A popular inference-time approach is constrained decoding (Anderson et al., 2016; Hokamp and Liu, 2017; Chatterjee et al., 2017; Hasler et al., 2018; Post and Vilar, 2018), which modifies beam search to require that user-specified words or phrases to be present in the output hypotheses. Constrained decoding can be used to ensure that target entries from a bilingual lexicon be present in the MT output whenever their corresponding source entries are present in the input. Constrained decoding with multiple target options (e.g. when a source word can be translated into one of several target words) is addressed in Chatterjee et al. (2017) and Hasler et al. (2018).

2.3 Datasets Used in Prior Studies

Prior work has used either human-generated general purpose bilingual lexicons not tailored to a test set (Arthur et al., 2016; Zhang and Zong, 2016) or automatic alignments (Fadaee et al., 2017; Hokamp and Liu, 2017; Chatterjee et al., 2017; Hasler et al., 2018; Kothur et al., 2018) which likely contain errors (especially on rare words). There exist manually word-aligned parallel corpora for Japanese-English Wikipedia data (Neubig, 2011) and for Chinese-English mixed-domain data (Liu and Sun, 2015), from which it would be possible to extract lexicons.

[3]Although this method involves adapting the model, it is done prior to translating each document, so we view it as a decoding-time modification.

Most prior work experimented in a single language pair,[4] making it difficult to predict if a method will generalize. Our work addresses these issues by providing a multi-language testbed for comparisons, focusing on a consistent and lexically-challenging domain.

3 HABLex Dataset

Our motivation is to allow straightforward evaluation of lexicon incorporation methods. By building a reference-derived bilingual lexicon, we ensure that if a method successfully learns correct translations from the lexicon while maintaining overall system performance, BLEU will increase.

We annotate the existing parallel text with alignments for certain vocabulary items, allowing us to extract bilingual lexicons that are specific to the context in which the translation should appear. This produces a cleaner and more well-tailored bilingual lexicon than would be found in most real-world scenarios. However, it could also be used as a standardized starting point to produce a noisier lexicon that more closely mimics real-world lexicons (e.g. by adding irrelevant entries or relevant morphological variants, lemmatizing entries, or subsampling).

At a high level, our lexicons are created by a two-step process: (1) identifying interesting words on the source side of the test and development sets, and (2) human annotators correcting or validating automatic alignments of the identified words.

3.1 Patent Domain & Languages

We chose the patent domain because it contains interesting technical terminology and because of the availability of the high-quality, multilingual World Intellectual Property Organization (WIPO) COPPA-V2 corpus (Junczys-Dowmunt et al., 2016). We build bilingual lexicons for three language pairs: Russian→English (Ru→En), Korean→English (Ko→En), and Chinese→English (Zh→En). We also release the development and test splits from which the annotations were produced.

3.2 Interesting Word Selection

We select interesting words (from the source side of the data) as follows: words that appear less than 5 times in WIPO data, words that appear less than

[4]Except Hokamp and Liu (2017) and Hasler et al. (2018).

	Development		Test	
	Entries	Sentences	Entries	Sentences
Ru	8001	2142	9040	2412
Ko	5595	1756	5593	1744
Zh	1352	1025	1042	885

Table 2: Number of bilingual lexicon entries and sentences containing at least one annotation for each language pair. Most source entries (between 87% and 96%) have a unique translation; the remainder have 7 or fewer target translations.

5 times in general domain training data (see section 4), and words that appear less than 5 times in both.[5] These represent three types of words that may be challenging to translate: words that have only recently been learned, words that may have been forgotten during continued training, and generally rare words.

3.3 Human Annotations

Our bilingual annotators used the LDC Word Aligner tool (Grimes, 2010) to annotate words of interest in context. Table 1 shows example lexicon entries resulting from this annotation process. In order to save annotator time and effort, we displayed highlighted automatic alignments[6] of each of the words of interest in their parallel sentence context (similar to Grimes et al. (2012)). The annotator confirms or corrects the automatic alignment, adding or removing source or target side words as needed to complete a valid alignment. Since annotation is cumbersome with very long sentences, we omit sentences of length 100 or more tokens. Filtering out numerical entries, discontiguous entries, and phrases longer than 3 words[7] results in bilingual lexicons with sizes shown in Table 2.

4 Baseline Experiments and Results

To build strong baseline systems, we first train models on general domain data. As general domain data, we use the OpenSubtitles18 (Lison et al., 2018) corpora for both Ru→En and Ko→En. For Ru→En and Zh→En we also use the parallel portion of the WMT17 news translation task (Bojar et al., 2017). We then fine-tune these general-domain models on WIPO training data (Luong and Manning, 2015), using the dev set for validation. These domain-adapted models are then used as the initial systems for our lexicon incorporation experiments.

We build the systems in Sockeye (Hieber et al., 2017), using a two-layer LSTM network with hidden unit size 512. We use an initial learning rate of 3e-4 both for training the general domain model and adapting to WIPO. We apply the Moses tokenizer (Koehn et al., 2007), lowercasing, and byte-pair encoding (BPE; Sennrich et al., 2016) with a vocabulary size of 30k. BPE is trained on the general domain corpus only, then applied to all data.

4.1 Evaluation Metrics

We evaluate lexicon incorporation approaches using two main metrics: BLEU and recall. For each annotated instance of a source-side lexical entry, we can check whether the system output contains the correct aligned target-side translation. Recall is computed as the percentage of the time that the system produces the correct output, averaged over all annotations. Note that this does not guarantee that the words are placed in a sensible location in the sentence, only that they appear.

We also consider training and decoding speed. All of these factors help determine which approaches are best given a particular use case. For example, if a user requires exact fidelity to a lexicon (e.g. branding), they may care the most about recall (while still ensuring that overall translation quality is still acceptable).

4.2 Continued Training on HABLex

We perform continued training (CT; Luong and Manning, 2015)—typically used for domain adaptation—on the bilingual lexicon data. With bilingual lexicons approximately two orders of magnitude larger than those used successfully in Kothur et al. (2018), we find that performance drops dramatically with standard CT. To address this problem, we apply EWC (Kirkpatrick et al., 2017), a method for training a neural network to learn a new task without catastrophically forgetting how to perform a previously learned task. EWC has recently been shown to significantly reduce general domain performance loss during domain adaptation in NMT (Thompson et al., 2019); we

[5] We focus on 5-count (and rarer) words because we expect them to be particularly challenging for MT, but given time and resources there is nothing to prevent the application of the annotation protocol to other terms.

[6] For strong initial alignments, GIZA++ (Och and Ney, 2003) is trained on train, development, and test for all data described in section 4 as well as a TED talk corpus (Cettolo et al., 2012).

[7] While we want the dictionary to match the reference, we did not want to train on large phrases from the reference.

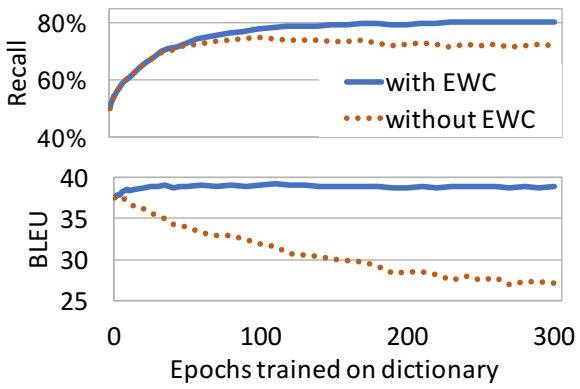

Figure 1: Ru→En recall and BLEU during continued training on bilingual lexicon for the development set.

			CT		CD	
		BL	CT	+EWC	Rand.	Oracle
Ru	bleu	37.5	27.1	38.9	40.0	40.5
	rec.	48.2	72.1	80.2	95.9	99.9
Ko	bleu	34.1	10.9	31.5	31.6	33.7
	rec.	55.0	47.3	69.7	87.6	99.0
Zh	bleu	39.9	34.8	39.0	42.2	42.5
	rec.	38.9	78.7	81.2	97.4	99.9

Table 3: BLEU and recall % (rec.) of baseline (BL), continued training (CT) with and without EWC, and oracle and random constrained decoding (CD) on development set.[8]

apply it to retain the ability to translate full sentences while training on a bilingual lexicon.

We experimented with initial learning rates (0.001, 0.00316, 0.01, 0.0316, 0.1), all using SGD for 300 epochs, and EWC weight decay values (1e-1, 1e-2, 1e-3, 1e-4, 1e-5). We chose a learning rate 0.1 because it allowed recall to (at least approximately) converge, and a weight decay value of 1e-4 because it performed reasonably well on the dev sets for all 3 languages. All results reported are for the final checkpoint.

	bleu		recall (%)	
	Baseline	Random	Baseline	Random
Ru	37.5	40.3	46.7	96.5
Ko	34.5	32.7	54.7	89.3
Zh	39.0	40.9	36.3	96.2

Table 4: Baseline and constrained decoding (random) on test set.

4.3 Constrained Decoding

We employ *dynamic beam allocation* (DBA; Post and Vilar, 2018) for constrained decoding (CD). At each time step of decoding, DBA groups hypotheses into *banks* based on the number of translated constraints, and a fixed-size beam is dynamically allocated across the banks. While DBA has a time complexity constant in the number of constraints, in practice we find it to be approximately an order of magnitude slower than regular decoding, primarily because Sockeye does not currently support batched DBA.[9]

One limitation of DBA is that it only works on constraints that have only one translation. In this work, we report **oracle** choice (use the right sense for the specific test sentence) as an upper bound on performance and **random** choice (choose a random possible translation) as another baseline. Our dictionary may contain more than one possible translation for a given target word. For example, we observe the following three English translations for the Russian word арматурного: *rebar, reinforced,* and *reinforcement*. These translations are appropriate in different contexts and are not interchangeable, so the oracle always selects the translation that is appropriate for the given sentence (according to its reference translation). The random approach selects one of the translations uniformly at random; if there is only one translation, random is identical to oracle.

4.4 Results & Discussion

Table 3 summarizes key exploratory results for the baseline, CT, and CD approaches on the development set. Table 4 shows baseline and random CD benchmarks on the test set, which we otherwise reserve and release for future evaluation. We confine the remainder of our discussion to the experiments we performed on the development set.

EWC noticeably improves BLEU performance as compared to standard CT, while also increasing recall. (See Figure 1 for example performance as the model is trained on the bilingual lexicon and Table 3 for results on all three language pairs.) CD outperforms CT in terms of both BLEU score and recall, at the expense of decoding speed. Random CD nears oracle CD performance because most source-side entries have only one translation. We

[8]The recall of the oracle method would be 100%, if there were no out-of-vocabulary subwords in the bilingual lexicon.

[9]Constrained decoding with DBA takes 3.1 seconds per sentence on average on a Tesla K80 GPU.

would not necessarily expect such high random CD performance if the bilingual lexicon averaged more senses per source entry.

The use case for bilingual lexicon incorporation should also influence user decisions about what approaches to use. If exact translations (e.g. brand names or highly technical translations) are of the utmost importance, a CD approach might be preferred even if it is slower. In the case that a general lexicon has been provided but there is more flexibility in terminology, it may be better to perform CT, or perhaps even a combination of the two.

5 Conclusions

Bilingual lexicons are important resources in translation, but it is not clear how to best incorporate them in NMT. To address this challenge, we present the HABLex dataset, a multi-language, reference-derived development and test set that facilitates the evaluation of lexicon incorporation. We compare two baselines, based on incorporation at training time or at decode time, in terms of BLEU, recall, and speed. We also present a novel application of EWC to continued training which addresses lexicon overfitting.

Acknowledgments

We thank the annotators who worked on building this dataset, as well as the reviewers for their helpful comments. Brian Thompson is supported through the National Defense Science and Engineering Graduate (NDSEG) Fellowship Program.

Handling Syntactic Divergence in Low-resource Machine Translation

Chunting Zhou, Xuezhe Ma, Junjie Hu, Graham Neubig

Abstract

Despite impressive empirical successes of neural machine translation (NMT) on standard benchmarks, limited parallel data impedes the application of NMT models to many language pairs. Data augmentation methods such as back-translation make it possible to use monolingual data to help alleviate these issues, but back-translation itself fails in extreme low-resource scenarios, especially for syntactically divergent languages. In this paper, we propose a simple yet effective solution, whereby target-language sentences are re-ordered to match the order of the source and used as an additional source of training-time supervision. Experiments with simulated low-resource Japanese-to-English, and real low-resource Uyghur-to-English scenarios find significant improvements over other semi-supervised alternatives[1]

1 Introduction

While neural machine translation (NMT; Bahdanau et al. (2015); Vaswani et al. (2017)) now represents the state of the art in the majority of large-scale MT benchmarks (Bojar et al., 2017), it is highly dependent on the availability of copious parallel resources; NMT under-performs previous phrase-based methods when the training data is small (Koehn and Knowles, 2017). Unfortunately, million-sentence parallel corpora are often unavailable for many language pairs. Conversely, monolingual sentences, particularly in English, are often much easier to find, making semi-supervised approaches that can use monolingual data a desirable solution to this problem.[2]

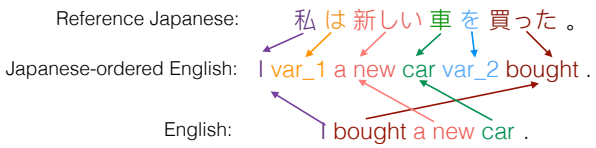

Figure 1: An English sentence re-ordered into Japanese order using the rule-based method of Isozaki et al. (2010b), and its reference Japanese translation.

Semi-supervised approaches for NMT are often based on automatically creating pseudo-parallel sentences through methods such as back-translation (Irvine and Callison-Burch, 2013; Sennrich et al., 2016) or adding an auxiliary auto-encoding task on monolingual data (Cheng et al., 2016; He et al., 2016; Currey et al., 2017). However, both methods have problems with low-resource and syntactically divergent language pairs. Back translation assumes enough data to create a functional NMT system, an unrealistic requirement in low-resource scenarios, while auto-encoding target sentences by definition will not be able to learn source-target word reordering.

This paper proposes a method to create pseudo-parallel sentences for NMT for language pairs with divergent syntactic structures. Prior to NMT, word reordering was a major challenge for statistical machine translation (SMT), and many techniques have emerged over the years to address this challenge (Xia and McCord, 2004; Bisazza and Federico, 2016). Importantly, even simple heuristic reordering methods with a few hand-created rules have been shown to be highly effective in closing syntactic gaps (Collins et al. (2005); Isozaki et al. (2010b); Fig. 1). Because these rules usually function solely in high-resourced languages such as English with high-quality syn-

[1] https://github.com/violet-zct/pytorch-.reorder-nmt

[2] Unsupervised MT (Artetxe et al., 2018a) has achieved success on simulated low-resource scenarios with related languages, but limited success on real low-resource settings and syntactically divergent language pairs (Neubig and Hu, 2018; Guzmán et al., 2019). Hence we focus on semi-supervised methods in this paper.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1388–1394, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tactic analysis tools, a linguist with rudimentary knowledge of the structure of the target language can create them in short order using these tools.

However, similar pre-ordering methods have not proven useful in NMT (Du and Way, 2017), largely because high-resource scenarios NMT is much more effective at learning reordering than previous SMT methods were (Bentivogli et al., 2016). However, in low-resource scenarios it is less realistic to expect that NMT could learn this reordering from scratch on its own.

Here we ask "how can we efficiently leverage the monolingual target data to improve the performance of the NMT system in low-resource, syntactically divergent language pairs?" We tackle this problem via a simple two-step data augmentation method: (1) we first reorder monolingual target sentences to create *source-ordered target sentences* as shown in Fig. 1, (2) we then replace the words in the reordered sentences with source words using a bilingual dictionary, and add them as the source side of a pseudo-parallel corpus. Experiments demonstrate the effectiveness of our approach on translation from Japanese and Uyghur to English, with a simple, linguistically motivated method of head finalization (HF; Isozaki et al. (2010b)) as our reordering method.

2 The Proposed Method

Training Framework We assume that there are two types of available resources: a small parallel corpus $\mathcal{P} = \{(s, t)\}$ and a large monolingual target corpus $\mathcal{Q}$. The goal of our method is to create a pseudo-parallel corpus $\hat{\mathcal{Q}} = \{(\hat{s}, t)\}$, where $\hat{s}$ is a pseudo-parallel sentence automatically created in two steps of (1) word reordering, and (2) word-by-word translation.

Word Reordering The first step reorders monolingual target sentences $t \in \mathcal{Q}$ into the source order t_s. Instead of devising an entirely new word-ordering method, we can simply rely on methods that have already been widely studied and proven useful in SMT (Bisazza and Federico, 2016). Reordering can be done either using rules based on linguistic knowledge (Isozaki et al., 2010b; Collins et al., 2005) or learning from aligned parallel data (Xia and McCord, 2004; Habash, 2007), and in principle our pseudo-corpus creation paradigm is compatible with any of these methods.

Specifically, in this work we utilize rule-based methods, as our goal is to improve translation of low-resource languages, where large quantities of high-quality parallel data do not exist and we posit that current data-driven reordering methods are unlikely to function well. Examples of rule-based methods include those to reorder English into German (Navratil et al., 2012), Arabic (Badr et al., 2009), or Japanese (Isozaki et al., 2010b). In experiments we use Isozaki et al. (2010b)'s method of reordering SVO languages (e.g. English) into the order of SOV languages (e.g. Japanese) by simply (1) applying a syntactic parser to English (Tsuruoka et al., 2004), (2) identifying the head constituent of each phrase and moving it to the end of the phrase, and (3) inserting special tokens after subjects and objects of predicates to mimic Japanese case markers.

Word-by-word Translation To generate data for training MT models, we next perform word-by-word translation of t_s into pseudo-source sentence $\hat{s}$ using a bilingual dictionary (Xie et al., 2018).[3] There are many ways we can obtain this dictionary: even for many low-resource languages with a paucity of bilingual text, we can obtain manually-curated lexicons with reasonable coverage, or run unsupervised word alignment on whatever parallel data we have available. In addition, we can induce word translations for more words in target language using methods for bilingual lexicon induction over pre-trained word embeddings (e.g. Grave et al. (2018)).

3 Experiments

We evaluate our method on two language pairs: Japanese-to-English (`ja-en`) and Uyghur-to-English (`ug-en`). Japanese and Uyghur are phylogenetically distant languages, but they share similar SOV syntactic structure, which is greatly divergent from English SVO structure.

3.1 Experimental Setup

For both language pairs, we use an attention-based encoder-decoder NMT model with a one-layer bidirectional LSTM as the encoder and one-layer uni-directional LSTM as the decoder.[4] Embeddings and LSTM states were set to 300 and

[3] We also performed extensive preliminary experiments that learned bilingual word embeddings a-priori and froze them when training the NMT model, or continued to align the bilingual word embedding space during NMT training, but the word-by-word translation approach worked best.

[4] We experimented with small Transformers (Vaswani et al., 2017) but they under-performed LSTM-based models.

