analyze the performance of the relation classifier in two scenarios: i) when the sentence includes information regarding a single person; and ii) when a given sentence includes information about two or more different persons. In the former case, the relation classifier achieves 0.98, 0.97, and 0.98 for precision, recall, and F-score respectively, while in the latter case, it achieves 0.83, 0.91, and 0.87 for the same metrics.

	Precision	Recall	F-score
Name	0.833	0.882	0.857
Gender	0.865	0.884	0.874
Age	0.874	0.877	0.875
Age at diagnosis	0.756	0.674	0.713
Age at death	0.746	0.423	0.540
Illness	0.842	0.784	0.812
Cancer	0.889	0.856	0.872
Cancer type	0.839	0.737	0.775
Cause of death	0.737	0.569	0.642
Relation	0.913	0.954	0.933

Table 6: The precision, recall, and F-score of our models for entity and relation classification.

Because the two subsections – AMT and GCS – are slightly different despite being obtained using the same questionnaire (see Table 3), we test whether this difference influences the relation extraction models. We evaluate models trained using training data from one source and tested using data from the other source. A robust model should be able to detect and extract the targeted relations even when they appear in sentences of different structure and complexity. This would be reflected in close results on its own (same as training) or the other subset's test data. Table 7 shows the results in terms of accuracy for the various experimental set-ups. The results reflect the difference between the two subsets: the results on the GCS data fluctuate more (between 0.79 and 0.94 accuracy) when the AMT or the GCS data is used for training, while AMT is rather stable (0.86 – 0.89 accuracy). Using all available training data leads to best results on both test subsets, for both simple and complex sentences.

Test data	Simple	Complex	All
AMT training data			
AMT	0.99	0.78	0.89
GCS	0.99	0.76	0.79
AMT + GCS	0.99	0.77	0.88
GCS training data			
AMT	0.96	0.76	0.86
GCS	0.97	0.94	0.94
AMT + GCS	0.96	0.82	0.87
AMT & GCS training data			
AMT	0.99	0.90	0.95
GCS	0.98	0.94	0.95
AMT + GCS	0.99	0.91	0.95

Table 7: Accuracy of models trained and evaluated on different parts of the dataset. We report the results on simple, complex, and all sentences.

6 Conclusions

We have presented a dataset of natural language answers to a questionnaire designed to obtain a patient's medical history. The questionnaire, designed by medical professionals, contains 159 questions. We obtained answers through crowdsourcing and from sessions with a genetic counselor. The data was annotated by medical professionals with attributes and relations relevant to constructing a patient's medical history. The dataset consists of 228 questionnaire answers, covering 20,447 annotations. Relation extraction experiments using a two step system – entity identification and relation classification – show high performance on the task, further confirming the quality and usefulness of the annotations.

To our knowledge, this is the largest dataset of medical family history that has been developed so far. The dataset and the relation extraction system will both be made available to the community, to foster research in extracting relations to construct family medical histories.

The dataset introduced in this paper is publicly available from `http://lit.eecs.umich.edu/downloads.html`.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable comments and suggestions. We would also like to thank Quincy Davenport and our genetic counseling experts Professor Elena Stoffel, Professor Monica Marvin, Erika Koeppe, and Kara Milliron, who helped us with the construction of this dataset.

Multi-task Learning for Natural Language Generation in Task-Oriented Dialogue

Chenguang Zhu **Michael Zeng** **Xuedong Huang**

Microsoft Speech and Dialogue Research Group, Redmond, WA, USA
{chezhu, nzeng, xdh}@microsoft.com

Abstract

In task-oriented dialogues, Natural Language Generation (NLG) is the final and crucial step to produce user-facing system utterances. The result of NLG is directly related to the perceived quality and usability of a dialogue system. While most existing systems provide semantically correct responses given goals to present, they struggle to match the variation and fluency in the human language. In this paper, we propose a novel multi-task learning framework, NLG-LM, for natural language generation. In addition to generating high-quality responses conveying the required information, it also explicitly targets for naturalness in generated responses via an unconditioned language model. This can significantly improve the learning of style and variation in human language. Empirical results show that this multi-task learning framework outperforms previous models across multiple datasets. For example, it improves the previous best BLEU score on the E2E-NLG dataset by 2.2%, and on the Laptop dataset by 6.1%.

1 Introduction

Natural Language Generation (NLG) is the final procedure in the pipeline of task-oriented dialogues. As the result of NLG is directly facing users, its readability and informativeness have a direct impact on users' perception of the entire dialogue system. On one hand, the response must contain the desired information, referred to as *meaning representation* (MR), in order to provide or request a user's information. On the other hand, the system response needs to mimic the fluency and variation in human language to improve the user experience. To this end, there have been numerous studies on methods to generate natural responses for task-driven dialogues.

Early work primarily employ predefined rules or syntax (Cheyer and Guzzoni, 2014; Langkilde and Knight, 1998). Though these frameworks can provide adequate information, their lack of naturalness and variation in language make the response rather rigid. Moreover, these methods usually require non-trivial manual work to create templates, rendering them unscalable across domains.

Recently, corpus-based methods have gained considerable popularity in natural language generation (Wen et al., 2015a,b; Dušek and Jurčíček, 2016). With the increasing availability of rich dialogue task data, corpus-based frameworks design end-to-end trainable systems. With minimum human effort, these methods directly learn the pattern and styles of human responses from the data, while conveying the required task-specific meaning representation information. Furthermore, the booming of deep learning technology in natural language processing increases these models' capacity to generate sophisticated human-like responses. For instance, Dušek and Jurčíček (2016) employs sequence-to-sequence structure and attention mechanism to generate response tokens from the MR sequence. Wen et al. (2015b) uses a semantic control vector integrated into an LSTM to guide the response generation process. Li et al. (2015) uses maximum mutual information as objective function to generate diverse and appropriate responses. Wen et al. (2016) proposes data counterfeiting to reduce the complexity of transferring trained parameters across multiple domains. However, it still remains a challenge in task-oriented dialogue systems to generate truly natural utterance indistinguishable from a human's response.

On the other hand, language modeling is a technique typically employed to learn language patterns from text. It has been successfully used to generate natural and semantically sound utterances for text summarization, speech recognition and other NLP tasks (Roark et al., 2004; Rush

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1261–1266, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

et al., 2015). As task-oriented dialogue datasets usually contain rich human responses, leveraging language modeling has a great potential to boost an NLG model's capacity to mimic human language.

Due to recent successes of multi-task learning in NLP (Collobert et al., 2011; Xu et al., 2018), we propose a multi-task scheme to tackle natural language generation in task-oriented dialogues. For the NLG task, we employ a sequence-to-sequence framework. The decoder uses an attention mechanism to carry over information from the encoder on an MR sequence. Therefore, the NLG task generates response conditioned on input MR.

The primary contribution of our work is to incorporate a language modeling task on human-generated responses as an *unconditioned* complementary process that brings in more language-related elements, without the intervention of required MR information. Furthermore, the unsupervised nature of language modeling means we do not need additional labelled data. Thus, under multi-task learning framework, we simultaneously train the NLG and language modeling tasks. To facilitate multi-task learning, we carry out language modeling task in decoder and it partially shares parameters from the NLG task.

To evaluate the effectiveness of our model, NLG-LM, we conduct evaluation on 5 task-oriented dialogue NLG tasks: E2E-NLG (Novikova et al., 2017), TV, Laptop, Hotel and the Restaurant datasets (Wen et al., 2015b, 2016). NLG-LM achieves new state-of-the-art results on all 5 datasets. For example, it outperforms Slug (Juraska et al., 2018), the best model in E2E-NLG competition, by 2.2% in BLEU score. Ablation studies show that the introduction of language modeling task during training can improve the result by 2.4% in BLEU score on average.

2 Problem Description

In task-oriented dialogues, the natural language generation (NLG) process is to produce system utterances as natural language, given system-generated meaning representations from previous steps in the pipeline. Each MR is a slot-value pair, where the slot indicates the category of the information to convey and the value represents the content. For example, *(area, city south)* is a meaning representation and the corresponding utterance should indicate city south as area information.

In addition to meaning representation, *dialogue acts* (DA) are given to differentiate between different types of system actions. Typical examples of dialogue acts include *inform*, *request* and *confirm*. For a given meaning representation, the NLG process should generate different utterances for different dialogue acts. For instance, *confirm* dialogue act usually leads to system response starting with "Let me confirm" or "Correct me if I'm wrong".

In task-oriented dialogues, NLG is framed as a supervised learning problem. Given training data $\{(d_i, r_i, u_i)\}$, where d_i is the dialogue act, $r_i = \{(s_1, v_1), (s_2, v_2), ..., (s_k, v_k)\}$ is the set of meaning representations, and u_i is a sample utterance generated by human labellers, the goal is to generate utterance u given a new pair of dialogue act d and meaning representations r.

As certain types of meaning representation contain entities like location names and product types that are usually proper nouns, we use the *delexicalization* technique to replace values with a special slot token, $\langle$slot name$\rangle$, during training and generation. The ultimate response is obtained via a reversal *lexicalization* process to replace slot tokens with their corresponding values.

3 Model

3.1 The NLG task

We approach the NLG problem using the sequence-to-sequence method (Sutskever et al., 2014). Compared with SC-LSTM (Wen et al., 2015b), this method does not need to create additional one-hot MR vector, and can be much more easily extended across different domains with varying meaning representations.

We first concatenate dialogue act d and meaning representations r as a single input sequence $\mathcal{I}$ with m tokens. The output sequence $\mathcal{O}$ is similarly obtained from the given utterance u, with n tokens. Both sequences are delexicalized. We put special sentence tokens $\langle$BOS$\rangle$ and $\langle$EOS$\rangle$ around each sequence.

The goal is to generate output tokens one at a time, given previously predicted tokens and the input sequence. This can be modeled as maximizing the conditional probability distribution:

$$p(w_1, ..., w_n|\mathcal{I}) = \prod_{t=1}^{n} p(w_t|w_1, ..., w_{t-1}; \mathcal{I}) \quad (1)$$

To do this, we employ the encoder-decoder method.

Encoder. We train a dictionary $\mathcal{D}$ to map each token to a fixed-length vector of dimension d. The input embedding sequence then goes into a layer of bidirectional RNN to produce contextualized embeddings. We use GRU (Cho et al., 2014) as the RNN unit and sum up the forward and backward RNN outputs. The output of the encoder is denoted by $(\boldsymbol{u}_1, ..., \boldsymbol{u}_m) \in \mathbb{R}^{d_h \times m}$, where d_h is the RNN's output dimension and m is its input sequence length.

Decoder. The decoder employs an RNN with an attention mechanism to generate tokens one at a time. It starts with the beginning-of-sentence token and uses the final hidden state from encoder RNN as the initial hidden state. In the t-th step, we use the same dictionary $\mathcal{D}$ from the encoder to map the t-th output token into vector $\boldsymbol{s}_t$ and apply dropout. Then, given the previous hidden state $\boldsymbol{h}_{t-1}$, the decoder first computes attention weights over encoder outputs:

$$\boldsymbol{v}_i = [\boldsymbol{h}_{t-1}; \boldsymbol{u}_i] \in \mathbb{R}^{2d_h} \tag{2}$$

$$\boldsymbol{e}_i = \text{softmax}(\boldsymbol{W}_1 \boldsymbol{v}_i) \in \mathbb{R}^{d_h} \tag{3}$$

$$\alpha_i = \text{ReLU}(\boldsymbol{b}^T \boldsymbol{e}_i) \in \mathbb{R} \tag{4}$$

Here, $\boldsymbol{W}_1 \in \mathbb{R}^{d_h \times 2d_h}$ and $\boldsymbol{b} \in \mathbb{R}^{d_h}$ are parameters. The weights $\{\alpha_i\}_{i=1}^m$ are then applied to encoder outputs to obtain the context vector $\boldsymbol{c} = \sum_{1 \le i \le m} \alpha_i \boldsymbol{u}_i$.

The context vector $\boldsymbol{c}$ and embedded vector $\boldsymbol{s}_t$ are then concatenated and sent into decoder GRU with output $\boldsymbol{g} \in \mathbb{R}^{d_h}$ and a new hidden state $\boldsymbol{h}_t \in \mathbb{R}^{d_h}$.

To generate the next token, we reuse the dictionary $\mathcal{D}$ with its transposed weights $\boldsymbol{W}_{\mathcal{D}}$[1]. We again integrate the context vector to fuse in contextual information:

$$\boldsymbol{o} = \boldsymbol{W}_2[\boldsymbol{g}; \boldsymbol{c}] \in \mathbb{R}^d \tag{5}$$

$$\boldsymbol{p}_t = \boldsymbol{W}_{\mathcal{D}} \boldsymbol{o} \in \mathbb{R}^{|V|} \tag{6}$$

where $\boldsymbol{W}_2 \in \mathbb{R}^{d \times 2d_h}$ is a parametrized matrix. $\boldsymbol{p}_t$ is the probability distribution of the next token over all tokens in dictionary.

The loss function is cross entropy. Suppose the one-hot vector for the ground-truth at t-th step is $\boldsymbol{y}_t$, then the loss function for each training sample sequence pair is:

$$\mathcal{L}^{NLG}(\theta) = -\sum_{t=1}^{n} \boldsymbol{y}_t^T \log(\boldsymbol{p}_t) \tag{7}$$

3.2 Coupling with Language Model

The encoder-decoder approach above incorporates the information from dialogue act and meaning representation at each step via attention. However, due to this mechanism, the generated utterance inevitably relies to a great extent on the input sequence, focusing less on the fluency and variation of human language, which is as important as conveying the required information in task-oriented dialogues.

On the other hand, language modeling is typically used to characterize the naturalness of words, phrases and sentences. A well-trained language model can assign natural and semantically sound utterance higher scores than rigid and unnatural sentences. In deep learning, the language model task is often solved by a recurrent neural network. However, instead of depending on an input sequence like in Equation (1), the probability of the next token in language models only relies on preceding words:

$$p^{LM}(w_1, ..., w_n) = \prod_{t=1}^{n} p^{LM}(w_t | w_1, ..., w_{t-1}) \tag{8}$$

We propose that by integrating language modelling into the NLG process as an additional objective, the generated sentences will better approximate the styles and variation in human response.

To do this, we add another GRU unit, GRU^{LM}, to the decoder, that has its own hidden state $\boldsymbol{h}_{t-1}^{LM}$ and takes the embedded vector $\boldsymbol{s}_t$ as input. The output is $\boldsymbol{g}^{LM}$ and the new hidden state is $\boldsymbol{h}_t^{LM}$. The probability distribution of next token in language model is:

$$\boldsymbol{o}^{LM} = \boldsymbol{W}_2[: d_h] \boldsymbol{g}^{LM} \in \mathbb{R}^d \tag{9}$$

$$\boldsymbol{p}_t^{LM} = \boldsymbol{W}_{\mathcal{D}} \boldsymbol{o}^{LM} \in \mathbb{R}^{|V|} \tag{10}$$

where $\boldsymbol{W}_2[: d_h]$ are the first d_h columns of $\boldsymbol{W}_2$. As we can see, the context $\boldsymbol{c}$ does not affect the probability computation for language modeling. The loss function of language model is:

$$\mathcal{L}^{LM}(\theta) = -\sum_{t=1}^{n} \boldsymbol{y}_t^T \log(\boldsymbol{p}_t^{LM}) \tag{11}$$

[1] Suppose $\mathcal{D} \in \mathbb{R}^{|V| \times d}$, its transposed weights $\boldsymbol{W}_{\mathcal{D}} \in \mathbb{R}^{d \times |V|}$.

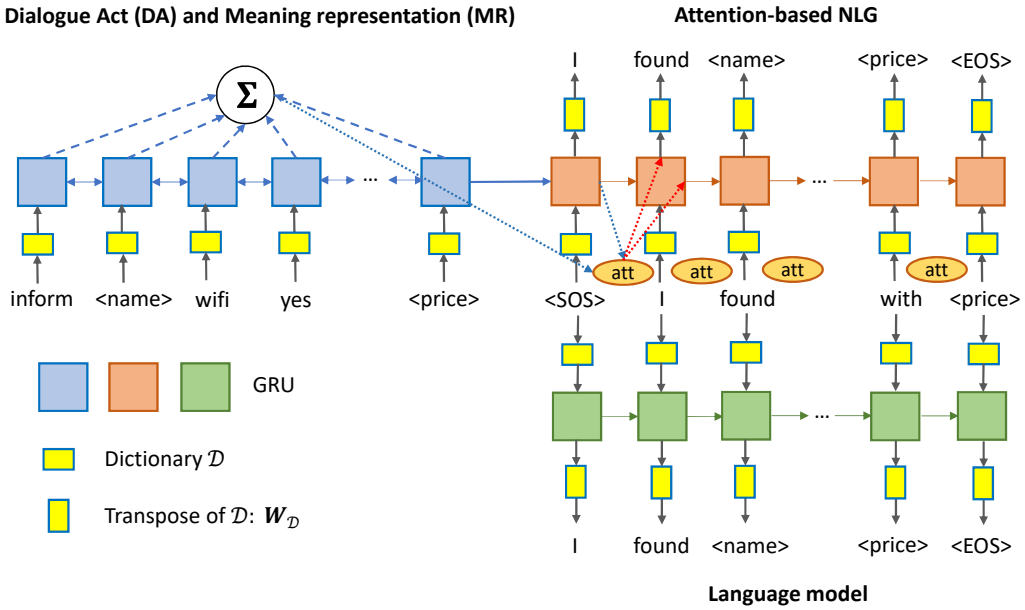

Figure 1: NLG-LM model structure. The encoder takes dialogue act (DA) and meaning representations (MR) as input. The decoder for NLG applies attention on encoder outputs, and the decoder for language modeling shares dictionary with NLG but uses a separate GRU unit.

Model	E	TV	L	H	R
TGen	0.659	/	/	/	/
Slug	0.662	0.529	0.524	/	/
SCLSTM	/	0.527	0.512	0.848	0.752
RALSTM	/	0.541	0.525	0.898	0.779
w/o LM	0.673	0.609	0.560	0.927	0.734
NLG-LM	**0.684**	**0.617**	**0.586**	**0.939**	**0.795**

Table 1: BLEU scores on E2E-NLG (**E**), TV, Laptop (**L**), Hotel (**H**) and Restaurant (**R**) *testset*. w/o LM is our model without language model task.

Model	TGen	Slug	w/o LM	NLG-LM
NIST	8.609	8.613	8.581	**8.626**

Table 2: NIST scores on E2E-NLG *testset*.

Finally, we linearly combine the two loss functions into a single multi-task loss function:

$$\mathcal{L}(\theta) = \mathcal{L}^{NLG}(\theta) + \alpha \mathcal{L}^{LM}(\theta) \qquad (12)$$

We depict our model structure in Figure 1. As shown, the dictionary $\mathcal{D}$ is shared between the NLG task and language modeling task.

4 Experiments

4.1 Datasets and settings

We evaluated the models on five datasets from different domains, covering restaurant booking, hotel booking and retail. The largest dataset is from the E2E-NLG task (Novikova et al., 2017), consisting of 51.2K MR-utterance pairs in the restaurant domain. We also use the four datasets from RNN-LG (Wen et al., 2016), including dialogue scenarios in TV retails, laptop retails, hotel-booking and restaurant-booking domains, with 14.1K, 26.5K, 8.7K and 8.5K samples respectively.

For fairness, we use the official evaluation scripts from E2E-NLG and RNN-LG (Wen et al., 2016) to assess models. We use the BLEU-4 (Papineni et al., 2002) and NIST (Przybocki et al., 2009) metrics.

Delexicalization. In the experiment, we do not delexicalize slots that have binary values or are inappropriate for verbatim substitution. For instance, in E2E-NLG datasets, we only delexicalize *name* and *near* slots. For TV dataset, we delexicalize all slots except *hasusbport*. In Laptop dataset, we delexicalize all slots except *isforbusinesscomputing* and *request*. In Hotel dataset, we delexicalize all slots except *acceptscreditcards*, *dogsallowed* and *hasinternet*. In Restaurant dataset, we delexicalize all slots except *kidsallowed* and *request*.

	E2E-NLG	TV	Laptop	Hotel	Restaurant
Dropout rate	0.4	0.2	0.2	0.3	0.3
Learning rate	0.005	0.001	0.001	0.005	0.001
Batch size	20	20	20	20	20
Dictionary dimension	100	50	50	200	50
RNN hidden size	512	128	512	256	512

Table 3: Hyperparameters of NLG-LM in experiments.

Baseline. Our baseline models include TGen (Dušek and Jurčíček, 2016), SC-LSTM (Wen et al., 2015b), RALSTM (Tran and Nguyen, 2017) and Slug (Juraska et al., 2018).

Training details. We use Adamax (Kingma and Ba, 2014) as the optimizer. We use teacher forcing, which means that during training, the decoder is always presented with the previous ground-truth token. The language modeling task is only used during training, and it uses utterances from the same batch as NLG task. The inference uses a beam search of width 10. We use the multi-task coefficient $\alpha = 0.5$ in all experiments. The hyper-parameters were chosen on the dev set with early stopping, as shown in Table 3.

4.2 Result

We present our experimental results in Table 1 and 2. As shown, our model, NLG-LM, outperforms the baseline models in all 5 datasets. In E2E-NLG dataset, it achieves 2.2% higher BLEU score and 0.013 higher NIST score than Slug. In TV, Laptop, Hotel and Restaurant datasets, NLG-LM greatly improves previously best result by 7.6%, 6.1%, 4.1%, and 1.6%, respectively. We also ran our model without the language modeling task as an ablation study, denoted by *w/o LM*. As seen, language modeling can improve the result by 0.8% to 6.1%, or on average 2.4%, which demonstrates the effectiveness of multi-task learning.

In the appendix, we examined some predicted samples generated from our model, which shows that the addition of the language model makes the generated responses more natural and variable.

Efficiency. We compared the training time of NLG-LM with that of w/o LM. As shown in Table 4, the additional language model only introduces 23.6% more training time, since it does not involve expensive attention computation. Therefore, NLG-LM can offer more natural response generation with comparable efficiency.

	NLG-LM	w/o LM
Per-batch	618.87s	500.64s

Table 4: Running time per batch of NLG-LM and w/o LM on E2ENLG training set. The machine has an Intel Xeon CPU E5 and a Tesla v100 GPU.

5 Conclusions

In this paper, we propose a novel multi-task learning method, NLG-LM. It incorporates a language model task into the response generation process as an unconditioned complementary process to boost the naturalness of generated utterances. We fit both tasks into a sequence-to-sequence structure under a multi-task learning scheme. Empirical results show that NLG-LM significantly outperforms previous methods in 5 large-scale datasets with reasonable computational efficiency. Ablation studies show the effectiveness of using the language modeling task within a multi-task scheme.

Dirichlet Latent Variable Hierarchical Recurrent Encoder-Decoder in Dialogue Generation

Min Zeng Yisen Wang† Yuan Luo
Department of Computer Science and Engineering
Shanghai Jiao Tong University
eewangyisen@gmail.com; {min_zeng, yuanluo}@sjtu.edu.cn

Abstract

Variational encoder-decoders have achieved well-recognized performance in the dialogue generation task. Existing works simply assume the Gaussian priors of the latent variable, which are incapable of representing complex latent variables effectively. To address the issues, we propose to use the Dirichlet distribution with flexible structures to characterize the latent variables in place of the traditional Gaussian distribution, called Dirichlet Latent Variable Hierarchical Recurrent Encoder-Decoder model (Dir-VHRED). Based on which, we further find that there is redundancy among the dimensions of latent variable, and the lengths and sentence patterns of the responses can be strongly correlated to each dimension of the latent variable. Therefore, controllable responses can be generated through specifying the value of each dimension of the latent variable. Experimental results on benchmarks show that our proposed Dir-VHRED yields substantial improvements on negative log-likelihood, word-embedding-based and human evaluations.

1 Introduction

Recurrent neural networks (RNNs) (Bengio et al., 2003) have achieved great success on many natural language processing tasks. For the dialogue generation task, a RNN-based Hierarchical Recurrent Encoder-Decoder (HRED) was first proposed in (Serban et al., 2016). It consists of three RNNs: encoder RNN, context RNN and decoder RNN. Firstly, the encoder RNN encodes each utterance into a fixed-size real-valued vector through word embedding. Then, the last hidden state of encoder RNN is feed into the context RNN to summarize the dialogue information. Finally, the decoder RNN takes the last state of context RNN as input and produces the probability distribution of the word in the next utterance.

Although it outperforms n-gram and other neural network language models, HRED only produces one word at a time, which is unable to fully grasp the holistic high-level syntactic properties (*e.g.*, topics, tones or sentiment) (Bowman et al., 2015). When the sentence grows longer, it has the drawback of tending to generate short and generic responses (Vinyals and Le, 2015). Thus, Serban et al. (2017) proposed the Variational Hierarchical Recurrent Encoder-Decoder (VHRED) by combining HRED with Variational Autoencoders (VAEs) (Kingma and Welling, 2013) that introduced a latent variable to characterize the sentence-level representation for learning holistic properties. However, VHRED imposes a symmetric distribution (*i.e.*, Gaussian distribution) to the latent variable, which, though facilitating analyzing, are incapable of representing complex latent variables effectively. Therefore, in order to generate more meaningful and expressive responses, a more flexible and tractable prior distribution of the latent variable is needed.

In this paper, we propose to use the Dirichlet distribution to characterize the latent variable in VHRED, named Dir-VHRED. Dirichlet distribution is a popular conjugate prior for Multinomial distributions in Bayesian statistics. It can be concave or convex, monotonously rising or decreasing, symmetrical or asymmetrical, which makes it more flexible for better capturing the sentence-level properties. Our main contributions are summarized as follows:

- We introduce Dirichlet distribution to VAE-based dialogue generation model and propose the Dir-VHRED model for better grasping the sentence-level properties and generating more meaningful and expressive responses.

†Corresponding author: Yisen Wang.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1267–1272, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- We find that the lengths and sentence patterns of the responses can be strongly correlated to each dimension of the latent variable.
- Experiments on three kinds of evaluation metrics demonstrate the superiority of our proposed Dir-VHRED model.

2 Preliminaries

2.1 Variational Autoencoders

The key idea of Variational autoencoders (VAEs) is to reconstruct the input x through the latent variable z (Kingma and Welling, 2013). As the log-likelihood $\log p_\theta(x)$ is intractable, its lower bound *Evidence Lower BOund* (ELBO), denoted as $\mathcal{L}(\theta, \phi; x)$, is involved to make the maximization tractable:

$$\begin{aligned}\log p_\theta(x) &\geq \mathcal{L}(\theta, \phi; x) \\ &= -KL(q_\phi(z|x)||p(z)) \\ &\quad + \mathbb{E}_{q_\phi(z|x)}[\log p_\theta(x|z)],\end{aligned} \tag{1}$$

where $p(z)$ denotes the prior distribution of z, and $q_\phi(z|x)$ is used for approximating the intractable true posterior distribution $p_\theta(z|x)$. Note that the total loss is the negative of ELBO.

2.2 Dialogue Model

Assuming dialogue $\mathcal{D}$ consisting of N utterances, the VAE-based dialogue model generates the responses by utilizing the latent variable z. The generation of the next utterance is defined by:

$$\begin{aligned}p_\theta(z_n|W_{<n}) &= \mathcal{N}(\mu_{prior(W_{<n})}, \Sigma_{prior(W_{<n})}), \\ p_\theta(W_n|z_n, W_{<n}) &= \prod_m p_\theta(w_{n,m}|z_n, w_{n,<m}, W_{<n}),\end{aligned} \tag{2}$$

where W_n is the n-th utterance of the dialogue and $w_{n,m}$ indicates the m-th word of the n-th utterance. As the log-likelihood is intractable, instead of pursuing the exact maximum of the log-likelihood, we maximize its lower bound ELBO:

$$\begin{aligned}&\log p_\theta(W_1, W_2, \cdots, W_N) \geq \\ &\sum_{n=1}^{N} -KL[q_\phi(z_n|W_1, W_2, \cdots, W_N)||p_\theta(z_n|W_{<n})] \\ &\quad + \mathbb{E}_{q_\phi(z_n|W_1, W_2, \cdots, W_N)}[\log(p_\theta(W_N|z_n, W_{<n}))],\end{aligned} \tag{3}$$

where $p_\theta(z_n|W_{<n})$ denotes the prior distribution of z_n, and $q_\phi(z_n|W_1, W_2, \cdots, W_N)$ is used for approximating the intractable true posterior distribution $p_\theta(z_n|W_1, W_2, \cdots, W_N)$.

2.3 Dirichlet Distribution

Dirichlet distribution, a family member of continuous multivariate probability distribution, is regarded as a multivariate generalization of the Beta distribution. In case of the Dirichlet distribution, it is a conjugate prior for the Multinomial distribution. The probability density function of Dirichlet distribution is given by:

$$f(x_1, \cdots, x_K; \alpha_1, \cdots, \alpha_K) = \frac{1}{B(\alpha)} \prod_{i=1}^{K} x_i^{\alpha_i - 1}, \tag{4}$$

where parameter $\alpha_i > 0$ is a K dimension vector and $B(\alpha)$ is a Beta function:

$$B(\alpha) = \frac{\prod_{i=1}^{K} \Gamma(\alpha_i)}{\Gamma(\sum_{i=1}^{K} \alpha_i)}, \quad \alpha = (\alpha_1, \cdots, \alpha_K), \tag{5}$$

When $\alpha_1 = \alpha_2 = \cdots = \alpha_K$, Dirichlet distribution is a symmetric distribution. Particularly, when all the factors in α equal 1, Dirichlet distribution becomes a uniform distribution.

3 The Proposed Dir-VHRED Model

Mathematically, Dirichlet distribution owns a flexible structure. With different settings of parameter α, Dirichlet distribution may have various forms, which can be concave or convex, monotonously rising or decreasing, symmetrical or asymmetrical. Therefore, equipped with the diverse structure, Dirichlet distribution is capable of modeling the complex latent variable. Furthermore, Dirichlet distribution has paved its way in many natural language processing tasks like topic model, text classification and so on. For example, it was introduced in the Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to model the topic distribution and word distribution, and experimentally presents a well-recognized performance.

Motivated by the above facts, we thus introduce Dirichlet distribution to model the latent variable z in order to better grasp the sentence-level properties which further encourages the better responses. With the distribution of z changing from Gaussian to Dirichlet, we may face a tough but

important problem: the reparameterization of z. The variables with any distribution can be generated through the transformation of the samples from standard Uniform distribution if the corresponding inverse Cumulative Distribution Function (CDF) is known. For the Gaussian latent variable, it can make use of the inverse CDF to do the reparameterization (Kingma and Welling, 2013). While for the Dirichlet latent variable, unlike the known CDF of Gaussian distribution, the CDF of Dirichlet distribution is too complex to obtain. Inspired from (Jankowiak and Obermeyer, 2018), we use the reject sampling to solve the Dirichlet reparameterization problem. Furthermore, to mitigate KL-vanishing problem, in contrast to the static weight scheme in (Bowman et al., 2015), the imposed weight on KL-divergence in our model is dynamic. Since the KL-divergence and reconstruction loss antagonize each other, by setting the weight as the reciprocal of the reconstruction loss, the KL and reconstruction loss enable to keep a dynamic balance, which leads to a more stable KL-divergence.

Following the techniques described above, ELBO then has the form:

$$\begin{aligned}\log p_\theta(x) &\geq \mathcal{L}(\theta, \phi; x) \\ &= -\lambda KL(q_\phi(z|x)||p(z)) \\ &\quad + \mathbb{E}_{q_\phi(z|x)}[\log(p_\theta(x|z))],\end{aligned} \tag{6}$$

where

$$\lambda = -1/\mathbb{E}_{q_\phi(z|x)}[\log(p_\theta(x|z))], \tag{7}$$

and the KL-divergence term can be derived as*:

$$\begin{aligned}&KL(q_\phi(z|x)||p(z)) = \\ &\log\Gamma(\sum_{k=1}^{K}\alpha_k) - \sum_{k=1}^{K}\log\Gamma(\alpha_k) - \log\Gamma(\sum_{k=1}^{K}\beta_k) \\ &+ \sum_{k=1}^{K}\log\Gamma(\beta_k) + \sum_{k=1}^{K}(\alpha_k - \beta_k)(\psi(\alpha_k) - \psi(\sum_{k=1}^{K}\alpha_k)),\end{aligned} \tag{8}$$

where α, β are parameters of Dirichlet distribution $q_\phi(z|x)$ and $p(z)$ respectively, K is the dimension of z, and ψ is the Digamma function.

4 Experiments

4.1 Datasets

All experiments are conducted on the following two dialogue datasets:

Ubuntu Dialogue Corpus (Ubuntu) (Lowe et al., 2015): Ubuntu Dialogue Corpus is a large dataset for research in unstructured multi-turn dialogue systems. It contains 1 million two-person conversation and the conversation consists of average 8 turns.

Cornell Movie Dialogs Corpus (Movie) (Danescu-Niculescu-Mizil and Lee, 2011): Cornell Movie Dialogs Corpus contains a large metadata-rich collection of fictional conversations extracted from raw movie scripts. It contains 220,579 conversations from 617 movies.

4.2 Experimental Setup

We conduct a series of experiments to compare our proposed Dir-VHRED with two baselines: HRED (Serban et al., 2016) and VHRED (Serban et al., 2017). All the RNN modules (*i.e.*, the encoder, context and decoder RNNs) adopt a single-layer GRU (Cho et al., 2014) with 1000 hidden units. The word drop rate is set to 0.25, the dimensionality of latent variable z is 3, and the word embedding size is 200†.

For VHRED, the weight parameter λ of KL-divergence is initialized as 0 and gradually increased to 1 at the $20,000$-th/$100,000$-th training steps for Movie/Ubuntu datasets. While, for Dir-VHRED, the parameter λ is adaptively determined by Eq. (7).

For the dataset, we truncate utterances longer than 30 words and split the train/validation/test sets by 0.8/0.1/0.1 respectively.

All models are trained by Adam optimizer (Kingma and Ba, 2014) with batch size 40 and learning rate 1×10^{-4}. At the training time, we stop the training when the loss on the validation set does not decrease within 5 epochs. At the evaluating time, beam search (Wiseman and Rush, 2016) with beam size 5 is used for generating output responses. Both the single response (1-turn) and the three consecutive responses (3-turn) are evaluated for each model. Our code is available at `https://github.com/cloversjtu/dir-vhred`.

4.3 Performance Evaluation

In order to comprehensively evaluate the model performance on dialogue generation, we adopt the following three evaluation metrics: 1) negative

*Detailed derivation can be found in Appendix A.1.

†The word embedding is obtained from Word2Vec embeddings trained on the Google News Corpus.

log-likelihood metric to measure the loss of the generating procedure; 2) word-embedding metric to measure the cosine distance between the generated responses and the ground truth responses; and 3) human evaluation.

4.3.1 Negative Log-likelihood Evaluation

Table 1 reports the comparisons of the per-word negative log-likelihood (NLL) composition of different models. NLL consists of the reconstruction loss (*reconstruction*) and the KL-divergence (*KL-div.*). KL-divergence indicates the information encoded in z, and reconstruction loss represents the loss of reconstructing x through z. As can be seen from Table 1, with almost the same KL-divergence, Dir-VHRED achieves the lowest NLL on both datasets, implying better performance compared with VHRED. Dir-VHRED also has the lower reconstruction loss, which indicates that Dirichlet prior is better than the Gaussian prior for reconstructing the responses.

Table 1: Results of NLL on Ubuntu and Movie datasets with different models. The $\leq$ symbol denotes the variational bound.

Ubuntu dataset			
Model	NLL	*reconstruction*	*KL-div.*
HRED	3.844	-	-
VHRED	$\leq$ 4.132	3.765	0.367
Dir-VHRED	$\leq$ 3.999	3.614	0.385
Movie dataset			
Model	NLL	*reconstruction*	*KL-div.*
HRED	3.944	-	-
VHRED	$\leq$ 4.233	3.904	0.330
Dir-VHRED	$\leq$ 4.073	3.741	0.332

4.3.2 Word-embedding-based Evaluation

Word-embedding metric is designed to measure the similarity between words, and can be divided into three categories: *average* (Foltz et al., 1998), *greedy* (Rus and Lintean, 2012) and *extrema* (Forgues et al., 2014). The *average* metric calculates sentence-level embeddings, while the *greedy* and *extrema* ones compute the word-to-word cosine similarity. Their difference lies on that *greedy* takes the average word vector in the sentence as the sentence embedding while *extrema* adopts the extreme value of these word vectors. Tables 2 and 3 demonstrate the results of word-embedding metric on 1-turn and 3-turn responses from different models. Embedding metrics first map the generating responses to a vector space and then compute the cosine similarly with corresponding ground responses. Therefore, it can be used to measure the sentence-level semantic similarity to a certain extent. Dir-VHRED achieves the best performance among the three word-embedding metrics on 1-turn and 3-turn responses of the two datasets. That is, the responses generated by Dir-VHRED own the highest topic similarity with the ground truth.

Table 2: Results of three embedding metrics on Ubuntu dataset with 1-turn and 3-turn responses.

Model	*Average*	*Greedy*	*Extrema*
1-turn			
HRED	0.448	0.297	0.271
VHRED	0.506	0.355	0.286
Dir-VHRED	**0.538**	**0.387**	**0.303**
3-turn			
HRED	0.426	0.275	0.260
VHRED	0.524	0.366	0.292
Dir-VHRED	**0.552**	**0.393**	**0.313**

Table 3: Results of three embedding metrics on Movie dataset with 1-turn and 3-turn responses.

Model	*Average*	*Greedy*	*Extrema*
1-turn			
HRED	0.461	0.316	0.329
VHRED	0.519	0.376	0.356
Dir-VHRED	**0.554**	**0.409**	**0.358**
3-turn			
HRED	0.483	0.334	0.337
VHRED	0.530	0.382	0.356
Dir-VHRED	**0.566**	**0.412**	**0.363**

4.3.3 Human Evaluation

Moreover, we invite 7 qualified volunteers to do the human evaluation on 700 randomly sampled dialogues from Ubuntu dataset. Volunteers are required to rate the generated responses from different models with scores from 1 to 3 (3 is the best), in term of the sentence coherence and contextual

Table 4: Responses generated by different models.

 # 1 Input sentence:
that is a upstream bug and red hat marked it <unk>.
 # 1 Generated response:
HRED: i know it's not a bug, but i'll try it out.
VHRED: can you provide a link for that?
Dir-VHRED: so i should report it to the bug report? i don't see any bug reports.
 # 2 Input sentence:
i tried but still its not workin.
 # 2 Generated response:
HRED: what kind of laptop?
VHRED: is it a laptop? or the fn key is not set?
Dir-VHRED: what is the model of your laptop? what model?
 # 3 Input sentence:
i tried that and even rebooting the pc.
 # 3 Generated response:
HRED: what does ifconfig say?
VHRED: check your etc network interfaces.
Dir-VHRED: what's the error message?

topic. The average human evaluation scores for HRED, VHRED and Dir-VHRED are 2.50, 2.65 and 2.70 respectively. We also conduct Friedman test (Friedman, 1940) on the human evaluation score to check its statistical significance, and the value of Chi-square test statistics is 5696.25 which indicates that the P-value is less than 0.05. Thus, Dir-VHRED is significantly better than others.

Table 4 lists some examples of the generated sentences of different models. It can be seen that the responses generated by Dir-VHRED best match the context given the input sentence, compared with other models. Dir-VHRED experimentally demonstrates to be able to generate fluent and diverse responses which match the human daily speaking style smoothly.

4.4 Interpretability of Dir-VHRED

In our above experiments, we find an interesting phenomenon for Dir-VHRED that there are many non-active dimensions of z and the number of active ones is almost always around 3. Therefore, we conduct additional ablation study experiments to analyze each dimension of z. To be specific, we circularly set one dimension of z to 1 and the others to 0, like "100", "010" and "001".

We demonstrate some generated responses through ablation study on each dimension of z on Ubuntu and Movie datasets in Table 5. We can observe that the **dimension 1** (*dim1*) is inclined to generate the shortest responses which, to a certain extent, shows the attitude of the speaker. Specifically, it prefers to generate the responses like "thanks", "no" or "yes". The **dimension 2** (*dim2*) usually generates longer and informative responses. For example on Movie dataset, the generated response is prone to end with "are you?" or "aren't you?", which shows a preference for rhetorical question. Other examples include "you're not going to be here, are you?" and "well, you're a good man, aren't you?". Intuitively, since the Movie dataset is a collection of conversations extracted from movie scripts, the generated responses are closer to daily dialogues. While for Ubuntu, the responses do not have strong individual emotion and rhetorical question rarely appear, as the conversations in this dataset are professional dialogue about Ubuntu system knowledge. The **dimension 3** (*dim3*) focuses on generating the longest and most comprehensive responses that are usually declarative sentences and are highest close to the dialogue topic.

Therefore, we can easily generate the responses with the preferred style and length through changing the value of each dimension of z.

Table 5: Responses generated by ablation study on different dimension of z in Dir-VHRED.

 # 1 Input sentence:
does grub stay into hdd after installing another os?
 # 1 Generated response:
dim1: yes.
dim2: yes, it will be in the mbr of the drive.
dim3: yes, it will overwrite grub, but it will overwrite the mbr, and then you can use the grub menu to boot the os.
 # 2 Input sentence:
that leads me to the next question lol ... i do not know how to create new volumes exactly in cmdline, usually i use a gui.
 # 2 Generated response:
dim1: gksudo.
dim2: alt f2 gksudo nautilus and gksudo nautilus will work.
dim3: <unk> is a gui app for managing users, you can use gksudo nautilus and you can use gksudo nautilus toget a root terminal and you can use.
 # 3 Input sentence:
i see this use at your own risk. http askubuntu.com questions <unk> ubuntu 12 04 nvidia gtx 460 video card installation.
 # 3 Generated response:
dim1: thanks.
dim2: thanks, i 'll give that a try. thanks !
dim3: i have the nvidia drivers installed, but i can't see the nvidia logo on the screen. i have to install the drivers for the graphics card.
 # 4 Input sentence:
she isn't my cousin.
 # 4 Generated response:
dim1: yes.
dim2: she 's a nurse, isn't she ?
dim3: yes, she 's a good friend of mine, she 's a nurse.