256 dimensions respectively. Target word embeddings are shared with the softmax weight matrix in the decoder. As noted above, we use HF (Isozaki et al., 2010b) as our re-ordering rule. HF was designed for transforming English into Japanese order, but we use it *as-is* for the Uyghur-English pair as well to demonstrate that simple, linguistically motivated rules can generalize across pairs with similar syntax with little or no modification. Further details regarding the experimental settings are in the supplementary material.

Simulated Japanese to English Experiments We first evaluate on a simulated low-resource `ja-en` translation task using the ASPEC dataset (Nakazawa et al., 2016). We randomly select 400k `ja-en` parallel sentence pairs to use as our full training data. We then randomly sub-sample low-resource datasets of 3k, 6k, 10k, and 20k parallel sentences, and use the remainder of the 400k English sentences as monolingual data. We duplicate the number of parallel sentences by 5 times in the training data augmented with the reordered pairs. For settings with supervised parallel sentences of 3k, 6k, 10k and 20k, we set the maximum vocabulary size of both Japanese and English to be 10k, 10k, 15k and 20k respectively.

To automatically learn a high-precision dictionary on the small amount of parallel data we have available for training, we use GIZA++ (Och and Ney, 2003) to learn alignments in both directions then take the intersection of alignments. We then learn the bilingual word embeddings with DeMa-BWE (Zhou et al., 2019), an unsupervised method that has shown strong results on syntactically divergent language pairs. We give the more reliable alignments extracted from GIZA++ high priority by querying the alignment dictionary first, then follow by querying the embedding-induced dictionary. When an English word is not within any vocabulary, we output the English word as-is into the pseudo-source sentence.

Real Uyghur to English Experiments We also consider the harder case of Uyghur, a truly low-resource language. We create test and validation sets using the test data from the DARPA LORELEI corpus (Christianson et al., 2018) which contains 2,275 sentence pairs (after filtering out noisy ones) related to incidents that happened in the Uyghur area. We hold out 300 pairs as the validation data and use the rest as the test set. The LORELEI language pack also contains the bilingual lexicons between Uyghur and English, and thousands of in-domain English sentences. We also use a large monolingual English corpus containing sentences related to various incidents occurring all over the world collected from ReliefWeb.[5] To sub-select a relevant subset of this corpus, we use the cross-entropy filtering (Moore and Lewis, 2010) to select 400k that are most like the in-domain English data.

For parallel data, like many low-resource languages, we only have access to data from the Bible[6] and Wikipedia language links (the total number of parallel Uyghur-English Wikipedia titles is 3,088), but no other in-domain parallel data. We run GIZA++ on this parallel data to obtain an alignment dictionary. We learn the bilingual word embeddings via the supervised Geometric approach (Jawanpuria et al., 2019) on FastText (Grave et al., 2018) pre-trained Uyghur and English monolingual embeddings.

3.2 Results and Comparison

Baselines In Tab. 1, we compare our models with baselines including regular supervised training (sup) and back-translation (Sennrich et al., 2016) (back).[7] To demonstrate the effectiveness of the reordering, we also compare our method against a copy-based data-augmentation method (No-reorder) where the original English sentences $t \in \mathcal{Q}$ rather than the reordered ones t_s are translated via the bilingual lexicon.[8] For each of the above settings, we also experimented with a phrased-based statistical machine translation (SMT) system (Dyer et al., 2010). In Tab. 1, we only show the results with supervised data and back-translation for SMT, since we observed that the data augmentation method performs poorly with SMT (complete results are presented in the Appendix).

Main Results In Tab. 1, we observe consistent improvements on both ja-en and ug-en translation tasks against other baseline methods. First, comparing our results with the NMT models trained using the same amount of parallel data, our word reordering-based semi-supervised models consistently outperform standard NMT models by a large margin. In the case that we have no access to in-domain parallel data at all, our method can still achieve some success in ug-en translation. Second, comparing our Reorder method with the No-Reorder one, reordering English sentences into the source language order consistently brings large performance gains, which demonstrates the importance of reordering. These results are notable given previous reports that explicit reordering is not beneficial for NMT (Du and Way, 2017). Third, for ja-en translation, when gradually decreasing the amount of parallel data, the improvements of our model over the supervised NMT models become more significant, demonstrating the effectiveness of our approach in low-resource settings. Fourth, back-translation is not very beneficial or even harmful, likely because the back-translation system trained on limited supervised data can not provide high-quality translations to train the model. Finally, we also notice that although SMT performs better than NMT with less supervised training data (3k, 6k supervised data and Uyghur), the performance gain is not as remarkable as NMT when the amount of supervised data increases. Moreover, in the case of less supervised data, our data augmentation method with reordering still outperforms SMT.

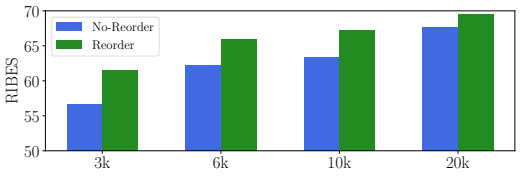

Figure 3: Comparison of RIBES score on Ja-En translation with different amounts of supervised data.

We give two examples of the translation outputs of our model and a supervised NMT model for ug-en and ja-en (trained with 6k supervised pairs) in Tab. 2. In the first example from ja-en, our model is able to output terminology such as "rotation rate" thanks to the enlarged vocabulary while the supervised model can not. In the example from ug-en, our model can produce a more fluent sentence with better information coverage.

[7] We also trained unsupervised NMT (Artetxe et al., 2018b) on 400k Japanese and English sentences from the ASPEC corpus or monolingual Uyghur and English corpus provided in the LORELEI data package, and it achieved BLEU of 0.6 and 0.0 respectively, corroborating previous results noting the difficulty of unsupervised NMT for low-resource scenarios (Neubig and Hu, 2018; Guzmán et al., 2019)

[8] This is similar to Currey et al. (2017) who simply copy target-language sentences to the source. But in our experiments, the source and target languages do not share the alphabet and thus we found translation necessary. This also increases consistency with our "Reorder" experiments.

Analysis To investigate the effects of reordering, we compare our method with "No-Reorder" described in 3.2. First, we bucket the test data by sentence length and compute the BLEU score accordingly. We present the comparison results in Fig. 2, from which we observe that "Reorder" outperforms "No-Reorder" consistently under different sentence length buckets, and the improvement is larger when the sentence length is longer.

Second, we also evaluate the model outputs on the test data with RIBES (Isozaki et al., 2010a) which is an automatic evaluation metric of translation quality designed for distant languages that is especially sensitive to word order. From Fig. 3, we can see that "Reorder" consistently outperforms "No-Reorder" on `ja-en` translation especially when the amount of supervised data decreases. This suggests that with reordered pairs as the augmented training data, the model is able to output more syntactically correct sentences.

4 Conclusion

This paper proposed a simple yet effective semi-supervised learning framework for low-resource machine translation that artificially creates source-ordered target sentences for data-augmentation. Experimental results on `ja-en` and `ug-en` translations show that our approach achieves significant improvements over baseline systems, demonstrating the effectiveness of the proposed approach on divergent language pairs.

Speculative Beam Search for Simultaneous Translation

Abstract

Beam search is universally used in full-sentence translation but its application to simultaneous translation remains non-trivial, where output words are committed on the fly. In particular, the recently proposed wait-k policy (Ma et al., 2019a) is a simple and effective method that (after an initial wait) commits one output word on receiving each input word, making beam search seemingly impossible. To address this challenge, we propose a speculative beam search algorithm that hallucinates several steps into the future in order to reach a more accurate decision, implicitly benefiting from a target language model. This makes beam search applicable for the first time to the generation of a single word in each step. Experiments over diverse language pairs show large improvements over previous work.

1 Introduction

Beam search has been widely used in neural text generation such as machine translation (Sutskever et al., 2014; Bahdanau et al., 2014), summarization (Rush et al., 2015; Ranzato et al., 2016), and image captioning (Vinyals et al., 2015; Xu et al., 2015). It often leads to substantial improvement over greedy search and becomes an essential component in almost all text generation systems.

However, beam search is easy for the above tasks because they are all *full-sequence* problems, where the whole input sequence is available at the beginning and the output sequence only needs to be revealed in full at the end. By contrast, in language and speech processing, there are many *incremental processing* tasks with *simultaneity requirements*, where the output needs to be revealed to the user incrementally without revision (word by word, or in chunks) and the input is also being received incrementally. Two most salient examples are streaming speech recognition (Chiu et al., 2018), widely used in speech input and dialog systems (such as Siri), and simultaneous translation (Bangalore et al., 2012; Oda et al., 2015; Grissom II et al., 2014; Jaitly et al., 2016), widely used in international conferences and negotiations. In these tasks, the use of full-sentence beam search becomes seemingly impossible as output words need to be committed on the fly.

How to adapt beam search for such incremental tasks in order to improve their generation quality? We propose a general technique of *speculative beam search* (SBS), and apply it to simultaneous translation. At a very high level, to generate a single word, instead of simply choosing the highest-scoring one (as in greedy search), we further speculate w steps into the future, and use the ranking at step $w+1$ to reach a more informed decision for step 1 (the current step); this method implicitly benefits from a target language model, alleviating the label bias problem in neural generation (Murray and Chiang, 2018; Ma et al., 2019b).

We apply this algorithm to two representative approaches to simultaneous translation: the fixed policy method (Ma et al., 2019a) and the adaptive policy method (Gu et al., 2017). In both cases, we show that SBS improves translation quality while maintaining latency (i.e., simultaneity).

2 Preliminaries

We first review standard full-sentence NMT and beam search to set up the notations, and then review different approaches to simultaneous MT.

2.1 Full Sentence NMT and Beam Search

The encoder processes the input sequence $\boldsymbol{x} = (x_1, ..., x_n)$, where $x_i \in \mathbb{R}^d$ represents an input token as a d dimensional vector, and produces a new list of hidden states $\boldsymbol{h} = f(\boldsymbol{x}) = (h_1, ..., h_n)$

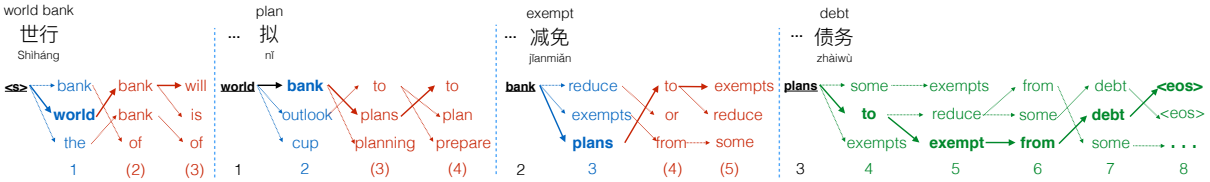

Figure 1: Wait-1 policy example to illustrate the procedure of SBS. The top Chinese words are the source side inputs which are incrementally revealed to the encoder. Gloss is annotated above Chinese word and Pinyin is underneath. There are two extra steps (speculative window) are taken (red part) beyond greedy. When source reaches the last word "债务" (debt), the decoder gets into tail and performs conventional beam search (in green).

to represent $\boldsymbol{x}$. The encoding function f can be RNN, CNN or Transformer.

On the other hand, the (greedy) decoder selects the highest-scoring word y_t given source representation $\boldsymbol{h}$ and previously generated target tokens, $\boldsymbol{y}_{<t} = (y_1, ..., y_{t-1})$. The greedy search continues until it emits <eos>, and the final hypothesis $\boldsymbol{y} = (y_1, ..., y_t)$ with $y_t =$ <eos>

$$p(\boldsymbol{y} \mid \boldsymbol{x}) = \prod_{t=1}^{|\boldsymbol{y}|} p(y_t \mid \boldsymbol{x}, \boldsymbol{y}_{<t}) \quad (1)$$

As greedy search only explores one single path among exponential many alternatives, beam search is used to improve the search. At each step t, it maintains a beam B_t of size b, which is an ordered list of ⟨hypothesis, probability⟩ pairs; for example $B_0 = [\langle \text{<s>}, 1 \rangle]$. We then define one-step transition from the previous beam to the next as

$$\text{next}_1^b(B) = \text{top}^b\{\langle \boldsymbol{y} \circ v,\ s \cdot p(v|\boldsymbol{x}, \boldsymbol{y}) \rangle \mid \langle \boldsymbol{y}, s \rangle \in B\}$$

where $\text{top}^b(\cdot)$ returns the top-scoring b pairs, and $\circ$ is the string concatenation operator. Now $B_t = \text{next}_1^b(B_{t-1})$. As a shorthand, we also define the multi-step beam search function recursively:

$$\text{next}_i^b(B) = \text{next}_1^b(\text{next}_{i-1}^b(B)) \quad (2)$$

Full-sentence beam search (over a maximum of T steps) yields the best hypothesis $\boldsymbol{y}^*$ with score s^* (see Huang et al. (2017) for stopping criteria):

$$\langle \boldsymbol{y}^*, s^* \rangle = \text{top}^1(\text{next}_T^b([\langle \text{<s>}, 1 \rangle])) \quad (3)$$

2.2 Simultaneous MT: Policies and Models

There are two main categories of policies in neural simultaneous translation decoding (Tab. 1):

1. The first method is to use a fixed-latency policy, such as the wait-k policy (Ma et al., 2019a). Such a method would, after an initial wait of k source words, commit one target word on receiving each new source word. When the source sentence ends, the decoder can do a *tail beam search* on the remaining target words, but beam search is seemingly impossible before the source sentence ends.

model / policy	*sequence-to-sequence* (full-sentence model)	*prefix-to-prefix* (simultaneous model)
fixed-latency	test-time wait-k (Dalvi et al., 2018; Ma et al., 2019a)	wait-k (Ma et al., 2019a)
adaptive	RL (Gu et al., 2017) Supervised Learning (Zheng et al., 2019a)	MILk (Arivazhagan et al., 2019) Imitation Learning (Zheng et al., 2019b)

Table 1: Recent advances in simultaneous translation.

2. The second method learns an adaptive policy which uses either supervised (Zheng et al., 2019a) or reinforcement learning (Grissom II et al., 2014; Gu et al., 2017) to decide whether to READ (the next source word) or WRITE (the next target word) . Here the decoder can commit a chunk of *multiple words* for a series of consecutive WRITEs.

In terms of modeling (which is orthogonal to decoding policies), we can also divide most simultaneous translatoin efforts into two camps:

1. Use the standard full-sentence translation model trained by classical seq-to-seq (Dalvi et al., 2018; Gu et al., 2017; Zheng et al., 2019a). For example, the "test-time wait-k" scheme (Ma et al., 2019a) uses the full-sentence translation model and performs wait-k decoding at test time. However, the obvious training-testing mismatch in this scheme usually leads to inferior quality.

2. Use a genuinely simultaneous model trained by the recently proposed prefix-to-prefix framework (Ma et al., 2019a; Arivazhagan et al., 2019; Zheng et al., 2019b). There is no training-testing mismatch in this new scheme, with the cost of slower training.

3 Speculative Beam Search

We first present our speculative beam search on the fixed-latency wait-k policy (generating a single word per step), and then adapt it to the adaptive policies (generating multiple words per step).

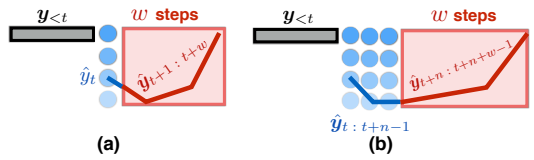

Figure 2: Illustration of SBS: (a) wait-k policy (Eqs. 4–5); (b) adaptive policy (Eqs. 6–7). Speculations in red.

3.1 Single-Step SBS

The wait-k policy conducts translation concurrently with the source input, committing output words one by one while the source sentence is still growing. In this case, conventional beam search is clearly inapplicable.

We propose to perform speculative beam search at each step by hallucinating w more steps into the future, and use the ranking after these $w+1$ steps to make a more informed decision for the current step. More formally, at step t, we generate y_t based on already committed prefix $\boldsymbol{y}_{<t}$:

$$\langle \hat{\boldsymbol{y}}, s_t \rangle = \text{top}^1\big(\text{next}^b_{1+w}([\langle \boldsymbol{y}_{<t}, 1\rangle])\big) \quad (4)$$

$$\boldsymbol{y}_{\leq t} = \boldsymbol{y}_{<t} \circ \hat{y}_t \quad (5)$$

where $\hat{\boldsymbol{y}} = \boldsymbol{y}_{<t} \circ \hat{y}_t \circ \hat{\boldsymbol{y}}_{t+1:t+w}$ has three parts, with the last one being a speculation of w steps (see Fig. 2). We use $\text{next}^b_{1+w}(\cdot)$ to speculate w steps. The candidate $\hat{y}_t$ is selected based on the accumulative model score w steps later. Then we commit $\hat{y}_t$ and move on to step $t+1$.

In the running example in Fig. 1, we have $w=2$ and $b=3$. In the greedy mode, after the wait-1 policy receives the first source word, "世行" (world bank), the basic wait-1 model commits "bank" which has the highest score. In SBS, we perform a beam search for $1+w=3$ steps with the two speculative steps marked in red. After 3 steps, the path "world bank will" becomes the top candidate, thus we choose to commit "world" instead of "bank" and restart a new speculative beam search with "world" when we receive a new source word, "拟"(plan to); the speculative part from the previous step (in red) is removed.

3.2 Chunk-based SBS

The RL-based adaptive policy system (Gu et al., 2017) can commit a chunk of multiple words whenever there is a series of consecutive WRITEs, and conventional beam search can be applied on each chunk to improve the search quality within that chunk, which is already used in that work.

However, on top of the obvious per-chunk beam search, we can still apply SBS to further speculate w steps after the chunk. For a chunk of length n starting at position t, we adapt SBS as:

$$\langle \hat{\boldsymbol{y}}, s_t \rangle = \text{top}^1\big(\text{next}^b_{n+w}([\langle \boldsymbol{y}_{<t}, 1\rangle])\big) \quad (6)$$

$$\boldsymbol{y}_{\leq t+n-1} = \boldsymbol{y}_{<t} \circ \hat{\boldsymbol{y}}_{t:t+n-1} \quad (7)$$

Here $\text{next}^b_{n+w}(\cdot)$ does a beam search of $n+w$ steps, with the last w steps speculated. Similarly,

$$\hat{\boldsymbol{y}} = \boldsymbol{y}_{<t} \circ \hat{\boldsymbol{y}}_{t:t+n-1} \circ \hat{\boldsymbol{y}}_{t+n:t+n+w-1}$$

has three parts, with the last being a speculation of w steps, and the middle one being the chunk of n steps returned and committed (see Fig. 2).

4 Experiments

4.1 Datasets and Latency Metrics

We evaluate our work on Chinese↔English simultaneous translation tasks. For the training data, we use the NIST corpus for Chinese↔English (2M sentence pairs). We first apply BPE (Sennrich et al., 2015) on all texts in order to reduce the vocabulary sizes. For Chinese↔English evaluation, we use NIST 2006 and NIST 2008 as our dev and test sets with 4 English references. For English→Chinese, we use the second among the four English references as the source text.