5 Conclusion

In this paper, we proposed to use Dirichlet distribution in place of traditional Gaussian distribution in VHRED for dialogue generation, called Dir-VHRED, to well capture the sentence-level properties. We also provided a new way on the setting of the weight of KL-divergence to alleviate KL-vanishing problem. Moreover, we found that the lengths and sentence patterns of the generated responses are correlated to the value of each dimension of the latent variable, which can be used for generating the required responses. Experiments on benchmark datasets show the superior of our proposed Dir-VHRED model.

Acknowledgments

We would like to thank Junqing Gu and Xiaoyu Shen for their constructive discussions. We also appreciate the code shared in (Park et al., 2018).

Abstract

Dialogue systems benefit greatly from optimizing on detailed annotations, such as transcribed utterances, internal dialogue state representations and dialogue act labels. However, collecting these annotations is expensive and time-consuming, holding back development in the area of dialogue modelling. In this paper, we investigate semi-supervised learning methods that are able to reduce the amount of required intermediate labelling. We find that by leveraging un-annotated data instead, the amount of turn-level annotations of dialogue state can be significantly reduced when building a neural dialogue system. Our analysis on the MultiWOZ corpus, covering a range of domains and topics, finds that annotations can be reduced by up to 30% while maintaining equivalent system performance. We also describe and evaluate the first end-to-end dialogue model created for the MultiWOZ corpus.

1 Introduction

Task-oriented dialogue models aim at assisting with well-defined and structured problems like booking tickets or providing information to visitors in a new city (Raux et al., 2005). Most current industry-oriented systems rely on modular, domain-focused frameworks (Young et al., 2013; Sarikaya et al., 2016), with separate components for user understanding (Henderson et al., 2014), decision making (Gašić et al., 2010) and system answer generation (Wen et al., 2015). Recent progress in sequence-to-sequence (seq2seq) modelling has enabled the development of fully neural end-to-end architectures, allowing for different components to be optimized jointly in order to share information (Wen et al., 2017; Zhao et al., 2017; Budzianowski and Vulić, 2019).

Dialogue systems benefit greatly from optimizing on detailed annotations, such as turn-level dialogue state labels (Henderson et al., 2014) or dialogue actions (Rieser and Lemon, 2011), with end-to-end architectures still relying on intermediate labels in order to obtain satisfactory results (Lei et al., 2018). Collecting these labels is often the bottleneck in dataset creation, as the process is expensive and time-consuming, requiring domain and expert knowledge (Asri et al., 2017). Due to this restriction, existing datasets for task-oriented dialogue are several orders of magnitude smaller compared to general open-domain dialogue corpora (Lowe et al., 2015; Henderson et al., 2019).

Arguably, one of the most challenging parts of dialogue modelling is maintaining an interpretable internal memory over crucial domain concepts (Williams et al., 2016). Although there is increasing research effort to learn Dialogue State Tracking (DST) jointly with the text generation component (Eric et al., 2017; Wu et al., 2019), the most effective models use it as an intermediate signal (Wen et al., 2017; Lei et al., 2018). The difficulty of state tracking has made this task a driving force behind most of the Dialog System Technology Challenges in recent years (Henderson et al., 2014; Kim et al., 2017).

In this paper, we reduce the reliance of task-oriented dialogue systems on data collection by leveraging semi-supervised training (Chapelle et al., 2009). Two approaches are investigated and evaluated for providing an improved training signal to the dialogue state tracking component in an end-to-end dialogue system. Automatically predicted DST output on unlabelled utterances is treated as additional annotation if the model confidence is sufficiently high. Furthermore, subtle perturbations of existing datapoints are created, optimizing for their predictions to be similar to the original instances. Our analysis on the MultiWOZ corpus (Budzianowski et al., 2018), covering a range of domains and topics, finds that these meth-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1273–1278, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

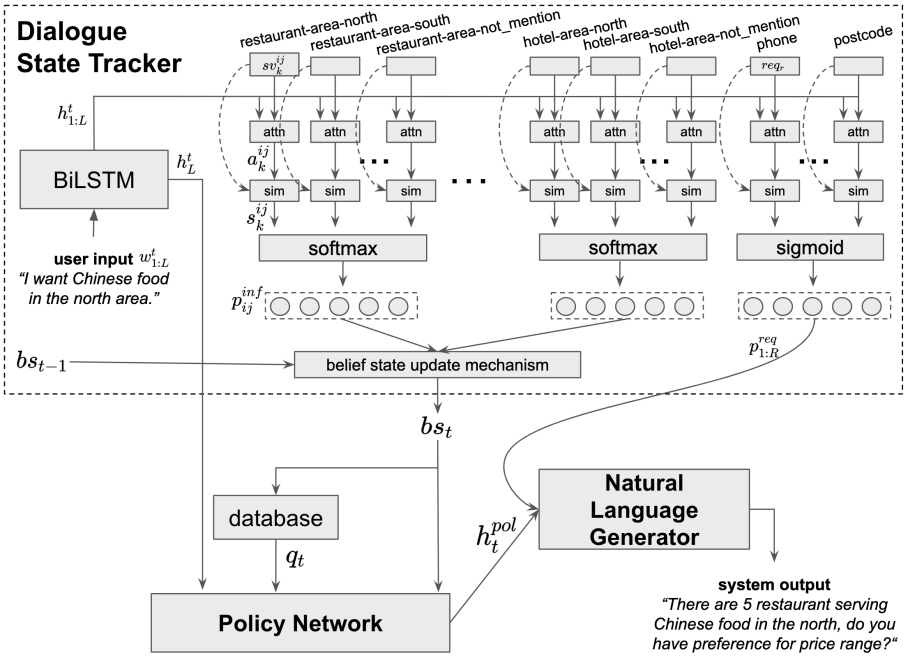

Figure 1: Overview of our end-to-end neural dialogue model. It is composed of three main components: Dialogue State Tracker, Policy Network and Natural Language Generator.

ods can reduce intermediate annotation by up to 30% while maintaining equivalent system performance. We also describe and evaluate the first end-to-end dialogue model created for the MultiWOZ corpus.

2 End-to-end Neural Dialogue Model

We now present the end-to-end neural dialogue model composed of three main components: dialogue state tracker, policy network and natural language generator. These components are trained jointly as a connected network and will be introduced in detail in the next paragraphs. The overall architecture can be seen in Figure 1.

Dialogue State Tracker (DST) The DST is responsible for both understanding the input user utterance and updating the internal dialogue state for the downstream components. There are two types of slots which can be detected in the input: informable slots and requestable slots. The former describes the attributes of the entity that the user is looking for, e.g., `pricerange` of a hotel. The latter captures information that the user desires to know about the entity, e.g., `postcode` of a hotel. Each informable slot contains several possible values with two special labels: `not-mentioned` and `don't-care`. A good DST should be able to correctly recognize the mentioned slot-value pairs in the user utterance and to maintain the updated dialogue (belief) state.

Let i, j and k denote the index of domain, slot and value. As depicted at the top of Figure 1, the user utterance w_1:w_L at turn t is first encoded by the BiLSTM to obtain the hidden states $h^t_{1:L}$. The encoding of the slot-value pair sv^{ij}_k is the output of the affine layer that takes the concatenation of the embeddings of domain i, slot j and value k as the input. The context vector a^{ij}_k is then computed by the attention mechanism, denoted as `attn` in Figure 1, following Luong et al. (2015):

$$e_l = \text{sim}(h_l, sv^{ij}_k) \quad (1)$$

$$a^{ij}_k = \sum_{l=1}^{L} e_l h_l, \quad (2)$$

where l is the word index of the user utterance and `sim` denotes any function that calculates the similarity of two vectors. We adopt here the dot product function, following Mrkšić et al. (2017); Zhong et al. (2018); Ramadan et al. (2018). The similarity score s^{ij}_k between a^{ij}_k and sv^{ij}_k is then computed to see whether the slot-value pair sv^{ij}_k is mentioned in the utterance. The mentioned pair should have higher similarity score to its context vector than those which are not mentioned. The softmax layer is then applied to form the probability distribution p^{inf}_{ij} for each informable slot s^{inf}_{ij}, where the predicted value is the value with

the highest probability. The same attention mechanism is used for each requestable slot req_r to decide whether the user has asked for the slot in the current turn. The sigmoid layer is used instead as it is a binary classification problem. The prediction of requestable slots will be used as input to the natural language generator.

The belief state is the concatenation of the distributions over all informable slot-value pairs that is updated at each turn to keep track of the information provided by the user during the entire conversation. To form the belief state bs_t at turn t, for each informable slot s_{ij}^{inf} the update mechanism checks if the predicted value is either `not-mention` or `dont-care` for the current turn. If it is, then the probabilistic distribution p_{ij}^{inf} in bs_{t-1} is kept, otherwise it is updated by the new distribution p_{ij}^{inf} at the current turn.

Policy Network The policy network is responsible for fusing the signals from the belief state $\mathbf{b}_t$, the encoding of the user utterance $\mathbf{h}_L^t$ and the database query result $\mathbf{q}_t$. The database query is constructed from the predicted belief state. The number of all entities that match the predictions of the DST form the database query vector[1]. We use a simple feedforward layer as the policy network:

$$\mathbf{z}_t = \tanh(W^z * [\mathbf{b}_t, \mathbf{h}_L^t, \mathbf{q}_t]). \quad (3)$$

where [*] denotes the concatenation of vectors.

Natural Language Generator Taking the input $\mathbf{z}_t$ from the policy network and predictions of requestable slots from the tracker, the generator outputs a system response word-by-word until the <EOS> token is generated. To improve the generation of correct slots corresponding to the user input, we adopt the semantically-conditioned LSTM (Wen et al., 2015) that contains a self-updating gate memory to record the produced slots in the generated sentence.

Optimization The model is optimized jointly against two sources of information – DST intermediate labels and system utterances. The DST loss consists of the cross-entropy over the multi-class classification of informable slots while binary cross-entropy is used for requestable slots:

$$L_{dst} = -\sum_i \sum_j t_{ij}^{inf} \log p_{ij}^{inf} - \sum_r t_r^{req} \log p_r^{req}, \quad (4)$$

where i, j and r are the index of domain, informable slot and requestable slot respectively; t^* is the target distribution. The generation error is a standard cross-entropy between the predicted words and target words:

$$L_{gen} = -\sum_{l'} t_{l'} \log p_{l'}, \quad (5)$$

where l' is the word index in the generated sentence. To jointly train the DST, the policy network, and the generator as a connected network, the final objective function becomes $L = L_{dst} + L_{gen}$.

Semi-supervised Training The DST loss requires each turn to be manually annotated with the correct slot-value pairs. We experiment with two different semi-supervised training methods that take advantage of unlabelled examples instead, allowing us to reduce the amount of required annotation. The first approach is based on the *pseudo-labelling* strategy by Chapelle et al. (2009). If the prediction probability of an unlabelled data point for a particular class is larger than a given threshold ν, the example is included in the DST loss with the predicted label. The ν parameter is optimized on the validation set during development.

The second semi-supervised technique investigated is the Π-*model* (Sajjadi et al., 2016) where the input is perturbed with random noise $\epsilon \sim \mathcal{N}(\mathbf{0}, \sigma)$. The perturbations are applied to both labelled and unlabelled data points at the level of embedding of user utterance. The model is then required to produce similar predictions p_{ij}^{inf} over the belief state compared to the original input, optimized with an additional loss:

$$L3 = \alpha \frac{1}{N} \sum_N \sum_{ij} (t_{ij}^{inf} - p_{ij}^{inf})^2, \quad (6)$$

where N is the batch size and α is a hyperparameter controlling the weight of the loss.

3 Experiments

We investigate the effects of semi-supervised training on optimizing the end-to-end neural dialogue system. In particular, we evaluate how much annotation at the intermediate-level could be reduced while preserving comparable results of the overall dialogue task completion metrics.

[1]Following (Wen et al., 2017), by querying the database using $\mathbf{b}_t$ as query, $\mathbf{q}_t$ is the 1-hot representation with each element indicating different number of the matching entities in the database. We use 5 bins to indicate the matching number from 0 to 3 and more than 3.

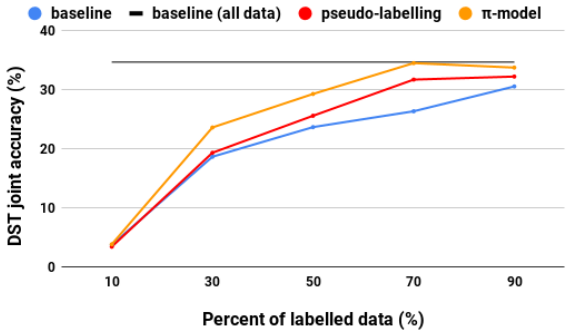

Figure 2: The DST joint accuracy for the three considered models as the amount of labelled data varies. The horizontal line denotes the baseline model trained on 100% labelled data.

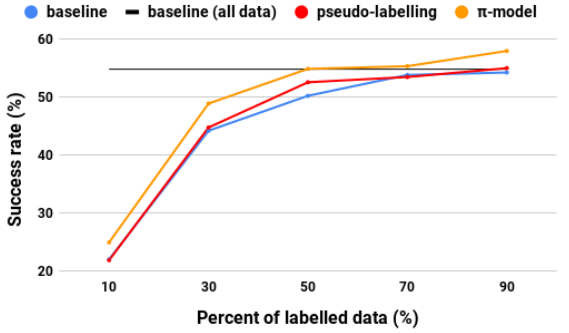

Figure 3: Success rate for different methods as the amounts of labelled data varies. Horizontal line denotes the baseline model trained on 100% labelled data.

Dataset The three analyzed models are evaluated on the MultiWOZ dataset consisting of 10,438 task-oriented dialogues (Budzianowski et al., 2018). The conversations in MultiWOZ are natural as they were gathered based on human-to-human interactions following the Wizard-of-Oz paradigm. The corpus includes multi-domain conversations spanning across 7 domains including Restaurant, Hotel, Attraction, Train and Taxi. The size of the dataset allows us to control the amount of available fully labelled datapoints.

Metrics There are two metrics of importance when evaluating task-oriented dialogue systems. The first is the DST joint goal accuracy, defined as an average joint accuracy over all slots per turn (Williams et al., 2016). The second is the *Success* metric that informs how many times systems have presented the entity satisfying the user's goal and provided them with all the additional requested information (Wen et al., 2017). The models are optimized using the validation set and the results are averaged over 10 different seeds.

Varying data amount We examine the performance of the baseline model compared to the two semi-supervised models as the amount of labelled data varies. The result of the DST joint accuracy is presented in Figure 2. The *pseudo-labelling* model performs better than the baseline when more than 50% of the dataset is labelled. At the scarce data levels (10% and 30%) , the *pseudo-labelling* model is not producing pseudo training points that help improve DST predictions. In contrast, the Π-*model* takes advantages of the additional regularization loss and effectively leverages unlabelled data to enhance the performance over the baseline. The improvements are consistently more than 5% when training with 30 to 90% of labelled data and even reach the performance of the fully trained baseline model with only 70% labelled data.

Figure 3 shows the *Success* metric results. The *pseudo-labelling* method is not able to improve performance over the baseline regardless of the amount of labelled data. However, the Π-*model* is capable of improving the success rate consistently and manages to reach the performance of the fully trained model with only 50% of the intermediate DST signal. Note that a better DST joint accuracy does not necessarily translate to a better success rate as the final metric is also influenced by the quality of the generator.

No. of examples	0	1-5	6-10	10-15	16-20
Baseline	6.17	15.93	25.71	35.07	28.88
Pseudo-labelling	6.5	16.27	26.96	33.46	28.55
Π-model	**6.6**	**21.93**	**31.29**	**36.22**	**30.72**

Table 1: The accuracy (%) of different classification of slot-value pairs in terms of their number of training examples.

DST analysis DST joint accuracy considers all slot-value pairs in an utterance and cannot give us further insight regarding the source of the improvements. We are particularly interested in whether the semi-supervised models can leverage unlabelled data to improve the prediction of rarely seen slot-value pairs. In this analysis, we classify all slot-value pairs in the test set in terms of their number of training examples in 50% of the labelled data. Table 1 presents the results, showing that the Π-*model* improves accuracy by 5% when the slot-value pair is rarely (1-10 times) seen during training. The improvement on few-shot slots contributes to the improvement of joint accuracy.

Figure 4: Success rates in each domain in the case of 50% labelled data.

Domain analysis We also investigate if the improvements in the success rate are consistent among all domains. Figure 4 shows the success rate on individual domains in the case of 50% of data is labelled. Both semi-supervised models improve performance over the baseline in all domains except for the taxi domain. We hypothesize this comes from the fact that the taxi domain is a relatively easy domain with only 4 possible slots.

4 Conclusions and Future Work

In this paper, we have analyzed how much semi-supervised techniques could help to reduce the need for intermediate-level annotations in training neural task-oriented dialogue models. The results suggest that we do not need to annotate all intermediate signals and are able to leverage unannotated examples for training these components instead. In the future, we plan to experiment with other intermediate signals like dialogue acts. Further improvements could potentially be obtained from employing more advanced regularization losses (Oliver et al., 2018).

A Progressive Model to Enable Continual Learning for Semantic Slot Filling

Abstract

Semantic slot filling is one of the major tasks in spoken language understanding (SLU). After a slot filling model is trained on pre-collected data, it is crucial to continually improve the model after deployment to learn users' new expressions. As the data amount grows, it becomes infeasible to either store such huge data and repeatedly retrain the model on all data or fine tune the model only on new data without forgetting old expressions. In this paper, we introduce a novel progressive slot filling model, *ProgModel*. ProgModel consists of a novel context gate that transfers previously learned knowledge to a small size expanded component; and meanwhile enables this new component to be fast trained to learn from new data. As such, ProgModel learns the new knowledge by only using new data at each time and meanwhile preserves the previously learned expressions. Our experiments show that ProgModel needs much less training time and smaller model size to outperform various model fine tuning competitors by up to 4.24% and 3.03% on two benchmark datasets.

1 Introduction

Spoken language understanding (SLU) systems play a vital role in ubiquitous artificially intelligent voice-enabled personal assistants. As one of the major tasks in SLU, semantic slot filling is treated as a sequential labeling problem to map a natural language sequence $\mathbf{x}$ to a slot label sequence $\mathbf{y}$ of the same length in IOB format (Yao et al., 2014). Typically, a slot filling model is trained offline on large scale corpora with pre-collected utterances. However, such corpora usually cannot cover all possible varieties of utterances exhaustively (e.g., personalized expressions, new vocabulary, utterances for new intent, etc.) from diverse users. Thus, it is critically desirable to develop a slot filling approach with the capability of continual learning after a personal assistant is deployed.

Unfortunately, existing approaches target on offline model training using a large scale training data. They are designed to either train a slot filling model independently (Yao et al., 2014; Peng et al., 2015; Kurata et al., 2016; Hakkani-Tür et al., 2016; Liu and Lane, 2016; Deng et al., 2019; Ray et al., 2019) or jointly with the other intent detection task in SLU (Guo et al., 2014; Liu and Lane, 2016; Zhang and Wang, 2016; Wang et al., 2018; Goo et al., 2018). Recently, (Shen et al., 2018a, 2019) developed cold start algorithms to generate training data with the hope of covering more varieties before deployment. On the other hand, (Ray et al., 2018; Shen et al., 2018b) attempt to personalize the slot filling model. However, they are still restricted to the offline training and cannot be applied to learn new user's expressions after deployment.

To support continual learning, a naive solution is to retrain the current model at each time. However, it suffers from several drawbacks: First, in order to maintain the SLU performance on both original and new expressions, it usually requires almost retraining the model using the whole dataset. However, as the size of training set grows, it becomes infeasible to repeatedly conduct time consuming retraining on such a large dataset. More importantly, the old training data typically is not stored permanently due to huge storage need and privacy protection. If only fine tuned on new utterances, the new model intends to lose the previously learned knowledge, a.k.a., *catastrophic forgetting* (French, 1999). Moreover, such fine-tuning of a large generic SLU model, even only on new utterances, is still quite inefficient. Recently, there are some progresses on continual learning in

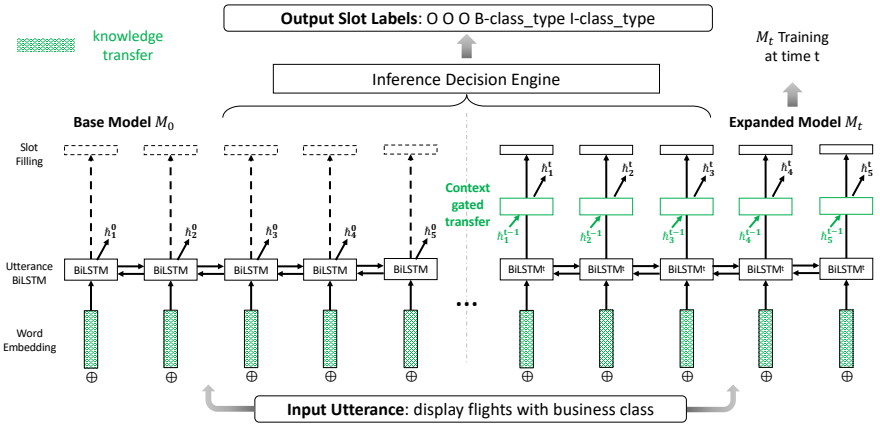

Figure 1: Our Proposed ProgModel Architecture: consists of an expanded component M^t at each batch t with context gated transfer of utterance contexts (Figure 2); and an inference decision engine to derive the label prediction. At each batch t, the last layers of base model and previous components (dotted lines) are only used for inference. Only the output of M^t is used to guide the training.

computer vision (Li and Hoiem, 2016; Lee et al., 2017), yet it still remains open in spoken language understanding systems.

In this paper, we consider a practical setting that a batch[1] of new training data U^t becomes available at each batch t. Our goal is to enable the continual learning capability of a slot filling model such that it can *keep learning new utterances efficiently as well as remember old knowledge without the needs of accessing old training data*. To achieve this, we design a novel *Progressive Slot Filling Model (ProgModel)* that can be gradually expanded at each batch by using a novel context gate for knowledge transfer. Unlike the baseline that repeatedly retrains the same model, ProgModel keeps the previously trained components untouched such that the catastrophic forgetting can be largely avoided. Using the transferred knowledge, each newly expanded component in ProgModel is trained in a progressive manner to achieve better performance with faster training compared with baseline model retraining approaches .

2 Proposed Approach

2.1 Progressive Model (ProgModel)

As the name indicates, the main idea of our proposed ProgModel is to progressively expand the model by transferring existing knowledge from the current model. Thus, ProgModel can continually enhance its capability of understanding user's new expressions without catastrophic forgetting. This is motivated by the recent success of progressive neural networks in various applications (Rusu et al., 2016).

As shown in Figure 1, ProgModel consists of the following components: (1) *Expanded Components:* The current model is expanded via context-gated knowledge transfer to allow only training on a new batch training set U^t at each batch t. (2) *Inference Decision Engine:* When we receive multiple outputs from base model and expanded components, the decision engine is to derive the slot filling label output without additional training.

2.1.1 Expanded Component M^t

At each batch t, a new component M^t (Figure 1 (right)) is expanded on the base model M^0 and previously expanded components $M^1 \dots M^{t-1}$, denoted as $M^{<t}$. The utterance BiLSTM^t is learned from scratch at each batch t such that it can learn the new sentence structures via word sequence correlations. Next, we focus on designing two knowledge transfer mechanisms (green parts in Figure 1) to maximally leverage the previously learned knowledge in $M^{<t}$.

Word Embeddings Transfer: Word embeddings in the newly expanded component M^t are initialized using those in M^0 based on the assumption that M^0 covers most vocabulary. For a new word w, we initialize using GloVe embedding. The embeddings will be fine tuned during training M^t.

Gated Utterance Context Transfer: We then design a novel *context gate* (Figure 2) by introducing lateral connections from most recent component M^{t-1}. *Note that this context gate is crucial to avoid retraining on all data or repeatedly duplicating a large base model every time.* Specifically, the lateral connections transfer the hidden states $\hbar_i^{t-1}$ for each word i from M^{t-1} to the newly expanded component M^t. They are projected to the same dimensional space of $\mathbf{h}_i^t$ via

[1]To avoid the confusion with the widely used timestamp in NLP (mean each word), we use each batch in our paper.

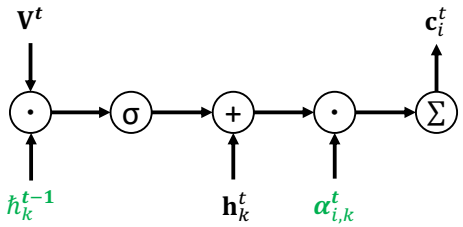

Figure 2: Context Gate for Transfer Utterance Context Knowledge from M^{t-1} (in green)

projection matrix $\mathbf{V}^t$ shared for each word:

$$\hbar_i^t = \mathbf{h}_i^t + \sigma(\mathbf{V}^t \hbar_i^{t-1})$$

where $\sigma(\cdot)$ is the sigmoid function.

Then, the context vector $\mathbf{c}_i^t$ for the i^{th} word in expanded component M^t is given as:

$$\mathbf{c}_i^t = \sum_{k=1}^{n} \alpha_{i,k}^t \hbar_k^t$$

where $\boldsymbol{\alpha}_i^t = softmax(\mathbf{e}_i)$ is fine tuned based on $\boldsymbol{\alpha}_i^0$ trained in base model M^0 as in Att-BiRNN model (Liu and Lane, 2016). We have $\alpha_{i,j}^0 = \frac{\exp(e_{i,j}^0)}{\sum_{k=1}^{T} \exp(e_{i,k}^0)}$ in which $e_{i,k}^0 = g^0(\mathbf{h}_{i-1}^0 \oplus \mathbf{c}_{i-1}^0, \mathbf{h}_k^0)$ is learned from a feed forward neural network g^0. In ProgModel, each model M^t has an independent g^t which is initialized by g^0 in M^0. Thus, $\boldsymbol{\alpha}_i^t$ will be fine tuned from $\boldsymbol{\alpha}_i^0$ during training M^t via updated g^t and $\hbar_i^t$.

2.1.2 Inference Decision Engine

We design the inference decision engine (IDE) as a non-trainable separate component to avoid the potential catastrophic forgetting. Thanks to the capability of knowledge transfer in ProgModel, M^t can already remember quite much previously learned knowledge to give good label prediction in many cases. Thus, we consider two types of decision engines: (1) *t-IDE*: ProgModel using only the output of M^t as decision engine; (2) *c-IDE*: for i^{th} word, it combines all outputs from each component M^t, $\sum_{k=0}^{t} P^k(i) I^k(i)$. $I^k(i)$ is an indicator function which is 1 when i^{th} word is in the vocabulary of M^k and 0 otherwise. The label with maximum probability is selected.

2.2 Progressive Training

The training procedure is progressively conducted at each batch t. The first step is to train the base model M^0 using the loss function $\mathcal{L}^0$:

$$\mathcal{L}^0(\boldsymbol{\theta}^0) \triangleq -\frac{1}{n} \sum_{j=1}^{|S|} \sum_{i=1}^{n} y_j(i) \log P_j^0(i)$$

where $\boldsymbol{\theta}^0$ are the parameters in M^0; $|S|$ is the number of semantic slots in IOB format; and n is the sequence length.

At each batch t, we train the expanded component M^t while fixing the parameters $\boldsymbol{\theta}^{<t}$ in previous components. The loss is backpropagated from the output of M^t using the loss function $\mathcal{L}^t$:

$$\mathcal{L}^t(\boldsymbol{\theta}^t, \boldsymbol{\phi}_{t-1}^t) \triangleq -\frac{1}{n} \sum_{j=1}^{|S|} \sum_{i=1}^{n} y_j(i) \log P_j^t(i)$$

where $\boldsymbol{\theta}^t$ and $\boldsymbol{\phi}_{t-1}^t$ are the parameters in model M^t and in the context gate between M^{t-1} and M^t. In both loss functions, $P_j^t(i)$ is output probability of slot j for the i^{th} word from M^t.

3 Experimental Results

3.1 Datasets & Settings

Dataset: We evaluate ProgModel on the following two benchmark datasets:

ATIS (Airline Travel Information Systems) dataset (Hemphill et al., 1990): a widely used dataset in SLU research. The training set contains 4,978 utterances from the ATIS-2 and ATIS-3 corpora, and the testing set contains 893 utterances from the ATIS-3 data sets. There are 127 distinct slot labels. We do not use the intent labels in ATIS.

Snips dataset (Snips, 2017): another NLU dataset custom-intent-engines collected by Snips for model evaluation. It contains 7 domains. In each domain, the training set contains 1,800 to 2,000 utterances and the testing set contains around 100 utterances. Since each domain in

Snips contains completely different slots and very few vocabulary are shared between the domains, we evaluate on each domain independently.

We use Amazon Mechanical Turk (MTurk) to split both training set into non-overlapping groups in each dataset (each domain in Snips as a separate dataset). Based on the size of each dataset, we consider 5 groups in ATIS and 3 groups in each domain of Snips dataset. Each turker is given 100 utterances from training set in one dataset; as well as the number of groups G for this dataset. He is asked to put utterances into no more than G groups based on their similarities. At last, we review the grouped utterances from turkers to further combine the similar utterances and derive the final grouping of the whole dataset. For each dataset, we consider the largest group of training set as a base dataset. At each batch t, one of leftover groups in training set is randomly selected to be U^t. Table 1 shows the detailed data statistics.

Competitors: First, only for reference purpose, we consider a *performance upper bound baseline*, i.e., train AttRNN on the all available dataset at each batch t. We compare with the following competitor approaches: (1) *FT-AttRNN* : fine tunes the current model only using new training data U^t at each batch t; (2) *FT-Lr-AttRNN* : fine tunes the current model using an adjusted lower learning rate (we use 0.3 times of base model learning rate which has the best performance) on the new training set U^t; (3) *FT-Cp-AttRNN* : copies the previous model and fine tunes the new copied model on new training data U^t at each batch t. During inference, FT-Cp-AttRNN uses both t-IDE and c-IDE decision engines and reports the one with better performance (F-1 score). We evaluate our ProgModel model with different inference engines: (1) *t-ProgModel*: ProgModel using only output of M^t as decision engine; (2) *c-ProgModel*: ProgModel using combined inference decision engine. All base models M^0 are trained on state-of-the-art AttRNN model (Liu and Lane, 2016). For fair evaluation, we test both ProgModel and competitors on the all standard testing sets.

Training: We implemented ProgModel model using TensorFlow 1.4.0 and conducted the experiments on NVIDIA Tesla M40. At each batch t, we train all models until their convergence. *We observe that ProgModel takes around 10 epochs due to less parameters and transferred knowledge in M^t while AttRNN retraining usually needs 100 epochs and various fine tuning competitors need around 30-50 epochs.*

3.2 Main Results

Table 2 and Table 3 show the F1 score of slot filling performance comparison results on ATIS dataset and each domain of Snips dataset. The results show that ProgModel consistently outperforms AttRNN in all domains, where the improvement gain is up to 4.24% in ATIS and 3.03% in Snips. As expected, ProgModel

continuously improves performance with more and more new batches of training data, even though it is only trained on new data at each batch. Among all competitors, FT-Cp-AttRNN achieves the closest performance to ProgModel by using much larger model size (shown in Section 3.4). In comparison, both FT-AttRNN and FT-Lr-AttRNN frequently suffer from catastrophic forgetting. The values in pink show that the performance of FT-AttRNN and FT-Cp-AttRNN drops up to 3.82% and 5.38% respectively. As a result, their F1 scores are significantly reduced in the end. At last, we observe that ProgModel is quite close to upper bound performance (Note that this is only for reference rather than comparison since upper bound performance assumes the availability of all training data while ProgModel does not).

3.3 Ablation Study

We further look into each competitor to better understand the advantage of our method. Since FT-AttRNN is only trained on new data, it is oftentimes overwhelmed by new knowledge and results in forgetting the old knowledge. On the other hand, FT-Lr-AttRNN has difficulty to learn new knowledge since it cannot jump out of local optimum due to a small learning rate. As a result, the performance of FT-Lr-AttRNN is even lower than FT-AttRNN most of the time. To make it even worse, the learning rate is very hard to tune at each batch. As we can see, it is non-trivial to achieve both goals, learn new knowledge and remember old knowledge.

FT-Cp-AttRNN performs slightly better than FT-AttRNN and FT-Lr-AttRNN . FT-Cp-AttRNN can be treated as a naive solution to achieve both goals by almost duplicating the model again and again. However, in addition to larger model size and longer training time, it still suffers from efficiently transfer previous knowledge and leads to catastrophic forgetting from time to time.

In comparison, ProgModel outperforms all above competitors since it provides a systematic mechanism to achieve both goals. The training of our designed context gate helps to determine which knowledge to transfer at each batch.

At last, we observe that c-ProgModel performs better than t-ProgModel in ATIS. This has two reasons: First, the utterances in different groups of ATIS are quite structurally similar such that c-IDE further enhances the correct slot label distribution by combing all outputs together. Second, many slots are not included in last group of ATIS dataset. In Snips, t-ProgModel outperforms c-ProgModel in most domains since the utterances in different groups have significant different structures and vocabularies. Thus, inference outputs could be conflicted and their combination leads to worse performance.

Table 4: Average Model Size (MB)

Domain	Batch	Approach		
		FT-AttRNN	FT-Cp-AttRNN	ProgModel
ATIS	0	18.0	18.0	18.0
	1		36.9	21.9
	2		56.2	25.5
	3		75.5	29.4
	4		94.8	33.3
Snips	0	25.3	25.3	25.3
	1		50.7	31.8
	2		76.2	38.1

3.4 Model Size Results

Table 4 reports the model size comparison between FT-AttRNN (FT-AttRNN and FT-Lr-AttRNN), FT-Cp-AttRNN and ProgModel (t-ProgModel and c-ProgModel). With more and more training data at each batch, the increase of ProgModel size is significantly slower than that of FT-Cp-AttRNN since the capability of knowledge transfer in ProgModel avoids the full model copy. Thus, our approach also better trades off the model size and performance. The small fluctuation of ProgModel model size expansion is due to the different size of vocabulary in each batch of training utterances. Each expanded model M^t will only keep the embedding of vocabulary in new training data U^t. One may concern that ProgModel will become large over time. In practice, it will be expanded only when the new data grows too large to handle by current model. Moreover, a new base model can be periodically reinitialized to reset the model size.

4 Conclusion

In this paper, we proposed a novel ProgModel model with the capability of efficient continual learning for semantic slot filling in SLU. ProgModel is designed to expand progressively at each batch of new training data with a new context gate for knowledge transfer. The model can be trained progressively without needing to store old training data. We showed that ProgModel need much shorter training time to significantly outperform baseline approaches and close to the upper bound performance.

Abstract

Natural Language Understanding (NLU) is a core component of dialog systems. It typically involves two tasks - intent classification (IC) and slot labeling (SL), which are then followed by a dialogue management (DM) component. Such NLU systems cater to utterances in isolation, thus pushing the problem of context management to DM. However, contextual information is critical to the correct prediction of intents and slots in a conversation. Prior work on contextual NLU has been limited in terms of the types of contextual signals used and the understanding of their impact on the model. In this work, we propose a context-aware self-attentive NLU (CASA-NLU) model that uses multiple signals, such as previous intents, slots, dialog acts and utterances over a variable context window, in addition to the current user utterance. CASA-NLU outperforms a recurrent contextual NLU baseline on two conversational datasets, yielding a gain of up to 7% on the IC task for one of the datasets. Moreover, a non-contextual variant of CASA-NLU achieves state-of-the-art performance for IC task on standard public datasets - SNIPS and ATIS.

1 Introduction

With the advent of smart conversational agents such as Amazon Alexa, Google Assistant, etc., dialogue systems are becoming ubiquitous. In the context of enterprises, the majority of these systems target task oriented dialogues with the user trying to achieve a goal, e.g. booking flight tickets or ordering food. Natural Language Understanding (NLU) captures the semantic meaning of a user's utterance within each dialogue turn, by identifying **intents** and **slots**. An intent specifies the goal underlying the expressed utterance while slots are additional parameters for these intents. These tasks are typically articulated as intent classification (IC) coupled with sequence tagging task of slot labeling (SL).

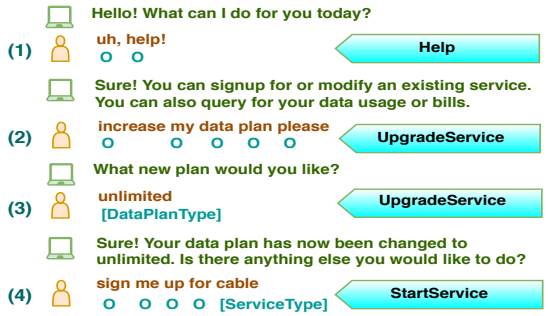

Figure 1: Snippet of a sample Cable data conversation with intents shown in boxes and slots aligned with user request

Over time, human-machine interactions have become more complex with greater reliance on contextual cues for utterance understanding (Figure 1). With traditional NLU frameworks, the resolution of contextual utterances is typically addressed in the DM component of the system using rule-based dialogue state trackers (DST). However, this pushes the problem of context resolution further down the dialogue pipeline, and despite the appeal of modularity in design, it opens the door for significant cascade of errors. To avoid this, end-to-end dialogue systems have been proposed (Wen et al., 2017; Bordes and Weston, 2016), but, to date, such systems are not scalable in industrial settings, and tend to be opaque where a level of transparency is needed, for instance, to understand various dialogue policies.

To address the propagation of error while maintaining a modular framework, Shi et al. (2015) proposed adding contextual signals to the joint IC-SL task. However, the contributions of their work were limited in terms of number of signals and how they were used, rendering the contextualization process still less interpretable. In this work, we present a multi-dimensional self-attention based contextual NLU model that overcomes prior work's shortcomings by supporting

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1285–1290, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

variable number of contextual signals (previous utterances, dialogue acts[1], intents and slot labels) that can be used concurrently over variable length of conversation context. In addition, our model allows for easy visualization and debugging of contextual signals which are essential, especially in production dialogue systems, where interpretability is a desirable feature. Our contributions are:

- Context-Aware Self-Attentive NLU (CASA-NLU) model that uses various contextual signals to perform joint IC-SL task, outperforming contextual and non-contextual NLU baselines by significant margins on two in-house conversational IC-SL datasets
- Propose a novel non-contextual variant of CASA-NLU that achieves SOTA performance on IC task for both SNIPS and ATIS datasets
- Analysis of the various contextual signals' contributions to model performance

2 Related Work

There have been numerous advancements in NLU systems for dialogues over the past two decades. While the traditional approaches used handcrafted features and word n-gram based features fed to SVM, logistic regression, etc. for IC task and conditional random fields (CRF) for SL task (Jeong and Lee, 2008; Wang1 et al., 2002; Raymond and Riccardi, 2007), more recent approaches rely on deep neural networks to jointly model IC and SL tasks (Yao et al., 2014a,b; Guo et al., 2014; Zhang and Wang, 2016; Liu and Lane, 2016c; Goo et al., 2018). Attention as introduced by Bahdanau et al. (2014) has played a major role in many of these systems (Liu and Lane, 2016a; Ma et al., 2017; Li et al., 2018a; Goo et al., 2018), for instance, for modeling interaction between intents and slots in (Goo et al., 2018).

Dahlbäck and Jönsson (1989) and Bertomeu et al. (2006) studied contextual phenomena and thematic relations in natural language, thereby highlighting the importance of using context. Few previous works focused on modeling turn-level predictions as DST task (Williams et al., 2013). However, these systems predict the possible slot-value pairs at utterance level (Zhong et al., 2018), making it necessary to maintain ontology of all possible slot values, which is infeasible for certain slot types (e.g., restaurant names). In industry settings, where IC-SL task is predominant, there is also an additional effort involved to invest in rules for converting utterance level dialog state annotations to token level annotations required for SL. Hence, our work mainly focuses on the IC-SL task which eliminates the need for maintaining any ontology or such handcrafted rules.

Bhargava et al. (2013) used previous intents and slots for IC and SL models. They were followed by Shi et al. (2015) who exploited previous intents and domain predictions to train a joint IC-SL model. However, both these studies lacked comprehensive context modeling framework that allows multiple contextual signals to be used together over a variable context window. Also, an intuitive interpretation of the impact of contextual signals on IC-SL task was missing.

3 CASA-NLU: Context-Aware Self-Attentive NLU

Our model architecture is composed of three sub sections - signal encoding, context fusion and IC-SL predictions (Figure 2).

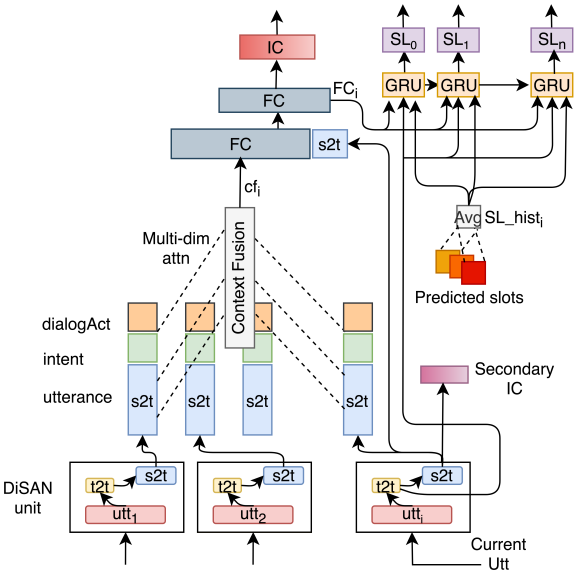

Figure 2: CASA-NLU model architecture for joint IC-SL

3.1 Signal Encoding

Utterance (Utt): For the utterance encoding, we adopt the directional self-attention (Shen et al., 2017) based encoder (DISAN), adding absolute position embedding (Gehring et al., 2017) to further improve the encoding performance.[2] DISAN unit consists of two types of multi-dimensional attention - word level token2token (t2t) attention fol-

[1]Dialog Act signifies the actions taken by the agent such as Close (when an intent is fulfilled), ElicitSlot, etc

[2]Details provided in Appendix A

lowed by sentence level source2token (s2t) attention. For turn i, the output of this unit is given by $\mathbf{h}(\text{Utt}_i) \in \mathbb{R}^{2d_h \times 1}$, where d_h is hidden layer size of the DISAN unit (Figure 2).