We re-implement wait-k model (Ma et al., 2019a), test-time wait-k model (Dalvi et al., 2018) and adaptive policy (Gu et al., 2017) based on PyTorch-based OpenNMT (Klein et al., 2017). To reach state-of-the-art performance, we use Transformer based wait-k model and also use Transformer based pre-trained full sentence model for learning adaptive policy. The architecture of Transformer is the same as the base model from the original paper (Vaswani et al., 2017). We use Average Lagging (AL) (Ma et al., 2019a) as the latency metrics. AL measures the number of words delay for translating a given source sentence.

b \ w	0	1	2	3	4	5
1	34.57	-	-	-	-	-
3	-	+1.3	+1.8	+1.2	+2.0	+1.7
5	-	+1.6	+1.9	+1.3	+1.5	+1.3
7	-	+1.5	+2.0	+1.0	+1.6	+1.4
10	-	+1.4	+2.2	+1.4	+1.5	+1.7

Table 2: Zh→En wait-1 model BLEU improvement of SBS against greedy search ($b=1$, $w=0$) on dev-set. When $w \geq 5$ the performance of SBS becomes stable.

Figure 5: Chinese-to-English example on dev set. †: test-time wait-k; ‡: wait-k. *: full-sentence beam search.

4.2 Performance on Wait-k Policy

We perform experiments on validation set using speculative beam search (SBS) with beam sizes $b \in \{3, 5, 7, 10\}$ and speculative window sizes $w \in \{1, 2, 3, 4, 5\}$. Table 2 shows the BLEU score of different b and w over wait-1 model. Compared with greedy decoding, SBS improves at least 1.0 BLEU score in all cases and achieves best performance by $b = 10, w = 2$. We search the best b and w for each model on dev-set and apply them on test-set in the following experiments.

Fig. 3 shows the performance of conventional greedy decoding, trivial tail beam search (only after source sentence is finished) and SBS on test set on Chinese↔English tasks. SBS largely boost test-time wait-k models with slightly worse latency (especially in English→Chinese because they tend to generate longer sentences). Wait-k models also benefit from speculation (especially in Chinese→English).

Fig. 5 shows a running example of greedy and SBS output of both wait-k and test-time wait-k models. SBS on test-time wait-k generates much better outputs than the greedy search, which misses some essential information. Wait-k models with speculation correctly translates "拟" into "intends to" instead of "to" in greedy output.

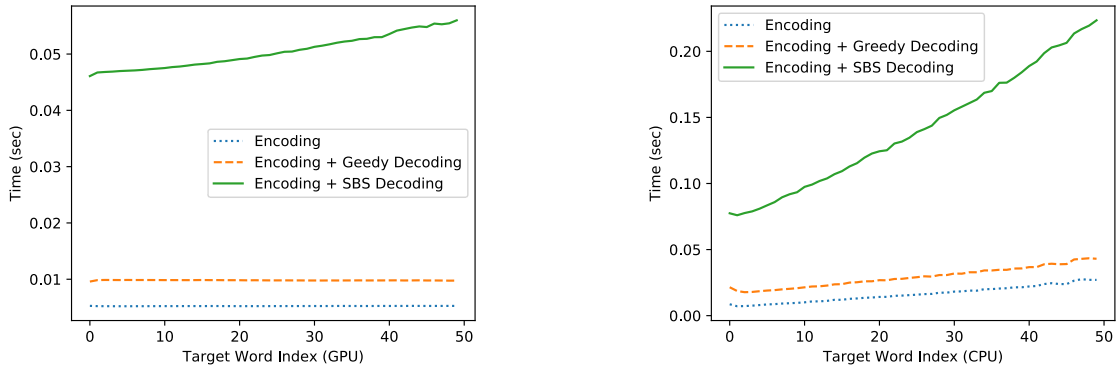

Figure 6: Average time of words with different indices (≤ 50) on zh→en wait-3 model. Results in left figure are measured on GPU while results in right figure results are measured on CPU. The SBS results adopt $w = 2, b = 5$.

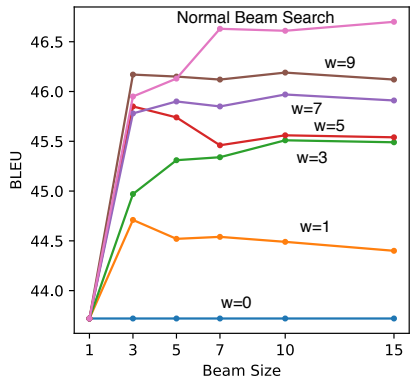

Figure 7: BLEU of SBS over full sentence translation with different window sizes w and beam sizes b. Window size $w = 0$ stands for greedy decoding. The top line stands for results using normal beam search.

4.3 Performance on Adaptive Policy

Fig. 4 shows the performance of proposed SBS on adaptive policies. We train adaptive policies using the combination of Consecutive Wait (CW $\in \{2, 5, 8\}$ (Gu et al., 2017)) and partial-BLEU as reward in reinforcement learning. We vary beam size $b \in \{5, 10\}$ in both chunk-based beam search (Gu et al., 2017) and our SBS with speculative window size $w \in \{2, 4\}$. Our proposed beam search achieves better results in most cases.

4.4 Running Time Analysis

Fig. 6 shows the average time for generating words with different target word indices on a GeForce GTX TITAN-X GPU and an Intel Core i7 2.8 GHz CPU. According to Ma et al. (2019a), wait-k models use bi-directional Transformer as the encoder, thus the time complexity of incrementally encoding one more source word is $O(m^2)$ where m is the source sentence length. This is the reason why it takes more time to encode words with larger index especially using CPU. It is generally accepted that Mandarin speech is about 120–150 syllables per minute, and in our corpus each token (after BPE) has on average 1.5 Chinese syllables (which is 1.5 characters since each Chinese character is monosyllabic), thus in the simultaneous Chinese-to-English speech-to-text translation scenario, the decoder receives a source token every 0.6–0.75 seconds which is much slower than our decoding speed (less than 0.25 seconds per token) even on a laptop CPU. Based on these statistics, our proposed speculative beam search algorithm can be used in real simultaneous translation.

4.5 Performance on Full Sentence MT

We analyze the performance of speculative beam search on full-sentence translation (see Fig. 7). By only performing beam search on a sliding speculative window, the proposed algorithm achieves much better BLEU scores compared with greedy decoding ($w = 0$) and even outperforms conventional beam search when $w = 9$, $b = 3$. Please note that the space complexity of this algorithm is $O((m + n + wb)d)$.[1] This is better than conventional beam search whose space complexity is $O((m + nb)d)$ when $w \ll n$.

5 Conclusions and Future Work

We have proposed speculative beam search for simultaneous translation. Experiments on three approaches to simultaneous translation demonstrate effectiveness of our method. This algorithm has the potential in other incremental tasks such as streaming ASR and incremental TTS.

Acknowledgments

We thank Kaibo Liu for his AL script[2] and help in training wait-k models, and the anonymous reviewers for suggestions.

A Supplemental Material

We also evaluate our work using Consecutive Wait (CW) as latency metric, which measures the average lengths of consecutive wait segments, and perform experiments on German↔English corpora available from WMT15[3]. We use newstest-2013 as dev-set and newstest-2015 as test-set.[4]

Fig. 8 show the translation quality on German↔English against AL of different decoding methods. Consistent to the results of Chinese↔English, our proposed speculative beam search gain large performance boost especially on test-time wait-k. Fig. 9 and Fig. 10 use CW as latency metrics. Since both the wait-k and test-time wait-k models use the same fixed policy, the CW latencies of the same k are identical.

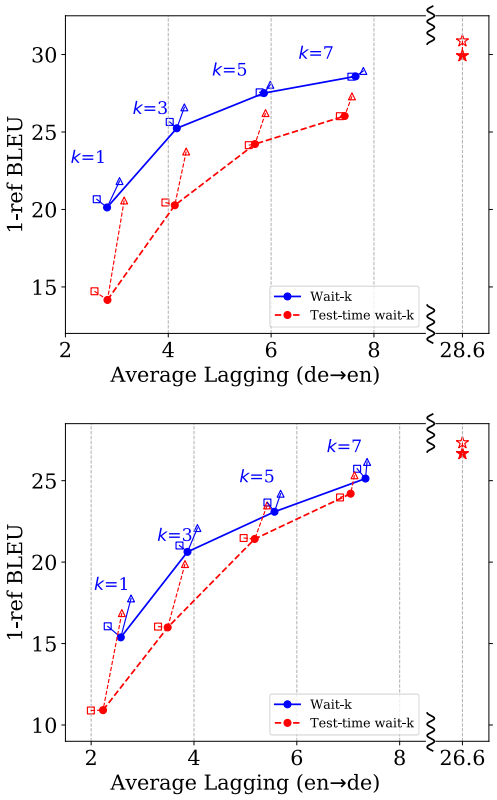

Figure 8: Translation quality against AL on English↔German simultaneous translation using wait-k model. □ □: conventional beam search only on target tail. △ △: speculative beam search. ★☆:full-sentence (greedy and beam-search).

[3] http://www.statmt.org/wmt15/translation-task.html

[4] The German↔English results are slightly different from those in Ma et al. (2019a) because of different decoding settings. We do not allow that the decoder stops earlier than the finish of source sentence while it is allowed in German↔English experiments of Ma et al. (2019a). This makes our generated sentences longer and further results in worse AL compared with the results in Ma et al. (2019a).

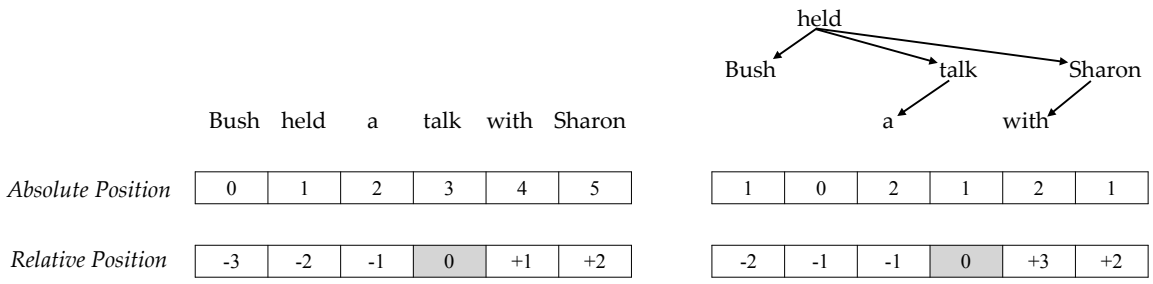
Abstract

Although self-attention networks (SANs) have advanced the state-of-the-art on various NLP tasks, one criticism of SANs is their ability of encoding positions of input words (Shaw et al., 2018). In this work, we propose to augment SANs with *structural position representations* to model the latent structure of the input sentence, which is complementary to the standard sequential positional representations. Specifically, we use dependency tree to represent the grammatical structure of a sentence, and propose two strategies to encode the positional relationships among words in the dependency tree. Experimental results on NIST Chinese⇒English and WMT14 English⇒German translation tasks show that the proposed approach consistently boosts performance over both the absolute and relative sequential position representations.

1 Introduction

In recent years, self-attention networks (SANs, Parikh et al., 2016; Lin et al., 2017) have achieved the state-of-the-art results on a variety of NLP tasks (Vaswani et al., 2017; Strubell et al., 2018; Devlin et al., 2019). SANs perform the attention operation under the position-unaware "bag-of-words" assumption, in which positions of the input words are ignored. Therefore, absolute position (Vaswani et al., 2017) or relative position (Shaw et al., 2018) are generally used to capture the sequential order of words in the sentence. However, several researches reveal that the sequential structure may not be sufficient for NLP tasks (Tai et al., 2015; Kim et al., 2017; Shen et al., 2019), since sentences inherently have hierarchical structures (Chomsky, 1965; Bever, 1970).

In response to this problem, we propose to augment SANs with *structural position representations* to capture the hierarchical structure of the input sentence. The starting point for our approach is a recent finding: the latent structure of a sentence can be captured by structural depths and distances (Hewitt and Manning, 2019). Accordingly, we propose *absolute structural position* to encode the depth of each word in a parsing tree, and *relative structural position* to encode the distance of each word pair in the tree.



We implement our structural encoding strategies on top of TRANSFORMER (Vaswani et al., 2017) and conduct experiments on both NIST Chinese⇒English and WMT14 English⇒German translation tasks. Experimental results show that exploiting structural position encoding strategies consistently boosts performance over both the absolute and relative sequential position representations across language pairs. Linguistic analyses (Conneau et al., 2018) reveal that the proposed structural position representation improves the translation performance with richer syntactic information. Our main contributions are:

- Our study demonstrates the necessity and effectiveness of exploiting structural position encoding for SANs, which benefits from modeling syntactic depth and distance under the latent structure of the sentence.
- We propose structural position representations for SANs to encode the latent structure of the input sentence, which are complementary to their sequential counterparts.

2 Background

Self-Attention SANs produce representations by applying attention to each pair of elements from the input sequence, regardless of their distance. Given an input sequence $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_I\} \in \mathbb{R}^{I \times d}$, the model first transforms

(a) **Sequential** Position Encoding (b) **Structural** Position Encoding

Figure 1: Illustration of (a) the standard *sequential position encoding* (Vaswani et al., 2017; Shaw et al., 2018), and (b) the proposed *structural position encoding*. The relative position in the example is for the word "talk".

it into queries $\mathbf{Q} \in \mathbb{R}^{I\times d}$, keys $\mathbf{K} \in \mathbb{R}^{I\times d}$, and values $\mathbf{V} \in \mathbb{R}^{I\times d}$:

$$\mathbf{Q}, \mathbf{K}, \mathbf{V} = \mathbf{X}\mathbf{W}_Q, \mathbf{X}\mathbf{W}_K, \mathbf{X}\mathbf{W}_V \in \mathbb{R}^{I\times d}, \quad (1)$$

where $\{\mathbf{W}_Q, \mathbf{W}_K, \mathbf{W}_V\} \in \mathbb{R}^{d\times d}$ are trainable parameters and d indicates the hidden size. The output sequence is calculated as

$$\mathbf{O} = \textsc{Att}(\mathbf{Q}, \mathbf{K})\, \mathbf{V} \qquad \in \mathbb{R}^{I\times d}, \quad (2)$$

where $\textsc{Att}(\cdot)$ is a dot-product attention model.

Sequential Position Encoding To make use of the order of the sequence, information about the absolute or relative position of the elements in the sequence is injected into SAN:

- *Absolute* Sequential PE (Vaswani et al., 2017) is defined as

$$\textsc{AbsPE}(abs) = f(abs/10000^{2i/d}), \quad (3)$$

  where abs is the absolute position in the sequence and i is the dimension of position representations. $f(\cdot)$ is $\sin(\cdot)$ for the even dimension, and $\cos(\cdot)$ for the odd dimension.

  Vaswani et al. (2017) propose to conduct element-wise addition to combine the fixed sequential position representation with word embedding and feed the combination representation to the SANs.

- *Relative* Sequential PE (Shaw et al., 2018) is calculated as

$$\textsc{RelPE}(rel) = \mathbf{R}[rel], \quad (4)$$

  where rel is the relative position to the queried word, which is used to index a learnable matrix $\mathbf{R}$ that represents relative position embeddings.

  Shaw et al. (2018) propose relation-aware SANs and take the relative sequential encoding as the additional key and value (Eq.2) in the attention computation.

Figure 1(a) shows an example of absolute (i.e., abs) and relative (i.e., rel) sequential positions.

3 Approach

3.1 Structural Position Representations

In this study, we choose dependency tree to represent sentence structure for its simplicity on modeling syntactic relationships among input words. Figure 1 shows an example to illustrate the idea of the proposed approach. From the perspective of relationship path between words, sequential PE measures the sequential distance between the words. As shown in Figure 1 (a), for each word, absolute sequential position represents the sequential distance to the beginning of the sentence, while relative sequential position measures the relative distance to the queried word ("talk" in the example).

The latent structure can be interpreted in various ways, from syntactic tree structures, e.g., constituency tree (Collins, 2003) or dependency tree (Kübler et al., 2009), to semantic graph structures, e.g., abstract meaning representation graph (Banarescu et al., 2013). In this work, dependency path, which is induced from the dependency tree, is adopted to provide a new perspective on modelling pairwise relationships.

Figure 1 shows the difference between the sequential path and dependency path. The sequential distance between the two words "held" and "talk" is 2, while their structural distance is only 1 as word "talk" is the dependent of the head "held" (Nivre, 2005).

***Absolute* Structural Position** We exploit the tree depth of the word in the dependency tree as its absolute structural position. Specifically, we treat the main verb (Tapanainen and Jarvinen, 1997) of the sentence as the origin and use the distance of the dependency path from the target word to the origin as the absolute structural position

$$abs_{stru}(x_i) = distance_{tree}(x_i, origin), \quad (5)$$

where x_i is the target word, $tree$ is the given dependency structure and the origin is the main verb of the $tree$.

In the field of NMT, *BPE sub-words* and *end-of-sentence symbol* should be carefully handled as they do not appear in the conventional dependency tree. In this work, we assign the *BPE sub-words* share the absolute structural position of the original word and set the the first larger integer than the max absolute structural position in dependency tree as the absolute structural position of *end-of-sentence symbol*.

***Relative* Structural Position** For the *relative* structural position $rel_{stru}(x_i, x_j)$, we calculate $rel_{stru}(x_i, x_j)$ in the dependency tree following two hierarchical rules:

1. if x_i and x_j are at same dependency edge, $rel_{stru}(x_i, x_j) = abs_{stru}(x_i) - abs_{stru}(x_j)$.
2. if x_i and x_j are at different dependency edges, $rel_{stru}(x_i, x_j) = f_{stru}(i - j) * (abs_{stru}(x_i) + abs_{stru}(x_j))$, where

$$f_{stru}(x) = \begin{cases} 1 & x > 0 \\ 0 & x = 0 \\ -1 & x < 0 \end{cases} \quad (6)$$

Following Shaw et al. (2018), we use clipping distance r to limit the maximum relative position.

3.2 Integrating Structural PE into SANs

We inherit position encoding functions from sequential approaches (Eq.3 and Eq.4) to implement the structural position encoding strategies. Since structural position representations capture complementary position information to their sequential counterparts, we also exploit to integrate the structural position encoding into SANs with the sequential counterparts approaches (Vaswani et al., 2017; Shaw et al., 2018).

For the *absolute* position, we use the nonlinear function to fuse the sequential and structure position representations[1]:

$$asb(x_i) = f_{abs}(\text{ABSPE}(abs_{seq}), \text{ABSPE}(abs_{stru})) \quad (7)$$

where f_{abs} is the nonlinear function. $\text{ABSPE}(abs_{seq})$ and $\text{ABSPE}(abs_{stru})$ are absolute sequential and structural position embedding in Eq.3 and Eq.5 respectively.

For the *relative* position, we follow Shaw et al. (2018) to extend the self-attention computation to consider the pairwise relationships and project the relative structural position as described at Eq.(3) and Eq.(4) in Shaw et al. (2018)[2].

4 Related Work

There has been growing interest in improving the representation power of SANs (Dou et al., 2018, 2019; Yang et al., 2018; Wang et al., 2018; Wu et al., 2018; Yang et al., 2019a,b; Sukhbaatar et al., 2019). Among these approaches, a straightforward strategy is that augmenting the SANs with position representations (Shaw et al., 2018; Ma et al., 2019; Bello et al., 2019; Yang et al., 2019c), as the position representations involves element-wise attention computation. In this work, we propose to augment SANs with structural position representations to model the latent structure of the input sentence.