Intent / Dialog Act (DA) / Slot Label History: We pass the one-hot representation of intent ground truth labels through an embedding layer to get intent history representation $\mathbf{h}(\text{I}_i) \in \mathbb{R}^{d_I \times 1}$ for any previous turn i with d_I being the intent embedding dimension. Similarly, for DA history, $\mathbf{h}(\text{DA}_i) \in \mathbb{R}^{d_{DA} \times 1}$. We use a special dummy symbol for the intent and DA of the current turn. For slot label history, for turn i, we take the average of all slot embeddings that were observed in previous turns giving $\mathbf{h}(\text{SL_hist}_i) \in \mathbb{R}^{d_{SL} \times 1}$.

3.2 Context Fusion

We combine the vectorized signals together in both spacial and temporal dimensions. For the former, we simply concatenate the contextual signals to get current turn feature vector, i.e. $\mathbf{T}_i = [\mathbf{h}(\text{Utt}_i); \mathbf{h}(\text{I}_i); \mathbf{h}(\text{DA}_i)]$. However, for the latter, concatenation becomes intractable if context window is large. To address this issue and automatically learn more relevant components of context for each turn, we add a source2token (Shen et al., 2017) multi-dimensional self-attention layer over the turn vectors. This is essentially a per dimension learned weighted average ($\mathbf{cf}_i$) over all the turn vectors within a context window (Equation 1). As shown later in Section 5, this enhances the model's robustness by learning different attention weights for different contextual signals.

$$\mathbf{cf}_i = \sum_{t=i-K}^{i} \mathbf{P}(\mathbf{T}_t) \odot \mathbf{T}_t \qquad (1)$$

where, K (= 3 in our experiments) is the context window, and $\mathbf{T}_t$ and $\mathbf{P}(\mathbf{T}_t)$ are the turn vector and attention weights for t^{th} time step respectively. We use padding tokens for $i - K < 0$.

One of the shortcomings with such attention mechanism is that it is position invariant. To address this problem, we add learned absolute position embedding $\mathbf{p}_c$ to the turn matrix $\mathbf{T}$ that learns temporal information across the turns.

3.3 IC-SL Predictions

Following (Liu and Lane, 2016b; Li et al., 2018b), we train a joint IC-SL model. To improve IC performance for our deep network, we also add a secondary IC loss function, $\text{L}_{\text{Sec_IC}}$ at the utterance level (Figure 2). The new aggregated loss is:

$$\text{L} = \text{L}_{\text{IC}} + \alpha \times \text{L}_{\text{SL}} + \beta \times \text{L}_{\text{Sec_IC}} \qquad (2)$$

IC: At turn i, we take the output of context fusion layer $\mathbf{cf}_i$, pass it through a fully connected layer and concatenate the output with the current utterance encoding $\mathbf{h}(\text{Utt}_i)$. This is then further projected down using a fully connected layer (FC_i) and finally fed into *softmax* layer to predict the intent.

SL: For turn i, the t2t attention output is first fused with the utterance embedding using a fusion gate (Hochreiter and Schmidhuber, 1997) to generate $\mathbf{h}_{ij}$ where j represents token index in the utterance. Then, for each token position in the utterance, we apply a sliding window, w (=3) over neighboring words that transforms each token's embedding space from $\mathbf{h}_{ij}$ to $w \times \mathbf{h}_{ij}$ (not shown in the Figure 2). To add contextual information to SL task, each token's dimension is augmented using slot history (SL_hist_i) as well as penultimate fully connected layer for IC task (FC_i), yielding a final dimension of $w \times \mathbf{h}_{ij} + \mathbf{h}(\text{SL_hist}_i) + \mathbf{h}(\text{FC}_i)$. Finally, a Gated Recurrent Unit (GRU) renders the labels auto-regressive followed by *softmax* layer.

4 Experiments

Datasets: Since there are no existing public datasets for contextual IC and SL task, we use two in-house datasets for evaluation - **Booking** dataset,[3] which is a variation of DSTC-2 dataset (Williams et al., 2014) with intent, slot and dialog act annotations, and **Cable** dataset, a synthetically created conversational dataset. The Booking dataset contains 9,351 training utterances (2,200 conversations) and 6,727 test utterances, with 19 intents and 5 slot types. Cable dataset comprises 1856 training utterances, 1,814 validation utterances and 1,836 test utterances, with 21 intents and 26 slot types.[4] In addition, we also evaluate the model on non-contextual IC-SL public datasets - ATIS (Hemphill et al., 1990) and SNIPS (Coucke et al., 2018).

Experimental setup: To emphasize the importance of contextual signals in modeling, we first devise a non-contextual baseline of our CASA-NLU model, NC-NLU. It is similar to CASA-

[3] Dataset will be released to the public

Table 1: Average IC accuracy scores (%) on non-contextual datasets. *: as reported in (Goo et al., 2018)

NLU in terms of model architecture except no contextual signals are used. Since neither datasets nor implementation details were shared in previous works on contextual NLU (Bhargava et al., 2013; Shi et al., 2015), we also implement another baseline, CGRU-NLU that uses GRU (Cho et al., 2014) instead of self-attention for temporal context fusion. For fair comparison to existing non-contextual baselines, no pre-trained embeddings are used in any of the experiments though the model design can easily benefit from pre-training.

5 Results and Analysis

Table 1 shows the performance of our non-contextual model on two datasets, ATIS and SNIPS. As shown, we obtain a **new SOTA** for IC on both the datasets.[5] We hypothesize that the high performance is due to the utterance-level position-aware multi-dimensional self-attention.

As shown in Table 2, CASA-NLU model outperforms non-contextual NLU on both the Booking and Cable datasets. Further, CASA-NLU model significantly **outperforms** CGRU-NLU on the Cable dataset by 7.26% on IC accuracy and 5.31% on SL F1 absolute, respectively. We believe the reason for strong performance yielded by the CASA-NLU model is due to its multi-dimensional nature, where we learn different weights for different dimensions within the context feature vector $\mathbf{T}_i$. This enables the model to learn different attention distributions for different contextual signals leading to more robust modeling compared to CGRU-NLU model. Table 3 gives further breakdown of the results by showing performance on first vs. follow-up turns in a dialogue. For the more challenging follow-up turns, CASA-NLU yields significant gains over the baseline IC performance.

Table 4 shows impact of some of the contextual signals on model performance for the Booking validation dataset. As expected, contextual signals improve IC and SL performance (Configs - II-V). We observe that adding intent history (I_{hist}) leads to highest gains in IC accuracy (Config - IV). At the same time, we see that slot history (SL_{hist}) has minimal impact on SL performance for this dataset. Exhaustive experiments showed that the choice of contextual signals is dependent upon the dataset. Our model facilitates switching these contextual signals on or off easily.

Model	Booking		Cable

Table 4: Impact of contextual signals on IC accuracy and SL F1 scores (%) on Booking validation set for CASA-NLU

Qualitative Analysis: Using example conversation in Figure 1, we highlight the relevance of contextual information in making intent predictions by visualizing attention weights $\mathbf{P}(\mathbf{T})$ (Equation 1) for different contextual signals as shown in Figure 3.[6] At user turn 2, the *intent* is switched to *UpgradeService* which the model successfully interprets by paying less attention to previous intents. At turn 3, however, contextual information is critical as user responds to elicitation by agent and hence model emphasizes on last utterance and intent rather than the current or other previous turns.

[5] Since we compute token-level F1, SL performance is not compared to results reported in previous work

[6] For each context signal, attention weights are averaged across all its feature dimensions in $\mathbf{P}(\mathbf{T})$

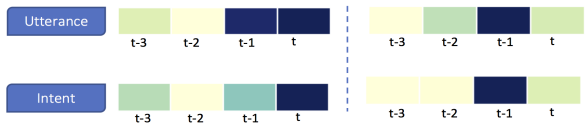

Figure 3: **Visualization of attention weights** given to two different context signals - previous utterances (top) and previous intents (bottom) for turns t=2 (left) and t=3 (right) from Figure 1; darker colors reflect higher attention weights.

6 Conclusion

We proposed CASA-NLU model that uses a variable context and various contextual signals in addition to the current utterance to predict the intent and slot labels for the current turn. CASA-NLU achieves gains of over 7% on IC accuracy for Cable dataset over CGRU-NLU baseline, and almost 29% over non-contextual version. This highlights the importance of using contextual information, meanwhile showing that, learning correct attention is also vital for NLU systems.

7 Implementation Details

We use hidden layer size of 56 with dropout probability of 0.3. Context history window K was varied from 1 to 5 and the optimal value of 3 was selected. Word embeddings are trained from scratch using an embedding layer size of 56. Adam (Kingma and Ba, 2014) algorithm with initial learning rate of 0.01 gave the optimal performance. Concatenation window size w of 3 is used. α and β in loss objective are set to 0.9. Early stopping is used with patience of 10 and threshold of 0.5. Each model is trained for 3 seeds and scores averaged across the seeds are reported.

Abstract

We study how to sample negative examples to automatically construct a training set for effective model learning in retrieval-based dialogue systems. Following an idea of dynamically adapting negative examples to matching models in learning, we consider four strategies including minimum sampling, maximum sampling, semi-hard sampling, and decay-hard sampling. Empirical studies on two benchmarks with three matching models indicate that compared with the widely used random sampling strategy, although the first two strategies lead to performance drop, the latter two ones can bring consistent improvement to the performance of all the models on both benchmarks.

1 Introduction

In this work, we study the problem of response selection as an approach to implementing a retrieval-based dialogue system (Ji et al., 2014; Wang et al., 2013). A key step in response selection is measuring the matching degree between a conversation context and a response candidate. Existing studies focus on constructing a matching model with sophisticated neural architectures (Lowe et al., 2015; Zhou et al., 2016; Yan et al., 2016; Wu et al., 2017; Zhang et al., 2018; Zhou et al., 2018; Tao et al., 2019), but pay little attention to how to effectively learn such architectures from data. On the one hand, it is well known that learning of complicated neural architectures requires large-scale high quality training data; on the other hand, since human labeling is expensive and exhausting, most of the existing work just adopts a simple heuristic to automatically build a training set where human responses are treated as positive examples and negative response candidates are randomly sampled. Such a training set might contain many false negatives and trivial true negatives that are very easy to distinguish from those true positives. As a result, models with advanced architectures can only reach sub-optimal performance after learning (Wu et al., 2018).

In this paper, instead of configuring new architectures, we investigate how to improve the performance of existing matching models with a better learning method. A learning method usually involves choice of loss functions and construction of training data, and we are particularly interested in automatic training data construction, as data are often more crucial to the performance of models. The key problem in training data construction lies in how to properly choose negative examples, and our idea is that negative examples should adapt to the matching models at different learning stages. Following this idea, we consider four negative sampling strategies, namely minimum sampling, maximum sampling, semi-hard sampling, and decay-hard sampling. In the first two strategies, a response candidate that corresponds to the minimal or the maximal matching score at the current step is picked from a pool as a negative example for the next step; and in the latter two strategies, we select negative examples by considering how hard they are to the current matching models. The semi-hard sampling prefers candidates with moderate difficulty to avoid both false negatives and trivial true negatives, and the decay-hard sampling gradually increases the difficulty of negative samples with the training process going on.

We compare different sampling strategies with three matching models in different levels of complexity on two benchmarks. Evaluation results indicate that minimum sampling and maximum sampling are inferior to randomly sampling, and both semi-hard sampling and decay-hard sampling can bring consistent improvement to the perfor-

mance of all the three models on both data sets.

Our contributions include (1) a systematic comparison of different sampling strategies with two benchmarks; and (2) proposal of semi-hard and decay-hard negative sampling strategies that can generally improve the performance of existing matching models on benchmarks.

2 Learning a Matching Model for Response Selection

Suppose that $\mathcal{D} = \{(c_i, \{r_{i,j}^+\}_{j=1}^{n_i^+}, \{r_{i,k}^-\}_{k=1}^{n_i^-})\}_{i=1}^N$ is a training set, where c_i is a conversation context, $\forall j \in \{1, \ldots, n_i^+\}$, $r_{i,j}^+$ is a positive response candidate that properly replies to c_i, and $\forall k \in \{1, \ldots, n_i^-\}$, $r_{i,k}^-$ is a negative response candidate that is used to indicate errors in responding to a model, then the learning problem of response selection is to estimate a matching model $g(\cdot, \cdot)$ from $\mathcal{D}$, which can be formulated as

$$\operatorname*{argmin}_{\Theta} \sum_{i=1}^{N} \Big[\sum_{j=1}^{n_i^+} L(+1, g(c_i, r_{i,j}^+)) + \sum_{k=1}^{n_i^-} L(-1, g(c_i, r_{i,k}^-)) \Big], \tag{1}$$

where Θ are the parameters of $g(\cdot, \cdot)$, and $L(\cdot, \cdot)$ is a loss function.

In practice, $L(\cdot, \cdot)$ is usually set as cross entropy, then the remaining problems become (1) how to define $g(\cdot, \cdot)$; and (2) how to construct $\mathcal{D}$ given that large-scale human labeling is infeasible. Existing work has paid enough effort to solving Problem (1), but only adopts a simple heuristic for Problem (2) where human responses are treated as $\{r_{i,j}^+\}_{j=1}^{n_i^+}$ (a common case is $n_i^+ = 1$ since only one response is available for a specific context), and some randomly sampled responses are utilized as $\{r_{i,k}^-\}_{k=1}^{n_i^-}$. The problem with this heuristic is that there is no guarantee on what responses will be sampled as $\{r_{i,k}^-\}_{k=1}^{n_i^-}$: some of them could be false negatives, and some could be too trivial to recognize. The clear drawback of random sampling motivates us to pursue better negative sampling strategies in training data construction, as will be elaborated in the next section.

3 Model Adaptive Negative Sampling

Our idea is to dynamically adapt negative examples to matching models in learning. The idea is inspired by how human learn knowledge: they adjust their learning materials according to their learning progress. Based on this idea, we consider four strategies to sample negative examples:

Minimum sampling: the strategy used to be exploited in answer selection (Rao et al., 2016), and here we apply it to response selection for open domain dialogue systems. Suppose that $\hat{g}(\cdot, \cdot)$ is a matching model obtained from the t-th mini-batch, then in the $(t+1)$-th mini-bach, we try to select the easiest negative example for a context c according to $\hat{g}(\cdot, \cdot)$, which can be formulated as

$$\operatorname*{argmin}_{r^- \in \mathcal{R}^-} \hat{g}(c, r^-), \tag{2}$$

where $\mathcal{R}^-$ is a pool of negative examples for c.

Maximum sampling: similar to minimum sampling, the strategy is also borrowed from answer selection (Rao et al., 2016), but attempts to select the hardest negative example by

$$\operatorname*{argmax}_{r^- \in \mathcal{R}^-} \hat{g}(c, r^-), \tag{3}$$

Semi-hard sampling: the first two strategies might be too aggressive, as the easiest negative example could bring no new information to $\hat{g}(\cdot, \cdot)$, and the hardest one could be a false negative. To avoid both cases, we propose a semi-hard sampling strategy which selects a negative sample with moderate difficulty. Formally, the strategy is defined as

$$\operatorname*{argmin}_{r^- \in \mathcal{R}^-} |\hat{g}(c, r^+) - \hat{g}(c, r^-) - \alpha|, \tag{4}$$

where r^+ is the positive response candidate of c[1], and α is a constant. In Equation (4), we exploit α as a margin to control the distance of matching degree between the selected r^- and r^+. The one with a matching degree closest to $\hat{g}(c, r^+) - \alpha$ is picked as a negative example.

Decay-hard sampling: to imitate the behavior that human gradually increase the difficulty of their learning materials at different stages, we propose a decay-hard sampling strategy which decays the margin in Equation (4) with the training process going on. Specifically, we consider two methods, namely exponential decay and linear decay.

[1] We assume that only one positive example is available as a common case, otherwise $\hat{g}(c, r^+)$ is replaced with $\min_{r^+ \in \mathcal{R}^+} \hat{g}(c, r^+)$.

In the first method, the margin shrinks in a exponential speed. In the t-th mini-bach, the margin α_t is defined by

$$\alpha_t = \varphi \times \exp(\omega \times t), \quad (5)$$

where $0 < \varphi < 1$ and $-1 < \omega < 0$ are parameters. In the second method, the margin linearly becomes small with the training steps, which is given by

$$\alpha_t = \lambda \times t + \theta, \quad (6)$$

where $0 < \theta < 1$ and , $-1 < \lambda < 0$ are parameters. We carefully choose θ and λ to make sure that $\alpha_t > 0$, $\forall t \in \{1, \ldots, T\}$, where T refers to the maximum number of iterations.

Note that descriptions above assume that for each context, only one negative example is selected from the pool. This is for a fair comparison with random sampling on benchmarks, as most of the existing work (Wu et al., 2017; Zhou et al., 2018) utilizes one negative example per context in training. It is easy to extend the strategies to sample multiple negative examples (e.g., by picking the top l examples with matching scores closest to $\hat{g}(c, r^+) - \alpha$ in semi-hard sampling).

4 Experiments

We compare different sampling strategies on two benchmarks.

4.1 Experimental Setup

The first data set we use is the Ubuntu Dialogue Corpus (Lowe et al., 2015) collected from chat logs of the Ubuntu Forum. We use the version provided by Xu et al. (2017). The data contains 1 million context-response pairs for training, and 0.5 million pairs for validation and test.

Following (Lowe et al., 2015), we employ recall at position k in n candidates (R_n@k) as evaluation metrics.

Besides the Ubuntu data, we also choose the Douban Conversation Corpus (Wu et al., 2017) as an experimental data set. The data consists of multi-turn Chinese conversations collected from Douban group[2]. There are 1 million context-response pairs for training, 50 thousand pairs for validation, and 6,670 pairs for test.

Following (Wu et al., 2017), we employ R_n@ks, mean average precision (MAP), mean reciprocal rank (MRR)(Voorhees et al., 1999) and precision at position 1 (P@1) as evaluation metrics.

[2] https://www.douban.com/group

4.2 Matching Models

The following matching models are selected:

Dual-LSTM (Lowe et al., 2015): the model individually encodes a context and a response candidate with LSTMs, and then calculates a matching score based on the final states of the two LSTMs.

SMN (Wu et al., 2017): the model lets each utterance in a context interact with a response, and forms the interaction matrices into a matching vector with CNN. The matching vectors are finally accumulated with an RNN as a matching score.

DAM (Zhou et al., 2018): the model performs matching in a similar manner as SMN but represents a context and a response candidate with stacked self-attention and cross-attention.

In terms of both complexity and performance under random sampling, Dual-LSTM<SMN<DAM. Regarding to baselines, we consider two random sampling strategies. The first one is a static strategy where negative examples are fixed in the entire learning procedure. This is how existing work learns a matching model with the data described in Section 4.1, and we denote the model as Model-Base. The second one is a dynamic strategy where in each mini-batch, a negative example is randomly sampled from $\mathcal{R}^-$. This is a simplification of model adaptive sampling strategies, and we denote a model learned with this strategy as Model-Rand. We denote a model trained with minimum sampling, maximum sampling, semi-hard sampling, exponential decay-hard sampling, and linear decay-hard sampling as Model-Min, Model-Max, Model-Semi, Model-EDecay, and Model-LDecay respectively. All models are implemented with TensorFlow and tuned on the validation sets. We make sure that Model-Base achieves the performance on both data sets as that reported in (Zhou et al., 2018).

4.3 Implementation Details

For static random sampling, we just use the published training sets of both data. For the remaining sampling strategies, we randomly sample 10 responses[3] for each context from the training sets as a pool of negative examples at each epoch. Every time, one response is sampled from the pool as a negative example for a context. Models trained with different sampling strategies are

[3] We set the size of $\mathcal{R}^-$ as 10 to balance efficacy and efficiency.

Table 1: Evaluation results of different sampling strategies on the two data sets. Numbers in bold indicate the best strategies for the corresponding models on specific metrics.

tuned with the same validation sets and evaluated with the same test sets (i.e., the original released sets). We vary α in semi-hard sampling in $\{0.01, 0.03, 0.05, 0.07, 0.09, 0.1, 0.3, 0.5\}$, and choose 0.07. In decay-hard sampling, we set ω, φ, λ, and θ as $-1.5e-5$, 0.1, $-8.75e-7$, and 0.1 on respectively.

4.4 Evaluation Results

Table 1 reports evaluation results on the two data sets. We can see that both semi-hard sampling and decay-hard sampling can generally improve the three matching models on both data sets. Minimum sampling and maximum sampling are consistently worse than random sampling, which verified the statement we make in Section 3 that the two strategies are too aggressive. Decay-hard sampling is a little worse than semi-hard sampling. The reason might be that false negatives are introduced to learning by decay-hard at late stages of training. Dynamic random sampling is better than static random sampling, because models can leverage more negative examples from the pool. It is worth noting that the proposed sampling strategies does not change the elapsed time for prediction, despite a little more training time. On the other hand, we do see improvement on the two data sets. Therefore, we believe it is worth paying a little more training time but obtaining the improvement.

Besides the comparison of different sampling strategies, we are also interested in how the hyper-parameter α affects the performance of semi-hard sampling. Figure 1 shows how the performance of SMN and DAM changes with respect to different margins (i.e., α). We observe a similar trend for both models: they first increase monotonically until the margin reaches 0.07, and then drop as the margin increases. Particularly, the performance of both models with the semi-hard sampling strategy is worse than that with the random sampling strategy when the margin reaches 0.5. The reason behind the phenomenon is that when the margin is small, semi-hard sampling is similar to maximum sampling and will introduce false negatives into learning, while when the margin is large, semi-hard sampling is like minimum sampling and is prone to provide trivial samples to learning.

(a) SMN (b) DAM

5 Related works

Negative sampling strategies have been studied in many machine learning tasks. In the computer vision fields, Faghri et al. (2017) studies hard negatives and introduces a simple change to common loss function on image-caption retrieval tasks. Guo et al. (2018) proposes a fast negative sampler which chooses negative examples that are most likely to meet the requirements of violation according to the latent factors of image. In natural language processing fields, Kotnis and Nastase (2017) analyses the impact of negative sampling strategies on the performance of link prediction in knowledge graphs. Saeidi et al. (2017) studies the affect of a tailored sample strategy on the performance of document retrieval task. Rao et al. (2016) uses three negative strategies to select the most informative negative samples on the pairwise ranking model for answer selection. Xu et al. (2015) introduces a straightforward negative sampling strategy to improve the assignment of subjects and objects on a convolution neural network. To our best knowledge, this is the first work to empirical study of negative sampling strategies for learning of matching models in multi-turn retrieval-based dialogue systems, which may enlighten future works in the learning of retrieval-based dialogue systems.

6 Conclusions

We present minimum sampling, maximum sampling, semi-hard sampling, and decay-hard sampling as four model adaptive negative sampling strategies to learn a matching model for retrieval-based dialogue systems. Evaluation results with three models on two benchmarks indicate that although minimum sampling and maximum sampling are worse than random sampling, both semi-hard sampling and decay-hard sampling can generally improve the performance of the models on both data sets. In the future, we would like to extend our negative sampling strategies to other tasks.

Abstract

Despite the surging demands for multilingual task-oriented dialog systems (e.g., Alexa, Google Home), there has been less research done in multilingual or cross-lingual scenarios. Hence, we propose a zero-shot adaptation of task-oriented dialogue system to low-resource languages. To tackle this challenge, we first use a set of very few parallel word pairs to refine the aligned cross-lingual word-level representations. We then employ a latent variable model to cope with the variance of similar sentences across different languages, which is induced by imperfect cross-lingual alignments and inherent differences in languages. Finally, the experimental results show that even though we utilize much less external resources, our model achieves better adaptation performance for natural language understanding task (i.e., the intent detection and slot filling) compared to the current state-of-the-art model in the zero-shot scenario.

1 Introduction

Task-oriented dialogue systems have been widely adopted in the industry (e.g., Amazon Alexa, Google Home, Apple Siri, Microsoft Cortana) as a virtual agent to tend to the needs of the users. However, these agents have mostly been trained with the monolingual dataset that is often expensive to build or acquire. In order to cope with the scarcity of low-resource language dialogue data, we are motivated to look into cross-lingual dialogue systems which can adapt with very little or no training data in the target language.

This task of zero-shot adaptation of dialogue systems to different languages is relatively new and has not been explored thoroughly enough yet. The main approach of previous work (Upadhyay et al., 2018; Chen et al., 2018; Schuster et al., 2019) in this task is using aligned cross-lingual word embeddings between source and target languages. However, this method suffers from imperfect alignments between the source and target language embeddings. This can be attributed not only to the noise in aligning two different embeddings, but also to the inherent discrepancies in different languages such as Thai and English which come from entirely different roots. To address such variance in the alignment, we turn to probabilistic modeling with latent variables as it has been successfully used in several recent task-oriented dialogue systems (Wen et al., 2017; Zhao et al., 2017, 2018; Zhao and Eskenazi, 2018; Le et al., 2018).

(a) Cross-lingual word embeddings (b) Seed dictionary refinement

Figure 1: (a) The aligned word embeddings. (b) Refined mapping $\mathbf{W}$ with seed dictionary; green circle represents close words in different languages.

However, we notice that naively using latent variables does not help the model improve much in slot filling and intent prediction. We hypothesize that the variance of the cross-lingual word embeddings is too large for the model to learn any meaningful latent variables. Hence, we propose to first refine the cross-lingual embeddings with $\sim$10 seed word-pairs related to the dialogue domains. We then add Gaussian noise (Zheng et al., 2016) to further compensate the imperfect alignment of cross-lingual embeddings.

As a result, a combination of these methods allows us to build a transferable latent variable model that learns the distribution of training language inputs that is invariant to noise in the cross-

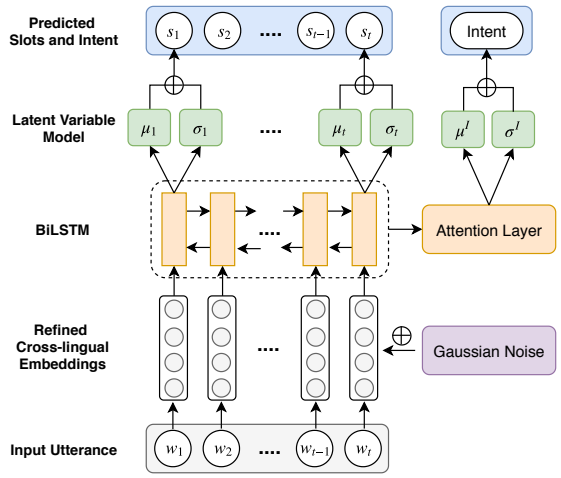

Figure 2: The structure of our proposed model.

lingual word embeddings. This enables our model to capture the variance of semantically similar sentences across different languages, and achieve state-of-the-art results in zero-shot adaptation of English to Spanish and Thai for the natural language understanding task (i.e., the intent prediction and slot filling) on the dataset proposed by Schuster et al. (2019), even though we use much less external resources (i.e., ∼10 seed word-pairs) while others utilize a large amount of bilingual corpus. We further visualize the learned latent variables to confirm that same-meaning words and sentences have similar distributions.

2 Related Work

Cross-lingual transfer learning which acts as one of the low-resource topics (Gu et al., 2018; Lee et al., 2019; Liu et al., 2019; Xu et al., 2018) has attracted more and more people recently, followed by the rapid development of cross-lingual word embeddings. Artetxe et al. (2017) proposed a self-learning framework and utilized a small size of word dictionary to learn the mapping between source and target word embeddings. Conneau et al. (2018) leveraged adversarial training to learn a linear mapping from a source to a target space without using parallel data. Joulin et al. (2018) utilized Relaxed CSLS loss to optimize this mapping problem. Winata et al. (2019) introduced a method to leverage cross-lingual meta-representations for code-switching name entity recognition by combining multiple monolingual word embeddings.

Chen et al. (2018) proposed a teacher-student framework leveraging bilingual data for cross-lingual transfer learning in dialogue state tracking. Upadhyay et al. (2018) leveraged joint training and cross-lingual embeddings to do zero-shot and almost zero-shot transfer learning in intent prediction and slot filling. Finally, Schuster et al. (2019) utilizes Multilingual CoVe embeddings obtained from training Machine Translation systems as in (McCann et al., 2017). The main difference of our work with previous work is that our model does not leverage any external bilingual data other than 11 word pairs for embeddings refinement.

3 Methodology

Our model consists of a refined cross-lingual embedding layer followed by a BiLSTM (Hochreiter and Schmidhuber, 1997) which parameterizes the Latent Variable Model, as illustrated in Figure 2. We jointly train our model to predict both slots and user intents. We denote $\mathbf{w} = [w_1, \ldots, w_T]$ as the input words and $\mathbf{e} = [e_1, \ldots, e_T]$ as the word embeddings of $\mathbf{w}$. The slot at time-step t is s_t, while the intent for each sentence $\mathbf{w}$ is denoted as I. Note that only matrices are bold-faced.

3.1 Cross-lingual Embeddings Refinement

To further refine the cross-lingual alignments to our task, we draw from the hypothesis that domain-related words are more important than others. Hence, as shown in Figure 1, we propose to refine the cross-lingual word embeddings (Joulin et al., 2018)[1] using very few parallel word pairs, which is obtained by selecting 11 English words related to dialogue domains (weather, alarm, and reminder) and translate them using bilingual lexicons. We refine the embeddings by leveraging the framework proposed in Artetxe et al. (2017).

Let $\mathbf{X}$ and $\mathbf{Z}$ be the aligned cross-lingual word embeddings between two languages. X_{i*} and Z_{j*} are the embeddings for the i^{th} source word and j^{th} target word. We denote a binary dictionary matrix $\mathbf{D}$: $D_{ij} = 1$ if the i^{th} source language word is aligned with the j^{th} target language word and $D_{ij} = 0$ otherwise. The goal is to find the optimal mapping matrix $\mathbf{W}^*$ by minimizing:

$$\mathbf{W}^* = \arg\min_{\mathbf{W}} \sum_{i,j} D_{ij} ||X_{i*}\mathbf{W} - Z_{j*}||^2. \quad (1)$$

Following Artetxe et al. (2016), with orthogonal constraints, mean centering, and length normaliza-

[1]The embeddings are available in https://fasttext.cc

tion, we can maximize the following instead:

$$\mathbf{W}^* = \arg\max_{\mathbf{W}} \text{Tr}(\mathbf{X}\mathbf{W}\mathbf{Z}^{\text{T}}\mathbf{D}^{\text{T}}). \quad (2)$$

We iteratively optimize Equation 2 until distances between domain-related seed words are closer than a certain threshold after refinement. Figure 1 illustrates better alignment for domain-related words after refinement.

3.2 Gaussian Noise Injection

To cope with the noise in alignments, we inject Gaussian noise to English embeddings, so the trained model will be more robust to variance. This is a regularization method to improve the generalization ability to the unseen inputs in different languages, particularly languages from different roots such as Thai and Spanish. The final embeddings are $\mathbf{e}^* = [e_1 + N_1, \ldots, e_T + N_T]$, where $\mathbf{N} \sim \mathcal{N}(0, 0.1\mathbf{I})$.

3.3 Latent Variable Model (LVM)

Given a near-perfect cross-lingual embedding, there is still noise caused by the inherent discrepancies between source and target languages. This noise amplifies when combined with imperfect alignment, and makes point estimation vulnerable to the small, but not negligible differences across languages. Instead, using latent variables will allow us to model the distribution that captures the variance of semantically similar sentences across different languages. The whole training process is defined as follows:

$$[h_1 ... h_t ... h_T] = \text{BiLSTM}(\mathbf{e}^*), \quad (3)$$

$$m_t = h_t w_a,\ a_t = \frac{exp(m_t)}{\sum_{j=1}^{T} exp(m_j)},\ v = \sum_{t=1}^{T} a_t h_t, \quad (4)$$

$$\begin{bmatrix} \mu_t^S \\ \log(\sigma_t^S)^2 \end{bmatrix} = \mathbf{W}_r^S h_t, \begin{bmatrix} \mu^I \\ \log(\sigma^I)^2 \end{bmatrix} = \mathbf{W}_r^I v, \quad (5)$$

$$z_t^S \sim q_t^S(z|h_t),\ \ z^I \sim q^I(z|v), \quad (6)$$

$$p_t^S(s_t|z_t^S) = \text{Softmax}(\mathbf{W}_g^S z_t^S), \quad (7)$$

$$p^I(I|z^I) = \text{Softmax}(\mathbf{W}_g^I z^I), \quad (8)$$

where attention vector (v) is obtained by following Felbo et al. (2017) and w_a is the weight matrix for the attention layer, $\mathbf{W}_{\{r,g\}}^{\{S,I\}}$ are trainable parameters, superscripts S and I refer to slot prediction and intent detection respectively, subscript "r" refers to "recognition" for obtaining the mean and variance vectors while subscript "g" refers to "generation" for predicting the slots and intents, and $q_t^S \sim \mathcal{N}(\mu_t^S, (\sigma_t^S)^2\mathbf{I})$ and $q^I \sim \mathcal{N}(\mu^I, (\sigma^I)^2\mathbf{I})$ are the posterior approximations which we sample our latent vectors z_t^S and z^I from. Finally, p_t^S and p^I are the predictions for the slot of the *t-th* token and the intent of the utterance respectively. The objective functions for slot filling and intent prediction are:

$$\mathcal{L}^I = \mathbb{E}_{z^I}[\log p^I(I|z^I)], \quad (9)$$

$$\mathcal{L}_t^S = \mathbb{E}_{z_t^S}[\log p_t^S(s_t|z_t^S)], \quad (10)$$

$$\mathcal{L}^S = \sum_{t=1}^{T} L_t^S, \quad (11)$$

hence, the final objective function to minimize is,

$$\mathcal{L} = \mathcal{L}^S + \mathcal{L}^I. \quad (12)$$

The model prediction is not deterministic since the latent variables z_t^S and z^I are sampled from the Gaussian distributions. Therefore, in the inference time, we use the true mean μ_t^S and μ^I to replace z_t^S and z^I respectively to make the prediction deterministic.

4 Experiments

4.1 Dataset

We conduct our experiments under the zero-shot scenario of multilingual task-oriented dialogue dataset presented by Schuster et al. (2019). Our model is trained only with the English data and then do a zero-shot test on Spanish and Thai test set. We delexicalize words by replacing the tokens which represent numbers, time (such as am, pm), and duration (such as 30min) with special tokens `<number>`, `<time>`, and `<last>` respectively.

4.2 Training Details

In the training procedure, we freeze the word embeddings of the primary language, and then replace them with the corresponding aligned word embeddings of the unseen languages for a zero-shot test. We use bi-directional LSTM model with hidden dimension size of 250, and the latent variable model with both mean and variance in the size of 100. Gaussian noise with zero mean and variance of 0.1 is injected dynamically in different iterations. We use the accuracy to evaluate the performance of intent prediction and the standard

(2018) model and evaluated with our test set. † Schuster et al. (2019) translated English data to Spanish and Thai with a trained supervised machine translation system and it is considered as our *upper bound* result.

BIO structure to calculate the F1 score for evaluating the performance of slot filling. In the zero-shot cross-lingual adaptation, we simply replace the training language (i.e., English) word embeddings with the cross-lingual target language (i.e., Spanish or Thai) word embeddings. Note that we never use any target language evaluation data to select the model for zero-shot cross-lingual adaptation, instead, we utilize the English validation set and early stop strategy according to the slot F1 score.

4.3 Word Pairs

We choose the number of word pairs based on the vocabulary size of the corpus. Intuitively, the larger the vocabulary size is, the more words we need to align across languages, and the more word pairs we need to achieve good performance. We select 11 domain-related words which frequently exist in the English training set. The number of words we select is around 0.25% of the vocabulary size for the English training set. The concrete information of the 11 word pairs is as follows:

The English seed words we selected are *weather, forecast, temperature, rain, hot, cold, remind, forget, alarm, cancel, tomorrow*, which are related to the three dialogue domains (weather, alarm, and reminder). We translate them by leveraging bilingual dictionaries[2]. The corresponding translations in Spanish and Thai are *clima, pronóstico, temperatura, lluvia, caliente, frío, recordar, olvidar, alarma, cancelar, mañana* and อากาศ, พยากรณ์, อุณหภูมิ, ฝน, ร้อน, หนาว, เตือน, ลืม, เตือน, ยกเลิก, พรุ่ง respectively.

Table 2: Ablation Study on LVM models. {- *LVM*} means removing LVM and {- *LVM* + *MLP*} means replacing LVM with a Multi-Layer Perceptron which has the same size as the LVM.

4.4 Evaluation

We implement and evaluate the following models:

Zero-shot SLU Upadhyay et al. (2018) used cross-lingual embeddings (Bojanowski et al., 2017) to do zero-shot transfer learning.

Conditional Random Fields (CRF) We reproduce the baseline model in Schuster et al. (2019), and also add embedding noise, cross-lingual refinement, and delexicalization.

Latent Variable Model (LVM) - Ours We replace the CRF module with latent variables and also apply it to intent prediction.

Besides, we directly compare with the baseline models illustrated in Schuster et al. (2019):

Multi. CoVe w/ auto They combined Multilingual CoVe (Yu et al., 2018) with an auto-encoder objective and then used the trained encoder with the CRF model.

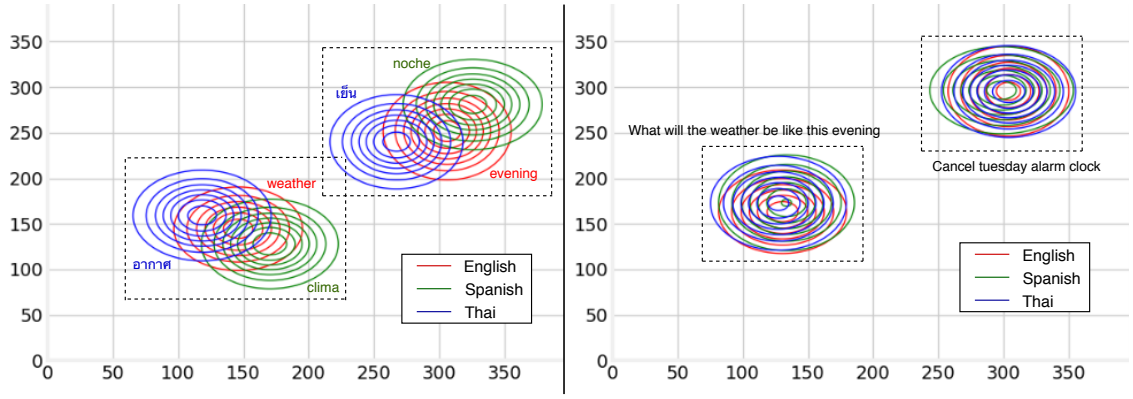

Figure 3: Visualization of latent variables on words **(left)** and sentences **(right)**. **Left:** We choose "weather-clima-อากาศ" and "evening-noche- เย็น" from parallel sentences. *English: "What will the weather be like this evening"*, *Spanish: "Cómo será el clima esta noche"*, *Thai:* "ตอน เย็น นี้ อากาศ จะ เป็น อย่างไร". **Right:** We choose two English sentences and show their distributions and those of the corresponding Spanish and Thai translations.

Translate Train They trained a supervised machine translation system to translate English data into the target language and then trained the CRF model on this translated dataset.

5 Results & Discussion

From Table 1, in general, LVM outperforms CRF models. This is because for semantically same words (e.g., weather and clima) LVM considers such close enough points as the same distribution, but CRF is more likely to classify them differently. This can be shown very clearly from Figure 3, in which the latent variables demonstrate similar distributions for semantically similar sentences and words. In addition, we can see that adding only Gaussian noise to the Vanilla BiLSTM improves our prediction performance significantly, which implies that the robustness of our model towards the noisy signals which come from the target embedding inputs.

Furthermore, it is clearly visible that cross-lingual embeddings refinement is more effective in Spanish than Thai. This is attributed to the quality of alignments in the two languages. Spanish is much more lexically and grammatically similar to English than Thai, so word-level embedding refinement is reasonably good. Jointly incorporating all three methods (Gaussian noise injection, cross-lingual embeddings refinement, and delexicalization) further reduces the noise in the inputs as well as makes the model more robust to noise, which help LVM to more easily approximate the distribution.

Finally, in Table 2, we ablate the usage of LVM to see whether the boost of performance comes simply from the increase of parameter size. By removing or replacing LVM with MLP, we can see the clear performance gains by using LVM.

6 Conclusion

In this paper, we propose a transferable latent variable that focuses on improving the zero-shot cross-lingual adaptation of natural language understanding task to low-resource languages. We show that a combination of 1) cross-lingual embeddings refinement, 2) Gaussian noise injection, and 3) latent variables are effective in coping with the variance of semantically similar sentences across different languages, and the visualizations of the latent variables confirm such. We leverage very few resources (i.e., 11 seed word pairs) and achieve state-of-the-art performance for English-to-Spanish and English-to-Thai in the zero-shot cross-lingual scenario.

Abstract

Dialogue management (DM) plays a key role in the quality of the interaction with the user in a task-oriented dialogue system. In most existing approaches, the agent predicts only one DM policy action per turn. This significantly limits the expressive power of the conversational agent and introduces unwanted turns of interactions that may challenge users' patience. Longer conversations also lead to more errors and the system needs to be more robust to handle them. In this paper, we compare the performance of several models on the task of predicting multiple acts for each turn. A novel policy model is proposed based on a recurrent cell called gated Continue-Act-Slots (gCAS) that overcomes the limitations of the existing models. Experimental results show that gCAS[1] outperforms other approaches.

1 Introduction

In a task-oriented dialogue system, the dialogue manager policy module predicts actions usually in terms of dialogue acts and domain specific slots. It is a crucial component that influences the efficiency (e.g., the conciseness and smoothness) of the communication between the user and the agent. Both supervised learning (SL) (Stent, 2002; Williams et al., 2017a; Williams and Zweig, 2016; Henderson et al., 2005, 2008) and reinforcement learning (RL) approaches (Walker, 2000; Young et al., 2007; Gasic and Young, 2014; Williams et al., 2017b; Su et al., 2017) have been adopted to learn policies. SL learns a policy to predict acts given the dialogue state. Recent work (Wen et al., 2017; Liu and Lane, 2018) also used SL as pre-training for RL to mitigate the sample inefficiency of RL approaches and to reduce the number of interactions. Sequence2Sequence (Seq2Seq) (Sutskever et al., 2014) approaches have also been adopted in user simulators to produce user acts (Gur et al., 2018). These approaches typically assume that the agent can only produce one act per turn through classification. Generating only one act per turn significantly limits what an agent can do in a turn and leads to lengthy dialogues, making tracking of state and context throughout the dialogue harder. An example in Table 1 shows how the agent can produce both an *inform* and a *multiple_choice* act, reducing the need for additional turns.

user msg	Hi! I'm looking for good thriller. Are there any playing right now?
agent msg	Yes, there are! The Witch, The Other Side of the Door, and The Boy are all thrillers. Would you like to find tickets for a showing for any of them?
agent acts	inform(moviename=The Witch, The Other Side of the Door, The Boy; genre=thriller) multiple_choice(moviename)

Table 1: Dialogue example.

The use of multiple actions has previously been used in interaction managers that keep track of the floor (who is speaking right now) (Raux and Eskénazi, 2007; Khouzaimi et al., 2015; Hastie et al., 2013, among others), but the option of generating multiple acts simultaneously at each turn for dialogue policy has been largely ignored, and only explored in simulated scenarios without real data (Chandramohan and Pietquin, 2010).

This task can be cast as a multi-label classification problem (if the sequential dependency among the acts is ignored) or as a sequence generation one as shown in Table 2.

In this paper, we introduce a novel policy model to output multiple actions per turn (called multi-act), generating a sequence of tuples and expanding agents' expressive power. Each tuple is defined as $(continue, act, slots)$, where *continue* indicates whether to continue or stop producing new acts, *act* is an *act type* (e.g., *inform* or *request*), and *slots* is a set of slots (names) associated with the current *act type*. Correspondingly, a novel decoder

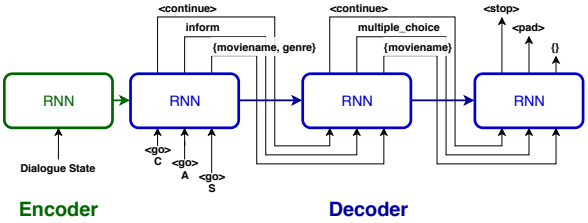

Figure 1: CAS decoder: at each step, a tuple of (continue, act, slots) is produced. The KB vector k regarding the queried result from knowledge base is not shown for brevity.

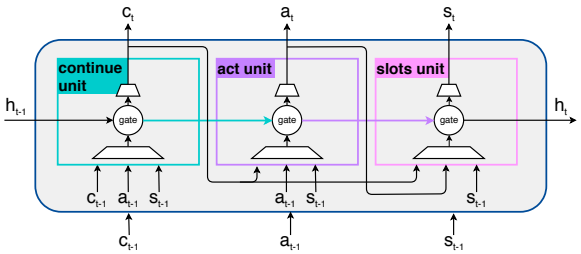

Figure 2: The gated CAS recurrent cell contains three units: continue unit, act unit and slots unit. The three units use a gating mechanism and are sequentially connected. The KB vector k is not shown for brevity.

(Figure 1) is proposed to produce such sequences. Each tuple is generated by a cell called gated Continue Act Slots (gCAS, as in Figure 2), which is composed of three sequentially connected gated units handling the three components of the tuple. This decoder can generate multi-acts in a double recurrent manner (Tay et al., 2018). We compare this model with baseline classifiers and sequence generation models and show that it consistently outperforms them.

2 Methodology

The proposed policy network adopts an encoder-decoder architecture (Figure 1). The input to the encoder is the current-turn dialogue state, which follows Li et al. (2018)'s definition. It contains policy actions from the previous turn, user dialogue acts from the current turn, user requested slots, the user informed slots, the agent requested slots and agent proposed slots. We treat the dialogue state as a sequence and adopt a GRU (Cho et al., 2014) to encode it. The encoded dialogue state is a sequence of vectors $\mathbf{E} = (e_0, \ldots, e_l)$ and the last hidden state is h^E. The CAS decoder recurrently generates tuples at each step. It takes h^E as initial hidden state h_0. At each decoding step, the input contains the previous (continue, act, slots) tuple $(c_{t-1}, a_{t-1}, s_{t-1})$. An additional vector k containing the number of results from the knowledge base (KB) query and the current turn number is given as input. The output of the decoder at each step is a tuple (c, a, s), where $c \in \{\langle\text{continue}\rangle, \langle\text{stop}\rangle, \langle\text{pad}\rangle\}$, $a \in A$ (one act from the act set), and $s \subset S$ (a subset from the slot set).

2.1 gCAS Cell

As shown in Figure 2, the gated CAS cell contains three sequentially connected units for outputting continue, act, and slots respectively.

The **Continue unit** maps the previous tuple $(c_{t-1}, a_{t-1}, s_{t-1})$ and the KB vector k into x_t^c. The hidden state from the previous step h_{t-1} and x_t^c are inputs to a GRU^c unit that produces output g_t^c and hidden state h_t^c. Finally, g_t^c is used to predict c_t through a linear projection and a softmax.

$$\begin{aligned} x_t^c &= W_x^c[c_{t-1}, a_{t-1}, s_{t-1}, k] + b_x^c, \\ g_t^c, h_t^c &= \text{GRU}^c(x_t^c, h_{t-1}), \\ P(c_t) &= \text{softmax}(W_g^c g_t^c + b_g^c), \\ \mathcal{L}^c &= -\sum_t \log P(c_t). \end{aligned} \tag{1}$$

The **Act unit** maps the tuple (c_t, a_{t-1}, s_{t-1}) and the KB vector k into x_t^a. The hidden state from the continue cell h_t^c and x_t^a are inputs to a GRU^a unit that produces output g_t^a and hidden state h_t^a. Finally, g_t^a is used to predict a_t through a linear projection and a softmax.

$$\begin{aligned} x_t^a &= W_x^a[c_t, a_{t-1}, s_{t-1}, k] + b_x^a, \\ g_t^a, h_t^a &= \text{GRU}^a(x_t^a, h_t^c), \\ P(a_t) &= \text{softmax}(W_g^a g_t^a + b_g^a), \\ \mathcal{L}^a &= -\sum_t \log P(a_t). \end{aligned} \tag{2}$$

The **Slots unit** maps the tuple (c_t, a_t, s_{t-1}) and the KB vector k into x_t^s. The hidden state from the act cell h_t^a and x_t^s are inputs to a GRU^s unit that produces output g_t^s and hidden state h_t^s. Finally, g_t^a is used to predict s_t through a linear projection and a sigmoid. Let z_t^i be the i-th slot's ground truth.

$$\begin{aligned} x_t^s &= W_x^s[c_t, a_t, s_{t-1}, k] + b_x^s, \\ g_t^s, h_t^s &= \text{GRU}^s(x_t^s, h_t^a), \\ s_t &= \text{sigmoid}(W_g^s g_t^s + b_g^s), \\ \mathcal{L}^s &= -\sum_t \sum_{i=0}^{|S|} z_t^i \log s_t^i + (1 - z_t^i) \log\left(1 - s_t^i\right). \end{aligned} \tag{3}$$

The overall loss is the sum of the losses of the three units: $\mathcal{L} = \mathcal{L}^c + \mathcal{L}^a + \mathcal{L}^s$

restaurant user	12726	1672	100	3
restaurant agent	10333	3755	403	10

Table 4: Dialogue act counts by turn.

3 Experiments

The experiment dataset comes from Microsoft Research (MSR) [2]. It contains three domains: movie, taxi, and restaurant. The total count of dialogues per domain and train/valid/test split is reported in Table 3. At every turn both user and agent acts are annotated, we use only the agent side as targets in our experiment. The acts are ordered in the dataset (each output sentence aligns with one act). The size of the sets of acts, slots, and act-slot pairs are also listed in Table 3. Table 4 shows the count of turns with multiple act annotations, which amounts to 23% of the dataset. We use MSR's dialogue management code and knowledge base to obtain the state at each turn and use it as input to every model.

3.1 Evaluation Metrics

We evaluate the performance at the act, frame and task completion level. For a frame to be correct, both the act and all the slots should match the ground truth. We report precision, recall, F_1 score of turn-level acts and frames. For task completion evaluation, **Entity F_1** score and **Success F_1** score (Lei et al., 2018) are reported. The Entity F_1 score, differently from the entity match rate in state tracking, compares the slots requested by the agent with the slots the user informed about and that were used to perform the KB query. We use it to measure agent performance in requesting information. The Success F_1 score compares the slots provided by the agent with the slots requested by the user. We use it to measure the agent performance in providing information.

Table 5: Entity F_1 and Success F_1 at dialogue level.

Critical slots and Non-critical slots: By 'non-critical', we mean slots that the user informs the system about by providing their values and thus it is not critical for the system to provide them in the output. Table 1 shows an example, with the genre slot provided by the user and the system repeating it in its answer. Critical slots refers to slots that the system must provide like moviename in the Table 1 example. Although non-critical slots do not impact task completion directly, they may influence the output quality by enriching the dialogue state and helping users understand the system's utterance correctly. Furthermore, given the same dialog state, utterances offering non-critical slots or not offering them can both be present in the dataset, as they are optional. This makes the prediction of those slots more challenging for the system. To provide a more detailed analysis, we report the precision, recall, F_1 score of turn-level for all slots, critical slots and non-critical slots of the *inform* act.

3.2 Baseline

We compare five methods on the multi-act task.

Classification replicates the MSR challenge (Li et al., 2018) policy network architecture: two fully connected layers. We replace the last activation from softmax to sigmoid in order to predict probabilities for each act-slot pair. It is equivalent to binary classification for each act-slot pair and the

gCAS	request {date; starttime}	inform {restaurantname} multiple_choice{restaurantname}

Table 7: Examples of predicted dialogue acts in the restaurant domain.

loss is the sum of the binary cross-entropy of all of them.

Seq2Seq (Sutskever et al., 2014) encodes the dialogue state as a sequence, and decodes agent acts as a sequence with attention (Bahdanau et al., 2015).

Copy Seq2Seq (Gu et al., 2016) adds a copy mechanism to Seq2Seq, which allows copying words from the encoder input.

CAS adopts a single GRU (Cho et al., 2014) for decoding and uses three different fully connected layers for mapping the output of the GRU to continue, act and slots. For each step in the sequence of CAS tuples, given the output of the GRU, continue, act and slot predictions are obtained by separate heads, each with one fully connected layer. The hidden state of the GRU and the predictions at the previous step are passed to the cell at the next step connecting them sequentially.

gCAS uses our proposed recurrent cell which contains separate continue, act and slots unit that are sequentially connected.

The classification architecture has two fully connected layers of size 128, and the remaining models have a hidden size of 64 and a teacher-forcing rate of 0.5. Seq2Seq and Copy Seq2Seq use a beam search with beam size 10 during inference. CAS and gCAS do not adopt a beam search since their inference steps are much less than Seq2Seq methods. All models use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001.

3.3 Result and Error Analysis

As shown in Table 5, gCAS outperforms all other methods on Entity F_1 in all three domains. Compared to Seq2Seq, the performance advantage of gCAS in the taxi and restaurant domains is small, while it is more evident in the movie domain. The reason is that in the movie domain the proportion of turns with multiple acts is higher (52%), while in the other two domains it is lower (30%). gCAS also outperforms all other models in terms of Success F_1 in the movie and restaurant domain but is outperformed by the classification model in the taxi domain. The reason is that in the taxi domain, the agent usually informs the user at the last turn, while in all previous turns the agent usually requests information from the user. It is easy for the classification model to overfit this pattern. The advantage of gCAS in the restaurant domain is much more evident: the agent's *inform* act usually has multiple slots (see example 2 in Table 7) and this makes classification and sequence generation harder, but gCAS multi-label slots decoder handles it easily.

Table 6 shows the turn-level acts and frame prediction performance. CAS and gCAS outperform all other models in acts prediction in terms of F_1 score. The main reason is that CAS and gCAS output a tuple at each recurrent step, which makes for shorter sequences that are easier to generate compared to the long sequences of Seq2Seq (example 2 in Table 7). The classification method has a good precision score, but a lower recall score, suggesting it has problems making granular decisions (example 2 in Table 7). At the frame level, gCAS still outperforms all other methods. The performance

Table 9: $\mathcal{P}$, $\mathcal{R}$ and $\mathcal{F}_1$ of turn-level *inform* critical slots.

difference between CAS and gCAS on frames becomes much more evident, suggesting that gCAS is more capable of predicting slots that are consistent with the act. This finding is also consistent with their Entity F_1 and Success F_1 performance.

However, gCAS's act-slot pair performance is far from perfect. The most common failure case is on non-critical slots (like 'genre' in the example in Table 2): gCAS does not predict them, while it predicts the critical ones (like 'moviename' in the example in Table 2).

Table 7 shows predictions of all methods from two emblematic examples. Example 1 is a frequent single-act multi-slots agent act. Example 2 is a complex multi-act example. The baseline classification method can predict frequent pairs in the dataset, but cannot predict any act in the complex example. The generated sequences of Copy Seq2Seq and Seq2Seq show that both models struggle in following the syntax. CAS cannot predict slots correctly even if the act is common in the dataset. gCAS returns a correct prediction for Example 1, but for Example 2 gCAS cannot predict 'starttime', which is a non-critical slot.

Tables 8 and 9 show the results of all slots, critical slots and non-critical slots under the *inform* act. gCAS performs better than the other methods on all slots in the movie and restaurant domains. The reason why classification performs the best here in the taxi domain is the same as the Success F_1. In the taxi domain, the agent usually informs the user at the last turn. The non-critical slots are also repeated frequently in the taxi domain, which makes their prediction easier. gCAS's performance is close to other methods on critical-slots. The reason is that the *inform* act is mostly the first act in multi-act and critical slots are usually frequent in the data. All methods can predict them well.

In the movie and restaurant domains, the *inform* act usually appears during the dialogue and there are many optional non-critical slots that can appear (see Table 3, movie and restaurant domains have more slots and pairs than the taxi domain). gCAS can better predict the non-critical slots than other methods. However, the overall performance on non-critical slots is much worse than critical slots since their appearances are optional and inconsistent in the data.

4 Conclusion and Future Work

In this paper, we introduced a multi-act dialogue policy model motivated by the need for a richer interaction between users and conversation agents. We studied classification and sequence generation methods for this task, and proposed a novel recurrent cell, gated CAS, which allows the decoder to output a tuple at each step. Experimental results showed that gCAS is the best performing model for multi-act prediction. The CAS decoder and the gCAS cell can also be used in a user simulator and gCAS can be applied in the encoder. A few directions for improvement have also been identified: 1) improving the performance on non-critical slots, 2) tuning the decoder with RL, 3) text generation from gCAS. We leave them as future work.

Acknowledgments

We would like to express our special thanks to Alexandros Papangelis and Gokhan Tur for their support and contribution. We also would like to thank Xiujun Li for his help on dataset preparation and Jane Hung for her valuable comments. Abstract

Task-oriented dialog systems need to know when a query falls outside their range of supported intents, but current text classification corpora only define label sets that cover every example. We introduce a new dataset that includes queries that are out-of-scope—i.e., queries that do not fall into any of the system's supported intents. This poses a new challenge because models cannot assume that every query at inference time belongs to a system-supported intent class. Our dataset also covers 150 intent classes over 10 domains, capturing the breadth that a production task-oriented agent must handle. We evaluate a range of benchmark classifiers on our dataset along with several different out-of-scope identification schemes. We find that while the classifiers perform well on in-scope intent classification, they struggle to identify out-of-scope queries. Our dataset and evaluation fill an important gap in the field, offering a way of more rigorously and realistically benchmarking text classification in task-driven dialog systems.

1 Introduction

Task-oriented dialog systems have become ubiquitous, providing a means for billions of people to interact with computers using natural language. Moreover, the recent influx of platforms and tools such as Google's DialogFlow or Amazon's Lex for building and deploying such systems makes them even more accessible to various industries and demographics across the globe.

Tools for developing such systems start by guiding developers to collect training data for intent classification: the task of identifying which of a fixed set of actions the user wishes to take based on their query. Relatively few public datasets exist for evaluating performance on this task, and those that do exist typically cover only a very small number of intents (e.g. Coucke et al. (2018), which has 7 intents). Furthermore, such resources do not facilitate analysis of *out-of-scope* queries: queries that users may reasonably make, but fall outside of the scope of the system-supported intents.

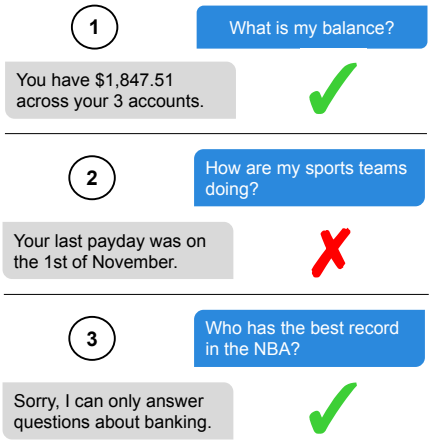

Figure 1: Example exchanges between a user (blue, right side) and a task-driven dialog system for personal finance (grey, left side). The system correctly identifies the user's query in (1), but in (2) the user's query is mis-identified as in-scope, and the system gives an unrelated response. In (3) the user's query is correctly identified as out-of-scope and the system gives a fallback response.

Figure 1 shows example query-response exchanges between a user and a task-driven dialog system for personal finance. In the first user-system exchange, the system correctly identifies the user's intent as an in-scope BALANCE query. In the second and third exchanges, the user queries with out-of-scope inputs. In the second exchange, the system incorrectly identifies the query as in-scope and yields an unrelated response. In the third exchange, the system correctly classifies the user's query as out-of-scope, and yields a fallback response.

Out-of-scope queries are inevitable for a task-oriented dialog system, as most users will not be fully cognizant of the system's capabilities, which are limited by the fixed number of intent classes.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1311–1316,

Correctly identifying out-of-scope cases is thus crucial in deployed systems—both to avoid performing the wrong action and also to identify potential future directions for development. However, this problem has seen little attention in analyses and evaluations of intent classification systems.

This paper fills this gap by analyzing intent classification performance with a focus on out-of-scope handling. To do so, we constructed a new dataset with 23,700 queries that are short and unstructured, in the same style made by real users of task-oriented systems. The queries cover 150 intents, plus out-of-scope queries that do not fall within any of the 150 in-scope intents.

We evaluate a range of benchmark classifiers and out-of-scope handling methods on our dataset. BERT (Devlin et al., 2019) yields the best in-scope accuracy, scoring 96% or above even when we limit the training data or introduce class imbalance. However, all methods struggle with identifying out-of-scope queries. Even when a large number of out-of-scope examples are provided for training, there is a major performance gap, with the best system scoring 66% out-of-scope recall. Our results show that while current models work on known classes, they have difficulty on out-of-scope queries, particularly when data is not plentiful. This dataset will enable future work to address this key gap in the research and development of dialog systems. All data introduced in this paper can be found at `https://github.com/clinc/oos-eval`.

2 Dataset

We introduce a new crowdsourced dataset of 23,700 queries, including 22,500 in-scope queries covering 150 intents, which can be grouped into 10 general domains. The dataset also includes 1,200 out-of-scope queries. Table 1 shows examples of the data.[1]

2.1 In-Scope Data Collection

We defined the intents with guidance from queries collected using a *scoping* crowdsourcing task, which prompted crowd workers to provide questions and commands related to topic domains in the manner they would interact with an artificially intelligent assistant. We manually grouped data generated by *scoping* tasks into intents. To collect additional data for each intent, we used the *rephrase* and *scenario* crowdsourcing tasks proposed by Kang et al. (2018).[2] For each intent, there are 100 training queries, which is representative of what a team with a limited budget could gather while developing a task-driven dialog system. Along with the 100 training queries, there are 20 validation and 30 testing queries per intent.

2.2 Out-of-Scope Data Collection

Out-of-scope queries were collected in two ways. First, using worker mistakes: queries written for one of the 150 intents that did not actually match any of the intents. Second, using *scoping* and *scenario* tasks with prompts based on topic areas found on Quora, Wikipedia, and elsewhere. To help ensure the richness of this additional out-of-scope data, each of these task prompts contributed to at most four queries. Since we use the same crowdsourcing method for collecting out-of-scope data, these queries are similar in style to their in-scope counterparts.

The out-of-scope data is difficult to collect, requiring expert knowledge of the in-scope intents to painstakingly ensure that no out-of-scope query sample is mistakenly labeled as in-scope (and vice versa). Indeed, roughly only 69% of queries collected with prompts targeting out-of-scope yielded out-of-scope queries. Of the 1,200 out-of-scope queries collected, 100 are used for validation and 100 are used for training, leaving 1,000 for testing.

2.3 Data Preprocessing and Partitioning

For all queries collected, all tokens were downcased, and all end-of-sentence punctuation was removed. Additionally, all duplicate queries were removed and replaced.

In an effort to reduce bias in the in-scope data, we placed all queries from a given crowd worker in a single split (train, validation, or test). This avoids the potential issue of similar queries from a crowd worker ending up in both the train and test sets, for instance, which would make the train and test distributions unrealistically similar. We note that this is a recommendation from concurrent work by Geva et al. (2019). We also used this procedure for the out-of-scope set, except that we split the data into train/validation/test based on task prompt instead of worker.

[1] See the supplementary material for a full list of domains and intents, as well as additional examples.

[2] In all cases, crowd workers were paid $0.20 per task. See the supplementary material for examples of each task.

Domain	Intent	Query
BANKING	TRANSFER	*move 100 dollars from my savings to my checking*
WORK	PTO REQUEST	*let me know how to make a vacation request*
META	CHANGE LANGUAGE	*switch the language setting over to german*
AUTO & COMMUTE	DISTANCE	*tell the miles it will take to get to las vegas from san diego*
TRAVEL	TRAVEL SUGGESTION	*what sites are there to see when in evans*
HOME	TODO LIST UPDATE	*nuke all items on my todo list*
UTILITY	TEXT	*send a text to mom saying i'm on my way*
KITCHEN & DINING	FOOD EXPIRATION	*is rice ok after 3 days in the refrigerator*
SMALL TALK	TELL JOKE	*can you tell me a joke about politicians*
CREDIT CARDS	REWARDS BALANCE	*how high are the rewards on my discover card*
OUT-OF-SCOPE	OUT-OF-SCOPE	*how are my sports teams doing*
OUT-OF-SCOPE	OUT-OF-SCOPE	*create a contact labeled mom*
OUT-OF-SCOPE	OUT-OF-SCOPE	*what's the extended zipcode for my address*

Table 1: Sample queries from our dataset. The out-of-scope queries are similar in style to the in-scope queries.

2.4 Dataset Variants

In addition to the full dataset, we consider three variations. First, **Small**, in which there are only 50 training queries per each in-scope intent, rather than 100. Second, **Imbalanced**, in which intents have either 25, 50, 75, or 100 training queries. Third, **OOS+**, in which there are 250 out-of-scope training examples, rather than 100. These are intended to represent production scenarios where data may be in limited or uneven supply.

3 Benchmark Evaluation

To quantify the challenges that our new dataset presents, we evaluated the performance of a range of classifier models[3] and out-of-scope prediction schemes.

3.1 Classifier Models

SVM: A linear support vector machine with bag-of-words sentence representations.
MLP: A multi-layer perceptron with USE embeddings (Cer et al., 2018) as input.
FastText: A shallow neural network that averages embeddings of *n*-grams (Joulin et al., 2017).
CNN: A convolutional neural network with non-static word embeddings initialized with GloVe (Pennington et al., 2014).
BERT: A neural network that is trained to predict elided words in text and then fine-tuned on our data (Devlin et al., 2019).
Platforms: Several platforms exist for the development of task-oriented agents. We consider Google's DialogFlow[4] and Rasa NLU[5] with spacy-sklearn.

[3]See the supplementary material for model details.
[4]https://dialogflow.com
[5]https://github.com/RasaHQ/rasa

3.2 Out-of-Scope Prediction

We use three baseline approaches for the task of predicting whether a query is out-of-scope: (1) ***oos-train***, where we train an additional (i.e. 151^{st}) intent on out-of-scope training data; (2) ***oos-threshold***, where we use a threshold on the classifier's probability estimate; and (3) ***oos-binary***, a two-stage process where we first classify a query as in- or out-of-scope, then classify it into one of the 150 intents if classified as in-scope.

To reduce the severity of the class imbalance between in-scope versus out-of-scope query samples (i.e., 15,000 versus 250 queries for OOS+), we investigate two strategies when using *oos-binary*: one where we undersample the in-scope data and train using 1,000 in-scope queries sampled evenly across all intents (versus 250 out-of-scope), and another where we augment the 250 OOS+ out-of-scope training queries with 14,750 sentences sampled from Wikipedia.

From a development point of view, the *oos-train* and *oos-binary* methods both require careful curation of an out-of-scope training set, and this set can be tailored to individual systems. The *oos-threshold* method is a more general decision rule that can be applied to any model that produces a probability. In our evaluation, the out-of-scope threshold was chosen to be the value which yielded the highest validation score across all intents, treating out-of-scope as its own intent.

3.3 Metrics

We consider two performance metrics for all scenarios: (1) accuracy over the 150 intents, and (2) recall on out-of-scope queries. We use recall to evaluate out-of-scope since we are more interested in cases where such queries are predicted as in-

	Classifier	In-Scope Accuracy Full	Small	Imbal	OOS+	Out-Of-Scope Recall Full	Small	Imbal	OOS+
oos-train	FastText	89.0	84.5	87.2	89.2	9.7	23.2	12.2	32.2
	SVM	91.0	89.6	89.9	90.1	14.5	18.6	16.0	29.8
	CNN	91.2	88.9	89.1	91.0	18.9	22.2	19.0	34.2
	DialogFlow	91.7	89.4	90.7	91.7	14.0	14.1	15.3	28.5
	Rasa	91.5	88.9	89.2	90.9	45.3	**55.0**	**49.6**	**66.0**
	MLP	93.5	91.5	92.5	94.1	**47.4**	52.2	35.6	53.9
	BERT	**96.9**	**96.4**	**96.3**	**96.7**	40.3	40.9	43.8	59.2
oos-threshold	SVM	88.2	85.6	86.0	—	18.0	13.0	0.0	—
	FastText	88.6	84.8	86.6	—	28.3	6.0	33.2	—
	DialogFlow	90.8	89.2	89.2	—	26.7	20.5	38.1	—
	Rasa	90.9	89.6	89.4	—	31.2	1.0	0.0	—
	CNN	90.9	88.9	90.0	—	30.9	25.5	26.9	—
	MLP	93.4	91.3	92.5	—	49.1	32.4	13.3	—
	BERT	**96.2**	**96.2**	**95.9**	—	**52.3**	**58.9**	**52.8**	—

Table 2: Benchmark classifier results under each data condition using the *oos-train* (top half) and *oos-threshold* (bottom half) prediction methods.

scope, as this would mean a system gives the user a response that is completely wrong. Precision errors are less problematic as the fallback response will prompt the user to try again, or inform the user of the system's scope of supported domains.

4 Results

4.1 Results with *oos-train*

Table 2 presents results for all models across the four variations of the dataset. First, BERT is consistently the best approach for in-scope, followed by MLP. Second, out-of-scope query performance is much lower than in-scope across all methods. Training on less data (Small and Imbalanced) yields models that perform slightly worse on in-scope queries. The trend is mostly the opposite when evaluating out-of-scope, where recall increases under the Small and Imbalanced training conditions. Under these two conditions, the size of the in-scope training set was decreased, while the number of out-of-scope training queries remained constant. This indicates that out-of-scope performance can be increased by increasing the relative number of out-of-scope training queries. We do just that in the OOS+ setting—where the models were trained on the full training set as well as 150 additional out-of-scope queries—and see that performance on out-of-scope increases substantially, yet still remains low relative to in-scope accuracy.

4.2 Results with *oos-threshold*

In-scope accuracy using the *oos-threshold* approach is largely comparable to *oos-train*. Out-of-scope recall tends to be much higher on Full, but several models suffer greatly on the limited datasets. BERT and MLP are the top *oos-threshold* performers, and for several models the threshold approach provided erratic results, particularly FastText and Rasa.

Classifier	In-Scope Accuracy under	wiki aug	Out-of-Scope Recall under	wiki aug
DialogFlow	84.7	—	37.3	—
Rasa	87.5	—	37.7	—
FastText	88.1	87.0	22.7	31.4
SVM	88.4	89.3	32.2	37.7
CNN	89.8	90.1	25.6	39.7
MLP	90.1	92.9	**52.8**	32.4
BERT	**94.4**	**96.0**	46.5	**40.4**

Table 3: Results of *oos-binary* experiments on OOS+, where we compare performance of undersampling (under) and augmentation using sentences from Wikipedia (wiki aug). The wiki aug approach was too large for the DialogFlow and Rasa classifiers.

4.3 Results with *oos-binary*

Table 3 compares classifier performance using the *oos-binary* scheme. In-scope accuracy suffers for all models using the undersampling scheme when compared to training on the full dataset using the *oos-train* and *oos-threshold* approaches shown in Table 2. However, out-of-scope recall improves compared to *oos-train* on Full but not OOS+. Augmenting the out-of-scope training set appears to help improve both in-scope and out-of-scope performance compared to undersampling, but out-of-scope performance remains weak.

Dataset	Num. Intents	Num. Utterances	Chatbot Style	Many Intents	Constrained Training Data	Out-of-Scope Utterances
Our Dataset (This Work)	150	23,700	✓	✓	✓	✓
TREC-6, (Li and Roth, 2002)	6	5,952	✗	✗	✗	✗
TREC-50, (Li and Roth, 2002)	50	5,952	✗	✓	✓	✗
Web Apps, (Braun et al., 2017)	8	89	✗	✗	✓	✗
Ask Ubuntu, (Braun et al., 2017)	5	162	✗	✗	✓	✗
Chatbot Corpus, (Braun et al., 2017)	2	206	✓	✗	✓	✗
Snips, (Coucke et al., 2018)	7	14,484	✓	✗	✗	✗
Liu et al. (2019)	54	25,716	✓	✓	✗	✗

Table 4: Classification dataset properties. Ours has the broadest range of intents and specially collected out-of-scope queries. We consider "chatbot style" queries to be short, possibly unstructured questions and commands.

5 Prior Work

In most other analyses and datasets, the idea of out-of-scope data is not considered, and instead the output classes are intended to cover all possible queries (e.g., TREC (Li and Roth, 2002)). Recent work by Hendrycks and Gimpel (2017) considers a similar problem they call out-of-distribution detection. They use other datasets or classes excluded during training to form the out-of-distribution samples. This means that the out-of-scope samples are from a small set of coherent classes that differ substantially from the in-distribution samples. Similar experiments were conducted for evaluating unknown intent discovery models in Lin and Xu (2019). In contrast, our out-of-scope queries cover a broad range of phenomena and are similar in style and often similar in topic to in-scope queries, representing things a user might say given partial knowledge of the capabilities of a system.

Table 4 compares our dataset with other short-query intent classification datasets. The Snips (Coucke et al., 2018) dataset and the dataset presented in Liu et al. (2019) are the most similar to the in-scope part of our work, with the same type of conversational agent requests. Like our work, both of these datasets were bootstrapped using crowdsourcing. However, the Snips dataset has only a small number of intents and an enormous number of examples of each. Snips does present a low-data variation, with 70 training queries per intent, in which performance drops slightly. The dataset presented in Liu et al. (2019) has a large number of intent classes, yet also contains a wide range of samples per intent class (ranging from 24 to 5,981 queries per intent, and so is not constrained in all cases).

Braun et al. (2017) created datasets with constrained training data, but with very few intents, presenting a very different type of challenge. We also include the TREC query classification datasets (Li and Roth, 2002), which have a large set of labels, but they describe the desired response type (e.g., distance, city, abbreviation) rather than the action intents we consider. Moreover, TREC contains only questions and no commands. Crucially, none of the other datasets summarized in Table 4 offer a feasible way to evaluate out-of-scope performance.

The Dialog State Tracking Challenge (DSTC) datasets are another related resource. Specifically, DSTC 1 (Williams et al., 2013), DSTC 2 (Henderson et al., 2014a), and DSTC 3 (Henderson et al., 2014b) contain "chatbot style" queries, but the datasets are focused on state tracking. Moreover, most if not all queries in these datasets are in-scope. In contrast, the focus of our analysis is on both in- and out-of-scope queries that challenge a virtual assistant to determine whether it can provide an acceptable response.

6 Conclusion

This paper analyzed intent classification and out-of-scope prediction methods with a new dataset consisting of carefully collected out-of-scope data. Our findings indicate that certain models like BERT perform better on in-scope classification, but all methods investigated struggle with identifying out-of-scope queries. Models that incorporate more out-of-scope training data tend to improve on out-of-scope performance, yet such data is expensive and difficult to generate. We believe our analysis and dataset will lead to developing better, more robust dialog systems.

Automatically Learning Data Augmentation Policies for Dialogue Tasks

Tong Niu **Mohit Bansal**

{tongn, mbansal}@cs.unc.edu

Abstract

Automatic data augmentation (AutoAugment) (Cubuk et al., 2019) searches for optimal perturbation policies via a controller trained using performance rewards of a sampled policy on the target task, hence reducing data-level model bias. While being a powerful algorithm, their work has focused on computer vision tasks, where it is comparatively easy to apply imperceptible perturbations without changing an image's semantic meaning. In our work, we adapt AutoAugment to automatically discover effective perturbation policies for natural language processing (NLP) tasks such as dialogue generation. We start with a pool of atomic operations that apply subtle semantic-preserving perturbations to the source inputs of a dialogue task (e.g., different POS-tag types of stopword dropout, grammatical errors, and paraphrasing). Next, we allow the controller to learn more complex augmentation policies by searching over the space of the various combinations of these atomic operations. Moreover, we also explore conditioning the controller on the source inputs of the target task, since certain strategies may not apply to inputs that do not contain that strategy's required linguistic features. Empirically, we demonstrate that both our input-agnostic and input-aware controllers discover useful data augmentation policies, and achieve significant improvements over the previous state-of-the-art, including trained on manually-designed policies.

1 Introduction

Data augmentation aims at teaching invariances to a model so that it generalizes better outside the training set distribution. Recently, there has been substantial progress in Automatic Data Augmentation (*AutoAugment*) for computer vision (Cubuk et al., 2019). This algorithm searches for optimal perturbation policies via a controller trained with reinforcement learning, where its reward comes from training the target model with data perturbed by the sampled augmentation policy. Each policy consists of 5 sub-policies sampled randomly during training, and each sub-policy consists of 2 operations applied in sequence. These operations are semantic-preserving image processing functions such as *translation* and *rotation*.

We adapt AutoAugment to NLP tasks, where the operations are subtle, semantic-preserving text perturbations. To collect a pool of such operations, the first challenge we face is that the discrete nature of text makes it less straightforward to come up with semantic-preserving perturbations. We thus employ as a starting point Should-Not-Change strategies (equivalent to *operations* in this paper) proposed by Niu and Bansal (2018) which are shown to improve their dialogue task performance when trained on data perturbed by these strategies. Importantly, we next divide their operations into several smaller ones (such as Grammar Errors divided into Singular/Plural Errors and Verb Inflection Errors) and also add a new operation Stammer (word repetition). This modification provides a much larger space of operation combinations for the model to explore from, so that it could potentially learn more complex and nuanced augmentation policies. Figure 1 shows a sub-policy containing two operations. It first paraphrases 2 tokens with probability 0.7 and then introduces 1 grammar error with probability 0.4.[1]

We choose the dialogue generation task based on the Ubuntu Dialogue Corpus (Lowe et al., 2015) because as opposed to Natural Language Inference and Question Answering tasks, real-world dialogue datasets more naturally afford such perturbation-style human errors (i.e., contain more noise), and thus are inherently compatible with

[1]Our code and sampled augmented data is publicly available at: https://github.com/WolfNiu/AutoAugDialogue. The learned policies are presented in Table 4.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1317–1323,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

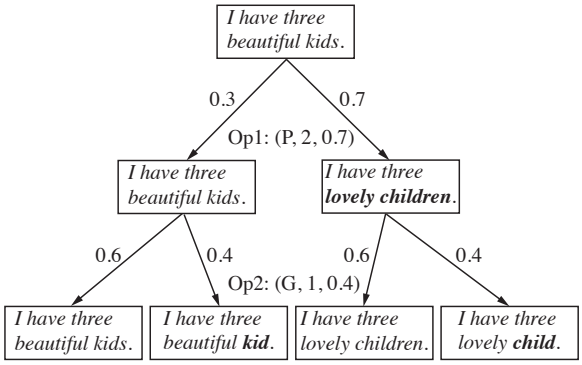

Figure 1: Example of a sub-policy applied to a source input. The first operation (Paraphrase, 2, 0.7) paraphrases the input twice with probability 0.7; the second operation (Grammar Errors, 1, 0.4) inserts 1 grammar error with probability 0.4. Thus there are at most 4 possible outcomes from each sub-policy.

a variety of artificial perturbations. Empirically, we show that our controller can self-learn policies that achieve state-of-the-art performance on Ubuntu, even compared with very strong baselines such as the best manually-designed policy in Niu and Bansal (2018). We also verify this result through human evaluation to show that our model indeed learns to generate higher-quality responses. We next analyze the best-learned policies and observe that the controller prefers to sample operations which work well on their own as augmentation policies, and then combines them into stronger policy sequences. Lastly, observing that some operations require the source inputs to have certain linguistic features (e.g., we cannot apply Stopword Dropout to inputs that do not contain stopwords), we also explore a controller that conditions on the source inputs of the target dataset, via a sequence-to-sequence (seq2seq) controller. We show that this input-aware model performs on par with the input-agnostic one (where the controller outputs do not depend on the source inputs), and may need more epochs to expose the model to the many diverse policies it generates. We also present selected best policies to demonstrate that the seq2seq controller can sometimes successfully attend to the source inputs.

2 Related Works

There has been extensive work that employs data augmentation in both computer vision (Simard et al., 2003; Krizhevsky et al., 2012; Cireşan et al., 2012; Wan et al., 2013; Sato et al., 2015; DeVries and Taylor, 2017; Tran et al., 2017; Lemley et al., 2017) and NLP (Fürstenau and Lapata, 2009; Sennrich et al., 2016; Wang and Yang, 2015; Zhang et al., 2015; Jia and Liang, 2016; Kim and Rush, 2016; Hu et al., 2017; Xu et al., 2017; Xia et al., 2017; Silfverberg et al., 2017; Kafle et al., 2017; Hou et al., 2018; Wang et al., 2018).

Automatic data augmentation is addressed via the AutoAugment algorithm proposed by Cubuk et al. (2019), which uses a hypernetwork (in our case, a controller) to train the target model, an approach inspired by neural architecture search (Zoph et al., 2017). Previous works have also adopted Generative Adversarial Networks (Goodfellow et al., 2014) to either directly generate augmented data (Tran et al., 2017; Sixt et al., 2018; Antoniou et al., 2017; Zhu et al., 2017; Mun et al., 2017; Wang and Perez, 2017), or generate augmentation strategies (Ratner et al., 2017). These approaches produce perturbations through continuous hidden representations. Motivated by the fact that our pool of candidate perturbations are discrete in nature, we identify AutoAugment as a more proper base model to use, and adapt it linguistically to the challenging task of generative dialogue tasks. Our work closely follows Niu and Bansal (2018) to obtain a pool of candidate operations. Although their work also used combinations of operations for data augmentation, their best model is manually designed, training on each operation in sequence, while our model automatically discovers more nuanced and detailed policies that have not only the operation types but also the intensity (the number of changes) and probability.

3 Model

AutoAugment Architecture: As shown in Figure 2, our AutoAugment model consists of a controller and a target model (Cubuk et al., 2019). The controller first samples a policy that transforms the original data to augmented data, on which the target model trains. After training, the target model is evaluated to obtain the performance on the validation set. This performance is then fed back to the controller as the reward signal. Figure 3 illustrates the details of input-agnostic and input-aware controllers. The former corresponds to the lower half of the figure. It consists of a single decoder that samples each operation in sequence. An operation is defined by 3 parameters: *Operation Type*, *Number of Changes* (the maximum number of times allowed to perform the operation, which

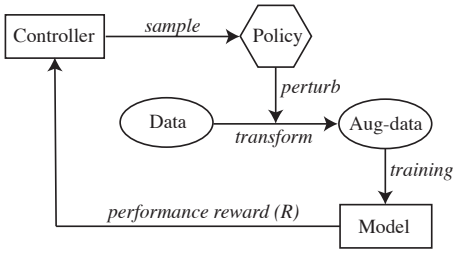

Figure 2: The controller samples a policy which is used to perturb the training data. After training on the augmented inputs, the model feeds the performance as reward back to the controller.

is a discrete equivalence of the continuous *Magnitude* in (Cubuk et al., 2019)), and the *Probability* of applying that operation. The input-aware controller corresponds to the whole figure, i.e., we novelly add in an encoder that takes as inputs the source of the training data, making it a seq2seq model. Since for each source input, there may be a different set of perturbations that are most suitable to it, our input-aware controller aims at providing customized operations for each training example.