Our work is also related to the structure modeling for SANs, as the proposed model utilizes the dependency tree to generate structural representations. Recently, Hao et al. (2019c,b) integrate the recurrence into the SANs and empirically demonstrate that the hybrid models achieve better performances by modeling structure of sentences. Hao et al. (2019a) further make use of the multi-head attention to form the multi-granularity self-attention, to capture the different granularity phrases in source sentences. The difference is that we treat the position representation as a medium to transfer the structure information from the dependency tree into the SANs.

[1] We also use parameter-free element-wise addition method to combine two absolute position embedding and get 0.28 BLEU point improvement on development set of NIST Chinese⇒English over the baseline model that only uses absolute sequential encoding.

[2] Due to the space limitations we do not show these functions. Please refer to Shaw et al. (2018) for more detail.

9			✓	✓	2.48	45.67

Table 1: Impact of the position encoding components on Chinese⇒English NIST02 development dataset using Transformer-Base model. "Abs." and "Rel." denote *absolute* and *relative* position encoding, respectively. "Spd." denotes the decoding speed (sentences/second) on a Tesla M40, the speed of structural position encoding strategies include the step of dependency parsing.

5 Experiment

We conduct experiments on the widely used NIST Chinese⇒English and WMT14 English⇒German data, and report the 4-gram BLEU score (Papineni et al., 2002).

Chinese⇒English We use the training dataset consists of about 1.25 million sentence pairs. NIST 2002 (MT02) dataset is used as development set. NIST 2003, 2004, 2005, 2006 datasets are used as test sets. We use byte-pair encoding (BPE) toolkit to alleviate the out-of-vocabulary problem with 32K merge operations.

English⇒German We use the dataset consisting of about 4.5 million sentence pairs as the training set. The newstest2013 and newstest2014 are used as the development set and the test set. We also apply BPE with 32K merge operations to obtain subword unit.

We evaluate the proposed position encoding strategies on TRANSFORMER (Vaswani et al., 2017) and implement them on top of THUMT (Zhang et al., 2017). We use the Stanford parser (Klein and Manning, 2003) to parse the sentences and obtain the structural structural absolute and relative position as described in Section 3. When using relative structural position encoding, we use clipping distance $r = 16$. To make a fair comparison, we valid different position encoding strategies on the encoder and keep the TRANSFORMER decoder unchanged. We study the variations of the BASE model on Chinese⇒English task, and evaluate the overall performance with the BIG model on both translation tasks.

5.1 Model Variations

We evaluate the importance of the proposed absolute and relative structural position encoding strategies and study the variations with *Transformer-Base* model on Chinese⇒English data. The experimental results on the development set are shown in Table 1.

Effect of Position Encoding We first remove the sequential encoding from the *Transformer* encoder (Model #1) and observe the translation performance degrades dramatically ($28.33 - 44.31 = -15.98$), which demonstrates the necessity of the position encoding strategies.

Effect of Structural Position Encoding Then we valid our proposed structural position encoding strategies over the position-unaware model (Models #2-3). We find that absolute and relative structural position encoding strategies improve the translation performance by 7.10 BLEU points and 5.90 BLEU points respectively, which shows that the introducing of the proposed absolute and relative structural positions improves the translation performance in terms of BLEU score.

Combination of Sequential and Structural Position Encoding Strategies We integrate the absolute and relative structural position encoding strategies into the *Base* model equipped with absolute sequential position encoding (Models #4-6). We observe that the proposed two approaches are able to achieve improvements over the *Base* model with decoding speed marginally decreases.

Finally, we valid the proposed structural position encoding over the *Base* model equipped with absolute and relative sequential position encoding (Models #7-9). We find that sequential relative encoding obtains 0.71 BLEU points improvement (Model #7 vs. Model #4) and structural position encoding achieves a further improvement in performance by 0.65 BLEU points (Model #9 vs. Model #7), demonstrating the effectiveness of the proposed structural position encoding strategies.

5.2 Main Results

We valid the proposed structural encoding strategies over *Transformer-Big* model in

Model Architecture	Zh⇒En					En⇒De
	MT03	MT04	MT05	MT06	Avg	WMT14
Hao et al. (2019c)	-	-	-	-	-	28.98
Transformer-Big	45.30	46.49	45.21	44.87	45.47	28.58
+ *Structural* PE	45.62	47.12$^{\uparrow}$	45.84	45.64$^{\Uparrow}$	46.06	28.88
+ *Relative* Sequential PE	45.45	47.01	45.65	45.87$^{\Uparrow}$	46.00	28.90
+ *Structural* PE	45.85$^{\uparrow}$	47.37$^{\Uparrow}$	46.20$^{\Uparrow}$	46.18$^{\Uparrow}$	46.40	29.19$^{\Uparrow}$

Table 2: Evaluation of translation performance on NIST Zh⇒En and WMT14 En⇒De test sets. Hao et al. (2019c) is a *Transformer-Big* model which adopted an additional recurrence encoder with the attentive recurrent network to model syntactic structure. "↑ / ⇑": significant over the *Transformer-Big* ($p < 0.05/0.01$), tested by bootstrap resampling (Koehn, 2004).

Model	Surface			Syntactic				Semantic					
	SeLen	WC	Avg	TrDep	ToCo	BShif	Avg	Tense	SubN	ObjN	SoMo	CoIn	Avg
BASE	92.20	63.00	77.60	44.74	79.02	71.24	65.00	89.24	84.69	84.53	52.13	62.47	74.61
+ *Rel. Seq.* PE	89.82	63.17	76.50	45.09	78.45	71.40	64.98	88.74	87.00	85.53	51.68	62.21	75.03
+ *Stru.* PE	89.54	62.90	76.22	46.12	79.12	72.36	65.87	89.30	85.47	84.94	52.90	62.99	75.12

Table 3: Performance on linguistic probing tasks. The probing tasks were conducted by evaluating linguistics embedded in the *Transformer-Base* encoder outputs. "Base", "+ *Rel. Seq.* PE", "+ *Stru.* PE" denote *Transformer-Base*, *Transformer-Base* with relative sequential PE, *Transformer-Base* with relative sequential PE and structural PE models respectively.

Chinese⇒English and English⇒German data, and list the results in Table 2.

For Chinese⇒English, Structural position encoding (+ *Structural* PE) outperforms the *Transformer-Big* by 0.59 BLEU points on average over four NIST test sets. Sequential relative encoding approach (+*Relative* Sequential PE) outperforms the *Transformer-Big* by 0.53 BLEU points, and structural position encoding (+ *Structural* PE) achieves further improvement up to +0.40 BLEU points and outperforms the *Transformer-Big* by 0.93 BLEU points. For English⇒German, similar phenomenon is observed, which reveals that the proposed structural position encoding strategy can consistently boost translation performance over both the absolute and relative sequential position representations.

5.3 Linguistic Probing Evaluation

We conduct probing tasks[3] (Conneau et al., 2018) to evaluate structure knowledge embedded in the encoder output in the variations of the *Base* model that are trained on En⇒De translation task.

We follow Wang et al. (2019) to set model configurations. The experimental results on probing tasks are shown in Table 3, and the BLEU scores of "Base", "+ *Rel. Seq.* PE", "+ *Stru.* PE" are 27.31, 27.99 and 28.30. From the table, we can see 1) adding the relative sequential positional embedding achieves improvement over the baseline on semantic tasks (75.03 vs. 74.61). This may indicate the model benefits more from semantic modeling; 2) with the structural positional embedding, the model obtains improvement on syntactic tasks (65.87 v.s. 64.98), which indicates that the representations preserve more syntactic knowledge.

6 Conclusion

In this paper, we have presented a novel structural position encoding strategy to augment SANs by considering the latent structure of the input sentence. We extract structural absolute and relative positions from the dependency tree and integrate them into SANs. Experimental results on Chinese⇒English and English⇒German translation tasks have demonstrated that the proposed approach consistently improve translation performance over both the absolute and relative sequential position representations.

Future directions include inferring the structure representations from the AMR (Song et al., 2019) or the external SMT knowledge (Wang et al., 2017). Furthermore, the structural position encoding can be also applied to the decoder with RNN Grammars (Dyer et al., 2016; Eriguchi et al., 2017), which we leave for future work.

Abstract

This paper highlights the impressive utility of multi-parallel corpora for transfer learning in a one-to-many low-resource neural machine translation (NMT) setting. We report on a systematic comparison of multistage fine-tuning configurations, consisting of (1) pre-training on an external large (209k–440k) parallel corpus for English and a helping target language, (2) mixed pre-training or fine-tuning on a mixture of the external and low-resource (18k) target parallel corpora, and (3) pure fine-tuning on the target parallel corpora. Our experiments confirm that multi-parallel corpora are extremely useful despite their scarcity and content-wise redundancy thus exhibiting the true power of multilingualism. Even when the helping target language is not one of the target languages of our concern, our multistage fine-tuning can give 3–9 BLEU score gains over a simple one-to-one model.

1 Introduction

Encoder-decoder based neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015) allows for end-to-end training of a translation model. While NMT is known to perform well for resource-rich language pairs, such as French–English and German–English (Bojar et al., 2018), it performs poorly for resource-poor pairs (Zoph et al., 2016; Riza et al., 2016).

Translating from a resource-poor language into English is typically easier than the other direction, because large parallel corpora between English and other languages can be used for transfer learning (Zoph et al., 2016) and many-to-one modeling.[1] Additionally, large English monolingual data can be back-translated to obtain pseudo-parallel corpora for augmenting the performance of such NMT models.

Translating from English into a resource-poor language is substantially more difficult. Dong et al. (2015) have shown that a one-to-many model trained on middle-sized parallel data (200k sentence pairs) can improve the translation quality over a one-to-one model. However, it is unclear whether this works for much resource-poorer, more distant, and more diverse language pairs. Using pseudo-parallel data is a potential solution, but for most resource-poor languages, the amount of available clean and in-domain monolingual data are limited. It is also unclear what the real reason behind improvements in translation is: increase in the training data or multilingualism.

This paper focuses on (a) improving the performance of NMT for translating English to low-resource languages (b) via exploiting multilingualism (c) through transfer learning based on multistage fine-tuning. The power of multilingualism is verified by using multi-parallel corpora, i.e., the same text in different languages.[2] Unlike previous studies that only apply single-stage fine-tuning for one-to-one translation (Zoph et al., 2016), we systematically compare multistage fine-tuning that exploits one-to-many modeling. We show that our approach can significantly improve the quality of translations from English to seven Asian languages (Bengali, Filipino, Indonesian, Japanese, Khmer, Malay, and Vietnamese) in the Asian Language Treebank (ALT) corpus (Riza et al., 2016),[3] as a result of soft division of labor: training of a strong English encoder, domain adaptation, and tuning of the decoder for each target language.

[1] Note that "many-to-one" does not mean multi-source machine translation (Zoph and Knight, 2016).

[2] Adding a new language does not add any new translation knowledge. Such corpora deserve more attention, since adding a new language to it leads to parallel corpora between the new language and all the other languages in the corpora.

[3] There exist other multi-parallel corpora, such as those for United Nations (Ziemski et al., 2016), Europarl (Koehn, 2005), Ted Talks (Cettolo et al., 2012), ILCI (Jha, 2010), and the Bible (Christodouloupoulos and Steedman, 2015).

2 Related Work

In this paper, we address (a) the importance of multilingualism (b) via one-to-many NMT (c) through robust fine-tuning for transfer learning. Dong et al. (2015) have worked on one-to-many NMT, whereas Firat et al. (2016) and Johnson et al. (2017) have worked on multilingual and multi-way NMT. These studies have focused on training a multilingual model from scratch, but we explore transfer learning for one-to-many NMT.

Fine-tuning based transfer learning has been studied for transferring proper parameters (Zoph et al., 2016; Gu et al., 2018b), lexical (Zoph et al., 2016; Nguyen and Chiang, 2017; Gu et al., 2018a; Lakew et al., 2018), and syntactic (Gu et al., 2018a; Murthy et al., 2018) knowledge from a resource-rich language pair to a resource-poor language pair. On the other hand, Chu et al. (2017) proposed a more robust training approach for domain adaptation, called mixed fine-tuning, which uses a mixture of data from different domains. Imankulova et al. (2019) proposed a multistage fine-tuning method which combines fine-tuning techniques for domain adaptation and back-translation (Sennrich et al., 2016). Unlike us, these approaches do not try to combine multilingualism with multistage fine-tuning using only parallel corpora involving a large number of languages.

3 Multistage Fine-Tuning for NMT

This paper focuses on translation from English (En) to N different languages. In particular, we consider exploiting two types of corpora. One is a small-scale multi-parallel corpus, En-YY_1-$\cdots$-YY_N, consisting of English and N target languages of interest. The other is a relatively larger helping parallel corpus, En-XX, where XX indicates the helping target language which needs not be one of the target languages in the multi-parallel corpus, YY_k $(1 \leq k \leq N)$.

All the fine-tuning techniques that we examine can be generalized as follows.

Pre-training (Pre): An initial NMT model is trained on a parallel corpus for a resource-rich language pair, i.e., En-XX.

Mixed pre-training / fine-tuning (Mix): Training of the NMT model is newly started or continued (Chu et al., 2017) on a mixture of parallel corpora for En-XX and one or more low-resource En-YY pairs.

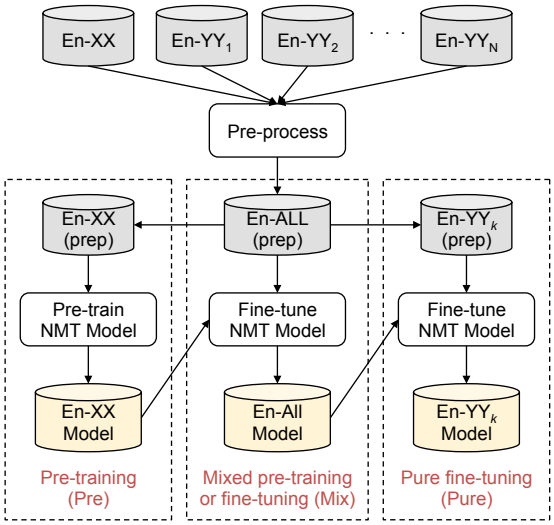

Figure 1: Our multistage fine-tuning for one-to-many NMT. Three dotted sections respectively indicate (a) the pre-training stage, (b) the mixed pre-training / fine-tuning stage, and (c) the pure fine-tuning stage The training data for (a) and (c), i.e., "En-XX (prep)" and "En-YY_k (prep)," are selectively extracted from the pre-processed data labeled "En-ALL (prep)."

Pure fine-tuning (Pure): Training further continues using only a parallel corpus for a particular En-YY pair.

Figure 1 illustrates the training procedure with all of the above three stages. Before starting the training, vocabularies for source and target languages are determined. First, to indicate the target language of each sentence pair, we prepend an artificial token, for instance "2zz" for a target language "zz," onto source sentences (Johnson et al., 2017). All corpora are then concatenated into a single corpus, "En-ALL (prep)," where each of the smaller corpora are enlarged by oversampling so that the size of each corpus matches the largest one. Finally, (sub-word) vocabularies are determined based on "En-ALL (prep)." For simplicity, we keep source and target vocabularies separate, but the target vocabulary is shared by multiple languages. Note that all the NMT models are essentially one-to-many, because they use a shared target vocabulary of XX and one or all of YY_k.

Our training procedure can be viewed as a soft division of labor in NMT training: the first stage learns a strong English encoder by training on a large parallel corpus,[4] whereas the remaining

[4]One may be interested in training an English encoder on a gigantic monolingual corpus. We leave a comparison of the utility of such monolingual corpora and the parallelism in bilingual corpora for our future work.

stages can focus more on training the decoder for the target language(s) of interest and updating the encoder. Whereas we pre-train an encoder for low-resource NMT, so do McCann et al. (2017) to improve several monolingual NLP tasks.

4 Experiments

We conducted a systematic comparison of multistage fine-tuning configurations, specifically focusing on low-resource English-to-Asian language translation.

4.1 Datasets and Pre-processing

As the test-bed, we chose the ALT multilingual multi-parallel corpus[5] (Riza et al., 2016), because it offers the same test sentences in different languages, allowing us to determine whether multilingualism is the true reason behind improved translation quality. We used seven Asian languages[6] as the target languages (i.e., YY): Bengali (Bn), Filipino (Tl), Indonesian (Id), Japanese (Ja), Khmer (Km), Malay (Ms), and Vietnamese (Vi). We randomly[7] split the ALT data into 18,000, 1,000, and 1,106 multi-parallel sentences for training, development, and testing, respectively.

As for the resource-rich En-XX data, we separately used two parallel corpora with two different target languages. One is the IWSLT 2015 English–Chinese corpus (IWSLT En-Zh) (Cettolo et al., 2015), comprising 209,491 parallel sentences. We chose it to examine whether the target language (Chinese) other than the target languages in our setting is helpful. Separately, we also experimented with the Kyoto free translation task English–Japanese corpus (KFTT En-Ja),[8] consisting of Japanese-to-English translations: 440,288 parallel sentences. With this corpus, we could additionally observe how ALT En-Ja can benefit from KFTT En-Ja. Note that the ALT, IWSLT, and KFTT corpora belong to the news, spoken, and Wikipedia domains, respectively.

We tokenized English sentences using the *tokenizer.perl* script in Moses.[9] To tokenize Chinese and Japanese sentences, we used KyotoMorph[10] and JUMAN,[11] respectively. For the other languages in the ALT corpus, we used the data in its raw form, except Khmer for which segmented data were provided by the ALT project.

4.2 Training NMT Models

We compared a total of seven training configurations as shown in Table 1. The model #1 is the simplest baseline model trained only on the En-YY parallel corpus. The models #2 to #4 are three conceivable combinations of fine-tuning stages that exploit an external large parallel corpus for En-XX, showing the limit reachable without a multi-parallel corpus. The models #5 to #7 follow the same training procedure with #2 to #4, respectively, exploiting a small-scale but multi-parallel corpus containing all the seven target languages.

Note that the source side vocabulary is the same across models #2 to #7 and is determined using the English side of the En-XX corpus and the English part of the multi-parallel corpus. On the other hand, the target side vocabulary for models #2 to #4 is different from the vocabulary for models #5 to #7. This is because vocabularies for models #2 to #4 involve the target side of the En-XX corpus and "one" non-English corpus from the multi-parallel corpus. On the other hand, the vocabularies for models #5 to #7 involve the target sides of the En-XX corpus and "all" non-English corpora from the multi-parallel corpus.