Search Space: Following Niu and Bansal (2018), our pool of operations contains Random Swap, Stopword Dropout, Paraphrase, Grammar Errors, and Stammer, which cover a substantial enough search space of real-world noise in text.[2] To allow the controller to learn more nuanced combinations of operations, we further divide Stopword Dropout into 7 categories: Noun, Adposition, Pronoun, Adverb, Verb, Determiner, and Other, and divide Grammar Errors into Noun (plural/singular confusion) and Verb (verb inflected/base form confusion). For Stopword Dropout, we chose the first six categories because they are the major universal POS tags in the set closed-class words. We perform this subdivision also because different categories of an operation can influence the model to different extents. Suppose the original utterance is "*What is the offer?*", dropping the interrogative pronoun "*what*" is more semantic-changing than dropping the determiner "*the*." Our pool thus consists of 12 operations. For generality, we do not distinguish in advance which operation alone is effective as an augmentation policy on the target dataset, but rather let the controller figure it out. Moreover, it is possible that an operation alone is not effective, but when applied in sequence with another operation, they collectively teach the model a new pattern of invariance in the data.

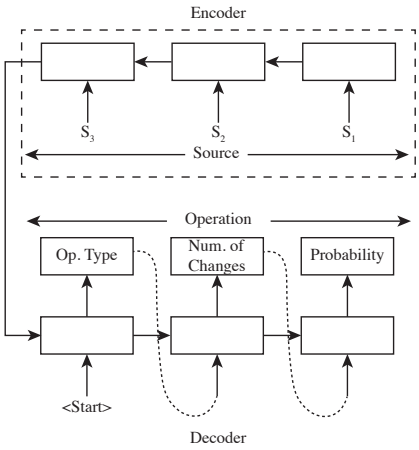

Figure 3: AutoAugment controller. An input-agnostic controller corresponds to the lower part of the figure. It samples a list of operations in sequence. An input-aware controller additionally has an encoder (upper part) that takes in the source inputs of the data.

Each policy consists of 4 sub-policies chosen randomly during training, each sub-policy consists of 2 operations,[3] and each operation has 3 hyperparameters. We discretize the Probability of applying an operation into 10 uniformly-spaced values starting from 0.1 and let the number of replaces range from 1 to 4. Thus, the search space size is $(12 \times 4 \times 10)^{(2\times4)} = 2.82 \times 10^{21}$. 2 operations allows more perturbations than exerted by a single strategy: in reality a sentence may contain several types of noise.

Search Algorithm: We use REINFORCE, a policy gradient method (Williams, 1992; Sutton et al., 2000) to train the controller. At each step, the decoder samples a token and feeds it into the next step. Since each policy consists of 4 sub-policies, each sub-policy contains 2 operations, and each operation is defined by 3 tokens (Operation Type, Number of Changes, Probability), the total number of steps for each policy is $4 \times 2 \times 3 = 24$. Sampling multiple sub-policies to form one policy provides us with a less biased estimation of the controller performance. We sample these 4 sub-policies at once rather than sample the controller 4 times to reduce repetition – the controller needs to keep track of what policies it has already sampled. To obtain the reward for the controller, we train the target model with the augmented data and obtain its validation set performance. We calculate a weighted average of two F1s (Activity and Entity)

[2]We did not use their Generative Paraphrasing where *number of changes* (which signifies the intensity of the policy) does not apply to this operation, because this operation can generate only one possible paraphrase for each input.

[3]Having 2 operations allows more perturbations than exerted by a single strategy: in reality a sentence may contain several types of noise.

as the reward R since both are important complementary measures of an informative response, as discussed in Serban et al. (2017a).[4] We use the reinforcement loss following Ranzato et al. (2016) and an exponential moving average baseline to reduce training variance. At the end of the search, we use the best policy to train the target model from scratch and evaluate on the test set.

4 Experimental Setup

Dataset and Model: We investigate Variational Hierarchical Encoder-Decoder (VHRED) (Serban et al., 2017b) on the troubleshooting Ubuntu Dialogue task (Lowe et al., 2015).[5] For this short paper, we focus on this dataset because it has a well-established F1 metric among dialogue tasks.[6] In future work, we plan to apply the idea to other datasets and NLP tasks since the proposed model is not specific to the Ubuntu dataset. We hypothesize that most web/online datasets that have regular human errors/noise (e.g. Twitter Dialogue Dataset (Serban et al., 2017b) and multiple movie corpora (Serban et al., 2016)) would be suitable for our framework.

Training Details: We employ code[7] from Niu and Bansal (2018) to reproduce the VHRED baseline results and follow methods described in Zoph et al. (2017) to train the controller. For details, please refer to their Appendix A.2 (Controller Architecture) and A.3 (Training of the Controller).

We adopt the following method to speed up controller training and hence facilitate scaling.[8] We let the target model resume from the converged baseline checkpoint and train on the perturbed data for 1 epoch. During testing, we use the policy that achieves the highest weighted average F1 score to train the final model for 1 epoch. For the All-operations model (which corresponds to the All-Should-Not-Change model in Niu and Bansal (2018)), we train on each operation (without subdivisions for Stopword Dropout and Grammar Errors) for 1 epoch in sequence.[9]

	Activity F1	Entity F1
LSTM	1.18	0.87
HRED	4.34	2.22
VHRED	4.63	2.53
VHRED (w/ attn.)	5.94	3.52
All-operations	6.53	3.79
Input-aware	**7.04**	3.90
Input-agnostic	7.02	**4.00**

Table 1: Activity, Entity F1 results reported by previous work (rows 1-4 from Serban et al. (2017a)), and the All-operations and AutoAugment models.

	W	T	L	W - L
Input-agnostic vs. baseline	48	23	29	19
Input-aware vs. baseline	45	27	28	17
Input-agnostic vs. All-ops	43	27	30	13
Input-aware vs. All-ops	50	13	37	13

Table 2: Human evaluation results on comparisons among the baseline, All-operations, and the two AutoAugment models. **W**: Win, **T**: Tie, **L**: Loss.

Automatic Evaluation: We follow Serban et al. (2017a) and evaluate on F1s for both activities (technical verbs) and entities (technical nouns).

Human Evaluation: We conducted human studies on MTurk. We compared each of the input-agnostic/aware models with the VHRED baseline and All-operations from Niu and Bansal (2018), where we followed the same setting. Each study contains 100 samples randomly chosen from the test set. The utterances were randomly shuffled and we only allowed US-located human evaluators with approval rate $> 98\%$, and at least $10,000$ approved HITs. More details are in the appendix.

5 Results and Analysis

Automatic Results: Table 1 shows that all data-augmentation approaches (last 3 rows) improve statistically significantly ($p < 0.01$) [10] over the strongest baseline VHRED (w/ attention). Moreover, our input-agnostic AutoAugment is statistically significantly ($p < 0.01$) better (on Activity and Entity F1) than the strong manual-policy All-operations model, while the input-aware model is stat. signif. ($p < 0.01$) better on Activity F1.[11]

Human Evaluation: In Table 2, both AutoAug-

[4] We use the weighted average F1 = Activity F1 + 5.94 / 3.52 $*$ Entity F1, where the weights are determined by the baseline results, for balance between the two F1s.

[5] http://www.iulianserban.com/Files/UbuntuDialogueCorpus.zip

[6] Serban et al. (2017a) found that F1 is particularly suited for the goal-oriented Ubuntu Dialogue Corpus based on manual inspection of the extracted activities and entities.

[7] https://github.com/WolfNiu/AdversarialDialogue

[8] It took us 3 days with 6 P100 GPUs to get our reported results for each of the input-aware and input-agnostic models. The VHRED model took 1.5 days to pre-train.

[9] We do not follow Cubuk et al. (2019) to train on a small portion of the data for many epochs because we empirically found that this approach decreases our task performance.

[10] Statistical significance is computed via the bootstrap test (Noreen, 1989) over 100K samples.

[11] Note that F1s are overall low (reported baselines in Table 1 are from Serban et al. (2017a)) because Ubuntu is semi-task-oriented; each context can have many valid responses containing different activities/entities from the ground-truth.

Perturbation Method	Policy	Source Inputs
Original Context	-	fresh install of crack of the day : gdm login → " can't access ACPI bla bla bla " __eou__ you don't want to be me ... __eou__ ah , it happened to you too ?
All-operations	(R , 4, 1.0)	fresh install **crack of** of the day : gdm login → " can't **ACPI access** bla bla bla " __eou__ you don't want **be to** me ... __eou__ ah , it happened **you to** too ?
Input-agnostic	(D_v, 3, 0.2)	fresh install of crack of the day : **login gdm** → " can't access ACPI bla bla bla "
	(R , 1, 0.5)	__eou__ you **don~~'~~t** want to **~~be~~** me ... __eou__ ah , it happened to you too ?
Input-aware	(S , 1, 0.8)	fresh install of crack of the day : gdm login → " can't access ACPI bla **bla** bla "
	(D_v, 2, 0.5)	__eou__ you don't want to be me ... __eou__ ah , it happened to you too ?

Table 3: Comparisons of perturbed outputs among the three Augmentation models. Note that only the sampled/applied sub-policy is shown for each model. The dashed line separates the original and augmented source inputs. Perturbed tokens are boldfaced.

Sub-policy1	Sub-policy2	Sub-policy3	Sub-policy4
P, 1, 0.5	D_v, 3, 0.2	R, 3, 0.9	D_p, 2, 0.3
D_{adv}, 4, 0.4	R, 1, 0.5	D_{adp}, 1, 0.5	D_{adp}, 2, 0.1
D_n, 1, 0.8	D_o, 3, 1.0	P, 4, 0.4	G_n, 3, 0.3
G_v, 1, 0.9	D_o, 3, 0.1	S, 3, 0.4	R, 1, 0.2
D_v, 2, 0.5	D_v, 2, 0.7	S, 3, 0.5	P, 1, 1.0
R, 2, 0.2	G_v, 1, 0.9	D_o, 1, 0.5	G_n, 2, 0.6

Table 4: Top 3 policies on the validation set and their test performances. **Operations**: R=Random Swap, D=Stopword Dropout, P=Paraphrase, G=Grammar Errors, S=Stammer. **Universal tags**: n=noun, v=verb, p=pronoun, adv=adverb, adp=adposition.

ment models obtained significantly more net wins (last column) than the VHRED-attn baseline. They both outperform even the strong manual-policy All-operations model.

Policy Learned by the Input-Agnostic Controller: We present 3 best learned policies from the Ubuntu val set (Table 4). Although there is a probability of $7/12 = 58.3\%$ to sample one of the Stopword Dropout operations from our pool, all 3 learned policies show much more diversity on the operations they choose. This is also the case for the other two hyperparameters: *Number of Changes* varies from 1 to 4, and *Probability* varies from 0.1 to 0.9, which basically extend their whole search range. Moreover, all best policies include Random Swap, which agrees with the results in Niu and Bansal (2018).

Example Analysis of Perturbation Procedure in Generated Responses: We also present a selected example of perturbed source inputs from the three Augmentation models with their respective best policies in Table 3. First of all, the All-operations model is forced to use an operation (in this case Random Swap) with a fixed number of changes and a probability of 1.0, leading to less variation in the source inputs. On the other hand, our Input-agnostic AutoAugment model samples 3 Verb Dropout's followed by Random Swap. Note that although the number of changes for the dropout is 3, there are only 2 verb stopwords in the utterance. Thus, it has to resort back to modifying only 2 tokens. The Input-aware model samples Stammer followed by 2 Verb Dropout's. Interestingly, it inserts an extra "*bla*" around other "*bla*'s" in the utterance. It also did not sample a policy that drops more than 2 verb stopwords (this operation is not applied due to its Probability parameter). These two observations indicate that the model can sometimes successfully attend to the source inputs to provide customized policies.

6 Conclusion and Future Work

We adapt AutoAugment to dialogue and extend its controller to a conditioned model. We show via automatic and human evaluations that our AutoAugment models learn useful augmentation policies which lead to state-of-the-art results on the Ubuntu task. Motivated by the promising success of our model in this short paper, we will apply it to other diverse NLP tasks in future work.

A Experimental Setup

Dataset and Model: We investigate Variational Hierarchical Encoder-Decoder (VHRED) (Serban et al., 2017b), a state-of-the-art dialogue model on the Ubuntu Dialogue Corpus (Lowe et al., 2015). Ubuntu is a troubleshooting dialogue dataset containing 1 million 2-person, multi-turn dialogues extracted from Ubuntu chat. The chat channels are used by customers to provide and receive technical support. We focus on the task of generating fluent, relevant, and goal-oriented responses. Following Niu and Bansal (2018), we apply additive attention mechanism (Bahdanau et al., 2015) to the source sequence while keeping the remaining VHRED architecture unchanged.

Automatic Evaluation: We follow Serban et al. (2017a) and evaluate the model on F1's for both activities (technical verbs, e.g., "boot", "delete") and entities (technical nouns, e.g., "root", "disk") computed by mapping the ground-truth and model responses to their corresponding activity-entity representations.

Human Evaluation: We conducted human studies on MTurk to evaluate the dialogue quality of generated responses from the investigated models. We compared each of the input-agnostic/aware models with All-operations and the baseline (i.e., 4 experiments in total). Studies involving the baseline are for sanity checks.

uniblock: Scoring and Filtering Corpus with Unicode Block Information

Abstract

The preprocessing pipelines in Natural Language Processing usually involve a step of removing sentences consisted of illegal characters. The definition of illegal characters and the specific removal strategy depend on the task, language, domain, etc, which often lead to tiresome and repetitive scripting of rules. In this paper, we introduce a simple statistical method, uniblock[1], to overcome this problem. For each sentence, uniblock generates a fixed-size feature vector using Unicode block information of the characters. A Gaussian mixture model is then estimated on some clean corpus using variational inference. The learned model can then be used to score sentences and filter corpus. We present experimental results on Sentiment Analysis, Language Modeling and Machine Translation, and show the simplicity and effectiveness of our method.

1 Introduction

Identification and removal of sentences with illegal characters is a common heuristic in the preprocessing pipelines in Natural Language Processing (NLP). While it has benefits of controlling the vocabulary size and dropping noisy data, it is often a tedious work to come up with appropriate rules and removal strategies when facing with different tasks, languages and domains. The lack of clear definition of what is illegal exacerbates the problem. For example, modern Chinese text may allow characters such as: traditional and simplified Chinese characters, special punctuation marks, full-width characters, emojis, mathematical symbols, Latin characters, currency symbols, scientific notations, etc. As a result, scripting robust rules often requires a considerable amount of time and effort.

In this paper, we introduce a simple statistical method, uniblock, to address the problem. The motivation of our approach is straightforward - good rules may vary greatly depending on the situation, therefore instead of designing rules by hand, we use "rules" defined by data. We assume that some clean corpus is available, in which all the characters are deemed legal and the character distributions are similar to the test cases. It is possible to learn a probabilistic model, which describes the clean corpus and assigns scores to sentences in another corpus. The scores can further be used for filtering. Since the legalness of characters is in question, Unicode block information is a natural choice for obtaining feature vectors. Note that, by designing alternative feature vectors, one can potentially adapt uniblock to implement other corpus filtering heuristics.

We develop uniblock mainly for Machine Translation (MT). It can also be easily applied to other NLP tasks. We present experimental results on Sentiment Analysis (SA), Language Modeling (LM) and MT, and show the simplicity and effectiveness of our method.

2 Related Work

Raw data in NLP is often noisy. Khayrallah and Koehn (2018) categorize five common noise sources in parallel corpora and count only about 23% of the sentences in the raw 2016 ParaCrawl corpus[2] to be "Okay". Although illegal characters is not listed as a separate noise source, misuse of characters and shifting of character distributions may result in a sentence being classified into one of the five noise sources. In previous work, a supervised model using bag-of-words translation features is developed to classify clean and noisy data (Xu and Koehn, 2017; Khayrallah et al.,

[1]The source code is available at https://github.com/ringoreality/uniblock

[2]https://paracrawl.eu/index.html

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1324–1329,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

2018). In contrast, our model, which is trained in an unsupervised manner, tackles the illegal character problem explicitly.

Koehn et al. (2018) describe a shared task on parallel corpus filtering. While participating systems focus on addressing both monolingual fluency and bilingual adequacy, character-level filtering is common to all submissions. Junczys-Dowmunt (2018) applies a language identification model to implicitly remove sentences with illegal characters. Rossenbach et al. (2018) keep sentences with more than three words, with each word having at least one character from the predefined alphabet of the language. Lu et al. (2018) remove characters outside of a predefined alphabet. Ash et al. (2018) count most frequent characters, set a cutoff around eighty for each language, and remove sentences with illegal characters. Erdmann and Gwinnup (2018) get rid of lines containing characters from the Unicode general category of "other". Papavassiliou et al. (2018) simply consider Latin Unicode characters to be legal.

Unicode is the de facto standard for encoding characters from various languages, domains and sources (The Unicode Consortium, 2019). It uses "blocks" to group characters with similar origins or functions. The current version 12.0 defines 300 blocks, including Basic Latin, Latin-1 Supplement, CJK (Chinese, Japanese and Korean) Symbols and Punctuation, etc. To identify the legalness of characters, the Unicode block information provides meaningful discriminative signals.

The Gaussian Mixture Model (GMM) is a classic algorithm that assumes data is generated from a mixture of finite number of Gaussian distributions, whose parameters are typcially estimated with the Expectation–Maximization (EM) algorithm. An extension to the EM algorithm is variational inference, which has the advantage of automatically choosing the number of components. Bishop (2006) gives a comprehensive introduction to the topic. We use the implementation of variational Bayesian estimation of Gaussian mixtures from `scikit-learn` (Pedregosa et al., 2011).

3 Methodology

3.1 Feature Vectors

In order to assign meaningful scores to sentences and eventually filter out those who contain illegal characters, we first need to design appropriate features. We believe, the Unicode block information has a good property that the blocks are grouped by origin and function. For instance, CJK Symbols and Punctuation has a dedicated Unicode block in range U+3000...U+303F. Specifically, we count the appearances of characters in each of the 300 blocks. This will result in feature vectors $c_1, c_2, ..., c_B$ with a fixed length of $B = 300$. If we further normalize them by the total number of characters in each sentence, probability distributions over the 300 blocks can be obtained. We observe that there are only few blocks whose counts are non-zero in natural language texts. This calls for dimensionality reduction methods. Empirically, we drop the zero-count dimensions directly during training and assign conceptually low scores[3] when a non-zero count is seen during scoring. That is, we use normalized feature vectors $e = e_1, e_2, ..., e_{B'}$, where $1, 2, ..., B'$ are dimensions in B whose original counts are non-zero, for training.

3.2 Bayesian Gaussian Mixture Model

Although many corpora are noisy, it is not appropriate to deem all sentences in them "dirty". While generating synthetic noisy data is always an option, it is unrealistic to cover all types of noises. Compared to the difficulty to obtain negatively labelled data, the development set is often available and can be deemed "clean" with high confidence. Therefore, we take the development set as training data for our scoring system and treat the problem as a clustering task rather than a classification task.

We assume that the training feature vectors e are generated by a mixture of Gaussian distributions.

$$
\begin{aligned}
p(e) &= \sum_{k=1}^{K} \pi_k \mathcal{N}(e|\mu_k, \Sigma_k) \\
\pi_k &\sim \mathcal{DP}(\alpha) \\
\mu_k &\sim \mathcal{N}(\mu_0, \sqrt{\frac{1}{\tau}}) \\
\Sigma_k &\sim \mathcal{W}_{B'}(V, n)
\end{aligned}
\tag{1}
$$

In the equation above, k is a running index in the number of mixtures K, π_k is the mixture weight for the k-th Gaussian, μ_k is a B'-dimensional vector parametrizing the k-th mean, Σ_k is the k-th $B' \times B'$ covariance matrix. We further impose priors on the model parameters: π_k follows a Dirichlet Process ($\mathcal{DP}$), which is parametrized by concetration prior α; μ_k follows a Normal distribution

[3] zeros in our experiments

($\mathcal{N}$), which is parametrized by the B'-dimensional mean prior μ_0 and the precision prior τ; Σ_k follows a Wishart distribution ($\mathcal{W}$) in B', which is parametrized by the covariance prior V and degree of freedom prior n. We estimate the model parameters using the EM algorithm. Note that operating in B' dimensions leads to significantly better model convergence than training in B dimensions.

3.3 Scoring and Filtering

Once the model is trained till convergence, it is possible to use it to assign scores to unseen feature vectors. We directly use the weighted log probabilities as scores. Compared to the sentences used during `uniblock` training, higher scored sentences have more similar Unicode block count distributions, or fewer illegal characters. Regarding how to remove noisy sentences, we implement two straightforward ideas: absolute thresholding and relative thresholding. The former removes sentences with scores lower than a given threshold while the later removes a given percentage of low-scored sentences. We also add support for filtering parallel data. A simple method is to combine scores across parallel sentences with a specified reduction method (minimum, maximum, average), and then apply thresholds. Alternatively, one can use the lowest score seen during training as an absolute threshold for each language and filter parallel data in a "one bad, remove all" manner.

4 Experiments

We conduct experiments on three NLP tasks: SA, LM and MT. As shown in related work, many different heuristics are used for the purpose of illegal character filtering, and there is no generally accepted "golden rule". Therefore, we focus on comparing "no filtering" versus "filtering", to examine how our method performs.

4.1 Sentiment Analysis

We conduct SA experiments on the Stanford Twitter Sentiment (STS) corpus (Go et al., 2009) using fastText (Joulin et al., 2017). Given 1.6M automatically annotated tweets, the task is to predict postive or negative sentiments on 498 test tweets. For the baseline, we use minimal preprocessing to handle casing, weblinks, usernames, hashtags and spacing in the raw training tweets, without explicit character-level filtering. For `uniblock`, we additionally train a GMM on the tweets in the test set[4] and use the minimum score as an absolute threshold to filter the training corpus. In total, about 0.9% training tweets are filtered out. We observe that only one Unicode block exists in the test set, which means all sentences with characters in other blocks are assigned conceptually low scores and removed. In this particular case, our general method reduces to a simple filtering rule similar to that of Papavassiliou et al. (2018). As shown in Table 1, our method improves the test accuracy over the baseline by 0.6%.

	test accuracy [%]
baseline	81.6
`uniblock`	**82.2**

Table 1: Test accuracies on STS.

4.2 Language Modeling

In MT pipelines, language models are often used for corpus filtering, fusion techniques and N-best reranking. Therefore, we perform LM experiments on MT corpora. Specifically, we take monolingual data from parallel corpora of WMT19 (Barrault et al., 2019) Chinese-English (zh-en) and Russian-English (ru-en) as training data. We use newsdev2017 for both sides of zh-en and newstest2016 for both sides of ru-en as development data. We concatenate newstest2017 and newstest2018 as test data for all four sides. The sizes of the corpora (WMT) are summarized in Table 2.

	zh-en	ru-en
train	26M	25M
valid	2K	3K
test	6K	6K

Table 2: Number of sentence pairs in WMT.

	zh-en		ru-en	
data	zh	en	ru	en
100%	40.9	135.0	181.0	**145.7**
90%	**36.9**	133.5	**176.7**	147.6
80%	37.1	132.9	180.6	149.3
70%	38.7	**131.4**	178.6	151.1

Table 3: Test perplexities on WMT.

[4]No develepment set is available for STS, this is why we trained the GMM on the test set. For LM and MT experiments, `uniblock` is trained on the development sets.

side	score	parallel text
zh	-48523.31	リリスノト
en	53.82	Open Directory - Unix
zh	67.71	健康、整洁、卫生和清洁技术组织
en	-158.57	Salubrité, propreté, hygiène et techniques d'assainissement
zh	0.00	从系统目录→位置→传送我的位置...

zh	36.01	在25℃下测定了样品的总交换容量和平衡等温线.
en	40.65	Cation exchange capacity and equilibria isotherm at 25 ℃ were determined.
zh	68.63	财务政策及发展小组
en	53.82	Financial Policy and Development Unit

Table 4: Several text samples from the zh-en parallel corpus with `uniblock` scores. We find empirically: sentences with only foreign characters are scored very low; sentences with some foreign characters are scored low; sentences with characters in unseen blocks are scored 0; sentences with only few foreign characters are scored high; sentences with no illegal characters are scored very high. Foreign (or illegal) characters are underlined.

For each of the four LM subtasks, we train `uniblock` on the corresponding development set and filter out 10%, 20% and 30% of the raw training corpus. We train 2-layer LSTM language models with hidden dimensions being 1024. For the zh subtask, we train character-level language models and include all seen characters in the vocabulary. For the other 3 subtasks, top 100k frequent words are used as the vocabulary and the rest of the words are replaced with unknown tokens. All LM experiments are conducted using the RETURNN framework (Doetsch et al., 2017; Zeyer et al., 2018). As shown in Table 3, we see consistent improvements in the `uniblock`-filtered setups of zh, ru and en under zh-en. For en under ru-en, the baseline system outperforms `uniblock`-filtered ones.

4.3 Machine Translation

We train MT systems to show the simplicity and effectiveness of our method in a more challenging task. We use the same parallel corpora as in Section 4.2 and train systems in four directions: zh-en, en-zh, ru-en and en-ru. The raw training corpora are filtered with `uniblock` as before. Before examining the performance of the translation systems, we first manually examine some filtered text samples. Five parallel text samples with `uniblock` scores are shown in Table 4. We observe that the trained GMM works properly and indeed assigns low scores to unreasonable or "dirty" sentences. We believe that `uniblock` is superior to other rule-based methods because the relative quality of the sentences is modeled. For example, a hard rule may eliminate a complete sentence pair encountering even one ℃ symbol, while `uniblock` only gives a small penalization due to the fact that one occurrence of the symbol ℃ does not alter the count-based feature vector e much.

	zh-en		en-zh	
data	test17	test18	test17	test18
100%	25.0	24.5	30.1	33.0
90%	**25.2**	**25.6**	**30.9**	33.1
80%	24.3	25.3	30.3	**33.2**
70%	24.3	24.8	30.2	33.0

	ru-en		en-ru	
data	test17	test18	test17	test18
100%	32.9	28.3	26.9	23.3
90%	**33.5**	**29.3**	**27.8**	**23.9**
80%	33.3	28.9	27.2	23.6
70%	32.9	28.1	26.6	23.2

Table 5: Case-sensitive BLEU(%) scores on four different translation tasks.

For all MT systems, we perform minimum preprocessing to handle the whitespaces and casing, and use SentencePiece (Kudo and Richardson, 2018) to obtain the subword units. All models adopt the Transformer (Vaswani et al., 2017) architecture and use the exact same hyperparameters as the base model. Trainings are done with the Sockeye (Hieber et al., 2017) toolkit and share the same optimization hyperparameters. No synthetic data is used and no ensembling is done during decoding. The only difference across the models is the training corpus - the baseline model uses the full parallel corpus, while the ones filtered

by `uniblock` use a subset of the full corpus. We take the checkpoint with the lowest perplexity on the validation set and report case-sensitive BLEU(%) (Papineni et al., 2002) scores on newstest2017 and newstest2018 using the sacreBLEU (Post, 2018) software. The translation qualities of the systems are shown in Table 5. As can be seen, without altering the architecture or the optimization process, only applying `uniblock` as a corpus filtering step leads to consistent improvements over the baseline systems for all four directions, up to 1.1 BLEU(%).

Linguistically, the zh-en and ru-en language pairs are rather distant. For more closely-related language pairs such as French and English, our method should also perform well. As shown in Table 4, a Chinese sentence could be corrupted with Japanese characters and an English sentence could be corrupted with French characters. For both cases, our method is able to discriminate the illegal characters and assign low scores to these sentences. Note that, our method would fail, if "clean" and "dirty" sentences share one exact same block. Because then after normalization all the feature vectors will be essentially the same and therefore indistinguishable. In this case, one should carefully design other features so that the GMM is able to assign meaningful scores. However, when "clean" and "dirty" sentences share the same set of blocks, our method still works fine because after normalization the empirical distributions are probably different.

5 Conclusion

In this work, we develop a simple and effective statistical method called `uniblock`. Using Unicode block information as feature vectors, a GMM is estimated with variational inference on some clean corpus, which can then be used to score and filter corpus. We release our implementation which supports parallel corpus filtering and different thresholding. Our experiments show concrete and consistent improvements in SA, LM and MT.

We believe that the method can be extended and improved by examining other dimensionality reduction methods and alternatives to GMM, and by introducing other heuristics into the feature vector, such as sentence length and punctuation marks[5].

[5]Common punctuation marks lie in the same Unicode block range U+0000..U+007F as the English alphabet and are currently not separated.

Abstract

Current multilingual word translation methods are focused on jointly learning mappings from each language to a shared space. The actual translation, however, is still performed as an isolated bilingual task. In this study we propose a multilingual translation procedure that uses all the learned mappings to translate a word from one language to another. For each source word, we first search for the most relevant languages. We then use the auxiliary translations to these languages to form an improved representation of the source word. Finally, this representation is used for the actual translation to the target language. Experiments on a standard multilingual word translation benchmark demonstrate that our model outperforms state of the art results.

1 Introduction

Monolingual continuous word embeddings are standard building blocks of many natural language tasks. The embedding spaces can exhibit similar structures across languages. Several studies (Mikolov et al., 2013; Klementiev et al., 2012) proposed to exploit this similarity by learning a linear mapping from a source to a target embedding space, and demonstrated this approach on a word translation task. Xing et al. (2015) showed that using orthogonality matrices can significantly improve performance.

Bilingual embedding can be extended to a multilingual setup by jointly learning mappings from each monolingual space to a shared word space. In recent years several studies have proposed aligning multiple languages simultaneously in a shared space by enforcing (or at least encouraging) transitive relations between the mappings (Chen and Cardie, 2018; Kementchedjhieva et al., 2018; Alaux et al., 2019; Jawanpuria et al., 2019; Taitelbaum et al., 2019). Dealing with multiple languages simultaneously has been shown to improve performance on some bilingual tasks by using knowledge learned from other languages (Ammar et al., 2016; Duong et al., 2017).

Once the multilingual mappings are learned, one can infer word correspondences for words that are not in the initial lexicons. Previous multilingual methods have focused on training procedures that benefit from the multilingual setting. The actual translation, however, is still done as an isolated bilingual task. It makes eminent sense however to go beyond this stage and utilize the relations between all the languages at the inference phase as it is done in the mapping learning phase.

In this study, we propose a new inference method for multilingual word translation that uses all the learned mappings to translate a word from one language to another. For each source word we first search for the most relevant languages that help translate the source word to the target language. We then use the auxiliary translations to form an improved representation of the source word. Finally, this multilingual-dependent representation is used for the actual translation to the target language.

Our main contributions is twofold: first, a new word translation inference method, which takes advantage of the multilingual setup not only in the train phase, but also in test phase. Second, evaluation on a recently-released multilingual word translation dataset on six languages (Lample et al., 2018) showing that our method outperforms state-of-the-art methods on this task.

2 Multilingual Word Mapping

In this section we review the concept of multilingual mapping to a shared space and in the next section we use it to form a multilingual translation method. Assume we are given a d-dimensional

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1330–1335, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

word embedding data from a set of k languages. The task is to learn linear mappings between every pair of languages. In order to learn these mappings, we are also given a dictionary for each pair of languages, which contains pairs of corresponding words from the two languages. These dictionaries can be obtained in either a supervised or an unsupervised manner, and can also be created at each iteration of a dictionary refinement method (Artetxe et al., 2017; Lample et al., 2018). We can learn cross-language mappings independently from each source to each target language. This approach fails to benefit from the multilingual setup, and is very expensive because it requires to learn k^2 mappings, each with its own independent parameters. Another approach consists of choosing one language as a "pivot" and learning a mapping from each language to the pivot independently. This strategy, however, does not guarantee good indirect word translations between pairs of languages that do not include the pivot.

Recent studies proposed to jointly map all languages into a shared space. This approach was shown to outperform the above two approaches (Chen and Cardie, 2018). Let $T_1, \ldots, T_k$ be a set of mappings that correspond to the k different languages. The mapping T_i is used to translate the words from language i to a shared space that can be viewed as an embedding space of a universal language.

The translation matrices $T_1, ..., T_k$ can be found by minimizing the following mean-square error:

$$S(T_1, ..., T_k) = \sum_{i<j} \sum_{t} \|T_i x_{it} - T_j x_{jt}\|^2 \quad (1)$$

such that x_{it} and x_{jt} are embeddings of two corresponding words in languages i and j respectively. The optimal transformations map pairs of words with similar meanings to vectors in the shared space that are close to one another.

When more than two languages are involved, there is no closed-form solution for the global minimum of Eq. (1). Recently, several studies addressed this optimization challenge. (Kementchedjhieva et al., 2018; Chen and Cardie, 2018; Alaux et al., 2019; Taitelbaum et al., 2019).

3 Multilingual Translation Method

In this section we propose an inference procedure for multilingual translation that uses *all* the learned mapping $T_1, \ldots, T_k$ to translate from one language to another.

Before we describe our method, consider first a generic formulation of the inference procedure. The translation of a word embedding x from language i to a language j is obtained by:

$$\hat{y} = \arg\max_{y \in V_j} sim(x, y) \quad (2)$$

where V_j is the vocabulary of language j. $sim(x, y)$ can be, for example, the cosine similarity in the embedded space: $sim(x, y) = cos(T_i x, T_j y)$. It is commonly observed that inference using the nearest embedded neighbor suffers from the *hubness problem* (Dinu and Baroni, 2014). Hubs are words that appear too frequently in the neighborhoods of other words. To mitigate this effect, one can simply replace the cosine similarity by another criterion, such as *Inverted Softmax* (ISF) (Smith et al., 2017) or *Cross-domain Similarity Local Scaling* (CSLS) (Lample et al., 2018). Following recent bilingual and multilingual translation studies (e.g., Lample et al. (2018); Alaux et al. (2019); Chen and Cardie (2018); Joulin et al. (2018)), this study uses the CSLS metric, namely, for $x \in V_i, y \in V_j$:

$$sim(x, y) = \text{CSLS}(T_i x, T_j y). \quad (3)$$

The CSLS similarity is calculated as follows:

$$\text{CSLS}(z, w) = 2\cos(z, w)$$

$$-\frac{1}{n} \sum_{z' \in N_z(w)} \cos(z', w) - \frac{1}{n} \sum_{w' \in N_w(z)} \cos(z, w')$$

where cos is the cosine similarity, $N_z(w)$ is the set of n nearest neighbors of the point w in the first set of word vectors and $N_w(z)$ is similarly defined. In practice, we used $n = 10$.

To describe our multilingual word translation, note that current word translation methods take into account only the source and target languages at inference time. Since the translation is performed via the shared embedding space one can potentially design a better representation of the source word in the shared space to be translated into the target word. We can translate x to all other languages (except the target language j): $y_m = \arg\max_{y \in V_m} \text{CSLS}(T_i x, T_m y)$ and then compute the average word in the shared space:

$$z = \frac{1}{k-1} \sum_{m \neq j} T_m y_m \quad (4)$$

(for the source word we set $y_i = x$). Here, all languages except the target are used as auxiliary

sources of information about the correct embedding in the shared space. Then, we use z as a new multilingual representation of $T_i x$, and translate x according to:

$$\hat{y} = \arg\max_{y \in V_j} \text{CSLS}(z, T_j y) \quad (5)$$

Unfortunately, using the average across all auxiliary languages, may hurt performance for some language pairs. For example, a German translation of a Spanish word may not help with translating that Spanish word to Portuguese. More generally, translations to auxiliary languages can yield words that are far from the source word in the shared space and therefore may lead to incorrect translation. Here we describe an approach to select the relevant auxiliary languages for a given source word and target language. The main idea is to apply CSLS to select those languages that would be helpful for translating the desired source word. Specifically, a language m is selected as an auxiliary language only if the translated word y_m is closer than the target word y_j to the source word x in the shared space. A language m is thus included in the summation of Eq. (4) only if:

$$\text{CSLS}(T_i x, T_m y_m) > \text{CSLS}(T_i x, T_j y_j) \quad (6)$$

When averaging the auxiliary translations all these languages are equally weighted. Because the source word is more important than its auxiliary translations, we set the weight of the source $T_i x$ to be sum of all the weights of the auxiliary words. The proposed *Multilingual Word Translation* (MWT) procedure is depicted in Algo. 1

Algorithm 1 Multilingual Word Translation

Required: A set of mappings $T_1, .., T_k$.
Task: Translate the word $x \in V_i$ to language j.

for $m = 1, ..., k$ **do**
  $y_m = \arg\max_{y \in V_m} \text{CSLS}(T_i x, T_m y)$
  $c_m = \text{CSLS}(T_i x, T_m y_m)$
end
$z = T_i x$
$S = \{m \in \{1, ..., k\} \backslash \{i, j\} \,|\, c_m > c_j\}$
if $|S| \neq 0$ **then**
  $z \leftarrow \frac{1}{2} T_i x + \frac{1}{2|S|} \sum_{m \in S} T_m y_m$
end
$\hat{y} = \arg\max_{y \in V_j} \mathit{CSLS}(z, T_j y)$
return $\hat{y}$

Several studies have recently proposed using word vector averaging of the source and target embeddings as an improved shared word representation. This can be done when the monolingual word embeddings are mapped to the same space (Doval et al., 2018). Meta-embedding using several embeddings of the same language can be achieved even without mapping the embeddings to a shared space (Coates and Bollegala, 2018). In this study, we also built an improved source word representation by averaging. However, the averaging is done with translations of the source word to suitable auxiliary languages instead of the target word.

4 Experiments

To evaluate the proposed MWT algorithm, we used a recently released multilingual word translation dataset (MUSE) in six European languages: English, German, French, Spanish, Italian and Portuguese (Lample et al., 2018)[1]. In addition, we conducted another experiment mixing European (English, German, French, Spanish and Italian) together with Asian languages (Japanese , Chinese and Korean). This experiment demonstrates the power of MWT even for distant languages. The available dictionaries in MUSE dataset are between the European languages, and between English and each of the Asian languages. For any available pair of languages, a ground-truth bilingual dictionary is provided with a train-test split of 5000 and 1500 unique source words, respectively. All systems are tested on the 1500 test word pairs for each pair of languages.

Monolingual Embeddings. Pre-trained 300d fastText (monolingual) embeddings[2] (Bojanowski et al., 2017) trained on the Wikipedia corpus. These embeddings are popular among word translation systems (e.g., Lample et al. (2018); Alaux et al. (2019); Chen and Cardie (2018); Hoshen and Wolf (2018); Joulin et al. (2018); Kementchedjhieva et al. (2018).

Implementation details. For the six European languages experiment, the multilingual mapping set was trained using the state-of-the-art unsupervised *Multilingual Adversarial Training* (MAT) + *Multilingual Pseudo-Supervised Refinement* (MPSR) method (Chen and Cardie, 2018). We used their source code[3], with their default

hyper-parameters, and got similar results to the reported results (+0.1% in average). For the European-Asian experiment, MAT failed to converge for some language pairs, so the multilingual mapping set was trained using supervised MPSR, where the supervision was obtained by pairs of words with identical string matching. For each experiment, we used the same mappings for all the methods we compare. Our code and mapping matrices will be publicly available.

Compared methods. All methods retrieve word translations using their CSLS similarity in the learned embedding space.

(1) BI (Bilingual Inference). A standard inference process which does not take the multilingual setup into account, as in Chen and Cardie (2018).

We implemented 3 translation variants using auxiliary languages:

(2) NT (Nearest Translation). Average the source word with the closest auxiliary translation.

(3) CNT (Conditional Nearest Translation). Only average the source word with the closest auxiliary translation, if it is closer than the translation to the target language. In fact, CNT chooses for each source word one of {BI, NT} depends on whether the closest auxiliary translation is closer than the target translation (NT) or not (BI).

(4) CAT (Conditional All Translations). Weighted average of the source word and all auxiliary translations, that are closer than the target language translation. CAT is formally described in Algorithm box 1.

Results. Table 1 presents detailed results for all 30 language pairs and the average results. It shows that using all relevant auxiliary languages (CAT) increases performance significantly (+1.7% on average, top method in 19/30 tasks, $p < 0.001$ [4]). The largest performance boost of CAT over BI was in languages pairs involving *German* (+3.17% on average), which is the most distant language in this set of languages, thus, gains a lot from using other languages. This was found in particular for the translations between German and Portuguese (*de-pt*: +6.8%, *pt-de*: +4.5%), which are the most distant languages in this language set. This suggests that using MWT for distant languages may help. However, for close languages pairs the best way is still to translate directly (BI), as can be seen for Spanish and Portuguese. Table 2 presents three examples of erroneous bilingual translations that were corrected using auxiliary languages.

A similar behaviour is shown in the European-Asian languages (Table 3). CAT seems to improve word translation, especially over BI (+1.6% on average, top method in 18/26 tasks, $p < 0.001$). Moreover, CAT especially improves word translations between English and the Asian languages

[4] We performed a statistical significance test as in (Glavas et al., 2019) in addition to a statistical significance test over the accuracies obtained from each language pair.

Table 4: Auxiliary languages that are most frequently selected by the CNT method ('–' is none), for every pair of source and target languages. Value in parenthesis denotes how often that auxiliary language was selected.

(+1.93% in average from English and +3.4% to English).

We next show more detailed analysis for CNT, when using at most one auxiliary language for the six European languages experiment. Table 4 shows auxiliary language that is most commonly selected, for each pair of source-target languages. Interestingly, Spanish and Portuguese often help each other. Also, German often uses English as an auxiliary language for translating better into all other languages.

For CAT, each source word may use a different number of auxiliary languages. We can see the number of auxiliary languages as a mean to qualitatively measure closeness of languages, by looking on the average number of auxiliary languages used for each source-target pair. We found Portuguese and Spanish to be the closest (*pt-es* 0.6), and German the farthest from them (*pt-de* 3.1, *es-de* 3.2).

5 Conclusion

We presented a general concept to improve the quality of bilingual word translation by using the translation of the source word to auxiliary languages. We discussed several variants for deciding which and how many languages should be used as suitable auxiliary languages. The same translation principle can be used in the dictionary refinement step of the mapping training process.

Abstract

Recent studies have shown that a hybrid of self-attention networks (SANs) and recurrent neural networks (RNNs) outperforms both individual architectures, while not much is known about why the hybrid models work. With the belief that modeling hierarchical structure is an essential complementary between SANs and RNNs, we propose to further enhance the strength of hybrid models with an advanced variant of RNNs – *Ordered Neurons* LSTM (ON-LSTM, Shen et al., 2019), which introduces a syntax-oriented inductive bias to perform tree-like composition. Experimental results on the benchmark machine translation task show that the proposed approach outperforms both individual architectures and a standard hybrid model. Further analyses on targeted linguistic evaluation and logical inference tasks demonstrate that the proposed approach indeed benefits from a better modeling of hierarchical structure.

1 Introduction

Self-attention networks (SANs, Lin et al., 2017) have advanced the state of the art on a variety of natural language processing (NLP) tasks, such as machine translation (Vaswani et al., 2017), semantic role labelling (Tan et al., 2018), and language representations (Devlin et al., 2018). However, a previous study empirically reveals that the hierarchical structure of the input sentence, which is essential for language understanding, is not well modeled by SANs (Tran et al., 2018). Recently, hybrid models which combine the strengths of SANs and recurrent neural networks (RNNs) have outperformed both individual architectures on a machine translation task (Chen et al., 2018). We attribute the improvement to that RNNs complement SANs on the representation limitation of hierarchical structure, which is exactly the strength of RNNs (Tran et al., 2018).

Starting with this intuition, we propose to further enhance the representational power of hybrid models with an advanced RNNs variant – *Ordered Neurons* LSTM (ON-LSTM, Shen et al., 2019). ON-LSTM is better at modeling hierarchical structure by introducing a syntax-oriented inductive bias, which enables RNNs to perform tree-like composition by controlling the update frequency of neurons. Specifically, we stack SANs encoder on top of ON-LSTM encoder (*cascaded encoder*). SANs encoder is able to extract richer representations from the input augmented with structure context. To reinforce the strength of modeling hierarchical structure, we propose to simultaneously expose both types of signals by explicitly combining outputs of the SANs and ON-LSTM encoders.

We validate our hypothesis across a range of tasks, including machine translation, targeted linguistic evaluation, and logical inference. While machine translation is a benchmark task for deep learning models, the last two tasks focus on evaluating how much structure information is encoded in the learned representations. Experimental results show that the proposed approach consistently improves performances in all tasks, and modeling hierarchical structure is indeed an essential complementary between SANs and RNNs.

The contributions of this paper are:

- We empirically demonstrate that a better modeling of hierarchical structure is an essential strength of hybrid models over the vanilla SANs.
- Our study proves that the idea of augmenting RNNs with ordered neurons (Shen et al., 2019) produces promising improvement on machine translation, which is one potential criticism of ON-LSTM.

2 Approach

Partially motivated by Wang et al. (2016) and Chen et al. (2018), we stack a SANs encoder on top of a RNNs encoder to form a cascaded encoder. In the cascaded encoder, hierarchical structure modeling is enhanced in the bottom RNNs encoder, based on which SANs encoder is able to extract representations with richer hierarchical information. Let $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_N\}$ be the input sequence, the representation of the cascaded encoder is calculated by

$$\mathbf{H}^K_{\text{RNNs}} = \text{ENC}_{\text{RNNs}}(\mathbf{X}), \quad (1)$$
$$\mathbf{H}^L_{\text{SANs}} = \text{ENC}_{\text{SANs}}(\mathbf{H}^K_{\text{RNNs}}), \quad (2)$$

where $\text{ENC}_{\text{RNNs}}(\cdot)$ is a K-layer RNNs encoder that reads the input sequence, and $\text{ENC}_{\text{SANs}}(\cdot)$ is a L-layer SANs encoder that takes the output of RNNs encoder as input.

In this work, we replace the standard RNNs with recently proposed ON-LSTM for better modeling of hierarchical structure, and directly combine the two encoder outputs to build even richer representations, as described below.

Modeling Hierarchical Structure with Ordered Neurons ON-LSTM introduces a new syntax-oriented inductive bias – *Ordered Neurons*, which enables LSTM models to perform tree-like composition without breaking its sequential form (Shen et al., 2019). Ordered neurons enables dynamic allocation of neurons to represent different time-scale dependencies by controlling the update frequency of neurons. The assumption behind ordered neurons is that some neurons always update more (or less) frequently than the others, and that order is pre-determined as part of the model architecture. Formally, ON-LSTM introduces novel ordered neuron rules to update cell state:

$$w_t = \tilde{f}_t \circ \tilde{i}_t, \quad (3)$$
$$\hat{f}_t = f_t \circ w_t + (\tilde{f}_t - w_t), \quad (4)$$
$$\hat{i}_t = i_t \circ w_t + (\tilde{i}_t - w_t), \quad (5)$$
$$c_t = \hat{f}_t \circ c_{t-1} + \hat{i}_t \circ \hat{c}_t, \quad (6)$$

where forget gate f_t, input gate i_t and state $\hat{c}_t$ are same as that in the standard LSTM (Hochreiter and Schmidhuber, 1997). The *master forget gate* $\tilde{f}_t$ and the *master input gate* $\tilde{i}_t$ are newly introduced to control the erasing and the writing behaviors respectively. w_t indicates the overlap, and when the overlap exists ($\exists k, w_{tk} > 0$), the corresponding neurons are further controlled by the standard gates f_t and i_t.

An ideal master gate is in binary format such as $(0, 0, 1, 1, 1)$, which splits the cell state into two continuous parts: 0-part and 1-part. The neurons corresponding to 0-part and 1-part are updated with more and less frequencies separately, so that the information in 0-part neurons will only keep a few time steps, while the information in 1-part neurons will last for more time steps. Since such binary gates are not differentiable, the goal turns to find the splitting point d (the index of the first 1 in the ideal master gate). To this end, Shen et al. (2019) introduced a new activation function:

$$\text{CU}(\cdot) = \text{CUMSUM}(softmax(\cdot)), \quad (7)$$

where $softmax(\cdot)$ produces a probability distribution (e.g.$(0.1, 0.2, 0.4, 0.2, 0.1)$) to indicate the probability of each position being the splitting point d. CUMSUM is the cumulative probability distribution, in which the k-th probability refers to the probability that d falls within the first k positions. The output for the above example is $(0.1, 0.3, 0.7, 0.9, 1.0)$, in which different values denotes different update frequencies. It also equals to the probability of each position's value being 1 in the ideal master gate. Since this ideal master gate is binary, $\text{CU}(\cdot)$ is the expectation of the ideal master gate.

Based on this activation function, the master gates are defined as

$$\tilde{f}_t = \text{CU}_f(\mathbf{x}_t, \mathbf{h}_{t-1}), \quad (8)$$
$$\tilde{i}_t = 1 - \text{CU}_i(\mathbf{x}_t, \mathbf{h}_{t-1}), \quad (9)$$

where $\mathbf{x}_t$ is the current input and $\mathbf{h}_{t-1}$ is the hidden state of previous step. CU_f and CU_i are two individual activation functions with their own trainable parameters.

Short-Cut Connection Inspired by previous work on exploiting deep representations (Peters et al., 2018; Dou et al., 2018), we propose to simultaneously expose both types of signals by explicitly combining them with a simple *short-cut connection* (He et al., 2016).

Similar to positional encoding injection in Transformer (Vaswani et al., 2017), we add the output of the ON-LSTM encoder to the output of SANs encoder:

$$\widehat{\mathbf{H}} = \mathbf{H}^K_{\text{ON-LSTM}} + \mathbf{H}^L_{\text{SANs}}, \quad (10)$$

#	Encoder Architecture	Para.	BLEU

9	Hybrid Model + Short-Cut	308M	**29.30**$^{\Uparrow}$

Table 1: Case-sensitive BLEU scores on the WMT14 English⇒German translation task. "↑ / ⇑": significant over the conventional self-attention counterpart ($p < 0.05/0.01$), tested by bootstrap resampling. "6L SANs" is the state-of-the-art Transformer model. "nL LSTM + mL SANs" denotes stacking n LSTM layers and m SANs layers subsequently. "Hybrid Model" denotes "3L ON-LSTM + 3L SANs".

where $\mathbf{H}^{K}_{\text{ON-LSTM}} \in \mathbb{R}^{N\times d}$ is the output of ON-LSTM encoder, and $\mathbf{H}^{L}_{\text{SANs}} \in \mathbb{R}^{N\times d}$ is output of SANs encoder.

3 Experiments

We chose machine translation, targeted linguistic evaluation and logical inference tasks to conduct experiments in this work. The first and the second tasks evaluate and analyze models as the hierarchical structure is an inherent attribute for natural language. The third task aims to directly evaluate the effects of hierarchical structure modeling on artificial language.

3.1 Machine Translation

For machine translation, we used the benchmark WMT14 English⇒German dataset. Sentences were encoded using byte-pair encoding (BPE) with 32K word-piece vocabulary (Sennrich et al., 2016). We implemented the proposed approaches on top of TRANSFORMER (Vaswani et al., 2017) – a state-of-the-art SANs-based model on machine translation, and followed the setting in previous work (Vaswani et al., 2017) to train the models, and reproduced their reported results. We tested on both the *Base* and *Big* models which differ at hidden size (512 vs. 1024), filter size (2048 vs. 4096) and number of attention heads (8 vs. 16). All the model variants were implemented on the encoder. The implementation details are introduced in Appendix A.1. Table 1 lists the results.

#	Encoder Architecture	Para.	BLEU
1	3L ON-LSTM → 3L SANs	99M	28.21
2	3L SANs → 3L ON-LSTM	99M	27.39
3	8L LSTM	102.2M	27.25
4	10L SANs	100.6M	27.76

Table 2: Results for encoder strategies. Case-sensitive BLEU scores on the WMT14 English⇒German translation task. "A → B" denotes stacking B on the top of A. The model in Row 1 is the hybrid model in Table 1.

Baselines (Rows 1-3) Following Chen et al. (2018), the three baselines are implemented with the same framework and optimization techniques as used in Vaswani et al. (2017). The difference between them is that they adopt SANs, LSTM and ON-LSTM as basic building blocks respectively. As seen, the three architectures achieve similar performances for their unique representational powers.

Hybrid Models (Rows 4-7) We first followed Chen et al. (2018) to stack 6 RNNs layers and 4 SANs layers subsequently (Row 4), which consistently outperforms the individual models. This is consistent with results reported by Chen et al. (2018). In this setting, the ON-LSTM model significantly outperforms its LSTM counterpart (Row 5), and reducing the encoder depth can still maintain the performance (Row 6). We attribute these to the strength of ON-LSTM on modeling hierarchical structure, which we believe is an essential complementarity between SANs and RNNs. In addition, the Short-Cut connection combination strategy improves translation performances by providing richer representations (Row 7).

Stronger Baseline (Rows 8-9) We finally conducted experiments on a stronger baseline – the TRANSFORMER-BIG model (Row 8), which outperforms its TRANSFORMER-BASE counterpart (Row 1) by 1.27 BLEU points. As seen, our model consistently improves performance over the stronger baseline by 0.72 BLEU points, demonstrating the effectiveness and universality of the proposed approach.

Assessing Encoder Strategies We first investigate the encoder stack strategies on different stack orders. From Table 2, to compare with the proposed hybrid model, we stack 3-layers ON-LSTM on the top of 3-layers SANs (Row 2). It performs worse than the strategy in the proposed hybrid model. The result support the viewpoint that the

Table 3: Performance on the linguistic probing tasks of evaluating linguistics embedded in the learned representations. "**S**" and "**O**" denote the SAN and ON-LSTM baseline models. "$\mathbf{H}_O$" and "$\mathbf{H}_S$" are respectively the outputs of the ON-LSTM encoder and the SAN encoder in the hybrid model, and "Final" denotes the final output exposed to decoder.

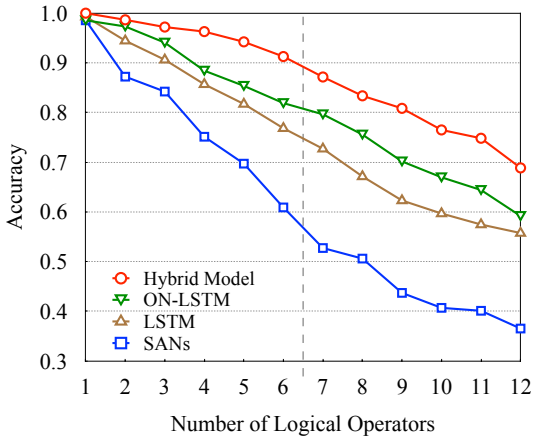

Figure 1: Accuracy of logical inference when training on logic data with at most 6 logical operators in the sequence.

SANs encoder is able to extract richer representations if the input is augmented with sequential context (Chen et al., 2018).

Moreover, to dispel the doubt that whether the improvement of hybrid model comes from the increasement of parameters. We investigate the 8-layers LSTM and 10-layers SANs encoders (Rows 3-4) which have more parameters compared with the proposed hybrid model. The results show that the hybrid model consistently outperforms these model variants with less parameters and the improvement should not be due to more parameters.

3.2 Targeted Linguistic Evaluation

To gain linguistic insights into the learned representations, we conducted probing tasks (Conneau et al., 2018) to evaluate linguistics knowledge embedded in the final encoding representation learned by model, as shown in Table 3. We evaluated SANs and proposed hybrid model with Short-Cut connection on these 10 targeted linguistic evaluation tasks. The tasks and model details are described in Appendix A.2.

Experimental results are presented in Table 3. Several observations can be made here. The proposed hybrid model with short-cut produces more informative representation in most tasks ("Final" in "S" vs. in "Hybrid+Short-Cut"), indicating that the effectiveness of the model. The only exception are surface tasks, which is consistent with the conclusion in Conneau et al. (2018): as a model captures deeper linguistic properties, it will tend to forget about these superficial features. Short-cut further improves the performance by providing richer representations ("$\mathbf{H}_S$" vs. "Final" in "Hybrid+Short-Cut"). Especially on syntactic tasks, our proposed model surpasses the baseline more than 13 points (74.36 vs. 60.66) on average, which again verifies that ON-LSTM enhance the strength of modeling hierarchical structure for self-attention.

3.3 Logical Inference

We also verified the model's performance in the logical inference task proposed by Bowman et al. (2015). This task is well suited to evaluate the ability of modeling hierarchical structure. Models need to learn the hierarchical and nested structures of language in order to predict accurate logical relations between sentences (Bowman et al., 2015; Tran et al., 2018; Shen et al., 2019). The artificial language of the task has six types of words {a, b, c, d, e, f} in the vocabulary and three logical operators {or, and, not}. The goal of the task is to predict one of seven logical relations between two given sentences. These seven relations are: two entailment types ($\sqsubset, \sqsupset$), equivalence ($\equiv$), exhaustive and non-exhaustive contradiction ($\wedge, |$), and semantic independence ($\#, \smile$).

We evaluated the SANs, LSTM, ON-LSTM and

proposed model. We followed Tran et al. (2018) to use two hidden layers with Short-Cut connection in all models. The model details and hyperparameters are described in Appendix A.3.

Figure 1 shows the results. The proposed hybrid model outperforms both the LSTM-based and the SANs-based baselines on all cases. Consistent with Shen et al. (2019), on the longer sequences ($\geq$ 7) that were not included during training, the proposed model also obtains the best performance and has a larger gap compared with other models than on the shorter sequences ($\leq$ 6), which verifies the proposed model is better at modeling more complex hierarchical structure in sequence. It also indicates that the hybrid model has a stronger generalization ability.

4 Related Work

Improved Self-Attention Networks Recently, there is a large body of work on improving SANs in various NLP tasks (Yang et al., 2018; Wu et al., 2018; Yang et al., 2019a,b; Guo et al., 2019; Wang et al., 2019a; Sukhbaatar et al., 2019), as well as image classification (Bello et al., 2019) and automatic speech recognition (Mohamed et al., 2019) tasks. In these works, several strategies are proposed to improve the utilize SANs with the enhancement of local and global information. In this work, we enhance the SANs with the On-Lstm to form a hybrid model (Chen et al., 2018), and thoroughly evaluate the performance on machine translation, targeted linguistic evaluation, and logical inference tasks.

Structure Modeling for Neural Networks in NLP Structure modeling in NLP has been studied for a long time as the natural language sentences inherently have hierarchical structures (Chomsky, 1965; Bever, 1970). With the emergence of deep learning, tree-based models have been proposed to integrate syntactic tree structure into Recursive Neural Networks (Socher et al., 2013), LSTMs (Tai et al., 2015), CNNs (Mou et al., 2016). As for SANs, Hao et al. (2019a), Ma et al. (2019) and Wang et al. (2019b) enhance the SANs with neural syntactic distance, multi-granularity attention scope and structural position representations, which are generated from the syntactic tree structures.

Closely related to our work, Hao et al. (2019b) find that the integration of the recurrence in SANs encoder can provide more syntactic structure features to the encoder representations. Our work follows this direction and empirically evaluates the structure modelling on the related tasks.

5 Conclusion

In this paper, we adopt the ON-LSTM, which models tree structure with a novel activation function and structured gating mechanism, as the RNNs counterpart to boost the hybrid model. We also propose a modification of the cascaded encoder by explicitly combining the outputs of individual components, to enhance the ability of hierarchical structure modeling in a hybrid model. Experimental results on machine translation, targeted linguistic evaluation and logical inference tasks show that the proposed models achieve better performances by modeling hierarchical structure of sequence.

Vecalign: Improved Sentence Alignment in Linear Time and Space

Brian Thompson
Johns Hopkins University
brian.thompson@jhu.edu

Philipp Koehn
Johns Hopkins University
phi@jhu.edu

Abstract

We introduce Vecalign, a novel bilingual sentence alignment method which is linear in time and space with respect to the number of sentences being aligned and which requires only bilingual sentence embeddings. On a standard German–French test set, Vecalign outperforms the previous state-of-the-art method (which has quadratic time complexity and requires a machine translation system) by 5 F_1 points. It substantially outperforms the popular Hunalign toolkit at recovering Bible verse alignments in medium- to low-resource language pairs, and it improves downstream MT quality by 1.7 and 1.6 BLEU in Sinhala→English and Nepali→English, respectively, compared to the Hunalign-based Paracrawl pipeline.

1 Introduction

Sentence alignment is the task of taking parallel documents, which have been split into sentences, and finding a bipartite graph which matches minimal groups of sentences that are translations of each other (see Figure 1). Following prior work, we assume non-crossing alignments but allow local sentence reordering within an alignment.

Sentence-aligned bitext is used to train nearly all machine translation (MT) systems. Alignment errors have been noted to have a small effect on statistical MT performance (Goutte et al., 2012). However, misaligned sentences have been shown to be much more detrimental to neural MT (NMT) (Khayrallah and Koehn, 2018).

Sentence alignment was a popular research topic in the early days of statistical MT, but received less attention once standard sentence-aligned parallel corpora became available. Interest in low-resource MT has led to a resurgence in data gathering methods (Buck and Koehn, 2016; Zweigenbaum et al., 2018; Koehn et al., 2019), but we find limited recent work on bilingual sentence alignment.

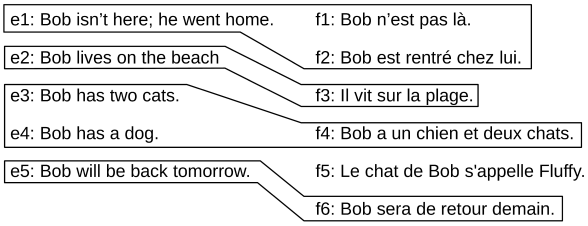

Figure 1: Sentence alignment takes sentences $e_1,...,e_N$ and $f_1,...,f_M$ and locates minimal groups of sentences which are translations of each other, in this case (e_1)-(f_1, f_2), (e_2)-(f_3), (e_3,e_4)-(f_4), and (e_5)-(f_6).

Automatic sentence alignment can be roughly decomposed into two parts:

1. A score function which takes one or more adjacent source sentences and one or more adjacent target sentences and returns a score indicating the likelihood that they are translations of each other;
2. An alignment algorithm which, using the score function above, takes in two documents and returns a hypothesis alignment.

We improve both parts, presenting (1) a novel scoring function based on normalized cosine distance between multilingual sentence embeddings, in conjunction with (2) a novel application of a dynamic programming approximation (Salvador and Chan, 2007) which makes our algorithm linear in time and space complexity with respect to the number of sentences being aligned. We release a toolkit containing our implementation.[1]

Our method outperforms previous state-of-the-art, which has quadratic complexity, indicating that our proposed score function outperforms prior work and the approximations we make in alignment are sufficiently accurate.

2 Related Work

Early sentence aligners (Brown et al., 1991; Gale and Church, 1993) use scoring functions based only on the number of words or characters in each sentence and alignment algorithms based on dynamic programming (DP; Bellman, 1953). DP is O(NM) time complexity, where N and M are the number of sentences in the source and target documents. Later work added lexical features and heuristics to speed up search, such as limiting the search space to be near the diagonal (Moore, 2002; Varga et al., 2007). More recent work introduced scoring methods that use MT to get both documents into the same language (Bleualign; Sennrich and Volk, 2010) or use pruned phrase tables from a statistical MT system (Coverage-Based; Gomes and Lopes, 2016). Both methods "anchor" high-probability 1–1 alignments in the search space and then fill in and refine alignments. Locating anchors is $O(NM)$ time complexity.

3 Method

We propose a novel sentence alignment scoring function based on the similarity of bilingual sentence embeddings. A distinct but non-obvious advantage of sentence embeddings is that blocks of sentences can be represented as the average of their sentence embeddings. The size of the resulting vector is not dependent on the number of sentence embeddings being averaged, thus the time/space cost of comparing the similarity of blocks of sentences *does not depend on the number of sentences being compared*. We show empirically (see § 4.2) that average embeddings for blocks of sentences are sufficient to produce approximate alignments, even in low-resource languages. This enables us to approximate DP in O($N+M$) in time and space.

3.1 Bilingual Sentence Embeddings

We propose to use the similarity between sentence embeddings as the scoring function for sentence alignment. Sentence embedding similarity has been shown effective at filtering out non-parallel sentences (Hassan et al., 2018; Chaudhary et al., 2019) and locating parallel sentences in comparable corpora (Guo et al., 2018). We use the publicly available LASER multilingual sentence embedding method (Artetxe and Schwenk, 2018) and model, which is pretrained on 93 languages. However, our method is not specific to LASER.

3.2 Scoring Function

Cosine similarity is an obvious choice for comparing embeddings but has been noted to be globally inconsistent due to "hubness" (Radovanović et al., 2010; Lazaridou et al., 2015). Guo et al. (2018) proposed a supervised training approach for calibration, and Artetxe and Schwenk (2019) proposed normalization using nearest neighbors. We propose normalizing instead with *randomly* selected embeddings as it has linear complexity. Sentence alignment seeks *minimal* parallel units, but we find that DP with cosine similarity favors many-to-many alignments (e.g. reporting a 3–3 alignment when it should report three 1–1 alignments). To remedy this issue, we scale the cost by the number of source and target sentences being considered in a given alignment. Our resulting scoring cost function is:

$$c(x,y) = \frac{(1-\cos(x,y))\,\mathrm{nSents}(x)\,\mathrm{nSents}(y)}{\sum_{s=1}^{S} 1-\cos(x,y_s) + \sum_{s=1}^{S} 1-\cos(x_s,y)}$$

where x, y denote one or more sequential sentences from the source/target document; $\cos(x,y)$ is the cosine similarity between embeddings[2] of x, y; $\mathrm{nSents}(x)$, $\mathrm{nSents}(y)$ denote the number of sentences in x, y; and $x_1,...,x_S$, $y_1,...,y_S$ are sampled uniformly from the given document.

Following standard practice, we model insertions and deletions in DP using a skip cost c_{skip}. The raw value of c_{skip} is only meaningful when compared to other costs, thus we do not expect it to generalize across different languages, normalizations, or resolutions. We propose specifying instead a parameter β_{skip} which defines the skip cost in terms of the distribution of 1–1 alignment costs at alignment time: $c_{skip} = \mathrm{CDF}^{-1}(\beta_{skip})$. CDF is an estimate of the cumulative distribution function of 1–1 alignments obtained by computing costs of randomly selected source/target sentences pairs.

3.3 Recursive DP Approximation

Instead of searching all possible sentence alignments via DP, consider first averaging adjacent pairs of sentence embeddings in both the source and target documents, halving the number of embeddings for each document. Aligning these vectors via DP (each of which are averages of 2 sentence embeddings) produces an *approximate* sen-

[2] If multiple sentences are considered on one side, they are concatenated together before embedding.

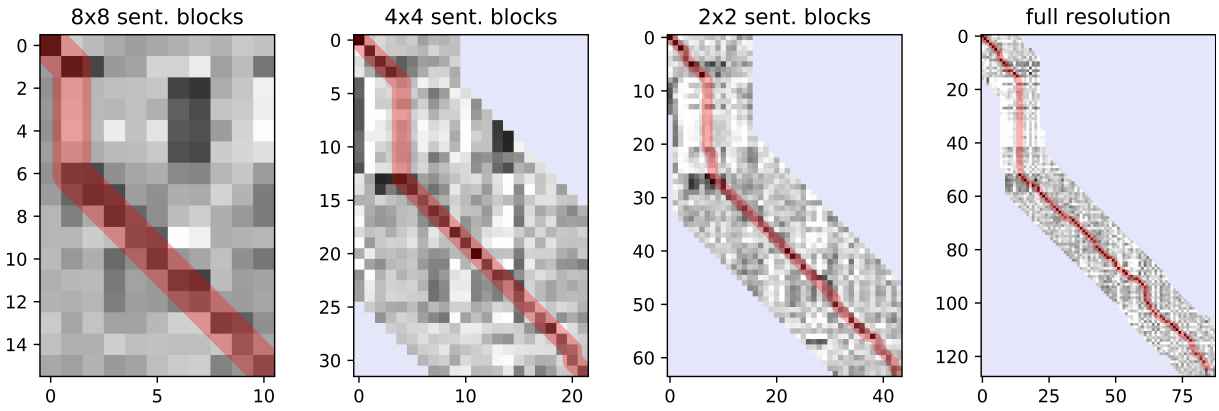

Figure 2: 1–1 alignment costs (darker = lower) for the first 88 De lines (x-axis) and 128 Fr lines (y-axis) at 4 different resolutions. The red highlight denotes alignment found by DP. The algorithm only searches near the path found at previous resolutions; light blue regions are excluded. The vertical part of the path in the top left of each plot is due to 36 extra lines being present in the Fr document. Window size is increased for visualization purposes.

tence alignment, at a cost of $\left(\frac{N}{2}\right)\left(\frac{M}{2}\right)$ comparisons. We can then refine this approximate alignment using the original sentence vectors, constraining ourselves to a small window around the approximate alignment. At a minimum, we must search a window size w large enough to consider all paths covered by the lower-resolution alignment path, but w can also be increased to allow recovery from small errors in the approximate alignment.[3] The length of the refinement path to search is at most $N+M$ (all deletions/insertions), so refining the path requires at most $(N+M)w$ comparisons. Thus the full NM comparisons can be approximated by $(N+M)w+\left(\frac{N}{2}\right)\left(\frac{M}{2}\right)$ comparisons. Applied recursively,[4] we can approximate our quadratic NM cost with a sum of linear costs:

$$(N+M)w+\left(\frac{N}{2}+\frac{M}{2}\right)w+\left(\frac{N}{4}+\frac{M}{4}\right)w+\ldots$$
$$=\sum_{k=0,1,2,\ldots}\frac{(N+M)w}{2^k}=2(N+M)w$$

See Figure 2 for an illustration of this method. We consider only insertions, deletions, and 1–1 alignments in all but the final search. Recursive down sampling and refining of DP was proposed for dynamic time warping in Salvador and Chan (2007), but has not previously been applied to sentence alignment. We direct the reader to that work for a more formal analysis showing the time/space complexity is linear.

[3]We use $w=10$ for all experiments in this work.

[4]In practice, we compute the full DP alignment once the down sampled sizes are below an acceptably small constant. We also find vectors for large blocks of sentences become correlated with each other, so we center them around $\vec{0}$.

4 Experiments & Results

4.1 Text+Berg Alignment Accuracy

We evaluate sentence alignment accuracy using the development/test split released with Bleualign, consisting of manually aligned yearbook articles published in both German and French by the Swiss Alpine Club from the Text+Berg corpus (Volk et al., 2010). Hyperparameters were chosen to optimize F_1 on the development set. We consider alignments of up to 6 total sentences; that is we allow alignments of size Q–R where $Q+R\leq 6$.

We compare to Gale and Church (1993), Moore (2002), Hunalign (Varga et al., 2007), Bleualign (Sennrich and Volk, 2010), Gargantua (Braune and Fraser, 2010), and Coverage-Based (Gomes and Lopes, 2016). We run Hunalign in both bootstrapping mode as well as using a publically available De–Fr lexicon from OPUS (Tiedemann, 2012)[5] created from Europarl (Koehn, 2005). Since Bleualign depends on the quality of MT output, we re-run it with a modern NMT system.[6]

Our proposed method outperforms the next best method (Coverage-Based) by 5 F_1 points: see Table 1. Gargantua and bootstrapped Hunalign have both been reported to perform well (Abdul-Rauf et al., 2012); this dataset may be too small to bootstrap good lexical features.[7] Bleualign improves by 3 F_1 points by using an NMT system.

4.2 Bible Alignment Accuracy

We are unaware of a multilingual, low resource, parallel dataset with human sentence-level annotations. As a substitute for gold standard sentence alignment, we use Bible verse alignment and sentence split each verse.[8]

The Bible has a number of properties which make it appealing for sentence alignment evaluation: It is much larger than existing sentence alignment test sets, and it is multi-way parallel in a large number of languages. Bibles are not aligned at the sentence level, but contain verse marking denoting segments typically on the scale of a partial sentence to a few sentences. This creates two potential issues for sentence alignment evaluation: First, a single sentence may span more than one verse. Inspecting the English Bible suggests that this is rare, and sentence aligners should be able to handle occasional over-segmentation of sentences as in practice they are run on errorful automatic sentence segmentation. Second, a verse may contain more than one sentence. This is problematic when it happens on both languages being aligned, since the true sentence alignment cannot be determined (e.g., a verse which is two sentences in each language could be two 1–1 alignments or one 2–2 alignment). To evaluate with verse-level annotations, we propose converting the sentence alignment output into verse alignments by combining any consecutive sentence alignments for which all sentences in the alignments, on both the source and target side, came from the same verse. We report F_1 compared to the gold-standard verse alignments, denoting it as *verse-level* F_1 to distinguish it from F_1 computed at the sentence level.

Languages	Verse-level F_1 Vecalign	Hunalign
Af–Ar	**0.863**	0.339
Af–Tl	**0.922**	0.775

Table 3: Bible verse alignment results.

We select six languages for which Christodouloupoulos and Steedman (2015) contains a full Bible: see Table 2. Languages were chosen to provide a range of amounts of training data used in LASER.[9] From those six languages, we randomly select 10 language pairs for testing. All parameters are kept the same as § 4.1 except we only consider alignments of up to 4 total sentences. We compare to Hunalign, run in bootstrap mode, as it is the only toolkit we tried which was robust enough to run on documents of this size. Results are shown in Table 3.

On average, we see an improvement of 28 verse-level F_1 points over Hunalign. In manual analysis of the alignments we find large stretches where the Hunalign alignments are nowhere near the gold alignment in the language pairs with verse-level $F_1 < 0.35$. By contrast, errors in the proposed method are predominately local, indicating success of Vecalign's recursive DP approximation even for very long documents in low-resource languages.

[8]There is no clear choice for sentence segmentation in low-resource languages. We use https://github.com/berkmancenter/mediacloud-sentence-splitter, falling back on English for unsupported languages.

[9]Data amounts are all between the given language and English. LASER used no bitext in the language pairs under test.

4.3 Improvements to Downstream MT

One of the primary applications of sentence alignment is creating bitext for training MT systems. To test Vecalign's impact on downstream MT quality, we re-align noisy, web-crawled data in two low-resource language pairs: Sinhala–English and Nepali–English. The data is collected via Paracrawl[10] and is very similar to that released in the WMT 2019 sentence filtering task (Koehn et al., 2019), but some new data has been collected and a small amount of data was lost due to a hard disk failure. Our baseline is the standard Paracrawl pipeline using Hunalign in conjunction with a dictionary extracted from the clean data released in the shared task.

We filter the output of Vecalign and Hunalign following (Chaudhary et al., 2019), including filtering out sentences with the wrong languages and sentences with high token overlap, as this was the best performing method from the shared task.[11] We train and evaluate NMT models following the procedure/hyperparameters from the shared task.

Results are shown in Figure 3. Using Vecalign, we see improvements of 1.7 and 1.6 BLEU for the best data sizes in Sinhala→English and Nepali→English, respectively, compared to the systems trained on Hunalign output.

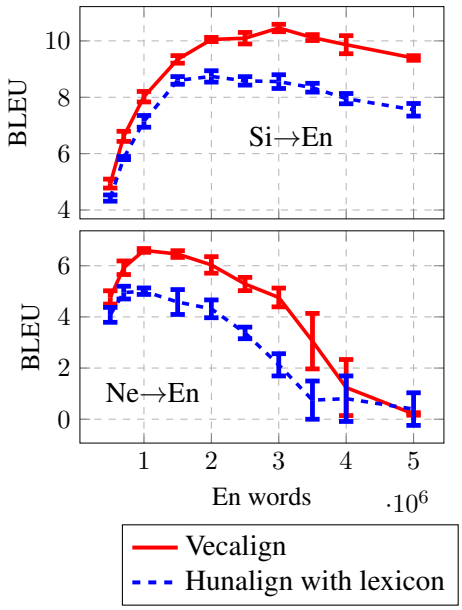

Figure 3: sacreBLEU scores (mean +/- standard deviation for 5 training runs) on FLoRes test sets for systems trained on data aligned with Vecalign vs Hunalign.

[10] https://paracrawl.eu/

[11] We use the publicly available multilingual LASER model, which is not trained on Nepali.

5 Empirical Runtime Analysis

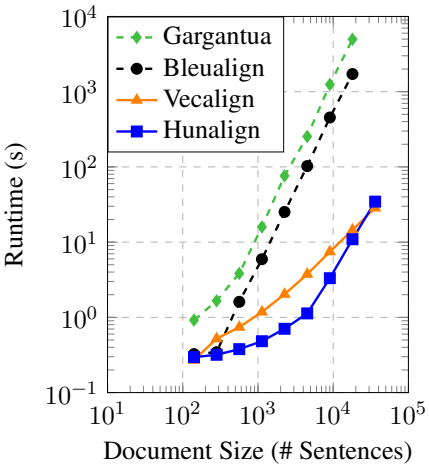

Figure 4: Time required to align various portions of En→Hu Bibles, for various systems. Plot is logarithmic in both runtime and number of sentences, thus a slope of one (i.e. runtime doubles each time the number of sentences doubles) indicates $O(N)$, while a slope of two (i.e. runtime quadruples each time the number of sentences doubles) indicates $O(N^2)$.

Time required to align documents of various sizes are shown for Vecalign, Bleualign, Gartantua, and Hunalign in see Figure 4. As expected, Vecalign has approximately linear runtime characteristics. We use truncated portions of Hu–En Bibles in order to use the dictionary provided with Hunalign. Bleualign is run on NMT output. Vecalign settings match § 4.2. Experiments are run on a Thinkpad T480 with 32GB RAM. Times do not include translation (Bleualign), lexicon building (Hunalign), or sentence embedding (Vecalign). For reference, producing embeddings for 32k sentences, including overlaps, in each language took ~120 s on a GeForce RTX 2080 Ti GPU. Bleualign and Gargantua run out of memory on 32k sentences. Hunalign and Vecalign use ~1GB and are both very fast, aligning 32k sentences in ~30 s.

6 Conclusions

We present Vecalign, a novel sentence alignment method based on similarity of sentence embeddings and a DP approximation which is fast even for long documents. Our method has state-of-the-art accuracy in high and low resource settings and improves downstream MT quality.

Simpler and Faster Learning of Adaptive Policies for Simultaneous Translation

Abstract

Simultaneous translation is widely useful but remains challenging. Previous work falls into two main categories: (a) fixed-latency policies such as Ma et al. (2019) and (b) adaptive policies such as Gu et al. (2017). The former are simple and effective, but have to aggressively predict future content due to diverging source-target word order; the latter do not anticipate, but suffer from unstable and inefficient training. To combine the merits of both approaches, we propose a simple supervised-learning framework to learn an adaptive policy from oracle READ/WRITE sequences generated from parallel text. At each step, such an oracle sequence chooses to WRITE the next target word if the available source sentence context provides enough information to do so, otherwise READ the next source word. Experiments on German↔English show that our method, without retraining the underlying NMT model, can learn flexible policies with better BLEU scores and similar latencies compared to previous work.

1 Introduction

Simultaneous translation outputs target words while the source sentence is being received, and is widely useful in international conferences, negotiations and press releases. However, although there is significant progress in machine translation (MT) recently, simultaneous machine translation is still one of the most challenging tasks. This is because it is hard to balance translation quality and latency, especially for the syntactically divergent language pairs, such as English and Japanese.

Researchers previously study simultaneous translation as a part of real-time speech-to-speech translation system (Yarmohammadi et al., 2013; Bangalore et al., 2012; Fügen et al., 2007; Sridhar et al., 2013; Jaitly et al., 2016; Graves et al., 2013). Recent simultaneous translation research focuses on obtaining a strategy, called a *policy*, to decide whether to wait for another source word (READ action) or emit a target word (WRITE action). The obtained policies fall into two main categories: (1) fixed-latency policies (Ma et al., 2019; Dalvi et al., 2018) and (2) context-dependent adaptive policies (Grissom II et al., 2014; Cho and Esipova, 2016; Gu et al., 2017; Alinejad et al., 2018; Arivazhagan et al., 2019; Zheng et al., 2019a). As an example of fixed-latency policies, wait-k (Ma et al., 2019) starts by waiting for the first few source words and then outputs one target word after receiving each new source word until the source sentence ends. It is easy to see that this kind of policy will inevitably need to guess the future content, which can often be incorrect. Thus, an adaptive policy (see Table 1 as an example), which can decides on the fly whether to take READ action or WRITE action, is more desirable for simultaneous translation. Moreover, the widely-used beam search technique become non-trivial for fixed policies (Zheng et al., 2019b).

To represent an adaptive policy, previous work shows three different ways: (1) a rule-based decoding algorithm (Cho and Esipova, 2016), (2) an original MT model with an extended vocabulary (Zheng et al., 2019a), and (3) a separate policy model (Grissom II et al., 2014; Gu et al., 2017; Alinejad et al., 2018; Arivazhagan et al., 2019). The decoding algorithm (Cho and Esipova, 2016) applies heuristics measures and does not exploit information in the hidden representation, while the MT model with an extended vocabulary (Zheng et al., 2019a) needs guidance from a restricted dynamic oracle to learn an adaptive policy, whose size is exponentially large so that approximation is needed. A separate policy model could avoid these issues. However, previous policy-learning

methods either depends on reinforcement learning (RL) (Grissom II et al., 2014; Gu et al., 2017; Alinejad et al., 2018), which makes the training process unstable and inefficient due to exploration, or applies advanced attention mechanisms (Arivazhagan et al., 2019), which requires its training process to be autoregressive, and hence inefficient. Furthermore, each such learned policy cannot change its behaviour according to different latency requirements at testing time, and we will need to train multiple policy models for scenarios with different latency requirements.

To combine the merits of fixed and adaptive policies, and to resolve the mentioned drawbacks, we propose a simple supervised learning framework to learn an adaptive policy, and show how to apply it with controllable latency. This framework is based on sequences of READ/WRITE actions for parallel sentence pairs, so we present a simple method to generate such an action sequence for each sentence pair with a pre-trained neural machine translation (NMT) model.[1] Our experiments on German↔English dataset show that our method, without retraining the underlying NMT model, leads to better policies than previous methods, and achieves better BLEU scores than (the retrained) wait-k models at low latency scenarios.

2 Generating Action Sequences

In this section, we show how to generate action sequences for parallel text. Our simultaneous translation policy can take two actions: READ (receive a new source word) and WRITE (output a new target word). A sequence of such actions for a sentence pair $(\mathbf{s}, \mathbf{t})$ defines one way to translate $\mathbf{s}$ into $\mathbf{t}$. Thus, such a sequence must have $|\mathbf{t}|$ number of WRITE actions. However, not every action sequence is good for simultaneous translation. For instance, a sequence without any READ action will not provide any source information, while a sequence with all $|\mathbf{s}|$ number of READ actions before all WRITE actions usually has large latency. Thus the ideal sequences for simultaneous translation should have the following two properties:

- there is no anticipation during translation, i.e. when choosing WRITE action, there is enough source information for the MT model to generate the correct target word;
- the latency is as low as possible, i.e. the WRITE action for each target word appears as early as possible.

Table 1 gives an example for such a sequence.