We used the open-source implementation of the Transformer model (Vaswani et al., 2017) in the version 1.6 branch of *tensor2tensor*,[12] and used hyper-parameter settings[13] corresponding to *transformer_base_single_gpu* which uses dropout by default. We also used the default sub-word segmentation mechanism of tensor2tensor. The "En-YY" models (#1) used a vocabulary of 8,192 (2^{13}) sub-words due to small corpora sizes, whereas all the other models used a vocabulary of 32,768 (2^{15}) sub-words to account for the larger amount of parallel data in multiple languages. We trained the models for a sufficient number of iterations till

[5] http://www2.nict.go.jp/astrec-att/member/mutiyama/ALT/

[6] Thai and Burmese (Myanmar) were excluded due to the unavailability of reliable tokenized data. Although some of the YY languages in our experiments, such as Japanese, were relatively resource-rich, we exploited only a small parallel corpus between them and English to highlight the importance of multilingualism.

[7] Our results might not be comparable to those obtained using the official splits mentioned on the website.

Table 1: BLEU scores for all the tested configurations. The "XX" column indicates the resource-rich external (helping) parallel corpus if used, where "Zh" and "Ja" stand for using the IWSLT English–Chinese and the KFTT English–Japanese corpora, respectively. The columns under "YY test set" indicate the the target languages in our multi-parallel corpus, where **bold** marks the best scores for each target language with each external parallel corpus. The "$*$," "$+$," and "$\dagger$" respectively mark the scores significantly (bootstrap re-sampling with $p < 0.05$) better than the 1-to-1 "En-YY" model (#1), the best model without the multi-parallel corpus (#2–#4), and the strongest baselines (#5–#6).

the BLEU score on the development set (simply concatenated unlike training data) did not vary by more than 0.1 BLEU over 10 checkpoints.

Instead of choosing the model with the best development set BLEU, we averaged the last 10 checkpoints saved every after 1,000 updates, following Vaswani et al. (2017), and decoded the test sets with a beam size of 4 and a length penalty, α, of 0.6 consistently across all the models.

4.3 Results

Table 1 gives the BLEU scores (Papineni et al., 2002) for all the configurations. Among the seven configurations, irrespective of the external parallel corpus for En-XX, the three-stage fine-tuned model (#7) achieved the highest BLEU scores for all the seven target languages.

Results for #1 demonstrate that NMT systems trained on 18k parallel sentences can achieve only poor results for Bn and Ja, whereas reasonably high BLEU scores (> 20) are achieved for the other target languages.

Introducing a large external En-XX parallel corpus improved the translation quality consistently and significantly for all the seven target languages,[14] irrespective of the way of its use: simple pre-training (#2), mixed pre-training (#3), and their combination (#4). Among these three training configurations, in most cases, the simple pre-training (#2) attained the best performance. The BLEU gains over #1 were 2.67 (Ms) to 8.04 (Ja) points with the IWSLT En-Zh corpus and 2.43 (Id) to 10.52 (Ja) points with the KFTT En-Ja corpus.

Simple fine-tuning (#2 and #5) gave great improvements over the baseline. However, #5 was worse than #2, despite being trained in the same way, because #5 involves up to eight target languages, inevitably reducing the allowance for each target language. In contrast, exploiting the multi-parallel corpus through mixed pre-training (#6) or mixed fine-tuning (#7) brought consistent improvements over the corresponding 1-to-2 models (#3 and #4). Three-stage fine-tuning (#4 and #7) was always better than two-stage fine-tuning (#3 and #6), because the pre-final model in #4 and #7, obtained using mixed-fine tuning, was superior to and more robust than the one in #3 and #6, obtained using naive multilingual training. These comparisons also justifies the utility of external large parallel corpus for En-XX. #7 was substantially better than #5 simply because the pre-final model in #7 was also trained on multilingual data, unlike the one in #5.

Irrespective of the external parallel corpus for En-XX, the three-stage fine-tuned model (#7) achieved the highest BLEU scores for all the seven target languages, consistently outperforming the other models, with gains over the best scores of 0.14 (Id) to 0.87 (Bn) BLEU points with the

[14] We suspected that the gain is partially owing to the use of the larger vocabularies of these models. However, we only obtained translations of degraded quality with a larger vocabulary size of #1, presumably due to the scarce parallel data for En-YY language pair.

IWSLT En-Zh corpus and 0.23 (Tl) to 1.67 (Id) BLEU points with the KFTT En-Ja corpus. As mentioned in Section 4.2, these models do not introduce any new source sentences compared to the models #2 to #4. Therefore, we can safely conclude that the gain is due to multilingualism.

5 Discussion

In this section, we discuss the effect of the two types of corpora, i.e., external large parallel corpora and small multi-parallel corpora.

5.1 Does the Nature of Corpora Matter?

When using only one En-YY language pair (#2 to #4), only for the three-stage fine-tuned model (#4), the KFTT En-Ja corpus showed slight but consistent superiority (for Tl, Id, Km, and Vi) over the IWSLT En-Zh corpus. In contrast, when all the target languages were exploited (#5–#7), the KFTT En-Ja corpus consistently helped achieve significantly better results than the IWSLT En-Zh corpus. The reason could be three-fold: corpus size, overlap or similarity of helping target language with the target language of interest, and proximity of domain.

En-Ja translation using KFTT En-Ja corpus as a helping data was better by 2.52 BLEU points than when IWSLT En-Zh corpus was used. The difference in BLEU is significant, but it could be because the En-Ja corpus is more than twice the size of the En-Zh corpus. Whereas it is possible that En-Ja translation improves from the overlapping vocabularies of Chinese and Japanese, the performance of other languages also improves despite no vocabulary overlap. Consequently, we believe that translation into a low-resource target language might benefit when the language is also target side of the helping corpus but multistage fine-tuning does not require such overlap and instead shows optimal performance when it leverages multilingualism during stage-wise tuning.

In the future, we will test the above hypotheses thoroughly via some controlled experiments by using, for instance, larger scale multi-parallel corpora (Imamura and Sumita, 2018) and varieties of helping corpora.

5.2 How Does Multilingualism Help?

The ALT corpus is multi-parallel and merely comprises of the same sentences in multiple languages. Although we used seven target languages, we did not introduce new English sentences to the source side. Table 1 shows that some languages are better translated (En-Vi) than others (En-Bn). We speculate that the representations for En-Vi might be better learned than those for En-Bn. When learning all language pairs jointly, the representations of sentences with the same meaning tend to be similar. As such, the representations for En-Bn will be similar to those of En-Vi and hence the former might benefit from the potentially better representations of the latter, leading to improvements in translation quality for the former. This might be how multilingualism is responsible for the improvement in translation quality.

The results also shed light on the value of multi-parallel corpora despite their resource-scarce nature. In a practical situation, a collection of existing multiple bilingual corpora may potentially improve translation quality. Nevertheless, when we create new parallel data, multi-parallel fashion can be a less expensive option, since adding new language leads to parallel corpora between that language and all the other languages in the corpora.

6 Conclusion

We explored the use of small multi-parallel corpora and large helping parallel corpora for one-to-many NMT, which translates English to multiple languages. We proposed multistage fine-tuning and confirmed that it works significantly better than training models via fewer fine-tuning stages despite the resource-scarce and content-redundant nature of the multi-parallel corpora, thereby highlighting the usefulness of multilingualism behind the improvement in translation quality.

In the future, we will explore the utility of multistage fine-tuning for many-to-one and many-to-many NMT. We will also try to explicitly determine the impact of corpora sizes, language similarity, and domain on our approach, and propose further improvements according to our findings.

Acknowledgments

Unsupervised Domain Adaptation for Neural Machine Translation with Domain-Aware Feature Embeddings

Abstract

The recent success of neural machine translation models relies on the availability of high quality, in-domain data. Domain adaptation is required when domain-specific data is scarce or nonexistent. Previous unsupervised domain adaptation strategies include training the model with in-domain copied monolingual or back-translated data. However, these methods use generic representations for text regardless of domain shift, which makes it infeasible for translation models to control outputs conditional on a specific domain. In this work, we propose an approach that adapts models with domain-aware feature embeddings, which are learned via an auxiliary language modeling task. Our approach allows the model to assign domain-specific representations to words and output sentences in the desired domain. Our empirical results demonstrate the effectiveness of the proposed strategy, achieving consistent improvements in multiple experimental settings. In addition, we show that combining our method with back translation can further improve the performance of the model.[1]

1 Introduction

While neural machine translation (NMT) systems have proven to be effective in scenarios where large amounts of in-domain data are available (Gehring et al., 2017; Vaswani et al., 2017; Chen et al., 2018), they have been demonstrated to perform poorly when the test domain does not match the training data (Koehn and Knowles, 2017). Collecting large amounts of parallel data in all possible domains we are interested in is costly, and in many cases impossible. Therefore, it is essential to explore effective methods to train models that generalize well to new domains.

[1]Our code is publicly available at: https://github.com/zdou0830/DAFE.

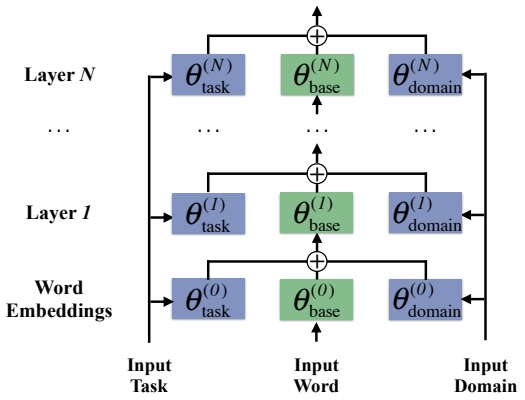

Figure 1: Main architecture of DAFE. Embedding learners generate domain- and task-specific features at each layer, which are then integrated into the output of the base network.

Domain adaptation for neural machine translation has attracted much attention in the research community, with the majority of work focusing on the supervised setting where a small amount of in-domain data is available (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016; Chu et al., 2017; Vilar, 2018). An established approach is to use domain tags as additional input, with the domain representations learned over parallel data (Kobus et al., 2017). In this work, we focus on *unsupervised* adaptation, where there are no in-domain parallel data available. Within this paradigm, Currey et al. (2017) copy the in-domain monolingual data from the target side to the source side and Sennrich et al. (2016a) concatenate back-translated data with the original corpus. However, these methods learn generic representations for all the text, as the learned representations are shared for all the domains and synthetic and natural data are treated equally. Sharing embeddings may be sub-optimal as data from different domains are inherently different. This problem is exacerbated

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1417–1422,

when words have different senses in different domains.

In this work, we propose a method of *Domain-Aware Feature Embedding* (DAFE) that performs unsupervised domain adaptation by disentangling representations into different parts. Because we have no in-domain parallel data, we learn DAFEs via an auxiliary task, namely language modeling. Specifically, our proposed model consists of a base network, whose parameters are shared across settings, as well as both domain and task embedding learners. By separating the model into different components, DAFE can learn representations tailored to specific domains and tasks, which can then be utilized for domain adaptation.

We evaluate our method in a Transformer-based NMT system (Vaswani et al., 2017) under two different data settings. Our approach demonstrates consistent improvements of up to 5 BLEU points over unadapted baselines, and up to 2 BLEU points over strong back-translation models. Combining our method with back translation can further improve the performance of the model, suggesting the orthogonality of the proposed approach and methods that rely on synthesized data.

2 Methods

In this section, we first illustrate the architecture of DAFE, then describe the overall training strategy.

2.1 Architecture

DAFE disentangles hidden states into different parts so that the network can learn representations for particular domains or tasks, as illustrated in Figure 1. Specifically, it consists of three parts: a *base network* with parameters θ_{base} that learns common features across different tasks and domains, a *domain-aware feature embedding learner* that generates embeddings $\theta^{\tau}_{\text{domain}}$ given input domain τ and a *task-aware feature embedding learner* that outputs task representations $\theta^{\gamma}_{\text{task}}$ given input task γ. The final outputs for each layer are obtained by a combination of the base network outputs and feature embeddings.

The base network is implemented in the encoder-decoder framework (Sutskever et al., 2014; Cho et al., 2014). Both the task and domain embedding learners directly output feature embeddings with look-up operations.

In this work, the domain-aware embedding learner learns domain representations $\theta^{in}_{\text{domain}}$ and $\theta^{out}_{\text{domain}}$ from in-domain and out-of-domain data respectively, and the task-aware embedding leaner learns task embeddings $\theta^{mt}_{\text{task}}$ and $\theta^{lm}_{\text{task}}$ for machine translation and language modeling.

Algorithm 1 Training Strategy

while $\theta_{\text{base}}, \theta_{\text{domain}}, \theta_{\text{task}}$ have not converged **do**
  Sample $\{(C(\mathbf{y}), \mathbf{y})\}$ from Y^{in}
  Train $\{\theta_{\text{base}}, \theta^{in}_{\text{domain}}, \theta^{lm}_{\text{task}}\}$ with Eqn. 2
  Sample $\{(C(\mathbf{y}), \mathbf{y})\}$ from Y^{out}
  Train $\{\theta_{\text{base}}, \theta^{out}_{\text{domain}}, \theta^{lm}_{\text{task}}\}$ with Eqn. 2
  Sample $\{(\mathbf{x}, \mathbf{y})\}$ from (X^{out}, Y^{out})
  Train $\{\theta_{\text{base}}, \theta^{out}_{\text{domain}}, \theta^{mt}_{\text{task}}\}$ with Eqn. 1
end while

The feature embeddings are generated at *each* encoding layer (including the source word embedding layer) and have the same size as the hidden states of the base model. It should be noted that feature embedding learners generate different embeddings at different layers.

Formally, given a specific domain τ and task γ, the output of the l-th encoding layer $\mathbf{H}^{(l)}_e$ would be:

$$\mathbf{H}^{(l)}_e = \textsc{Layer}_e(\mathbf{H}^{(l-1)}_e; \theta^{(l)}_{\text{base}}) + \theta^{\gamma,(l)}_{\text{domain}} + \theta^{\tau,(l)}_{\text{task}},$$

where $\theta^{\gamma,(l)}_{\text{domain}}$ and $\theta^{\tau,(l)}_{\text{task}}$ are single vectors and $\textsc{Layer}_e(\cdot)$ can be any layer encoding function, such as an LSTM (Hochreiter and Schmidhuber, 1997) or Transformer (Vaswani et al., 2017).

In this paper, we adopt a simple, add operation to combine outputs of different parts which already achieves satisfactory performance as shown in Section 3. We leave investigating more sophisticated combination strategies for future work.

2.2 Training Objectives

In the unsupervised domain adaptation setting, we assume access to an out-of-domain parallel training corpus (X^{out}, Y^{out}) and target-language in-domain monolingual data Y^{in}.

Neural machine translation. Our target task is machine translation. Both the base network and embedding learners are jointly trained with the objective:

$$\max_{\theta} \sum_{(\mathbf{x},\mathbf{y})\in(X^{out},Y^{out})} \log p(\mathbf{y}|\mathbf{x};\theta), \qquad (1)$$

where $\theta = \{\theta_{\text{base}}, \theta^{mt}_{\text{task}}, \theta^{out}_{\text{domain}}\}$.

Table 1: Translation accuracy (BLEU) under different settings. The second and third rows list source and target domains respectively. "DAFE w/o Embed" denotes DAFE without embedding learners and "Back-DAFE" denotes back-translation by target-to-source model trained with DAFE. DAFE outperforms other approaches when adapting between domains (row 1-5, column 2-7) and is complementary to back-translation (row 6-8).

Language modeling. We choose masked language modeling (LM) as our auxiliary task. Following Lample et al. (2018a,b), we create corrupted versions $C(\mathbf{y})$ for each target sentence $\mathbf{y}$ by randomly dropping and slightly shuffling words. During training, gradient ascent is used to maximize the objective:

$$\max_{\theta} \sum_{\mathbf{y} \in \{Y^{in} \cup Y^{out}\}} \log p(\mathbf{y}|C(\mathbf{y}); \theta), \quad (2)$$

where $\theta = \{\theta_{\text{base}}, \theta^{lm}_{\text{task}}, \theta^{out}_{\text{domain}}\}$ for out-of-domain data and $\{\theta_{\text{base}}, \theta^{lm}_{\text{task}}, \theta^{in}_{\text{domain}}\}$ for in-domain data.

Training strategy. Our training strategy is shown in Algorithm 1. The ultimate goal is to learn a set of parameters $\{\theta_{\text{base}}, \theta^{in}_{\text{domain}}, \theta^{mt}_{\text{task}}\}$ for in-domain machine translation. While out-of-domain parallel data allows us to train $\{\theta_{\text{base}}, \theta^{out}_{\text{domain}}, \theta^{mt}_{\text{task}}\}$, the monolingual data help the model learn both $\theta^{in}_{\text{domain}}$ and $\theta^{out}_{\text{domain}}$.

3 Experiments

3.1 Setup

Datasets. We validate our models in two different data settings. First, we train on the law, medical and IT datasets of the German-English OPUS corpus (Tiedemann, 2012) and test our methods' ability to adapt from one domain to another. The dataset contain 2K development and test sentences in each domain, and about 715K, 1M and 337K training sentences respectively. These datasets are relatively small and the domains are quite distant from each other. In the second setting, we adapt models trained on the general-domain WMT-14 datasets into both the TED (Duh, 2018) and law, medical OPUS datasets. For this setting, we consider two language pairs, namely Czech and German to English. The Czech-English and German-English datasets consist of 1M and 4.5M sentences and the development and test sets contain about 2K sentences.

Models. We implement DAFE on top of the Transformer model. Both the encoder and decoder consist of 4 layers and the hidden size is set to 512. Byte-pair encoding (Sennrich et al., 2016b) is employed to process training data into subwords for a final shared vocabulary size of 50K.

Baselines. We compare our methods with two baseline models: 1) The copied monolingual data model (Currey et al., 2017) which copies target in-domain monolingual data to the source side; 2) Back-translation (Sennrich et al., 2016a) which enriches the training data by generating synthetic in-domain parallel data via a target-to-source NMT model. We characterize the two baselines as *data-centric* methods as they rely on synthesized data. In contrast, our approach is *model-centric* as we mainly focus on modifying the model architecture. We also perform an ablation study by removing the embedding learners (denoted as "DAFE w/o Embed") and the model will just perform multi-task learning.

3.2 Main Results

Adapting between domains. As shown in the first 6 results columns of Table 1, the unadapted baseline model (row 1) performs poorly when adapting between domains. The copy method

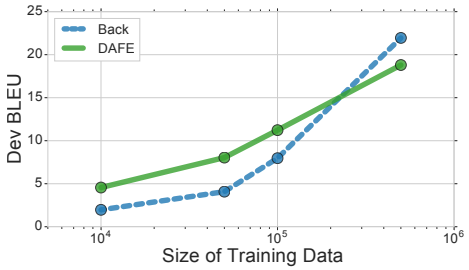

Figure 2: DAFE outperforms back-translation in low-resource scenarios.

(row 2) and back translation (row 3) both improve the model significantly, with back-translation being a better alternative to copying. DAFE (row 5) achieves superior performance compared to back-translation, with improvements of up to 2 BLEU points. Also, removing the embedding learners leads to degraded performance (row 4), indicating the necessity of their existence.

Adapting from a general to a specific domain. In the second data setting (last 6 columns of Table 1), with relatively large amounts of general-domain datasets, back-translation achieves competitive performance. In this setting, DAFE improves the unadapted baseline significantly but it does not outperform back-translation. We hypothesize this is because the quality of back-translated data is relatively good.