Algorithm 1 Generating Action Sequence

Input: sentence pair $(\mathbf{s}, \mathbf{t})$, integer r, model M
$id_s \leftarrow 1, id_t \leftarrow 1$
Seq $\leftarrow [R]$
while $id_t \leq |\mathbf{t}|$ **do**
  if $rank_M(t_{id_t}|\mathbf{s}_{\leq id_s}) \leq r$ or $id_s = |\mathbf{s}|$ **then**
    Seq $\leftarrow$ Seq $+[W]$
    $id_t \leftarrow id_t + 1$
  else
    Seq $\leftarrow$ Seq $+[R]$
    $id_s \leftarrow id_s + 1$
return Seq

In the following, we present a simple method to generate such an action sequence for a sentence pair $(\mathbf{s}, \mathbf{t})$ using a pre-trained NMT model, assuming this model can make reasonable prediction given incomplete source sentence. Our method is based on this observation: *if the rank of the next ground-truth target word is high enough in the prediction of the model, then this implies that there is enough source-side information for the model to make a correct prediction.* Specifically, we sequentially input the source words to the pre-trained model, and use it to predict next target word. If the rank of the gold target word is high enough, we will append a WRITE action to the sequence and then try the next target word; otherwise, we append a READ action and input a new source word. Let r be a positive integer, M be a pre-trained NMT model, $\mathbf{s}_{\leq i}$ be the source sequence consisting of the first i words of $\mathbf{s}$, and $rank_M(t_j|\mathbf{s}_{\leq i})$ be the rank of the target word t_j in the prediction of model M

[1] Previous work (He et al., 2015; Niehues et al., 2018) shows that carefully generated parallel training data can help improve simultaneous MT or low-latency speech translation. This is different from our work in that we generates action sequences for training policy model instead of parallel translation data for MT model.

given sequence $\mathbf{s}_{\leq i}$. Then the generating process can be summarized as Algorithm 1.

Although we can generate action sequences balancing the two wanted properties with appropriate value of parameter r, the latency of generated action sequence may still be large due to the word order difference between the two sentences. To avoid this issue, we filter the generated sequences with the latency metric *Average Lagging* (AL) proposed by Ma et al. (2019), which quantifies the latency in terms of the number of source words and avoids some flaws of other metrics like *Average Proportion* (AP) (Cho and Esipova, 2016) and *Consecutive Wait* (CW) (Gu et al., 2017). Another issue we observed is that, the pre-trained model may be too aggressive for some sentence pair, meaning that it may write all target words without seeing the whole source sentence. This may be because the model is also trained on the same dataset. To overcome this, we only keep the action sequences that will receive all the source words before the last WRITE action. After the filtering process, each action sequence has AL less than a fixed constant α and receives all source words.

3 Supervised-Learning Framework for Simultaneous Translation Policy

Given a sentence pair and an action sequence for this pair, we can apply supervised learning method to learn a parameterized policy for simultaneous translation. For the policy to be able to choose the correct action, its input should include information from both source and target sides. Since we use Transformer (Vaswani et al., 2017) as our underlying NMT model in this work, we need to recompute encoder hidden states for all previous seen source words, which is the same as done for wait-k model training (Ma et al., 2019).[2] The policy input o_i at step i consists of three components from this model:

- h_i^s: the last-layer hidden state from the encoder for the first source word at step i;
- h_i^t: the last-layer hidden state from the decoder for the first target word at step i;[3]
- c_i: cross-attention scores at step i for the current input target word on all attention layers in decoder, averaged over all current source words.

That is $o_i = [h_i^s, h_i^t, c_i]$.

Let a_i be the i-th action in the given action sequence $\mathbf{a}$. Then the decision of our policy on the i-th step depends on all previous inputs $\mathbf{o}_{\leq i}$ and all taken actions $\mathbf{a}_{<i}$. We want to maximize the probability of the next action a_i given those information:

$$\max p_\theta(a_i|\mathbf{o}_{\leq i}, \mathbf{a}_{<i})$$

where p_θ is the action distribution of our policy parameterized by θ.

4 Decoding with Controllable Latency

To apply the learned policy for simultaneous translation, we can choose at each step the action with higher probability . However, different scenarios may have different latency requirements. Thus, this greedy policy may not always be the best choice for all situations. Here we present a simple way to implicitly control the latency of the learned policy without retraining the policy model.

Let ρ be a probability threshold. For each step in translation, we choose READ action only if the probability of READ is greater than ρ; otherwise we choose WRITE action. Thus, this threshold balances the tradeoff between latency and translation quality: with larger ρ, the policy prefers to take WRITE actions, providing lower latency; and with smaller ρ, the policy prefers to take READ actions, and provides more conservative translation with larger latency.

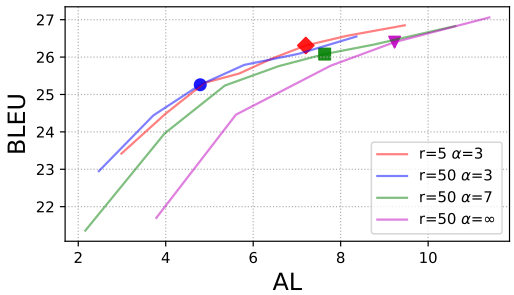

Figure 1: Translation quality against latency on DE→EN dev set. Lines are obtained with different probability thresholds ρ. Markers represent $\rho = 0.5$.

5 Experiments

Dataset We conduct experiments on English↔German (EN↔DE) simultaneous translation. We use the parallel corpora from

[2] In our experiments, the decoder and policy model combined need about 0.0445 seconds on average to generate one target word (this might include multiple READ's), while it takes on average only about 0.0058 seconds to recompute all encoder states for each new source word. So we think this re-computation might not be a serious issue for system efficiency.

[3] The hidden states of the first target word will be recomputed at each step.

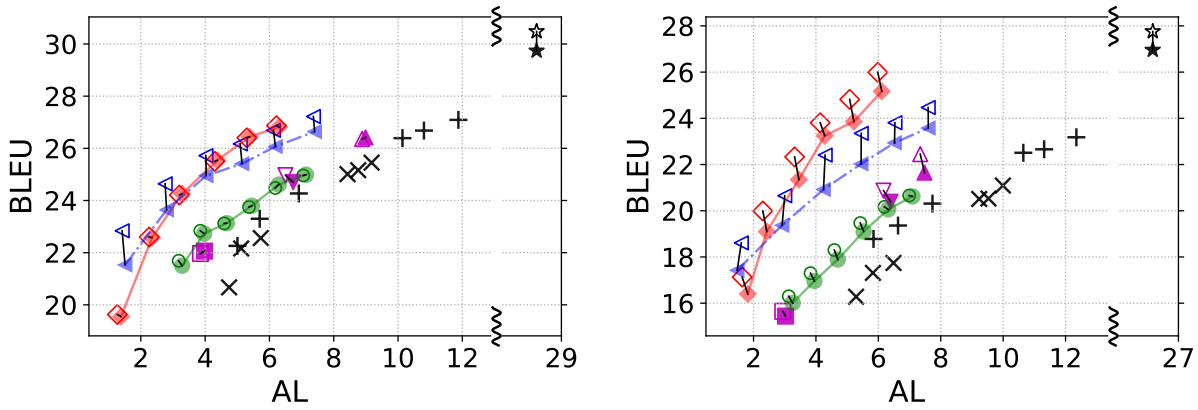

Figure 2: Comparing performances of different methods on testing sets. Left: DE→EN. Right: EN→DE. The shown pairs are results of greedy decoding (solid shapes) and beam search (empty shapes, beam-size = 5). ◆: wait-k models for $k \in \{1,2,3,4,5,6\}$, ●: test-time wait-k for $k \in \{1,2,3,4,5,6\}$, ◀: our SL model with threshold $\rho \in \{0.65, 0.6, 0.55, 0.5, 0.45, 0.4\}$, ★: full-sentence translation model, ■: RL with CW = 2, ▼: RL with CW = 5, ▲: RL with CW = 8, ×: WID for $s_0 \in \{2,4,6\}$ and $\delta \in \{2,4\}$, +: WIW for $s_0 \in \{2,4,6\}$ and $\delta \in \{1,2\}$.

WMT 15 for training, newstest-2013 for validation and newstest-2015 for testing.[4] All datasets are tokenized and segmented into sub-word units with byte-pair encoding (BPE) (Sennrich et al., 2016), and we only use the sentence pairs of lengths less than 50 (on both sides) for training.

Model Configuration We use Transformer-base (Vaswani et al., 2017) as our NMT model and our implementation is based on PyTorch-based OpenNMT (Klein et al., 2017). We add an <eos> token on the source side, which is not included in the original OpenNMT codebase. Our recurrent policy model consists of one GRU layer with 512 units, one fully-connected layer of dimension 64 followed by ReLU activation, and one fully-connected layer of dimension 2 followed by a softmax function to produce the action distribution. We use BLEU (Papineni et al., 2002) as the translation quality metric and Averaged Lagging (AL) (Ma et al., 2019) as the latency metric.

Effects of Generated Action Sequences We first analyze the effects of the two parameters in the generation process of action sequences: the rank r and the filtering latency α. We fix $\alpha = 3$ and choose the rank $r \in \{5, 50\}$; then we fix $r = 50$ and choose the latency $\alpha \in \{3, 7, \infty\}$ to generate action sequences on DE→EN direction.Figure 1 shows the performances of resulting models with different probability thresholds ρ. We find that smaller α helps achieve better performance and our model is not very sensitive to values of rank. Therefore, in the following experiments, we report results with $r = 50$ and $\alpha = 3$.

Performance Comparison We compare our method on EN↔DE directions with different methods: greedy decoding algorithms Wait-If-Worse/Wait-If-Diff (WIW/WID) of Cho and Esipova (2016), RL method of Gu et al. (2017), wait-k models and test-time wait-k methods of Ma et al. (2019). Both of WIW and WID only use the pre-trained NMT model, and the algorithm initially reads s_0 number of source words and chooses READ only if the probability of the most likely target word decreases when given another δ number of source words (WIW) or the most likely target word changes when given another δ number of source words (WID). For RL method, we use the same kind of input and architecture for policy model.[5] Test-time wait-k means decoding with wait-k policy using the pre-trained NMT model. All methods share the same underlying pre-trained NMT model except for the wait-k method, which retrains the NMT model from scratch, but with the same architecture as the pre-trained model.

Figure 2 shows the performance comparison. Our models on both directions can achieve higher BLEU scores with the similar latency than WIW, WID, RL model and test-time wait-k method, implying that our method learns a better policy model than the other methods when the underlying NMT model is not retrained.[6] Compared with wait-k models, our models with beam search achieve

[4] http://www.statmt.org/wmt15/translation-task.html

[5] We only report results obtained with CW-based reward functions for they outperform those with AP-based ones.

[6] Our test-time wait-k results are better than those in Ma et al. (2019), because the added source side <eos> token helps the full-sentence model to learn when the source sentence

Table 2: German-to-English example from validation set.

higher BLEU scores when latency AL is small, which we think will be the most useful scenarios of simultaneous translation. Furthermore, this figure also shows that our model can achieve good performance on different latency conditions by controlling the threshold ρ, so we do not need to train multiple models for different latency requirements. We also provide a translation example in Table 2 to compare different methods.

Learning Process Analysis We analyze two aspects of the learning processes of different methods: stability and training time. Figure 3 shows the learning curves of the training processes of RL method and our SL method, averaged over four different runs with different random seeds on DE→EN direction. We can see that the training process of our method is more stable and converges faster than the RL method. Although there are some steps where the RL training process can achieve better BLEU scores than our SL method, the corresponding latencies are usually very big, which are not appropriate for simultaneous translation. We present the training time of different methods in Table 3. Our method only need about 12 hours to train the policy model with 1 GPU, while the wait-k method needs more than 600 hours with 8 GPUs to finish the training process, showing that our method is very efficient. Note that this table does not include the time needed to generate action sequences. The time for this process could be very flexible since we can parallelize this by dividing the training data into separating parts. In our experiments, we need about 2 hours to generate all action sequences in parallel.

6 Conclusions

We have proposed a simple supervised-learning framework to learn an adaptive policy based on generated action sequences for simultaneous translation, which leads to faster training and better policies than previous methods, without the need to retrain the underlying NMT model.

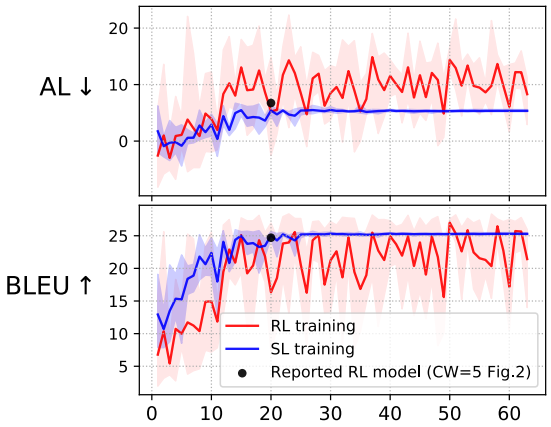

Figure 3: Learning curves averaged over four independent training runs on DE→EN direction. The x-axis represents training steps ($\times$ 50).

DE→EN	pre-train: 64		wait-1	wait-3	wait-5
	SL: +12	RL: +14.3	938	966	945
EN→DE	pre-train: 68		wait-1	wait-3	wait-5
	SL: +11	RL: +11.2	665	665	630

Table 3: Training time (in hours) of different methods. Wait-k training uses 8 GPUs, while others use 1 GPU. The RL time is the average time needed to obtain the three RL models in Figure 2.

Adversarial Learning with Contextual Embeddings for Zero-resource Cross-lingual Classification and NER

Phillip Keung, Yichao Lu, Vikas Bhardwaj

{keung, yichaolu, vikab}@amazon.com

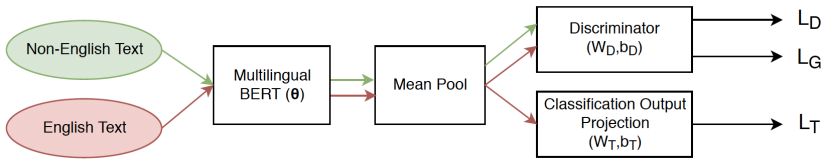
Abstract

Contextual word embeddings (e.g. GPT, BERT, ELMo, etc.) have demonstrated state-of-the-art performance on various NLP tasks. Recent work with the multilingual version of BERT has shown that the model performs very well in cross-lingual settings, even when only labeled English data is used to finetune the model. We improve upon multilingual BERT's zero-resource cross-lingual performance via adversarial learning. We report the magnitude of the improvement on the multilingual MLDoc text classification and CoNLL 2002/2003 named entity recognition tasks. Furthermore, we show that language-adversarial training encourages BERT to align the embeddings of English documents and their translations, which may be the cause of the observed performance gains.

1 Introduction

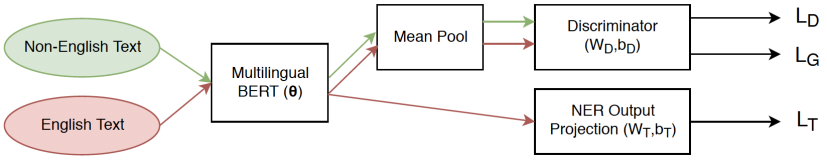
Contextual word embeddings (Devlin et al., 2019; Peters et al., 2018; Radford et al., 2019) have been successfully applied to various NLP tasks, including named entity recognition, document classification, and textual entailment. The multilingual version of BERT (which is trained on Wikipedia articles from 100 languages and equipped with a 110,000 shared wordpiece vocabulary) has also demonstrated the ability to perform 'zero-resource' cross-lingual classification on the XNLI dataset (Conneau et al., 2018). Specifically, when multilingual BERT is finetuned for XNLI with English data alone, the model also gains the ability to handle the same task in other languages. We believe that this zero-resource transfer learning can be extended to other multilingual datasets.

In this work, we explore BERT's[1] zero-resource performance on the multilingual MLDoc classification and CoNLL 2002/2003 NER tasks. We find that the baseline zero-resource performance of BERT exceeds the results reported in other work, even though cross-lingual resources (e.g. parallel text, dictionaries, etc.) are not used during BERT pretraining or finetuning. We apply adversarial learning to further improve upon this baseline, achieving state-of-the-art zero-resource results.



There are many recent approaches to zero-resource cross-lingual classification and NER, including adversarial learning (Chen et al., 2019; Kim et al., 2017; Xie et al., 2018; Joty et al., 2017), using a model pretrained on parallel text (Artetxe and Schwenk, 2018; Lu et al., 2018; Lample and Conneau, 2019) and self-training (Hajmohammadi et al., 2015). Due to the newness of the subject matter, the definition of 'zero-resource' varies somewhat from author to author. For the experiments that follow, 'zero-resource' means that, during model training, we do not use labels from non-English data, nor do we use human or machine-generated parallel text. Only labeled English text and unlabeled non-English text are used during training, and hyperparameters are selected using English evaluation sets.

Our contributions are the following:



- We demonstrate that the addition of a language-adversarial task during finetuning for multilingual BERT can significantly improve the zero-resource cross-lingual transfer performance.
- For both MLDoc classification and CoNLL NER, we find that, even without adversarial training, the baseline multilingual BERT performance can exceed previously published results on zero-resource performance.
- We show that adversarial techniques encourage BERT to align the representations of En-

[1] 'BERT' hereafter refers to multilingual BERT

glish documents and their translations. We speculate that this alignment causes the observed improvement in zero-resource performance.

2 Related Work

2.1 Adversarial Learning

Language-adversarial training (Zhang et al., 2017) was proposed for generating bilingual dictionaries without parallel data. This idea was extended to zero-resource cross-lingual tasks in NER (Kim et al., 2017; Xie et al., 2018) and text classification (Chen et al., 2019), where we would expect that language-adversarial techniques induce features that are language-independent.

2.2 Self-training Techniques

Self-training, where an initial model is used to generate labels on an unlabeled corpus for the purpose of domain or cross-lingual adaptation, was studied in the context of text classification (Hajmohammadi et al., 2015) and parsing (McClosky et al., 2006; Zeman and Resnik, 2008). A similar idea based on expectation-maximization, where the unobserved label is treated as a latent variable, has also been applied to cross-lingual text classification in Rigutini et al. (2005).

2.3 Translation as Pretraining

Artetxe and Schwenk (2018) and Lu et al. (2018) use the encoders from machine translation models as a starting point for task-specific finetuning, which permits various degrees of multilingual transfer. Lample and Conneau (2019) add an additional masked translation task to the BERT pretraining process, and the authors observed an improvement in the cross-lingual setting over using the monolingual masked text task alone.

3 Experiments

3.1 Model Training

We present an overview of the adversarial training process in Figure 1. We used the pretrained cased multilingual BERT model[2] as the initialization for all of our experiments. Note that the BERT model has 768 units.

We always use the labeled English data of each corpus. We use the non-English text portion (without the labels) for the adversarial training.

We formulate the adversarial task as a binary classification problem (i.e. English versus non-English.) We add a *language discriminator* module which uses the BERT embeddings to classify whether the input sentence was written in English or the non-English language. We also add a *generator* loss which encourages BERT to produce embeddings that are difficult for the discriminator to classify correctly. In this way, the BERT model learns to generate embeddings that do not contain language-specific information.

The pseudocode for our procedure can be found in Algorithm 1. In the description that follows, we use a batch size of 1 for clarity.

For language-adversarial training for the classification task, we have 3 loss functions: the task-specific loss L_T, the generator loss L_G, and the

[2]https://github.com/google-research/bert/blob/master/multilingual.md

discriminator loss L_D:

$$L_T(y^T; x) = \sum_{i=1}^{K} -y_i^T \log p(Y = i|x)$$

$$p(Y|x) = \text{Softmax}(W_T \bar{h}_\theta(x) + b_T)$$

$$L_G(y^A; x) = -(1 - y^A)\log p(E = 1|x) - y^A \log p(E = 0|x)$$

$$L_D(y^A; x) = -(1 - y^A)\log p(E = 0|x) - y^A \log p(E = 1|x)$$

$$p(E = 1|x) = \text{Sigmoid}(w_D \cdot \bar{h}_\theta(x) + b_D)$$

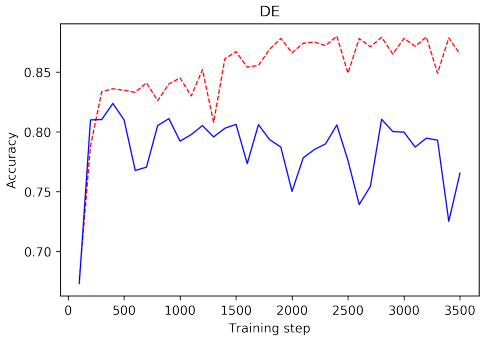
where K is the number of classes for the task, $p(Y|x)$ (dim: $K \times 1$) is the task-specific prediction, $p(E = 1|x)$ (dim: scalar) is the probability that the input is in English, $\bar{h}_\theta(x)$ (dim: 768×1) is the mean-pooled BERT output embedding for the input word-pieces x, θ is the BERT parameters, W_T, b_T, w_D, b_D (dim: $K \times 768$, $K \times 1$, 768×1, scalar) are the output projections for the task-specific loss and discriminator respectively, y^T (dim: $K \times 1$) is the one-hot vector representation for the task label and y^A (dim: scalar) is the binary label for the adversarial task (i.e. 1 or 0 for English or non-English).

In the case of NER, the task-specific loss has an additional summation over the length of the sequence:

$$L_T(y^T; x) = \sum_{i=1}^{K} \sum_{t=1}^{L} -y_{it}^T \log p(Y_t = i|x)$$

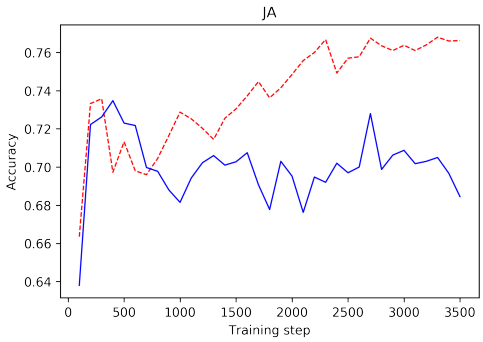
$$p(Y_t|x) = \text{Softmax}(W_T h_\theta(x)_t + b_T)$$

where $p(Y_t|x)$ (dim: $K \times 1$) is the prediction for the t^{th} word, L is the number of words in the sentence, y^T (dim: $K \times L$) is the matrix of one-hot entity labels, and $h_\theta(x)_t$ (dim: 768×1) refers to the BERT embedding of the t^{th} word.



The generator and discriminator losses remain the same for NER, and we continue to use the mean-pooled BERT embedding during adversarial training.

We then take the gradients with respect to the 3 losses and the relevant parameter subsets. The parameter subsets are $\theta_D = \{w_D, b_D\}$, $\theta_T = \{\theta, W_T, b_T\}$, and $\theta_G = \{\theta\}$. We apply the gradient updates sequentially at a 1:1:1 ratio.



During BERT finetuning, the learning rates for the task loss, generator loss and discriminator loss were kept constant; we do not apply a learning rate decay.

All hyperparameters were tuned on the English dev sets only, and we use the Adam optimizer in all experiments. We report results based on the average of 4 training runs.

3.2 MLDoc Classification Results

(a) German test accuracy vs steps taken

(b) Japanese test accuracy vs steps taken

Figure 2: German and Japanese MLDoc test accuracy versus the number of training steps, with and without adversarial training. The solid line shows the performance of the non-adversarial BERT baseline. The dashed line shows the performance with adversarial training.

We finetuned BERT on the English portion of the MLDoc corpus (Schwenk and Li, 2018). The MLDoc task is a 4-class classification problem, where the data is a class-balanced subset of the Reuters News RCV1 and RCV2 datasets. We used the `english.train.1000` dataset for the classification loss, which contains 1000 labeled documents. For language-adversarial training, we used the text portion of `german.train.10000`, `french.train.10000`, etc. without the labels.

Algorithm 1 Pseudocode for adversarial training on the multilingual text classification task. The batch size is set at 1 for clarity. The parameter subsets are $\theta_D = \{w_D, b_D\}$, $\theta_T = \{\theta, W_T, b_T\}$, and $\theta_G = \{\theta\}$.

Input: pre-trained BERT model h_θ, data iterators for English and the non-English language L, learning rates η_D, η_G, η_T for each loss function, initializations for discriminator output projection w_D, b_D, task-specific output projection W_T, b_T, and BERT parameters θ

Table 1: Classification accuracy on the MLDoc test sets. We present results for BERT finetuned on labeled English data and BERT finetuned on labeled English data with language-adversarial training. Our results are averaged across 4 training runs, and hyperparameters are tuned on English dev data.

We used a learning rate of 2×10^{-6} for the task loss, 2×10^{-8} for the generator loss and 5×10^{-5} for the discriminator loss.

In Table 1, we report the classification accuracy for all of the languages in MLDoc. Generally, adversarial training improves the accuracy across all languages, and the improvement is sometimes dramatic versus the BERT non-adversarial baseline.

In Figure 2, we plot the zero-resource German and Japanese test set accuracy as a function of the number of steps taken, with and without adversarial training. The plot shows that the variation in the test accuracy is reduced with adversarial training, which suggests that the cross-lingual performance is more consistent when adversarial training is applied. (We note that the batch size and learning rates are the same for all the languages in MLDoc, so the variation seen in Figure 2 are not affected by those factors.)

3.3 CoNLL NER Results

We finetuned BERT on the English portion of the CoNLL 2002/2003 NER corpus (Sang and De Meulder, 2003). We followed the text preprocessing in Devlin et al. (2019).

We used a learning rate of 6×10^{-6} for the task loss, 6×10^{-8} for the generator loss and 5×10^{-4} for the discriminator loss.

In Table 2, we report the F1 scores for all of the CoNLL NER languages. When combined with adversarial learning, the BERT cross-lingual F1 scores increased for German over the

non-adversarial baseline, and the scores remained largely the same for Spanish and Dutch. Regardless, the BERT zero-resource performance far exceeds the results published in previous work.

Mayhew et al. (2017) and Ni et al. (2017) do use some cross-lingual resources (like bilingual dictionaries) in their experiments, but it appears that BERT with multilingual pretraining performs better, even though it does not have access to cross-lingual information.

3.4 Alignment of Embeddings for Parallel Documents

	Ru	0.72	**0.89**
	Zh	0.69	**0.91**

Table 3: Median cosine similarity between the mean-pooled BERT embeddings of MLDoc English documents and their translations, with and without language-adversarial training. The median cosine similarity increased with adversarial training for every language pair, which suggests that the adversarial loss encourages BERT to learn language-independent representations.

If language-adversarial training encourages language-independent features, then the English documents and their translations should be close in the embedding space. To examine this hypothesis, we take the English documents from the MLDoc training corpus and translate them into German, Spanish, French, etc. using Amazon Translate.

We construct the embeddings for each document using BERT models finetuned on MLDoc. We mean-pool each document embedding to create a single vector per document. We then calculate the cosine similarity between the embeddings for the English document and its translation. In Table 3, we observe that the median cosine similarity increases dramatically with adversarial training, which suggests that the embeddings became more language-independent.

4 Discussion

For many of the languages examined, we were able to improve on BERT's zero-resource cross-lingual performance on the MLDoc classification and CoNLL NER tasks. Language-adversarial training was generally effective, though the size of the effect appears to depend on the task. We observed that adversarial training moves the embeddings of English text and their non-English translations closer together, which may explain why it improves cross-lingual performance.

Future directions include adding the language-adversarial task during BERT pre-training on the multilingual Wikipedia corpus, which may further improve zero-resource performance, and finding better stopping criteria for zero-resource cross-lingual tasks besides using the English dev set.

Acknowledgments

We would like to thank Jiateng Xie, Julian Salazar and Faisal Ladhak for the helpful comments and discussions.

Abstract

In the Transformer network architecture, positional embeddings are used to encode order dependencies into the input representation. However, this input representation only involves static order dependencies based on discrete numerical information, that is, are independent of word content. To address this issue, this work proposes a recurrent positional embedding approach based on word vector. In this approach, these recurrent positional embeddings are learned by a recurrent neural network, encoding word content-based order dependencies into the input representation. They are then integrated into the existing multi-head self-attention model as independent heads or part of each head. The experimental results revealed that the proposed approach improved translation performance over that of the state-of-the-art Transformer baseline in WMT'14 English-to-German and NIST Chinese-to-English translation tasks.

1 Introduction

Transformer translation systems (Vaswani et al., 2017), without recurrent and convolutional neural networks, rely on a positional embedding (**PE**) approach to encode order information into the input representation. PE is typically learned based on the position index of each word and is added to corresponding word embedding. This allows the Transformer to encode order dependencies between words in addition to the words themselves. Finally, the Transformer uses these combined vectors as the input to self-attention networks (**SANs**), achieving state-of-the-art translation performance with several language pairs (Vaswani et al., 2017; Dou et al., 2018; Zhang et al., 2018a; Marie et al., 2018, 2019).

In spite of their success, the input representation only involves static order dependencies based on discrete numerical information. That is, any word in the entire vocabulary has the same PE on the same position index. As a result, the dependencies encoded by the original PEs are independent of word content, which may further hinder the improvement of translation capacity. Recently, Chen et al. (2018) and Hao et al. (2019) introduced the additional source representation learned by an RNN-based encoder into Transformer to alleviate this issue, and reported improvements on the WMT'14 English-to-German translation task.

Inspired by their works (Chen et al., 2018; Hao et al., 2019), we propose an simple and efficient recurrent positional embedding approach to capture order dependencies based on word content in a sentence, thus learning a more effective sentence representation for the Transformer. In addition, we designed two simple multi-head self-attentions to introduce these learned RPEs and original input representation into the existing Transformer model for enhancing the sentence representation of Transformer. Experimental results on WMT'14 English-to-German and NIST Chinese-to-English translation tasks show that our models significantly improved translation performance over a strong Transformer baseline.

2 Background

2.1 Input Representation

In the Transformer network architecture (Vaswani et al., 2017), given a sentence of length J, the positional embedding of each word is firstly computed based on its position:

$$\begin{aligned} \mathbf{pe}_{(j,2i)} &= \sin(j/10000^{2i/d_{model}}), \\ \mathbf{pe}_{(j,2i+1)} &= \cos(j/10000^{2i/d_{model}}), \end{aligned} \quad (1)$$

* Corresponding author

where j is the word's numerical position index in the sentence and i is the dimension of position index. The word embedding $\mathbf{x}_j$ is then added with $\mathbf{pe}_j$ to get a combined embedding $\mathbf{v}_j$:

$$\mathbf{v}_j = \mathbf{x}_j + \mathbf{pe}_j. \quad (2)$$

As a result, there is a sequence of vectors $\{\mathbf{v}_1, \cdots, \mathbf{v}_J\}$ as the input to the encoder or decoder of the Transformer to learn the source or target sentence representations.

2.2 Self-Attention Mechanism

Following the input layer, the self-attention layer is used to learn the sentence representation for the Transformer (Vaswani et al., 2017). These combined vectors $\{\mathbf{v}_1, \cdots, \mathbf{v}_J\}$ are then packed into a query matrix $\boldsymbol{Q}$, their keys and values matrices $\boldsymbol{K}$ and $\boldsymbol{V}$. The output of the self-attention layer can be computed by Eq.(3):

$$\text{Att}(\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}) = \text{softmax}(\frac{\boldsymbol{Q}\boldsymbol{K}^T}{\sqrt{d_{model}}})\boldsymbol{V}. \quad (3)$$

Moreover, self-attention can be further refined as multi-head self-attention to jointly attend to the information from different representation subspaces at different positions. Specifically, $\boldsymbol{Q}$, $\boldsymbol{K}$, and $\boldsymbol{V}$ are linearly projected H times with different, learned linear projections to d_k and d_v dimensions, respectively. On each of these projected versions of queries, keys, and values, the attention function is performed in parallel, yielding d_v-dimensional output values. Take a single head as an example, the output of the h-th head $\boldsymbol{O}_h$ is computed by Eq.(4):

$$\boldsymbol{O}_h = \text{Att}(\boldsymbol{Q}\boldsymbol{W}_h^Q, \boldsymbol{K}\boldsymbol{W}_h^K, \boldsymbol{V}\boldsymbol{W}_h^V), \quad (4)$$

where the parameter matrices are $\boldsymbol{W}_h^Q \in \mathbb{R}^{d_{model} \times d_k}$, $\boldsymbol{W}_h^K \in \mathbb{R}^{d_{model} \times d_k}$, and $\boldsymbol{W}_h^V \in \mathbb{R}^{d_{model} \times d_v}$. For example, if there are H=8 heads and d_{model} is 512, d_k=d_v=512/8=64. Finally, the outputs of H heads are concatenated to serve as the sentence representation $\boldsymbol{S}$:

$$\boldsymbol{S} = \text{Concat}(\boldsymbol{O}_1, \cdots, \boldsymbol{O}_{H-1}, \boldsymbol{O}_H)\boldsymbol{W}^O, \quad (5)$$

where $\boldsymbol{W}^O \in \mathbb{R}^{Hd_v \times d_{model}}$ is a parameter matrix.

3 Recurrent Positional Embedding

We propose a recurrent positional embedding approach based on part of word embedding instead of numerical indices of words to capture order dependencies between words in a sentence. Specifically, the embedding of each word $\mathbf{x}_j$ is divided into two parts $\mathbf{x}_j^p$ and $\mathbf{x}_j^r$, and their dimensions are d_p and d_r (d_{model}=d_p+d_r), respectively. As a result, the sequence of word vectors $\{\mathbf{x}_1, \cdots, \mathbf{x}_J\}$ are spited into $\{\mathbf{x}_1^p, \cdots, \mathbf{x}_J^p\}$ and $\{\mathbf{x}_1^r, \cdots, \mathbf{x}_J^r\}$. An RNN with an non-linear projection layer is then designed to learn its recurrent state $\mathbf{r}_j$ for each word over $\{\mathbf{x}_1^r, \cdots, \mathbf{x}_J^r\}$:

$$\mathbf{r}_j = \text{Tanh}(f_{\text{RNN}}(\mathbf{x}_j^r, \mathbf{r}_{j-1})\mathbf{W}^r + \mathbf{b}^r), \quad (6)$$

where $\mathbf{W}^r \in \mathbb{R}^{d_r \times d_r}$ is a parameter matrix and $\mathbf{b}^r \in \mathbb{R}^{d_r}$ is a bias item.[1] Note that the $\mathbf{x}_j^r$ is derived from part of the word embedding $\mathbf{x}_j$. Finally, there is a sequence $\boldsymbol{R}$ =$\{\mathbf{r}_1, \cdots, \mathbf{r}_J\}$, called as recurrent positional embeddings (**RPEs**). In this work, a bidirectional RNN and a forward RNN (Bahdanau et al., 2015) are used to learn source RPEs and target RPEs, respectively. Noth that the RNN is also replaced by other neural networks for learning order dependency information, such as GRU (Cho et al., 2014), and SRU (Li et al., 2018a).

In addition, other sub-sequence $\{\mathbf{x}_1^p, \cdots, \mathbf{x}_J^p\}$ is used to gain the reduced dimension input representation $\boldsymbol{P}$=$\{\mathbf{p}_1, \cdots, \mathbf{p}_J\}$ according to the Section 2.1. Both of $\boldsymbol{R}$ and $\boldsymbol{P}$ will be together as the input to the encoder (or decoder) to learn a more effective source (or target) representation for the Transformer.

4 Neural Machine Translation with RPE

To make use of these learned RPEs, we propose two simple methods: RPE head (**RPEHead**) self-attention and mixed positional representation head (**MPRHead**) self-attention. Both of RPEHead and MPRHead can utilize RPEs to learn sentence representation for the Transformer.

4.1 RPEHead Self-Attention

For the RPEHead self-Attention, these learned RPEs are integrated into multi-head self-attention (Fig 1(a)) as several independent heads to learn the sentence representation, as shown in Fig 1(b).

First, we concatenate $\boldsymbol{P}$=$\{\mathbf{p}_1, \cdots, \mathbf{p}_J\}$ and $\boldsymbol{R}$ =$\{\mathbf{r}_1, \cdots, \mathbf{r}_J\}$ as a new combined input representation $\boldsymbol{\mathcal{T}}$. To perform the attention function in Eq.(3) over the combined input representation $\boldsymbol{\mathcal{T}}$, d_r and d_p are set to t*d_{model}/H

[1] The $\mathbf{r}_0$ is set as a zero vector.

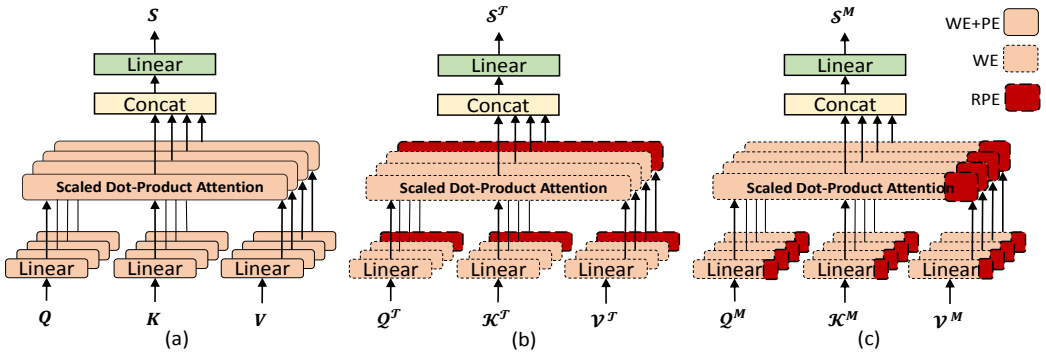

Figure 1: (a) Multi-Head Self-Attention; (b) RPEHead Self-Attention; (c) MPRHead Self-Attention.

and d_{model}-d_r in the process of learning RPEs, respectively. This guarantees that there are two types of heads: one type of head only contains RPE and other type of head only contains the original reduced dimension input representation. Second, the $\mathcal{T}$ is mapped to a new query matrix $\mathcal{Q}^{\mathcal{T}}$, and their keys and values matrices $\mathcal{K}^{\mathcal{T}}$ and $\mathcal{V}^{\mathcal{T}}$. According to Eq.(4), the output of each head is computed by Eq.(7):

$$\mathcal{O}_h^{\mathcal{T}} = \text{Att}(\mathcal{Q}^{\mathcal{T}}\boldsymbol{W}_h^{\mathcal{Q}}, \mathcal{K}^{\mathcal{T}}\boldsymbol{W}_h^{\mathcal{K}}, \mathcal{V}^{\mathcal{T}}\boldsymbol{W}_h^{\mathcal{V}}). \quad (7)$$

Therefore, the final sentence representation $\mathcal{S}^{\mathcal{T}}$ is formally represented as:

$$\mathcal{S}^{\mathcal{T}} = \text{Concat}(\mathcal{O}_1^{\mathcal{T}}, \cdots, \mathcal{O}_{H-1}^{\mathcal{T}}, \mathcal{O}_H^{\mathcal{T}})\boldsymbol{\mathcal{W}}^O. \quad (8)$$

4.2 MPRHead Self-Attention

Compared with the RPEHead model, the MPRHead model applies the multi-head mechanism to the RPEs. In other words, RPEs are encoded into the sentence representation from different vector sub-spaces, as shown in Fig 1(c).

To this end, each vector of $\boldsymbol{P}$ is divided into the H heads $\{\mathbf{p}_j^1, \cdots, \mathbf{p}_j^H\}$. Similarly, each vector of $\boldsymbol{R}$ is divided into the H heads $\{\mathbf{r}_j^1, \cdots, \mathbf{r}_j^H\}$. The corresponding heads for $\mathbf{p}_j$ and $\mathbf{r}_j$ are then concatenated as a combined sequence $\mathbf{pr}_j$, in turn:

$$\mathbf{pr}_j = \{\mathbf{p}_j^1 : \mathbf{r}_j^1, \cdots, \mathbf{p}_j^H : \mathbf{r}_j^H\}, \quad (9)$$

where ":" is the concatenation operation. All heads in $\mathbf{pr}_j$ are further concatenated as a mixed embedding $\mathbf{m}_j \in \mathbb{R}^{d_{model}}$ in turn. As a result, there is a new sequence of mixed embeddings:

$$\boldsymbol{M} = \{\mathbf{m}_1, \cdots, \mathbf{m}_J\}. \quad (10)$$

The $\boldsymbol{M}$ is mapped to a query matrix $\mathcal{Q}^{\boldsymbol{M}}$, and their keys and values matrices $\mathcal{K}^{\boldsymbol{M}}$ and $\mathcal{V}^{\boldsymbol{M}}$. According to Eq.(4) and Eq.(5), the final sentence representation $\mathcal{S}^{\boldsymbol{M}}$ is represented as:

$$\mathcal{O}_h^{\boldsymbol{M}} = \text{Att}(\mathcal{Q}^{\boldsymbol{M}}\boldsymbol{W}_h^{\mathcal{Q}}, \mathcal{K}^{\boldsymbol{M}}\boldsymbol{W}_h^{\mathcal{K}}, \mathcal{V}^{\boldsymbol{M}}\boldsymbol{W}_h^{\mathcal{V}}),$$
$$\mathcal{S}^{\boldsymbol{M}} = \text{Concat}(\mathcal{O}_1^{\boldsymbol{M}}, \cdots, \mathcal{O}_{H-1}^{\boldsymbol{M}}, \mathcal{O}_H^{\boldsymbol{M}})\boldsymbol{\mathcal{W}}^O. \quad (11)$$

Note that for both RPEHead and MPRHead models, the RPEs will be jointly learned with the existing Transformer architecture.

5 Experiments

5.1 Experimental Setup

The proposed methods were evaluated on the WMT'14 English to German (EN-DE) and NIST Chinese-to-English (ZH-EN) translation tasks. The ZH-EN training set includes *1.28* million bilingual sentence pairs from the LDC corpora, where the NIST06 and the NIST02/NIST03/NIST04 data sets were used as the development and test sets, respectively. The EN-DE training set includes *4.43* million bilingual sentence pairs of the WMT'14 corpora, where the newstest2013 and newstest2014 data sets were used as the development and test sets, respectively.

The BPE (Sennrich et al., 2016) was adopted and the vocabulary size was set as 32K. The dimension of all input and output layers was set to *512*, and that of the inner feedforward neural network layer was set to *2048*. The total heads of all multi-head modules were set to *8* in both encoder and decoder layers. In each training batch, there was a set of sentence pairs containing approximately *4096*4* source tokens and *4096*4* target tokens. For the other setting not mentioned, we followed the setting in Vaswani et al. (2017).