3.3 Combining DAFE with Back-Translation

We conjecture that DAFE is complementary to the data-centric methods. We attempt to support this intuition by combining DAFE with back-translation (the best data-centric approach). We try three different strategies to combine DAFE with back-translation, outlined in Table 1.

Simply using back-translated data to train DAFE (row 6) already achieves notable improvements of up to 4 BLEU points. We can also generate back-translated data using target-to-source models trained with DAFE, with which we train the forward model (Back-DAFE, row 7). By doing so, the back-translated data will be of higher quality and thus the performance of the source-to-target model can be improved. The overall best strategy is to use Back-DAFE to generate synthetic in-domain data and train the DAFE model with the back-translated data (Back-DAFE+DAFE, row 8). Across almost all adaptation settings, Back-DAFE+DAFE leads to higher translation quality, as per our intuition. An advantage of this setting is that the back-translated data allow us to learn $\theta^{in}_{\text{domain}}$ with the translation task.

Table 3: Controlling the output domain by providing different domain embeddings. We use compare-mt (Neubig et al., 2019) to select examples.

3.4 Analysis

Low-resource scenarios. One advantage of DAFE over back-translation is that we do not need a good target-to-source translation model, which can be difficult be acquire in low-resource scenarios. We randomly sample different amounts of training data and evaluate the performance of DAFE and back-translation on the development set. As shown in Figure 2, DAFE significantly outperforms back-translation in data-scarce scenarios, as low quality back-translated data can actually be harmful to downstream performance.

Controlling the output domain. An added perk of our model is the ability to control the output domain by providing the desired domain embeddings. As shown in Table 2, feeding mismatched domain embeddings leads to worse performance. Examples in Table 3 further suggest the model with medical embeddings as input can generate domain-specific words like "EMEA" (European Medicines Evaluation Agency) and "intramuscular", while IT embeddings encourage the model to generate words like "bug" and "developers".

4 Related Work

Most previous domain adaptation work for NMT focus on the setting where a small amount of in-domain data is available. Continued training (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016) methods first train an NMT model on out-of-domain data and then fine-tune it on the in-domain data. Similar to our work, Kobus et al.

(2017) propose to use domain tags to control the output domain, but it still needs a in-domain parallel corpus and our architecture allows more flexible modifications than just adding additional tags.

Unsupervised domain adaptation techniques for NMT can be divided into data- and model-centric methods (Chu and Wang, 2018). Data-centric approaches mainly focus on selecting or generating the domain-related data using existing in-domain monolingual data. Both the copy method (Currey et al., 2017) and back-translation (Sennrich et al., 2016a) are representative data-centric methods. In addition, Moore and Lewis (2010); Axelrod et al. (2011); Duh et al. (2013) use LMs to score the out-of-domain data, based on which they select data similar to in-domain text. Model-centric methods have not been fully investigated yet. Gulcehre et al. (2015) propose to fuse LMs and NMT models, but their methods require querying two models during inference and have been demonstrated to underperform the data-centric ones (Chu et al., 2018). There are also work on adaptation via retrieving sentences or n-grams in the training data similar to the test set (Farajian et al., 2017; Bapna and Firat, 2019). However, it can be difficult to find similar parallel sentences in domain adaptation settings.

5 Conclusion

In this work, we propose a simple yet effective unsupervised domain adaptation technique for neural machine translation, which adapts the model by domain-aware feature embeddings learned with language modeling. Experimental results demonstrate the effectiveness of the proposed approach across settings. In addition, analysis reveals that our method allows us to control the output domain of translation results. Future work include designing more sophisticated architectures and combination strategies as well as validating our model on other language pairs and datasets.

Abstract

Grammar induction aims to discover syntactic structures from unannotated sentences. In this paper, we propose a framework in which the learning process of the grammar model of one language is influenced by knowledge from the model of another language. Unlike previous work on multilingual grammar induction, our approach does not rely on any external resources, such as parallel corpora, word alignments or linguistic phylogenetic trees. We propose three regularization methods that encourage similarity between model parameters, dependency edge scores, and parse trees respectively. We deploy our methods on a state-of-the-art unsupervised discriminative parser and evaluate it on both transfer grammar induction and bilingual grammar induction. Empirical results on multiple languages show that our methods outperform strong baselines.

1 Introduction

Syntactic parsing is an important task in natural language processing. Supervised parsing requires manual labeling of gold parse trees, which is a very labor-intensive task. On the other hand, unsupervised parsing (a.k.a. grammar induction) does not require labeled data and can make use of large amounts of unlabeled data that are freely available. However, grammar induction is very challenging and its accuracy is still far below that of supervised parsing. To compensate the lack of supervision in grammar induction, some previous work considers multilingual grammar induction, i.e., simultaneously learning grammars of multiple languages (Snyder et al., 2009; Berg-Kirkpatrick and Klein, 2010; Liu et al., 2013). Existing multilingual approaches require external resources such as parallel corpora, word alignments, and linguistic phylogenetic trees.

Language	German	English	Spanish	French	Indonesian
Code	DE	EN	ES	FR	ID

Table 1: Directed dependency accuracy (DDA) on the universal treebanks with universal POS tags, on sentences of length ≤ 10. C-MST denotes the original Convex-MST model. D-Tran denotes direct transfer. Δ refers to the difference between C-MST and D-Tran.

In this paper, we aim at bilingual grammar induction without external resource. We are motivated by our observation that learning the unsupervised Convex-MST model (Grave and Elhadad, 2015) on the English corpus and then directly applying it to parse other languages produces surprisingly good results (Table 1). From the table, we can see that even with this simplistic method (which we call *direct transfer*), the dependency accuracy on each language is often very close to the accuracy of the model specifically trained on the corpus of that language. For the Swedish language, the accuracy of direct transfer is even better than that of the specifically trained model. This surprising result suggests that grammars of different languages, even those from different language families (e.g., English and Japanese), may have non-trivial similarity that can be helpful in bilingual grammar induction.

Inspired by this observation, we propose a regularization-based framework to bilingual grammar induction that encourage knowledge sharing between models learned on a language pair. We build our framework on top of Convex-MST, a state-of-the-art unsupervised dependency parser,

and propose three regularization terms that encourage similarity between model parameters, edge scores, and parse trees respectively. We test our methods on ten languages on the tasks of transfer grammar induction and bilingual grammar induction and show that our methods can achieve a significant boost over strong baselines.

2 Background

2.1 Unsupervised Dependency Parsing

Dependency parsing is the task of mapping an input sentence $\mathbf{x} = x_1, x_2, ..., x_n$ of length n to an output dependency structure $\mathbf{y}$. A dummy root x_0 is typically added at the beginning of the sentence to denote the head of the dependency tree. There are several approaches to represent the parse tree $\mathbf{y}$. In transition based dependency parsers, the dependency tree can be regarded as a sequence of actions. In graph based dependency parsers, the dependency tree can be represented as a spanning tree in the graph. In chart based parsers (a.k.a., grammar based parsers), the dependency tree is denoted as a set of grammar rules. In unsupervised graph based dependency parsers, since gold trees are not available, carefully designed models and objective functions are required for learning a dependency parser. Regardless of model architectures, current unsupervised dependency models usually use the following form of objective function,

$$J(\mathbf{w}; \mathcal{X}) = \sum_{\mathbf{x} \in \mathcal{X}} \mathrm{O}_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} \Big(D(\mathbf{w}, \mathbf{x}, \mathbf{y}) + R(\mathbf{w}) \Big)$$

where $\mathcal{Y}$ is the set of all possible dependency tree, $\mathbf{w}$ is the model parameter, $\mathcal{X}$ is the unlabeled training corpus, D is the measurement between the parse $\mathbf{y}$ and model prediction on sentence $\mathbf{x}$, $R(\mathbf{w})$ is the regularization term of parameter $\mathbf{w}$, $\mathrm{O} \in \{\min, \sum\}$ is an operator. Table 2 shows the choices of O, D and R for several widely used models.

2.2 Graph based Dependency Parsing

In this paper, we focus on graph based dependency parsers, though we believe that our approaches can be generalized to other types of parsers. Previous work on unsupervised graph based dependency parsing utilizes the autoencoder structure (Cai et al., 2017) or the discriminative clustering techniques (Grave and Elhadad, 2015).

Following (McDonald et al., 2005), we can use a discriminative model for dependency parsing with first order factorization such that the score of a dependency tree $\mathbf{y}$ is the sum of the scores of its dependency edges. The score of an edge from word h to word m , $\mathbf{s}_{\mathbf{w}}(\mathbf{x}, h, m)$, can be computed as the inner product of a feature vector $\mathbf{f}(\mathbf{x}, h, m)$ and a parameter vector $\mathbf{w}$. The optimal dependency tree for sentence $\mathbf{x}$ be discovered in polynomial time (Eisner, 1996; McDonald et al., 2005).

3 Bilingual Knowledge Sharing

Given non-parallel corpora of two languages $\mathcal{X}_s$ and $\mathcal{X}_t$, our goal is to learn two models with parameters $\mathbf{w}_s$ and $\mathbf{w}_t$ for the two languages. The simplest learning objective function is,

$$J(\mathbf{w}_s, \mathbf{w}_t; \mathcal{X}_s, \mathcal{X}_t) = J(\mathbf{w}_s; \mathcal{X}_s) + J(\mathbf{w}_t; \mathcal{X}_t)$$

which contains no interaction between the two models.

As suggested by our empirical observation in Table 1, the model of one language may provide a useful inductive bias in learning the model of another language. Note that given a sentence, a graph-based dependency parser has three levels of representations: the model parameters, the scores of dependency edges computed from the parameters, and the parse tree computed from the edge scores. Therefore, we propose three different regularization terms to effectively encourage similarity of the two models. An example is shown in Figure 1.

Regularization of Weight Parameters (W-Reg) Motivated by the approach of Berg-Kirkpatrick and Klein (2010), we encourage the similarity between the two weight parameters $\mathbf{w}_s$ and $\mathbf{w}_t$ measured by l2 norm distance:

$$J(\mathbf{w}_s, \mathbf{w}_t; \mathcal{X}_s, \mathcal{X}_t) = \\ J(\mathbf{w}_s; \mathcal{X}_s) + J(\mathbf{w}_t; \mathcal{X}_t) + \lambda ||\mathbf{w}_s - \mathbf{w}_t||_2^2$$

in which λ is a hyper-parameter.

Regularization on Edge Scores (E-Reg) Directly encouraging weight similarity might result in an inductive bias that is too strong, because the difference between the two languages (e.g., different word orders) may lead to different meanings of each feature dimension. Therefore, we propose to encourage similarity between the scores computed by the two models for each dependency edge of

Parsers	O	D	R
DMV (Klein and Manning, 2004)	$\sum$	negative log likelihood	-
Convex-MST (Grave and Elhadad, 2015)	min	ℓ_2 distance	ℓ_2 norm
LC-DMV (Noji et al., 2016)	$\sum$	negative log likelihood	ℓ_2 norm
NDMV (Jiang et al., 2016)	$\sum$, min	negative log likelihood	-
CRFAE (Cai et al., 2017)	min	negative conditional log likelihood	ℓ_1 norm
D-NDMV (Han et al., 2019)	$\sum$, min	negative (conditional) log likelihood	-

Table 2: Notations of several widely used models.

each sentence, which can be seen as a soft version of weight regularization.

$$J(\mathbf{w}_s, \mathbf{w}_t; \mathcal{X}_s, \mathcal{X}_t) = J(\mathbf{w}_s; \mathcal{X}_s) + J(\mathbf{w}_t; \mathcal{X}_t) + \lambda \sum_{\mathbf{x} \in \mathcal{X}'} \sum_{(h,m) \in \mathcal{G}(\mathbf{x})} ||\mathbf{s}_{\mathbf{w}_s}(\mathbf{x}, h, m) - \mathbf{s}_{\mathbf{w}_t}(\mathbf{x}, h, m)||_2^2$$

where $\mathcal{X}' = \mathcal{X}_s \cup \mathcal{X}_t$. $\mathcal{G}(\mathbf{x})$ is the weighted dependency graph of sentence $\mathbf{x}$.

Regularization on Parse Trees (T-Reg) Another alternative is to encourage similarity between the parse trees predicted by the two models. Motivated by the idea of knowledge distillation (Kim and Rush, 2016), in the learning objective of each model, we add a fourth term to encourage the parse tree to be close to the prediction of the other model. Below we show the objective function for $\mathbf{w}_s$.

$$J'(\mathbf{w}_s, \mathbf{w}_t; \mathcal{X}_s) = \sum_{\mathbf{x} \in \mathcal{X}_s} \mathbf{O}_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} \Big(D(\mathbf{w}_s, \mathbf{x}, \mathbf{y}) + \underbrace{\lambda D(\mathbf{w}_t, \mathbf{x}, \mathbf{y})}_{\textbf{T-Reg term}} + R(\mathbf{w}_s) \Big)$$

$$J'(\mathbf{w}_t, \mathbf{w}_s; \mathcal{X}_t) = \sum_{\mathbf{x} \in \mathcal{X}_t} \mathbf{O}_{\mathbf{y} \in \mathcal{Y}(\mathbf{x})} \Big(D(\mathbf{w}_t, \mathbf{x}, \mathbf{y}) + \underbrace{\lambda D(\mathbf{w}_s, \mathbf{x}, \mathbf{y})}_{\textbf{T-Reg term}} + R(\mathbf{w}_t) \Big)$$

$$J(\mathbf{w}_s, \mathbf{w}_t; \mathcal{X}_s, \mathcal{X}_t) = J'(\mathbf{w}_s, \mathbf{w}_t; \mathcal{X}_s) + J'(\mathbf{w}_t, \mathbf{w}_s; \mathcal{X}_t)$$

We apply these regularization method to the Convex-MST model (Grave and Elhadad, 2015). Our three objective functions can be optimized with coordinate descent in a similar way to Convex-MST. In each iteration, we first fix parse $\mathbf{y}$ for each training sentence and update parameters $\mathbf{w}_s$ and $\mathbf{w}_t$ by stochastic gradient descent; then we fix $\mathbf{w}_s$ and $\mathbf{w}_t$ and update $\mathbf{y}$ of each sentence by the Frank-Wolfe algorithm.

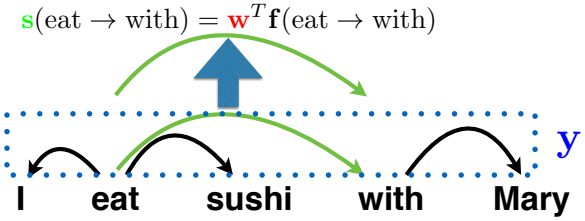

Figure 1: Three levels of representations of the parser: the parameter w, the edge score s, and the parse y.

While our three methods are applicable to any pair of languages, intuitively one may use weight regularization only for similar languages, and use edge regularization and tree regularization for an arbitrary language pair.

4 Experiments

To enable direct comparison with the Convex-MST model, we use the dataset used in their paper (Grave and Elhadad, 2015), the universal treebanks version 2.0[1], introduced by McDonald et al. (2013). The dataset contains ten different languages, which belong to five diverse families. In additional, we test our methods on twelve languages from the more recent UD Treebank 1.4[2], which is also used in previous grammar induction work (Jiang et al., 2017; Li et al., 2019). Following previous work, we train all the models on the gold POS tags of sentences no longer than ten. We tune hyper-parameters on the development dataset and report the DDA on sentences no longer than ten and all the sentences in the test dataset. As our goal is to investigate the benefits of our regularization methods, the two hyper-parameters μ and β

of Convex-MST are tuned on the English development dataset and then fixed ($\mu = 0.1, \beta = 0.001$) while λ is selected from $\{10, 5, 1, 5e-1, 1e-1, 5e-2, 1e-2, 5e-3, 1e-3, 1e-4\}$ for each language pair.

4.1 Experiments on Transfer Grammar Induction

In transfer grammar induction, we train the first model on the first language independent of the second language; then, with the first model fixed, we optimize our knowledge sharing objective with respect to the second model; finally, we evaluate the second model on the test set of the second language. In this way, we want to test whether our methods can transfer useful linguistic knowledge from the first language to the second language. We report the results of transfer grammar induction from English to the other nine languages in Table 3. Our edge regularization and tree regularization methods outperform the Convex-MST baseline in almost all the cases. The weight regularization method achieves worse results than Convex-MST except for the Swedish language, which demonstrates that directly regularizing weight parameters may not work well in the transfer grammar induction task. For the Swedish language, although direct transfer already achieves better performance than Convex-MST, our regularization methods can further boost the performance by a large margin. The Indonesian language is the only language for which transfer grammar induction provides no benefit, possibly because of its significant syntactic difference from the English language. Our additional experimental results on UD treebank 1.4 show a similar trend.

Table 4: Results of bilingual grammar induction on test sentences no longer than 10 (except the Avg-All row which shows the average accuracies on all the sentences). BASE refers to the individually trained baseline. COMB refers to learning a single model from the combined training set of the two languages. *: for the UD 1.4 dataset we show the average results.

We perform transfer grammar induction from English to Swedish with different values of λ and show the results in Figure 2. We can see that the impact of different hyper-parameter values on the accuracy generally follows the same tendency for our three methods.

4.2 Experiments on Bilingual Grammar Induction

In bilingual grammar induction, we jointly train two models on two languages. In our experiments, we pair English with each of the other nine languages. The results are reported in Table 4. It can be seen that in most cases joint training leads to better accuracies than the individually trained models as well as the single model learned from the combined training set. By comparing table 4 with table 3, we can also see that bilingual joint training leads to better accuracies than transfer grammar induction, which shows the benefit of training two models simultaneously rather than sequentially. Again, our additional experimental results on UD treebank 1.4 show a similar trend.

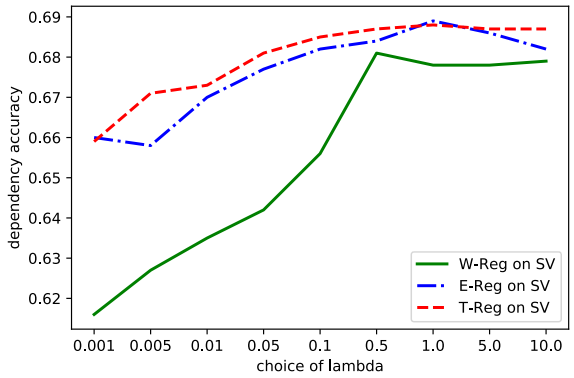

Figure 2: Transfer grammar induction on the SV language with different hyper-parameter values for the three regularization methods

5 Related Work

Our work is related to many previous work.

Unsupervised Transfer Learning There has been previous work aiming at solving an unsupervised learning task of a target domain with the help of knowledge learned from a source domain (Dai et al., 2008; Wang et al., 2008; Pan and Yang, 2010). There is no labeled data in both the source and the target domains during training. Our transfer grammar induction setting can be seen as an instance of unsupervised transfer learning.

Cross-lingual Supervised Dependency Parsing This task focuses on learning a parser with unlabeled training data and additional labeled training data of a second language (McDonald et al., 2011; Naseem et al., 2012; Guo et al., 2015). The main difference between our approach and theirs is that our approach is fully unsupervised. and do not utilize external information like word alignments or cross-lingual word embeddings.