Baseline systems included a vanilla Transformer (Vaswani et al., 2017), Relative PEs (Shaw et al., 2018), and directional SAN (**DiSAN**) (Shen

et al., 2018). Besides, we reported results of the existing works (Vaswani et al., 2017; Chen et al., 2018; Shaw et al., 2018; Hao et al., 2019; Liu et al., 2019; Chen et al., 2019). We re-implemented the baseline Transformer, Relative PEs, and DiSAN models on the OpenNMT toolkit (Klein et al., 2017). All the models were trained for 200k batches and evaluated on a single V100 GPU. The multi-bleu.perl was used as the evaluation metric to obtain the case-sensitive 4-gram BLEU score of EN-DE and ZH-EN tasks.

5.2 Effect of RPEs

In this work, we extracted d_r dimensions of each word vector to learn recurrent embeddings. To explore the relation between d_r and translation performance, Figure 2 shows the translation performance on the different d_r. For +RPEHead (or +MPRHead), with the increasing in the dimension of d_r, BLEU scores are gradually increasing, but BLEU scores begin to decrease when d_r is more than 320 (or 256). In particular, +RPEHead and +MPRHead achieve the highest BLEU scores at d_r=320 and d_r=256, respectively. This means that the original partial input representation and our RPE can complement each other to improve translation performance.

5.3 Main Results

According to the results of Fig 2, d_r of RPEHead is set to 320 and d_r of MPRHead is set to 256. The main translation results are shown in Table 1.

1) For the proposed methods, both RPEHead (base) and MPRHead (base) outperformed Transformer (base), especially are better than +RPE and +DiSAN. This indicates that the learned RPEs are beneficial for the Transformer system.

2) Moreover, +MPRHead (base) performed better than RPEHead/RPE (base). The reason may be that adding RPEs into variant heads can encode order dependencies based word vectors from variant vector sub-spaces, which is one of the advantages of the multi-head mechanism. In particular, +MPRHead (base/big) is slightly better than Transformer (base/big)+BiARN. This denotes that the RPEs can more effective improve the performance of Transformer.

3) MPRHead (big) was superior to Transformer (big) significantly. MPRHead (base) achieved a comparable performance compared to Transformer (big) which contains approximately three times parameters, indicating that the proposed RPE is efficient.

In addition, Table 2 shows that the proposed models also gave similar improvements over the baseline system and the compared methods on the NIST ZH-EN task. These results indicate that our

System	Architecture	NIST02	NIST03	NIST04	#Param

	+Relative PEs (Shaw et al., 2018)	46.91	46.47	45.96	77.01M
	+RPEHead	47.06	46.21	46.32	78.04M
	+MPRHead	47.69*	47.27*	47.31*	78.04M
	Transformer (big)	47.88	47.58	47.37	243.7M
	+MPRHead	48.73*	48.61*	48.21*	245.5M

Table 2: Results for ZH-EN translation Task. The mark "*" after scores indicates that the model was significantly better than the baseline Transformer (base or big) at the significance level p <0.01 (Collins et al., 2005).

approach is a universal method for improving the translation of other language pairs.

5.4 Ablation Experiments

To further explore the effect of position information, PEs and RPEs were applied on the encoder (**Enc**) and decoder (**Dec**) side, respectively. Table 3 shows the results of ablation experiments on the EN-DE newstest2014 test set:

	newstest2014	#Speed
Transformer (base)	27.25	11.7K
- PE of Dec	26.73	11.7K
- PE of Enc	10.71	11.7K
RPEHead (base)	28.11	10.5K
- RPE&PE of Dec	27.54	11.2K
- RPE&PE of Enc	11.16	10.7K
MPRHead (base)	28.35	9.9K
- RPE&PE of Dec	27.74	11.2K
- RPE/PE of Enc	10.89	10.7K
- RPE&PE of Enc&Dec	10.43	11.7K

Table 3: Ablation experiments of position information. "#Speed" denotes the training speed (tokens/second).

1) For Enc/Dec/Enc&Dec, the proposed RPEHead/MPRHead outperformed the Transformer in corresponding ablation settings, indicating that our methods worked well on both the encoder and decoder.

2) For PE/RPEs, performance became slightly lower when PE was removed from the decoder. However, when PE was removed from the encoder, the translation performance drastically decreased. We think that the source sentence representation is more sensitive to position information than the target sentence representation. It is possible that each hidden state in the decoder takes the previous hidden state into consideration, which would be somewhat similar to the proposed RPEs. In contrast, the encoder would not be expected to contain this mechanism. Therefore, the position information would be more important in the encoder than the decoder.

3) The training speeds of the proposed RPEHead (base) and MPRHead (base) were just slightly slower than those of the vanilla Transformer (base), because we nearly did not introduce additional (less than 2%) parameters.

6 Conclusion and Future Work

In this paper, we presented a recurrent embedding to capture the order dependencies in a sentence. Empirical results show that this method can improve the performance of NMT efficiently. In future work, we plan to extend this method to unsupervised NMT (Sun et al., 2019) and other natural language processing tasks, such as dependency parsing (Li et al., 2018b) and reading comprehension (Zhang et al., 2018b).

Abstract

We propose a neural machine translation (NMT) approach that, instead of pursuing adequacy and fluency ("human-oriented" quality criteria), aims to generate translations that are best suited as input to a natural language processing component designed for a specific downstream task (a "machine-oriented" criterion). Towards this objective, we present a reinforcement learning technique based on a new candidate sampling strategy, which exploits the results obtained on the downstream task as weak feedback. Experiments in sentiment classification of Twitter data in German and Italian show that feeding an English classifier with machine-oriented translations significantly improves its performance. Classification results outperform those obtained with translations produced by general-purpose NMT models as well as by an approach based on reinforcement learning. Moreover, our results on both languages approximate the classification accuracy computed on gold standard English tweets.

1 Introduction

Traditionally, machine translation (MT) pursues a "human-oriented" objective: generating fluent and adequate output to be consumed by speakers of the target language. But what if the intended use of MT is to feed a natural language processing (NLP) component instead of a human? This, for instance, happens when MT is used as a pre-processing step to perform a downstream NLP task in a language for which dedicated tools are not available due to the scarcity of task-specific training data. The rapid growth of cloud-based software-as-a-service offerings provides a typical example of this situation: a variety of affordable high-performance NLP tools can be easily accessed via APIs but often they are available only for a few languages. Translating into one of these high-resource languages gives the possibility to address the downstream task by: *i)* using existing tools for that language to process the translated text, and *ii)* projecting their output back to the original language.

However, using MT "as is" might not be optimal for different reasons. First, despite the qualitative leap brought by neural networks, MT is still not perfect (Koehn and Knowles, 2017). Second, previous literature shows that MT can alter some of the properties of the source text (Mirkin et al., 2015; Rabinovich et al., 2017; Vanmassenhove et al., 2018). Finally, even in the case of a perfect MT able to preserve all the traits of the source sentence, models are still trained on parallel data, which are created by humans and thus reflect quality criteria relevant for humans.

In this work, we posit that these criteria might not be the optimal ones for a machine (i.e. a downstream NLP tool fed with MT output). In this scenario, MT should pursue the objective of preserving and emphasizing those properties of the source text that are crucial for the downstream task at hand, even at the expense of human-quality standards. To this end, inspired by previous – human-oriented – MT approaches based on *Reinforcement Learning* (Ranzato et al., 2016; Shen et al., 2016) and *Bandit Learning* (Kreutzer et al., 2017; Nguyen et al., 2017), we explore a NMT optimization strategy that exploits the weak feedback from the downstream task to influence system's behaviour towards the generation of optimal "machine-oriented" output.

As a proof of concept, we test our approach on a sentiment classification task, in which Twitter data in German and Italian are to be classified according to their polarity by means of an English classifier. In this setting, a shortcoming of previous translation-based approaches (Denecke, 2008; Balahur et al., 2014) is that, similar to other traits,

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1368–1374,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

sentiment is often not preserved by MT (Salameh et al., 2015; Mohammad et al., 2016; Lohar et al., 2017). Although it represents a viable solution to leverage sentiment analysis to a wide number of languages (Araujo et al., 2016), the translation-based approach should hence be supported by advanced technology able to preserve the sentiment traits of the input. Along this direction, our experiments show that machine-oriented MT optimization makes the classifier's task easier and eventually results in significant classification improvements. Our results outperform those obtained with translations produced by general-purpose NMT models as well as by an NMT approach based on reinforcement learning (Ranzato et al., 2016). Most noticeably, on both languages we are able to approximate the classification accuracy computed on gold standard English tweets.

2 Background and Methodology

During training, NMT systems based on the encoder-decoder framework (Sutskever et al., 2014; Bahdanau et al., 2015) are optimized with maximum likelihood estimation (MLE), which aims to maximize the log-likelihood of the training data. In doing so, they indirectly model the human-oriented quality criteria (adequacy and fluency) expressed in the training corpus. A different strand of research (Ranzato et al., 2016; Shen et al., 2016; Kreutzer et al., 2018) focuses on optimizing the model parameters by maximizing an objective function that leverages either an evaluation metric like BLEU (Papineni et al., 2002) or an external human feedback. These methods are based on *Reinforcement Learning* (RL), in which the MT system parameters θ define a *policy* that chooses an *action*, i.e. generating the next word in a translation candidate $\hat{\mathbf{y}}$, and gets a *reward* $\Delta(\hat{\mathbf{y}})$ according to that action. Given S training sentences $\{\mathbf{x}^{(s)}\}_{s=1}^{S}$, the RL training goal is to maximize the expected reward:

$$\begin{aligned}\mathcal{L}_{RL} &= \sum_{s=1}^{S} E_{\hat{\mathbf{y}}\sim p_\theta(.|\mathbf{x}^{(s)})}\Delta(\hat{\mathbf{y}}) \\ &= \sum_{s=1}^{S}\sum_{\hat{\mathbf{y}}\in\mathbf{Y}} p_\theta(\hat{\mathbf{y}}|\mathbf{x}^{(s)})\Delta(\hat{\mathbf{y}})\end{aligned} \quad (1)$$

where $\mathbf{Y}$ is the set of all translation candidates. Since the size of this set is exponentially large, it is impossible to exhaustively compute the expected reward, which is thus estimated by sampling one or few candidates from this set. In the MT adaptation (Ranzato et al., 2016) of REINFORCE (Williams, 1992), the closest approach to the one we present, only one candidate is sampled.

$$\hat{\mathcal{L}}_{RL} = \sum_{s=1}^{S} p_\theta(\hat{\mathbf{y}}|\mathbf{x}^{(s)})\Delta(\hat{\mathbf{y}}), \hat{\mathbf{y}} \sim p_\theta(.|\mathbf{x}^{(s)}) \quad (2)$$

We now focus on how the key elements of RL methods have been adapted to properly work in the proposed "MT for machines" setting. Our novel *Machine-Oriented* approach is described in Algorithm 1.

Algorithm 1 *Machine-Oriented* RL

1: **Input:** $\mathbf{x}^{(s)}$ s-th source sentence in training data, $\mathbf{l}^{(s)}$ the ground-truth label, K number of sampled candidates
2: **Output:** sampled candidate $\hat{\mathbf{y}}^{(s)}$
3: $\mathbf{C} = \emptyset$ ▷ Candidates set
4: **for** k = 1,...,K **do**
5: $\quad \mathbf{c} \sim p_\theta(.|\mathbf{x}^{(s)})$
6: $\quad \mathbf{f} = P_{class}(\mathbf{l}^{(s)}|\mathbf{c})$ ▷ Feedback from the classifier
7: $\quad \mathbf{C} = \mathbf{C} \cup (\mathbf{c}, \mathbf{f})$
8: $\hat{\mathbf{y}}^{(s)} = \max_{\mathbf{f}}(\mathbf{C})$ ▷ Best candidate w.r.t. feedback

Reward Computation. In current RL approaches to MT, rewards are computed either on a development set containing reference translations (Ranzato et al., 2016; Bahdanau et al., 2017) or by means of a weak feedback (e.g. a 1-to-5 score) when ground-truth translations are not accessible (Kreutzer et al., 2017; Nguyen et al., 2017). In both cases, the reward reflects a human-oriented notion of MT quality. Instead, in our machine-oriented scenario, the reward reflects the performance on the downstream task, independently from translation quality.

In the sentiment classification use case, given a source sentence ($\mathbf{x}^{(s)}$) and its sentiment ground-truth label ($\mathbf{l}^{(s)}$), the reward is defined as the probability assigned by the classifier to the ground-truth class for each translated sentence $\mathbf{c}$ ($P_{class}(\mathbf{l}^{(s)}|\mathbf{c})$ in Algorithm 1, line 6). By maximizing this reward, the MT system learns to produce a translation that has higher chances to be correctly labeled by the classifier. This comes at the risk of obtaining less fluent and adequate output. However, as will be shown in Section 4, this

type of reward induces highly polarized translations that are best suited for our downstream task.

Sampling Approach. A possible sampling strategy is to exploit beam search (Sutskever et al., 2014) to find, at each decoding step, the candidate with the highest probability. Another solution is to use multinomial sampling (Ranzato et al., 2016) which, at each decoding step, samples tokens over the model's output distribution. In (Wu et al., 2018), the higher results achieved by multinomial sampling are ascribed to its capability to better explore the probability space by generating more diverse candidates. This finding is particularly relevant in the proposed "MT for machines" scenario, in which the emphasis on final performance in the downstream task admits radical (application-oriented) changes in the behaviour of the MT model, even at the expense of human quality standards.

To increase the possibility of such changes, we propose a new sampling strategy. Instead of generating only one candidate *token* via multinomial sampling, K candidate *sentences* are first randomly sampled (lines 4-5 in Algorithm 1). Then, the reward is collected for each of them (line 7) and the candidate with the highest reward is chosen (line 8). On one side, randomly exploring more candidates increases the probability to sample a "useful" one, possibly by diverting from the initial model behaviour. On the other side, selecting the candidate with the highest reward will push the system towards translations emphasizing input traits that are relevant for the downstream task at hand. In the sentiment classification use case, these are expected to be sentiment-bearing terms that help the classifier to predict the correct class.

3 Experiments

Our evaluation is done by feeding an English sentiment classifier with the translations of German and Italian tweets generated by:

- A general-purpose NMT system (*Generic*);
- The same system conditioned with REINFORCE (*Reinforce*);
- The same system conditioned with our *M*achine-*O*riented method (*MO-Reinforce*).

As other terms of comparison, we calculate the results of:

- The English classifier on the gold standard English tweets (*English*);
- German and Italian classifiers on the original, untranslated tweets (*Original*).

Task-specific data. We experiment with a dataset based on Semeval 2013 data (Nakov et al., 2013), which contains polarity-labeled parallel German/Italian–English corpora (Balahur et al., 2014). For each language pair, the development and test sets respectively comprise 583 (197 negative and 386 positive) and 2,173 tweets (601 negative and 1,572 positive). To cope with the skewed data distribution, the negative tweets in the development sets are over-sampled, leading to new balanced sets of 772 tweets.

NMT Systems. Our *Generic* models are based on Transformer (Vaswani et al., 2017), with parameters similar to those used in the original paper. Training data amount to 6.1M (De-En) and 4.56M (It-En) parallel sentences from freely-available corpora. The statistics of the parallel corpora are reported in Table 1. For each language pair, all data are merged and tokenized. Then, byte pair encoding (Sennrich et al., 2016) is applied to obtain 32K sub-word units.

	De-En	It-En
Europarl	2M	2M
JRC	0.7M	0.8M
Wikipedia	2.5M	1M
ECB	0.1M	0.2M
TED	0.1M	0.2M
KDE	0.3M	0.3M
News11	0.2M	0.04M
News	0.2M	0.02M
Total	6.1M	4.56M

Table 1: Statistics of the parallel corpora used for training the generic NMT systems

To emulate both scarce and sufficient training data conditions, MT systems are trained using 5% and 100% of the available parallel data. In the most favorable condition (i.e. with 100% of the data), the BLEU score of the two models is 30.48 for De-En and 28.68 for It-En.

To condition the generic models and obtain the *Reinforce* and *MO-Reinforce* systems, we use the polarity-labeled German/Italian tweets in our de-

velopment sets, with reward as defined in Section 2. The SGD optimizer is used, with learning rate set to 0.01. In *MO-Reinforce*, the number of sampled candidates is set to $K = 5$.

Classifiers. To simulate an English cloud-based classifier-as-a-service, the pre-trained BERT (Base-uncased) model (Devlin et al., 2019) is fine-tuned with a balanced set of 1.6M positive and negative English tweets (Go et al., 2009). The German and Italian classifiers are also created by fine-tuning BERT on the polarity-labeled tweets composing the source side of our development set (772 tweets).[1] Before being passed to the classifiers, URLs and user mentions are removed from the tweets, which are then tokenized and lower-cased.

4 Results and Discussion

Table 2 shows our classification results, presenting the F1 scores obtained by the different MT-based approaches in the two training conditions. When NMT is trained on 100% of the parallel data, for both languages *Reinforce* produces translations that lead to classification improvements over those produced by the *Generic* model (+0.5 De-En, +0.8 It-En). Although the scores are considerably better than those obtained by the *Original* classifiers (+9.3 De-En, +7.2 It-En), the gap with respect to the *English* classifier is still quite large (-1.4 De-En and -2.3 It-En).

The observed F1 gains over the *Generic* model reflect an improvement in translation quality. Indeed, the BLEU score (not reported in the table) increases for both languages (+0.83 De-En, +1.37 It-En). As suggested by Kreutzer et al. (2018), this can be motivated by the fact that, rather than actually leveraging the feedback, RL mainly benefits from the optimization on in-domain source sentences in the development set. This is confirmed by the fact that *MO-Reinforce*, which uses a different sampling strategy, is able to outperform *Reinforce* on both languages (+0.7 F1 on De-En, +1.7 on It-En), approaching the *English* upper bound.

Unsurprisingly, the BLEU score obtained by *MO-Reinforce* is close to zero. Indeed, the generated sentences are highly polarized and fluent, but not adequate with respect to the source sentence. For example, the positive instances in the test set are translated into "*It's good!*", "*I'm happy*" or "*I'm grateful*", and the negative ones into "*it is not good!*" or "*I'm sorry*". This polarization shows that *MO-Reinforce* maximizes the exploitation of the received sentiment feedback thus producing an output that, at the expense of adequacy, can be easily classified by the downstream task.

	De - En		It - En	
	5%	*100%*	*5%*	*100%*
Generic	79.7	83.2	78.2	81.6
Reinforce	80.4	83.7	77.8	82.8
MO-Reinforce	**80.9**	**84.4**	**80.3**	**84.5**
English	85.1			
Original	74.4		75.6	

Table 2: Classification results (F1) obtained with: *i)* automatic English translations by three models (*Generic*, *Reinforce*, *MO-Reinforce*), and *ii)* gold-standard English (*English*) and untranslated German/Italian (*Original*) tweets.

When reducing the MT training data to only 5%, emulating a condition of parallel data scarcity, all the classification results decrease (on average by 3-4 points). However, also in this case the output of *MO-Reinforce* yields the closest scores to the *English* upper bound. This indicates that our method does not require large data quantities to outperform the other approaches.

To validate the hypothesis that *MO-Reinforce* can better leverage the feedback from the downstream task, Figures 1 and 2 show the average rewards for the De-En and the It-En candidates generated by *Reinforce* and *MO-Reinforce* at each epoch of the adaptation process. In line with the findings of Kreutzer et al. (2018), for both languages, *Reinforce* is not able to leverage the feedback and to generate candidates that increase their reward during training. Indeed, its curves in the two figures show either a stable (It-En) or even a slightly downward trend (De-En) that confirms the known limitations of NMT to preserve sentiment traits of the source sentences (see Section 1). In contrast, the *MO-Reinforce* curves show a clear upward trend indicating a higher capability to exploit the feedback and produce, epoch by epoch, increasingly polarized translations that are easier

[1] This strategy is similar to the one proposed in (Eriguchi et al., 2018), where a pre-trained multilingual encoder is used to build a cross-lingual classifier that is then trained on task-specific data. In our case, however, labeled data are available in a small amount.

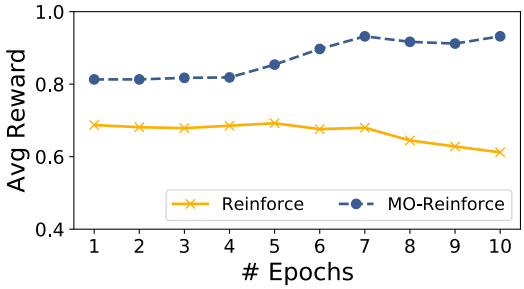

Figure 1: Average rewards for *Reinforce* and *MO-Reinforce* candidates at each training epoch (De-En).

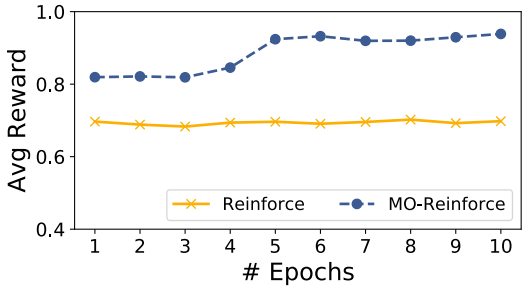

Figure 2: Average rewards for *Reinforce* and *MO-Reinforce* candidates at each training epoch (It-En).

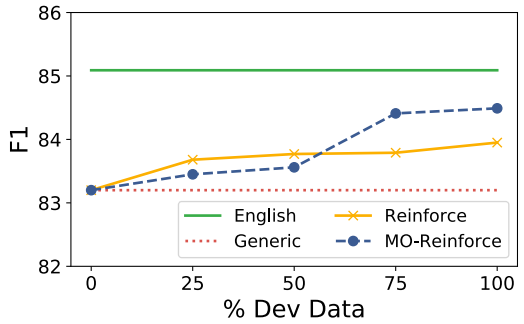

Figure 3: Classification results with increasing amounts of labeled development data (De-En).

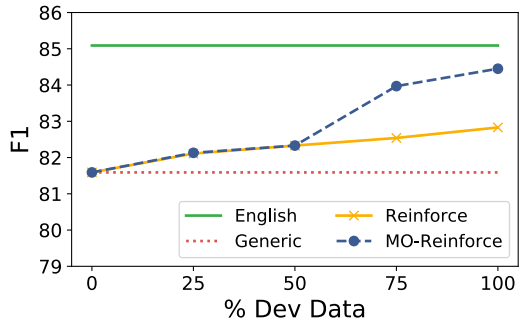

Figure 4: Classification results with increasing amounts of labeled development data (It-En).

to classify.

Another important aspect to investigate is the relation between the size of the development set (i.e. the amount of human-annotated source language tweets needed by the RL methods) and final classification performance. Figures 3 and 4 show the De-En and It-En performance variations of *Reinforce* and *MO-Reinforce* at different sizes of the development set. For comparison purposes, also the *Generic* and *English* results (which are independent from the development set size) are included. In both plots, each point is obtained by averaging the results of three different data shuffles. With limited amounts of data (25% and 50%) *Reinforce* and *MO-Reinforce* have a similar trend. When adding more data, *MO-Reinforce* shows a better use of the labeled development data, with a boost in performance that allows it to approach the *English* upper bound in both language settings. These results suggest that the effort to create labeled data can be minimal, and with 75% of the set (579 points) it is already possible to achieve a better performance than *Reinforce*.

5 Conclusions

We proposed a novel interpretation of the machine translation task, which pursues *machine-oriented* quality criteria (generating translations that are best suited as input to a downstream NLP component) rather than the traditional *human-oriented* ones (maximizing adequacy and fluency). We addressed the problem by adapting reinforcement learning techniques with a new, exploration-oriented sampling strategy that exploits the results obtained on the downstream task as weak feedback. Instead of generating only one candidate totally randomly via multinomial sampling (i.e. random stepwise selection of each word during generation, as in *Reinforce*), our approach selects K full translation candidates, it computes the reward for each of them and finally chooses the one with the highest reward from the downstream task. As shown by our experiments in sentiment classification, this more focused (and application-oriented) selection allows our "MT for machines" approach to: *i)* better explore the hypotheses space, *ii)* make better use of the collected rewards and eventually *iii)* obtain better downstream classification results compared to translation-based solutions exploiting either general-purpose models or previous reinforcement learning strategies. In future work, we will target new application scenarios, covering multi-class classification and regression tasks.

Investigating the Effectiveness of BPE: The Power of Shorter Sequences

Matthias Gallé
NAVER LABS Europe
matthias.galle@naverlabs.com

Abstract

Byte-Pair Encoding (BPE) is an unsupervised sub-word tokenization technique, commonly used in neural machine translation and other NLP tasks. Its effectiveness makes it a *de facto* standard, but the reasons for this are not well understood. We link BPE to the broader family of dictionary-based compression algorithms and compare it with other members of this family. Our experiments across datasets, language pairs, translation models, and vocabulary size show that – given a fixed vocabulary size budget – the fewer tokens an algorithm needs to cover the test set, the better the translation (as measured by BLEU).

1 Introduction

It is common practice in modern NLP to represent text in a continuous space. However, the interface between the discrete world of language and the continuous representation persists and is arguably nowhere so important as in deciding what should be the atomic symbols that will be used as input and/or output. While using words as tokens seems to be the most natural encoding, it has two major drawbacks: first it suffers from the out-of-vocabulary problems at inference time, and secondly the large number of words (which can easily reach the hundred of thousands) creates additional constraints on the memory and time that is required to train and infer with these models. On the other extreme, working at the character level has the advantage of a small and closed set. While current performance of character-level Neural Machine Translation (NMT) is competitive, its computational cost are much higher (up to 8 times (Cherry et al., 2018)). The commonly used intermediate approach is to pre-process the dataset by inferring sub-word tokens, which are then used as the atomic symbols to be translated. The most popular such method is known as **byte-pair encoding** (BPE), which merges iteratively the most frequent pair of symbols. Starting with characters as individual symbols, BPE creates new symbols representing bigrams and eventually higher-level order grams.

Such an approach has the advantage of incorporating some dataset-wide information in the local decision of what should be a token. It is however not linguistically motivated, and intents to create sub-word tokens based on morphological analyzer have failed to consistently improve the performance of the resulting translation (Zhou, 2018; Domingo et al., 2018), or do so only in special cases (morphological rich cases, target side only) (Huck et al., 2017; Pinnis et al., 2017). While this is unsatisfactory, to our knowledge the reasons for the effectivenesses of BPE has not been studied in the literature.

In this paper we hypothesize that the reason lies in the compression capacity of BPE: this is, that for two token vocabularies of the same size, the one that allows to cover better (with fewer number of symbols) a given sentence will achieve a better translation. To test this hypothesis, we link BPE to a large family of compression algorithms that aim to discover a dictionary of tokens and use that dictionary to parse the original dataset with the least amount of tokens. This allows us to take different algorithms from this family and to compare different unsupervised token inference techniques, all guided by the same compression principle. For a fixed number of token types, some of these algorithms need more tokens to cover the full sentence than BPE while others need less. Using different NMT models and experimenting across language pairs, datasets and vocabulary size, we show that the average number of tokens per sentence can be directly linked to the quality of translation.

2 Related Work and Context

2.1 Sub-word tokenization for NMT

Instead of relying on characters or words, unsupervised sub-word tokenization techniques induce a set of tokens that are then used to parse any new sequence. The standard approach is BPE, introduced for NMT in Sennrich et al. (2016) which merges incrementally the most frequent bigrams. Kudo (2018) proposes a different technique which allows the model to sample different tokenizations from the same word, resulting in a more robust translation model. The new tokenization method alone achieves comparable results, and no discussion of the size of the final parse is provided. In our experiments, we used the code of that paper.[1]

Alternative segmentations, using a morphological analyser for instance, have not shown consistent improvement (Zhou, 2018). Domingo et al. (2018) benchmark different segmentation techniques on different languages. While their results indicate that there is no clear winner, the vocabulary sizes of the different approaches are different and therefore harder to compare. Note that – differently from previous work (Cherry et al., 2018; Domingo et al., 2018) – our set-up allows us to compare models with the same vocabulary size. Comparing the compression capacity of models with different vocabulary size is misleading as a larger vocabulary size can obviously lead to smaller sequences. This however ignores the cost of expressing each symbol, which increases with the vocabulary size. Such an analysis could be achieved with an information-theoretical approach which is beyond the scope of this paper.

Indeed, BPE has the attractive characteristic that it allows to control the size of the vocabulary and can adapt to memory constraints. However, it introduces an additional hyper-parameter in the model and can be considered unsatisfactory from a modelling perspective. Recent proposals to avoid this include using several tokenizations at the same time, either hierarchically (Morishita et al., 2018) or through a lattice encoding (Su et al., 2017; Sperber et al., 2017); or dynamically, such as increasing the vocabulary size incrementally while training (Salesky et al., 2018) or reading the input sequence character by character and adding a halting gate which decides when to generate an output word (Kreutzer and Sokolov, 2018).

[1] https://github.com/google/sentencepiece

2.2 Byte-Pair Encoding

BPE is an instance of a the so-called *macro-based* compression algorithms, which seeks redundancies in the text by detecting repeated patterns, and compresses the sequences by replacing an occurrence of such a pattern with pointers to a previous occurrence. They achieve good compression by replacing subwords with (shorter) references, as opposed to statistical-based compression algorithms which are based on information theory and assign codewords to single symbols (but both can of course be combined). Its use for neural machine translation was introduced in (Sennrich et al., 2016), although a similar technique had been used previously for the creation of dictionaries and language models for voice search (Schuster and Nakajima, 2012). For the general framework, Storer and Szymanski (1982) provide a good overview of different possible frameworks of macro schemes. The authors differentiate between *external* and *internal* macro schemes. External macro schemes contain pointers to an external dictionary, while the pointers of internal macro schemes point to positions of the sequence itself.

From the external macro schemes, BPE belongs to the class of compression algorithms called **fixed size dictionary**. In this framework, the dictionary consists in a set of tokens $V = \{\omega_1, \dots \omega_n\}$ which are the atomic symbols. A sequence of ω_i has to be uniquely decodable, for instance by being of fixed length or prefix-free. In general in NMT, prefix-freeness is attained by separating these tokens with a special symbol (whitespace). Given a new sequence s (the words from the test sequences), the goal is then to find $d_1 \dots d_m$, $d_i \in V$, such that their concatenation $d_1 \cdot d_2 \cdot \dots d_m = s$ and m is minimal. This problem was proposed in 1973 by Wagner (1973) together with a dynamic algorithm that solves this problem in an optimal way. This optimal way is called **optimal parsing** by Bell et al. (1990) and "Minimal Space" by Schuegraf and Heaps (1974) where it is solved by a shortest-path algorithm. There also exist faster approximate algorithms: see Katajainen and Raita (1992) and Bell et al. (1990, Chapter 8.1).

This formulation assume that the set of words is given. Finding the set of words whose optimal parsing is minimal is an NP-complete problem: Storer and Szymanski (1982) proves this for variations where the pointers may be recursive (this is, enabling phrases themselves to be

parsed with pointer to other phrases) or the phrases may overlap. BPE is an instance of the recursive, non-overlapping version. This version is equivalent to the so-called Smallest Grammar Problem (Charikar et al., 2005), because the resulting parsing can be formalized as a non-branching, non–auto-recursive context free grammar, also called a straight-line program. This problem can be seen as a specific formulation of the Minimum Description Length principle (Rissanen, 1978) which states that the best model for some data is the one which minimizes cost of describing the data given the model *plus* the cost of describing the model. In a straight-line grammar the description of the data can be seen as the right-hand side of the starting non-terminal, while the description of the model is the combined parsing cost of all other non-terminals. This principle has been applied in a very similar form for unsupervised inference of linguistic structures in (De Marcken, 1996).

Several algorithms that approximate the Smallest Grammar Problem have been given in the literature, including the one that iteratively replaces the most frequent pair. The name BPE comes from Gage (1994) who applied it to data compression, although the same idea had been used before for pattern discovery in natural language (Wolff, 1975) as well as measuring the complexity of genetic sequences (Ángel Jiménez-Montaño, 1984). Larsson and Moffat (2000) propose the REPAIR implementation, whose time complexity is linear with respect to the size of the input sequence. A theoretical analysis of its compression capacity can be found in Navarro and Russo (2008), and recent research focuses on reducing its memory footprint (Gagie et al., 2019).

3 Other compression algorithms

We investigate the impact that different such algorithms have on the final translation, using the same budget on the vocabulary size. Our hypothesis is that smaller parses would result in improved translation, and that therefore algorithms that infer a dictionary of tokens that cover the sequence better should be preferred.

Despite its simplicity, BPE performs very well in standard compression benchmarks (Gage, 1994; Carrascosa et al., 2012). The best performing ones have an unreasonable time-complexity (including one of complexity $\mathcal{O}(n^7)$ (Carrascosa et al., 2011) and an even slower genetic algorithm (Benz and Kötzing, 2013)). Based on these benchmarks, we decided to use the so-called IRRMGP algorithm, which outperforms BPE, as well as other worse performing algorithms. **IRRMGP** works as follows: as BPE it is an iterative repeat replacement (IRR) algorithm, but instead of choosing in each iteration the most frequent bigram, it chooses the substring ω that maximizes $|\omega| \times occ(\omega)$ (where $occ(\omega)$ is the number of occurrences of ω in the training corpus). Once it has reached the desired number of tokens, it re-parses the sequences through an optimal parsing of the original sequence *and* inferred tokens so far (minimal grammar parsing, MGP), removes any un-used token and continues looking for new words. The modules of IRR and MGP are iterated until the dictionary budget is reached. While a worst-case analysis bounds its running time as $\mathcal{O}(n^4)$, in practice its running time increases quadratically with the sequence length (Carrascosa et al., 2012). Those high running times however precludes our analysis to run on very large data-sets.

We also compare against two other compression algorithm. **MAXLEN** (Bentley and McIlroy, 1999) is another iterative repeat replacement algorithm, but selects the longest repeat in each iteration. It can also be implement in linear-time (Nakamura et al., 2009). The second algorithm is the popular **SEQUITUR** (Nevill-Manning and Witten, 1997). It runs on-line, maintaining two invariants while it reads the sequence: (i) bigram uniqueness (no bigram appears more than once) and (ii) rule utility (each non-terminal is used more than once). Assuming a constant time hashing function, SEQUITUR runs in (amortized) linear time with respect to the sequence length, and only requires a linear amount of memory. In our experiments, the original implementation of SEQUITUR[2] runs about 3 times faster than SENTENCEPIECE.

3.1 Core tokens

It is not straightforward to run SEQUITUR to obtain a fixed number of tokens, as it constructs the dictionary online. For this, we run it until the end, and select a posteriori a set of good tokens. For that selection process, we use the parse tree of the final grammar and compute the "core nodes" (Siyari et al., 2016). This corresponds to the set of

[2] https://github.com/craignm/sequitur

tokens which are used the most in the hierarchical parse of the dataset. Siyari et al. (2016) show that the number of times token ω is used is equal to $|\omega| \times freq(\omega)$, where $freq(\omega)$ is the number of times ω appears in the derivation of the unique target sequence. The core is then computed by taking the highest scoring such token, removing it, updating the parse and iterating until reaching the vocabulary size.

4 Experiments

We worked on the lowercased Kyoto Free Translation Task (Neubig, 2011, KFTT) and IWSLT'14 (en↔de), without removing any sentences (see Table 1). For the translation model, we used ConvS2S (Gehring et al., 2017) and Transformer (Vaswani et al., 2017), allowing us to compare models with different field of view: local for ConvS2S, and global for Transformer. For ConvS2S, we used 4 layers and an embedding size of 256, dropout of 0.2, an initial step-size of 0.25. For Transformer, we used 4 attention heads, dropout was set to 0.5 and initial step-size to 0.001 (except for MAXLEN, for which we used 10e-4). These parameters were fixed in initial experiments maximising the performance on BPE. We ran training for 150 epochs, and use the average of the three best models (as measured on the validation set).

To apply sub-word tokenization over unseen sentences, several approaches are possible. First we tried to run an optimal parsing on each word with the given token set but the resulting translations were worse than the baseline BPE model. The reported results here are obtained with a greedy parsing, where the words in the dictionary are first sorted and then applied from the top downwards. Words are sorted first by their length (longer first) and then by their frequency (more frequent first). Using a consistent tokenization – applied equally in training and inference – seems to help the model, while in an optimal parsing setting a slight change in the context could substantially change the parsing. We believe that this brittleness causes the worse performance of the optimal parsing. Note that the standard BPE procedure also applies greedily the dictionary of words, in the order they were generated. Sub-word regularization (Kudo, 2018) could be used to make the training more robust to this tokenization mismatch. Moreover, that approach could be adapted to work with any of the inferred tokenization: while a vanilla optimal parsing does not seem to support a probabilistic approach which could allow a sampling procedure, there might be several optimal parsings of one word (Carrascosa et al. (2011) show both theoretical and empirical evidence that there can be an exponential number of parses with the same size) and generating several of those could make the translation system more robust.

We compare BPE, IRRMGP, MAXLEN, the core on the words inferred by SEQUITUR and an additional baseline RANDOM: given a vocabulary budget of N, we pick up N random *maximal repeats* (Gusfield, 1997) of the multi-sequence set of all tokens. Those are then applied to the training and testing data as before (applying them greedily, first by length – longer first – and then by frequency – more frequent first).

The training data of both languages were concatenated, and we used two different vocabulary sizes: 16k and 32k. Tokenization in all cases was done at the sub-word level, so that no token crossed word boundaries. Inference is done with a beam search of size 5, and for BLEU evaluation we used SacreBleu.[3]

The results in Fig. 1 show that there is indeed a strong correlation between the number of tokens used to cover the test sentences, and the resulting BLEU score. BPE is competitive with the best used compression algorithm, something which can be attributed to its compression capacity which is only slightly worse than that of IRRMGP (sometimes hard to distinguish for IWSLT in Fig. 1 because the numbers are relatively close).

5 Conclusion

In this paper we provide evidence that the effectiveness of BPE can be linked to its compression capacity, that is, the capacity of finding a set of words such that they are able to cover the sequence with as few words as possible. For this, we use other algorithms of the same family which allows us to control the number of tokens, as it is obviously easier to cover the sequence better if we can access more tokens. Our benchmark shows that the size of the final coverage can indeed be strongly linked to the translation quality.

Those conclusions however do not preclude the

use of morphological knowledge. For example, Huck et al. (2017) show that a combined approach can sometimes outperform pure BPE tokenization. Following standard practices in NMT, in our experiments we only performed intra-word tokenization, using the white-space as a starting segmentation beyond which no token could be formed. When this restriction was removed, the resulting sequences were even smaller but BLEU scores decreased. While this might be because the hyperparameters were set to maximise the BLEU score of BPE intra-word, it could be an indication that some linguistic prior (like word tokenization) trumps this specific formalization of Occam's Razor.

Abstract

Bilingual lexicons are valuable resources used by professional human translators. While these resources can be easily incorporated in statistical machine translation, it is unclear how to best do so in the neural framework. In this work, we present the HABLex dataset, designed to test methods for bilingual lexicon integration into neural machine translation. Our data consists of human-generated alignments of words and phrases in machine translation test sets in three language pairs (Russian→English, Chinese→English, and Korean→English), resulting in clean bilingual lexicons which are well matched to the reference. We also present two simple baselines—constrained decoding and continued training—and an improvement to continued training to address overfitting.

1 Introduction

Neural machine translation (NMT) is the current state-of-the-art. In contrast with statistical machine translation (SMT; Koehn et al., 2007), where there are several established methods of incorporating external knowledge,[1] recent work is still examining how best to incorporate bilingual lexicons into NMT systems. Bilingual lexicon integration is desirable in a number of scenarios: highly technical vocabulary (which might be rare, or require translations of a domain-specific sense), lower-resource settings (where bilingual lexicons might be a significant portion of the available parallel data), translation settings where a client requires particular terms to be used (e.g. brand names), or for improving rare word translation.

At present, there is no standard dataset for benchmarking bilingual lexicon integration, making it difficult to compare methods.

Source	на передней стенке корпуса установлены **амортизаторы** .
Lexical Entry	**амортизаторы↔shock absorbers**
Target	**shock absorbers** are mounted on a front wall of the housing .

Table 1: Example Russian source sentence, lexicon entry, and English target sentence.

We create and release[2] **H**uman **A**nnotated **B**ilingual **Lex**icons (HABLex). Our bilingual lexicons are (1) generated by bilingual experts to ensure high quality, (2) derived from the development and test references so the best-case-scenario impact on translation performance can be directly measured, (3) covering 3 language pairs, and (4) focused on challenging words.

We perform exploratory work on our development set, showing two representative baselines to compare incorporating the lexicon at training time (continued training) vs. at decoding time (constrained decoding). We examine the tradeoffs in terms of BLEU, recall, and speed.

We also present a novel application of Elastic Weight Consolidation (EWC; Kirkpatrick et al., 2017; Thompson et al., 2019) which significantly improves performance by preventing overfitting during continued training on the bilingual lexicon.

2 Related Work

We first review prior work on incorporation of bilingual lexicons into NMT and then discuss the datasets used and explain how our new dataset addresses some shortcomings.

Recent work on the incorporation of bilingual lexicons into NMT systems can be loosely clus-

tered into two categories: incorporation at training time or during decoding. These two general approaches have different performance characteristics: incorporation at training time may slow down training, but tends not to alter inference speed, while incorporation at inference time tends to significantly slow down decoding (see subsection 4.3), but without slowing down training.

2.1 Incorporation at Training Time

Zhang and Zong (2016) and Fadaee et al. (2017) both propose using bilingual lexicons to create synthetic bitext to augment training data for NMT systems. Arthur et al. (2016) use translation probabilities from a lexicon (like SMT phrase tables) in conjunction with NMT probabilities.

2.2 Incorporation at Decode Time

Kothur et al. (2018) perform fine-grained continued training adaptation on very small, document-specific bilingual lexicons of novel words.[3]