Other Approaches to Multilingual Grammar Induction To the best of our knowledge, this task is first proposed by Kuhn (2004). They assume that the syntax trees induced from parallel sentences share structured regularities and utilize the word alignments to guide parsing. From then on, many approaches are proposed on both constituency grammar induction and dependency grammar induction (Snyder et al., 2009; Berg-Kirkpatrick and Klein, 2010). We differ from these approaches in that we do not make use of any external rules or knowledge.

6 Conclusion

In this paper, we propose three regularization-based knowledge sharing methods to bilingual grammar induction problems. We test our methods on transfer grammar induction and bilingual grammar induction and show that our methods achieve better performance than the baselines. In future work, we plan to investigate the effectiveness of our approach in other types of induction tasks.

Abstract

Neural machine translation (NMT) has achieved new state-of-the-art performance in translating ambiguous words. However, it is still unclear which component dominates the process of disambiguation. In this paper, we explore the ability of NMT encoders and decoders to disambiguate word senses by evaluating hidden states and investigating the distributions of self-attention. We train a classifier to predict whether a translation is correct given the representation of an ambiguous noun. We find that encoder hidden states outperform word embeddings significantly which indicates that encoders adequately encode relevant information for disambiguation into hidden states. In contrast to encoders, the effect of decoder is different in models with different architectures. Moreover, the attention weights and attention entropy show that self-attention can detect ambiguous nouns and distribute more attention to the context.

1 Introduction

Neural machine translation (NMT) models (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015; Luong et al., 2015) have access to the whole source sentence for the prediction of each word, which intuitively allows them to perform word sense disambiguation (WSD) better than previous phrase-based methods, and Rios et al. (2018) have confirmed this empirically. However, it is still unclear which component dominates the ability to disambiguate word senses. We explore the ability of NMT encoders and decoders to disambiguate word senses by evaluating hidden states and investigating the self-attention distributions.

Marvin and Koehn (2018) find that the hidden states in higher encoder layers do not perform disambiguation better than those in lower layers and conclude that encoders do not encode enough relevant context for disambiguation. However, their results are based on small data sets, and we wish to revisit this question with larger-scale data sets. Tang et al. (2018b) speculate that encoders have encoded the relevant information for WSD into hidden states before decoding but without any experimental tests.

In this paper, we first train a classifier for WSD, on a much larger data set than Marvin and Koehn (2018), extracted from ContraWSD (Rios et al., 2017), for both German→English (DE→EN) and German→French (DE→FR). The classifier is fed a representation of ambiguous nouns and a word sense (represented as the embedding of a translation candidate), and has to predict whether the two match. We can learn the role that encoders play in encoding information relevant for WSD by comparing different representations: word embeddings and encoder hidden states at different layers. We extract encoder hidden states from both RNN-based (*RNNS2S*) (Luong et al., 2015) and *Transformer* (Vaswani et al., 2017) models. Belinkov et al. (2017a,b) have shown that the higher layers are better at learning semantics. We hypothesize that the hidden states in higher layers incorporate more relevant information for WSD than those in lower layers. In addition to encoders, we also probe how much do decoder hidden states contribute to the WSD classification task.

Recently, the distributions of attention mechanisms have been used for interpreting NMT models (Ghader and Monz, 2017; Voita et al., 2018; Tang et al., 2018b; Voita et al., 2019; Tang et al., 2019). We further investigate the attention weights and attention entropy of self-attention in encoders to explore how self-attention incorporates relevant information for WSD into hidden states. As sentential information is helpful in disambiguating ambiguous words, we hypothesize that self-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1429–1435, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

attention pays more attention to the context when modeling ambiguous words, compared to modeling words in general.

Here are our findings:

- Encoders encode lots of relevant information for word sense disambiguation into hidden states, even in the first layer. The higher the encoder layer, the more relevant information is encoded into hidden states.
- Forward RNNs are better than backward RNNs in modeling ambiguous nouns.
- Decoders hidden states have different effects on WSD in *Transformer* and *RNNS2S*.
- Self-attention focuses on the ambiguous nouns themselves in the first layer and keeps extracting relevant information from the context in higher layers.
- Self-attention can recognize the ambiguous nouns and distribute more attention to the context words compared to dealing with nouns in general.

2 Methodology

2.1 WSD Classifier

ContraWSD (Rios et al., 2017) is a WSD test set for NMT. Each ambiguous noun in a specific sentence has a small number of translation candidates. We generate instances that are labelled with one candidate and a binary value indicating whether it corresponds to the correct sense.

Encoders Given an input sentence, NMT encoders generate hidden states of all input tokens. Our analysis focuses on the hidden states of ambiguous nouns (R_{ambi}). We use word embeddings from NMT models to represent the translation candidates (R_{sense}). If the ambiguous nouns or translation candidates are split into subwords, we just sum the representations.

Figure 1 illustrates the WSD classification task. We first generate hidden states for each sentence. The classifier is a feed-forward neural network with only one hidden layer. The input of the classifier is the concatenation of R_{ambi} and R_{sense}. The classifier predicts whether the translation is the correct sense of the ambiguous noun.

As the baseline, we use word embeddings from NMT models as representations of ambiguous nouns. Each ambiguous noun has only one corresponding word embedding, so such a classifier can at best learn a most-frequent-sense solution, while

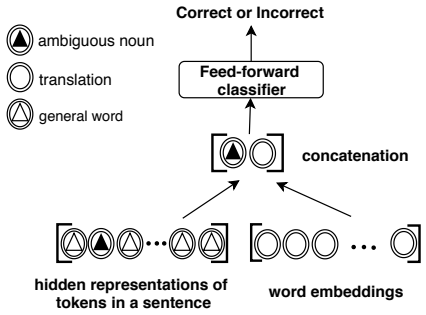

Figure 1: Illustration of the WSD classification task, using encoder hidden states to represent ambiguous nouns. The input of the classifier is the concatenation of the ambiguous word and the translation. The output of the classifier is "correct" or "incorrect".

hidden states are based on sentential information, so that ambiguous nouns have different representations in different source sentences. We can learn to what extent relevant information for WSD is encoded by encoders by comparing to the baseline.

Decoders To explore the role of decoders, we feed the decoder hidden state at the time step predicting the translation of the ambiguous noun, and the word embedding of the current translate candidate into the classifier. The decoder hidden state is extracted from the last decoder layer. To get these hidden states. we force NMT models to generate the reference translations using constrained decoding (Post and Vilar, 2018). Since decoders are crucial in NMT, we assume that the decoder hidden states incorporate more relevant information for WSD from the decoder side. Thus, we hypothesize that using decoder hidden states can achieve better WSD performance.

2.2 Attention Distribution

The attention weights can be viewed as the degree of contribution to the current word representation, which provides a way to interpret NMT models. Tang et al. (2018a) have shown that Transformers with self-attention are better at WSD than RNNs. However, the working mechanism of self-attention has not been explored. We try to use the attention distributions in different encoder layers to interpret how self-attention incorporates relevant information to disambiguate word senses.

All the ambiguous words in the test set are nouns. Ghader and Monz (2017) have shown that nouns have different attention distributions from other word types. Thus, we compare the attention distributions of ambiguous nouns to nouns in gen-

eral[1] in two respects. One is the attention weight over the word itself. The other one is the concentration of attention distributions. We use attention entropy (Ghader and Monz, 2017) to measure the concentration.

$$E_{At}(x_t) = -\sum_{i=1}^{|x|} At(x_i, x_t) \log At(x_i, x_t) \quad (1)$$

Here x_i denotes the ith source token, x_t is the current source token, and $At(x_i, x_t)$ represents the attention weight from x_t to x_i. We merge subwords after encoding, following the method in Koehn and Knowles (2017).[2] Each self-attention layer has multiple heads and we average the attention weights from all the heads.

In theory, sentential information is more important for ambiguous words that need to be disambiguated than non-ambiguous words. From the perspective of attention weights, for ambiguous words, we hypothesize that self-attention distributes more attention to the context words to capture the relevant sentential information, compared to words in general. From the perspective of attention entropy, we hypothesize that self-attention focuses on the related context words rather than the entire sentence which produces a smaller entropy. If ambiguous words have a lower weight and a smaller entropy than words in general, the results can confirm our hypotheses.

3 Experiments

For NMT models, we use the *Sockeye* (Hieber et al., 2017) toolkit to train *RNNS2S*s and *Transformer*s. DE→EN training data is from the WMT17 shared task (Bojar et al., 2017). DE→FR training data is from Europarl (v7) (Koehn, 2005) and News Commentary (v11) cleaned by Rios et al. (2017).[3] In *ContraWSD*, each ambiguous noun has a small number of translation candidates. The average number of word senses per noun is 2.4 and 2.3 in DE→EN and DE→FR, respectively. We generate instances that are labelled with one candidate and a binary value indicating whether it corresponds to the correct sense. we get 50,792 and 43,268 instances in DE→EN and DE→FR, respectively. 5K/5K examples are randomly selected as the test/development set. The remaining examples are used for training. We train 10 times with different seeds for each classifier and apply average accuracy. Table 1 lists the detailed statistics of the data. More experimental details are provided in the Appendix.

	DE→EN	DE→FR
NMT training data	5.9M	2.1M
Word senses	84	71
Lexical ambiguities	7,359	6,746
Instances	50,792	43,268

Table 1: Training data for NMT, and data extracted from ContraWSD: Word senses: total number of senses. Lexical ambiguities: number of sentences containing an ambiguous word. Instances: number of instances generated for WSD classification.

3.1 Results

Table 2 provides the BLEU scores and the WSD accuracy on test sets, using different representations to represent ambiguous nouns. *ENC* denotes encoder hidden states; *DEC* means decoder hidden states.

	DE→EN		DE→FR	
	RNN.	*Trans.*	*RNN.*	*Trans.*
BLEU	29.1	32.6	17.0	19.3
Embedding	63.1	63.2	68.7	68.9
ENC	94.2	97.2	91.7	95.6
DEC	97.9	91.2	95.1	91.6

Table 2: BLEU scores of NMT models, and WSD accuracy on the test set using word embeddings or hidden states to represent ambiguous nouns. The hidden states are from the highest layer.[4] *RNN.* and *Trans.* denote *RNNS2S* and *Transformer* models, respectively.

ENC achieves much higher accuracy than *Embedding*. The WSD accuracy of *Embedding* are around 63% and 69% in the two languages. While the accuracy of *ENC* increases to over 91%. The absolute accuracy gap varies from 23% to 34%, which is substantial. This result indicates that encoders have encoded a lot of relevant information for WSD into hidden states. In addition, *DEC* achieves even higher accuracy than *ENC* in *RNNS2S* models but not in *Transformer* models.

[1] We use *TreeTagger* (Schmid, 1995) to identify nouns.

[2] (1) If a query word is split into subwords, we add their attention weights. (2) If a key word is split into subwords, we average their attention weights.

[4] For encoders in *RNNS2S*s, this is the last backward RNN.

4 Analysis

4.1 WSD Classification

4.1.1 RNNS2S vs. Transformer

*RNNS2S*s are inferior to *Transformer*s distinctly in BLEU score. However, the hidden states from *RNNS2S* also improve accuracy significantly, just not as much as those from *Transformer* models. This result indicates that *Transformer*s encode more relevant context for WSD than *RNNS2S*s and accords with the finding in Tang et al. (2018a) that *Transformer*s perform WSD better than *RNNS2S*s.

The results of *ENC* using *RNNS2S* in Table 2 are only based on hidden states from the last backward RNN. We also concatenate the hidden states from both forward and backward RNNs and get higher accuracy, 96.8% in DE→EN and 95.7% in DE→FR. The WSD accuracy of using bidirectional hidden states are competitive to using hidden states from Transformer models. However, concatenating forward and backward hidden states doubles the dimension. Thus, the comparison is not completely fair.

4.1.2 Encoder Depth

Figure 2 illustrates WSD accuracy in different encoder layers, with standard deviation as error bars. Even the hidden states from the first layer boost the WSD performance substantially compared to using word embeddings. This means that most of the relevant information for WSD has been encoded into hidden states in the first encoder layer. For *Transformer*s, the WSD accuracy goes up consistently as the encoder layer gets higher. *RNNS2S* has 3 stacked bi-directional RNNs. Both forward and backward layers get higher accuracy when the depth increases. All the models show that hidden states in higher layers incorporate more relevant information for WSD.

Our results conflict with the findings in Marvin and Koehn (2018) where they find that hidden states in higher encoder layers do not perform disambiguation better than those in lower layers. One of the distinct differences from Marvin and Koehn (2018) is that we train the classifier with ∼40K instances. While they employ 426 examples. Moreover, they extract encoder hidden states from NMT models with different layers rather than different layers of the same model.

Moreover, it is interesting that the forward layers surpass the backward layers in the same bi-directional RNN. One possible explanation is that there is more relevant information for WSD before ambiguous nouns rather than after ambiguous nouns, which makes forward RNNs inject more relevant information into the hidden states of ambiguous nouns than backward RNNs.

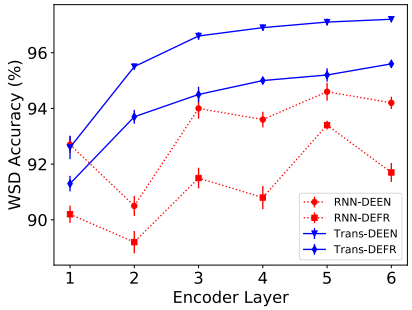

Figure 2: The WSD accuracy of using hidden states in different encoder layers, with standard deviation as error bars. For *RNNS2S*s, the odd layers (1, 3, 5) are forward RNNs and the even layers (2, 4, 6) are backward RNNs.

4.1.3 Decoders

As Table 2 shows, RNN decoder hidden states could further improve the classification accuracy which accords with our hypothesis. It implies that the relevant information for WSD in the target-side has been well incorporated into the decoder hidden states to predict the translations of ambiguous nouns. It is curious that Transformer decoder hidden states are inferior to Transformer encoder hidden states in our WSD classification task, given that Tang et al. (2018a) and Rios et al. (2018) report better results with contrastive evaluation and semi-automatic evaluation of 1-best translations for Transformer models than for *RNNS2S*. However, note that our evaluation merely tests whether the information necessary for word sense disambiguation is encoded in hidden states and can be extracted by our binary classifier. In practice, decoder hidden states are used for predicting a target word from the entire vocabulary, and thus need to encode additional information which may confound our classifier.

Despite these differences between *RNNS2S* and the Transformer, our results show that WSD is already possible on the basis of the encoder representation of the ambiguous noun, and that extracting contextual information via encoder-decoder attention or from the target history is not essential for WSD.

4.2 Self-attention

4.2.1 Attention Weights

Figure 3 exhibits the average attention weights of ambiguous nouns and all nouns over themselves in different layers. In the first layer, the attention weights are distinctly higher than those in higher layers. 87% and 90% of ambiguous nouns assign the highest attention to themselves in DE→EN and DE→FR, respectively. The attention weights drop dramatically from the second layer. It thus seems that self-attention pays more attention to the ambiguous nouns themselves in the first layer and to context words in the following layers.

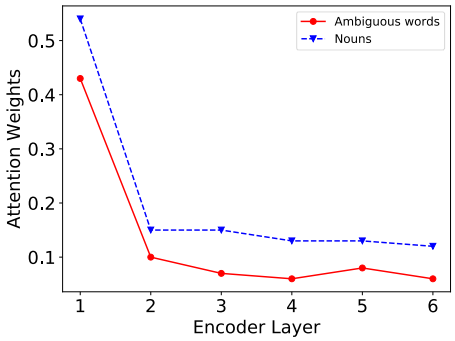

Figure 3: The average attention weights of ambiguous nouns and general nouns over themselves in different layers, in DE→EN (same pattern in DE→FR).

The attention weights of ambiguous nouns are lower than those of nouns in general. That is, more attention is distributed to context words, which implies that self-attention recognizes ambiguous nouns and distributes more attention to the context. We can conclude that self-attention pays more attention to context words to extract relevant information for disambiguation in all the layers, compared to nouns in general.

4.2.2 Attention Entropy

Section 4.2.1 has shown that self-attention of ambiguous nouns distributes more attention to the context than self-attention of nouns in general but what does the attention distribution look like? Figure 4 displays the average attention entropy of ambiguous nouns and all nouns in different layers. From the second layer, ambiguous nouns have smaller attention entropy than nouns in general, which means that self-attention mainly distributes attention to some specific words rather than all the words. As self-attention focuses on the ambiguous nouns themselves in the first layer, this result accords with our hypothesis as well.

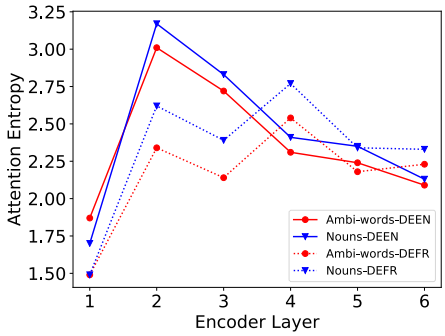

Figure 4: The average attention entropy of ambiguous nouns and nouns in different encoder layers.

In addition, there is a roughly general pattern that the attention entropy first rises and then drops. A plausible explanation is that the attention entropy first rises because context information is extracted from the entire sentence and later drops due to focusing on the most relevant context tokens.

5 Conclusion

In this paper, we investigate the ability of NMT encoders and decoders to disambiguate word senses. We first train a neural classifier to predict whether the translation is correct given the representations of ambiguous nouns. We find that encoder hidden states outperform word embeddings significantly in the classification task which indicates that relevant information for WSD has been well integrated by encoders. In addition, the higher the encoder layer, the more relevant information is encoded into hidden states. Moreover, the effect of decoder hidden states on WSD is different in Transformer and *RNNS2S* models.

We further explore the attention distributions of self-attention in encoders. The results show that self-attention can detect ambiguous nouns and distribute more attention to context words. Besides, self-attention focuses on the ambiguous nouns themselves in the first layer, then keeps extracting features from context words in higher layers.

Abstract

Korean morphological analysis has been considered as a sequence of morpheme processing and POS tagging. Thus, a pipeline model of the tasks has been adopted widely by previous studies. However, the model has a problem that it cannot utilize interactions among the tasks. This paper formulates Korean morphological analysis as a combination of the tasks and presents a tied sequence-to-sequence multi-task model for training the two tasks simultaneously without any explicit regularization. The experiments prove the proposed model achieves the state-of-the-art performance.

1 Introduction

Korean is an agglutinative language (Song, 2006). Thus, it is a fundamental step for understanding a sentence to analyze the grammatical structure of *eojeol*s, where an eojeol is a linguistic unit segmented by a white space. An eojeol is composed of one or more morphemes. As a result, one eojeol can be analyzed into several morpheme combinations depending on a context, which yields different part-of-speech (POS) tags of the morpheme combinations. In addition, some morphemes have a different surface form from their base form when they are derived from an eojeol. Therefore, the goal of Korean morphological analyzer is not only to decompose and recover morphemes from eojeols precisely (morpheme processing), but also to assign POS tags to the decomposed and/or recovered morphemes accurately according to a context (POS tagging).

Traditional approaches to Korean morphological analysis have adopted a pipeline model of morpheme processing and POS tagging (Lee and Rim, 2009; Na, 2015; Choi et al., 2016; Matteson et al., 2018; Song and Park, 2018). That is, they first decompose and recover morphemes from eojeols or assign so-called POSMORPH tags (Heigold et al., 2016), and then an actual POS tag sequence is determined or resolved from the POSMORPH tags using a sequential labeling algorithm. However, this pipeline model suffers from two kinds of weaknesses. One weakness is that the errors from morpheme processing are apt to be propagated to POS tagging, and the other is that it is difficult to model mutual interactions between morpheme processing and POS tagging under the pipeline model.

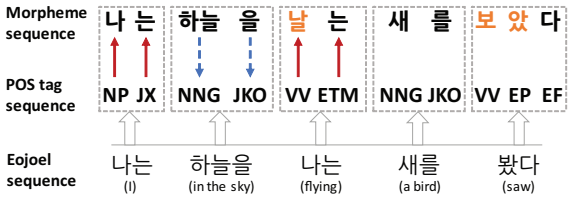

Figure 1: Korean morphological analysis of a sentence "나는 하늘을 나는 새를 봤다" of which meaning is "*I saw a bird flying in the sky*". Correct morpheme analysis helps predicting POS tags (blue dotted arrows) while POS tagging affects morpheme analysis (red arrows). Orange morphemes in the morpheme sequence are recovered morphemes. Best viewed in color.

In Korean, morpheme processing and POS tagging affect each other. That is, correct morpheme analysis helps POS tagging, and POS tags are helpful in analyzing morphemes. Figure 1 shows such an example in Korean morphological analysis. The second eojeol '하늘을 (in the sky)' is composed of two morphemes '하늘 (sky)' and '을 (*objective postposition*)'. If '하늘을' is precisely decomposed into '하늘' and '을', their POS tags can be predicted easily. This is the information flow on which the previous studies focus. On the other hand, the eojeol '나는' which appears twice in this figure is morphologically ambiguous and thus can

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1436–1441,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

be analyzed in two ways. However, if morpheme processing obtains some information from POS tagging, it can decompose ambiguous eojeols correctly. That is, the first '나는' is decomposed into '나 (I)' and '는 (*topical postposition*)', while the second '나는' is into '날 (fly)' and '는 (*verbal ending*)'. Therefore, morpheme processing and POS tagging should be trained simultaneously.

This paper proposes a model to train morpheme processing and POS tagging simultaneously in Korean morphological analysis. The proposed model regards morpheme processing and POS tagging as individual tasks. Then, the two tasks are jointly trained under a sequence-to-sequence multi-task framework (Luong et al., 2016; Anastasopoulos and Chiang, 2018). The main characteristic of the proposed model is that there is a single decoder for both generating a morpheme sequence and assigning POS tags to the generated morphemes. As a result, the decoder shares general representations of both tasks and forces a one-to-one mapping between morphemes and POS tags without additional regularization. Morpheme processing is accomplished by a pointer-generator network (See et al., 2017), while POS tagging is done by a CRF network (Huang et al., 2015; Lample et al., 2016) utilizing the information from morpheme processing. Our experimental results show that the proposed model outperforms existing Korean morphological analyzers with its state-of-the-art performance.

2 Korean Morphological Analysis

2.1 Morpheme Processing and POS Tagging

Given an input sequence $\mathbf{x} = (w_1, ..., w_n)$ where w_i is the i-th eojeol, Korean morphological analysis aims to produce an output sequence $\mathbf{y} = (\langle m_1, t_1 \rangle, ..., \langle m_k, t_k \rangle)$ where m_j is the j-th morpheme and t_j is its POS tag. Korean morphological analysis is different from existing NLP tasks such as English POS tagging (Toutanova et al., 2003; Manning, 2011), and joint word segmentation and POS tagging for Chinese (Zhang and Clark, 2008; Shao et al., 2017; Chen et al., 2017). In English POS tagging, a word and its tag have a one-to-one mapping so that the length of an input sequence is equal to that of an output sequence. On the other hand, they are usually different in Korean, because an eojeol consists of several morphemes. That is, $n < k$ in general. The key distinguishing factor between Chinese and Korean morphological analysis is that lemmatization that recovers a base form for every morpheme as well as morpheme segmentation is a must in Korean morphological analysis, while Chinese morphological analysis requires only word segmentation. That is, in Korean, $\bigoplus_{i=1}^{n} w_i \neq \bigoplus_{i=1}^{k} m_i$ in general, where $\bigoplus$ is a concatenate operator. According to Figure 1, the eojeol sequence '나는 하늘을 나는 새를 봤다' is different from its morpheme sequence '나는 하늘을 날는 새를 보았다' where underline marks indicate the difference.[1]

Given an annotated corpus $\mathcal{D} = (\langle \mathbf{x}_i, \mathbf{y}_i \rangle)_{i=1}^{N}$ where N is the number of sentences, Korean morphological analyzer is obtained by maximizing the conditional probability $p(\mathbf{y}|\mathbf{x})$. The conditional probability can be calculated as

$$p(\mathbf{y}|\mathbf{x}) \approx \underbrace{p(\mathbf{t}|\mathbf{m}, \mathbf{x})}_{\text{POS tagging}} \quad \underbrace{p(\mathbf{m}|\mathbf{x})}_{\text{Morpheme processing}}, \tag{1}$$

where $\mathbf{m} = (m_1, \ldots, m_k)$ is a morpheme sequence, and $\mathbf{t} = (t_1, \ldots, t_k)$ is a tag sequence. Equation (1) implies that $p(\mathbf{y}|\mathbf{x})$ can be further decomposed into two another conditional probabilities. One conditional probability, $p(\mathbf{m}|\mathbf{x})$, generates a morpheme sequence $\mathbf{m}$ from the input sequence $\mathbf{x}$, and the other $p(\mathbf{t}|\mathbf{m}, \mathbf{x})$ assigns POS tags considering the morpheme sequence $\mathbf{m}$ and the input sequence $\mathbf{x}$. Therefore, $p(\mathbf{m}|\mathbf{x})$ corresponds to morpheme processing, while $p(\mathbf{t}|\mathbf{m}, \mathbf{x})$ is POS tagging.

2.2 Linguistic Unit in Morphological Analysis

Eojeol is the unit of spacing in Korean sentences. However, it is inappropriate to use eojeols directly in sequence-to-sequence models, because the number of eojeols is extremely huge due to the agglutinative characteristics of Korean. For instance, there exist 624,655 kinds of eojeols in the corpus used in the experiments. This large eojeol size causes a complexity problem in morphological analysis.

According to Korean orthography, an eojeol is a sequence of *syllables*. For instance, an eojeol '하늘을' is a sequence of three syllables '하', '늘', and '을'. A morpheme in Korean is also a sequence of syllables like an eojeol. The number of distinguished syllables in the corpus above is just

[1] We skip morpheme segmentation symbols in the morpheme sequence in order to emphasis the difference between the eojeol sequence and the morpheme one.

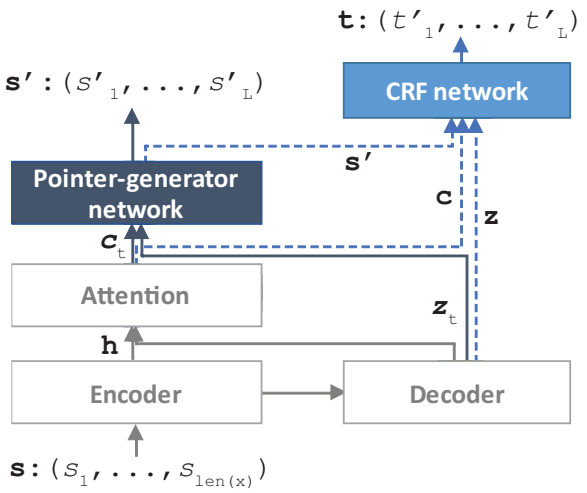

Figure 2: The proposed model for Korean morphological analysis based on a Tied sequence-to-sequence multi-task model. Since syllable is adopted as a unit for the proposed model, the input for the encoder is a syllable sequence $\mathbf{s}$. For clarity's sake, there are some dependencies not shown.

5,245 which is much smaller than that of eojeols. Therefore, this paper adopts syllable as a unit for sequence-to-sequence models for Korean morphological analysis.

3 Tied Sequence-to-Sequence Multi-Task Model

The proposed model is based on the sequence-to-sequence model with attention (Bahdanau et al., 2015) and extends the model for multi-task learning similarly to the work of Anastasopoulos and Chiang (2018). The proposed model consists of four parts: a recurrent encoder, a recurrent decoder, attention, and task-dependent networks. Figure 2 shows an overall structure of the proposed model. The encoder encodes an input sequence $\mathbf{x}$ into a sequence of hidden states. Since syllable is adopted as the unit for the model, the encoder (bidirectional LSTM) actually transforms an input syllable sequence $\mathbf{s} = (s_1, \ldots, s_{len(\mathbf{x})})$ into a sequence of encoder hidden states $\mathbf{h}_1, \ldots, \mathbf{h}_{len(\mathbf{x})}$, where $len(\cdot)$ is the number of syllables including white spaces. The attention transforms the encoder hidden states $\mathbf{h}$ into a sequence of context vectors $\mathbf{c}$ through attention weights. The context vectors capture relevant source-side information for both morpheme processing and POS tagging.

Unlike other multi-task models, there is only one decoder for the two tasks of morpheme processing and POS tagging in the proposed model. Note that a morpheme and its POS tag should have a one-to-one mapping relation. Since the two tasks are forced to share the same decoder states, a one-to-one mapping between a morpheme and its POS tag is guaranteed without any explicit regularization or task-specific token. In detail, the decoder (unidirectional LSTM) first computes a sequence of decoder hidden states $\mathbf{z}$. At every time t, the decoder hidden state $\mathbf{z}_t$ is calculated from the embedding of the previous syllable $\mathbf{s}'_{t-1}$, the decoder state $\mathbf{z}_{t-1}$, and the context vector $\mathbf{c}_t$. Then, two task-dependent networks solve their own task using the same $\mathbf{z}$.

In morpheme processing represented by solid arrows in Figure 2, a syllable s'_t is produced at every time t. Most syllables are directly copied from the input syllables while some syllables are newly generated from a vocabulary to recover the base form of a morpheme. To do this, we adopt the pointer-generator network (See et al., 2017) which allows both copying syllables via pointing and generating syllables from a fixed vocabulary. The advantage of this approach is that we can handle non-Korean characters such as *hanja* (Chinese character) and special symbols with ease.

In POS tagging represented by dotted arrows in Figure 2, it is possible to generate a POS tag at every time t by paying attention to the encoder syllable states as done in morpheme processing. However, this approach does not reflect the global dependency among adjacent tags. To solve this problem, this paper adopts a CRF network (Huang et al., 2015; Lample et al., 2016) over the pointer-generator network. When the morpheme sequence generated at the morpheme processing is given, the CRF network predicts POS tags for the morpheme sequence by considering the global dependency among tags (Lafferty et al., 2001). Furthermore, this paper uses skip-connections (He et al., 2016) in order for the CRF network to pay attention to the hidden states of the decoder. Since some POS tags can be predicted directly from input syllables, the skip-connections help the CRF network consider the information of input syllables. In detail, a sequence of syllables generated by the pointer-generator network is transformed to vectors, and the vectors are concatenated with the decoder state $\mathbf{z}$ and the context vector $\mathbf{c}$. Then, the concatenated vectors are fed to the CRF layer to predict POS tags.

Methods				F1-score	Acc (%)
Model	Morpheme processing	POS tagging	Type		
Single-Task	Pointer-Generator			97.36	95.57
Multi-Task	Generator	Generator	Non-cascade	97.10	95.09
	Generator	CRF	Cascade	97.25	95.30
	Generator	CRF	Tied	97.31	95.49
	Pointer-Generator	Generator	Non-cascade	97.30	95.45
	Pointer-Generator	CRF	Cascade	97.40	95.61
	Pointer-Generator	CRF	Tied	**97.43**	**95.68**
Pipeline	Na (2015) (CRF → CRF → Post-processing)			97.21	95.22
	Song and Park (2018) (Generator → CRF)			97.27	95.29
	khaiii (CNN → Post-processing)			94.88	91.86

Table 1: Performances of Korean morphological analyzers

Information	Training	Development	Test
Sentences	197,508	5,000	50,631
Eojeols	2,674,571	97,292	694,524
Morphemes	5,952,985	203,244	1,542,483
Avg. eojeols	13.54	19.46	13.72
No. of POS tags	42		

Table 2: Simple statistics on the data set used.

Note that syllable is the unit for the model and one POS tag spans several syllables of a morpheme. Thus, to identify morpheme boundaries, morpheme processing of the proposed model generates a special symbol of morpheme ending for every explicit morpheme boundary instead of adopting the IOB tagging scheme. Such an approach reduces the number of POS tags and is helpful in segmenting eojeols into morphemes precisely.

The proposed model is trained to maximize the weighted sum of conditional log-likelihood of each task where the weights are set to be equal.

4 Experiments

4.1 Experimental Settings

The same data set with the work of Na (2015) is used for the experiments. This data set is derived from Sejong corpus.[2] Each eojeol in the Sejong corpus is annotated with pairs of a morpheme and its POS tag. The simple statistics on the data set used in the experiments is given in Table 2.

We set the syllable embedding size and the hidden size to 100. The number of LSTM layers is set to three and the batch size is 128. We use the gradient normalization with a threshold of five.

Three baselines are adopted to show the superiority of the proposed model. The first baseline is the model of Na (2015). This model consists of three sub-models (CRF segmentation, CRF tagging, and post-processing) and executes these three models in consecutive order. The second is the model of Song and Park (2018) which consists of two sub-models (generator and CRF tagger). The last is khaiii, a publicly-available CNN based morphological analyzer.[3] This analyzer assigns a POSMORPH tag for every syllable using a CNN classifier and then resolves the tag through post-processing. These baselines are all pipeline models. We also compare the proposed model with a single task non-pipeline model which generates a single sequence of morphemes and POS tags using the pointer-generator network.

The F1-measure at the morpheme level and the accuracy at the eojeol level are used as evaluation metrics, and all performances are micro-averaged.

4.2 Experimental Results

Table 1 shows the performances of the proposed model and the baselines. It also contains the results of the ablation study on the proposed model by changing the network of sub-tasks or the structure of multi-task models. 'Non-cascade' is similar to the standard multi-task model (Dong et al., 2015) in which each task just shares a decoder and there is no direct connection between tasks. According to Figure 2, there are no dotted arrows (marked $\mathbf{s}'$ and $\mathbf{c}$) from the Pointer-generator network and the CRF network in 'Non-cascade' model. 'Cascade'

[2] Available at https://ithub.korean.go.kr

[3] https://github.com/kakao/khaiii

Type	Percentage
Morpheme segmentation	5.8%
POS tagging	39.3%
Morpheme recovery	54.9%

Table 3: The ratio of different error types.

is a multi-task model where the POS tagging network has a connection from the morpheme processing network but no skip connection from the decoder. In Figure 2, 'Cascade' model has no dotted arrow (marked $\mathbf{z}$) from the decoder to the CRF network. 'Tied' is the proposed model that considers both connections.

According to the table, all multi-task models that adopt Pointer-Generator and/or CRF outperform the baseline Generator-Generator, which proves their adoption is effective in improving the performance of morphological analysis. It is also noticed from the table that 'Cascade' multi-task model achieves better performance than 'Non-cascade' model, which implies that the unimpeded information from morpheme processing to POS tagging helps predict accurate POS tags. The proposed 'Tied' multi-task model yields higher performances than 'Cascade' model. When training the 'Tied' multi-task model, the feedbacks from POS tagging network influence decoder states directly. As a result, the 'Tied' model is able to learn better representation for both morpheme processing and POS tagging. All these results indicate that 'Tied' multi-task model with Pointer-Generator network and CRF is the best choice for Korean morphological analysis.

Compared to the pipeline models which showed the state-of-the-art performance previously, even simple multi-task models report a similar performance, which means that morphological analysis can be improved by training morpheme processing and POS tagging jointly. Even if the single-task non-pipeline model achieves a reasonable performance, its performance is not as high as that of the proposed model. This is because the single-task model does not consider the global tag dependency explicitly. To sum up, Korean morphological analysis should be solved by training the two tasks jointly with appropriate networks.

4.3 Error Analysis

Even if the proposed method achieves over 97.4% F1-score at the morpheme level, we believe that there still exists some room to improve the performance of Korean morphological analysis. To do this, we analyzed the errors by the proposed method.

Table 3 shows error types and their percentages. Morpheme segmentation is when all results are correct except some morphemes that are decomposed wrongly. This type happens mostly in Korean compound nouns where Korean compound nouns can be written as one or more eojeols. If a compound noun represented as one eojeol is given, the proposed method sometimes decomposes the compound noun into a series of nouns. 5.8% errors belong to this type. POS tagging error type is when morphemes are correctly recovered and segmented but their POS tags are predicted wrongly. Its percentage is 39.3%. In this type, 37% errors occur between noun and proper noun. The remaining but majority errors are related to morpheme recovery. That is, these errors occur when the proposed method fails in recovering morphemes from eojeols accurately. Its percentage is 54.9%. Therefore, it is inferred from the error analysis that developing a more accurate morpheme processing model is required to improve the performance of the proposed Korean morphological analyzer.

5 Conclusion

This paper has formulated Korean morphological analysis as a combination of morpheme processing and POS tagging. Thus, the two tasks are trained simultaneously through the tied sequence-to-sequence multi-task model with the pointer-generator network and the CRF network. According to the experiment results, the jointly trained morphological analyzer achieves higher performances than the legacy analyzers which are pipeline models of morpheme processing and POS tagging.[4]

Abstract

Diacritic restoration has gained importance with the growing need for machines to understand written texts. The task is typically modeled as a sequence labeling problem and currently Bidirectional Long Short Term Memory (BiLSTM) models provide state-of-the-art results. Recently, Bai et al. (2018) show the advantages of Temporal Convolutional Neural Networks (TCN) over Recurrent Neural Networks (RNN) for sequence modeling in terms of performance and computational resources. As diacritic restoration benefits from both previous as well as subsequent timesteps, we further apply and evaluate a variant of TCN, Acausal TCN (A-TCN), which incorporates context from both directions (previous and future) rather than strictly incorporating previous context as in the case of TCN. A-TCN yields significant improvement over TCN for diacritization in three different languages: Arabic, Yoruba, and Vietnamese. Furthermore, A-TCN and BiLSTM have comparable performance, making A-TCN an efficient alternative over BiLSTM since convolutions can be trained in parallel. A-TCN is significantly faster than BiLSTM at inference time (270%∼334% improvement in the amount of text diacritized per minute).

1 Introduction

A diacritic is a mark that is added above, below, or within a letter, constructing a new letter or characterizing it with a different sound (Wells, 2000). In languages such as Arabic and Hebrew, some vowels are not part of the alphabet and diacritics are used for vowel specification. Moreover, many languages that include diacritics such as Yoruba and Vietnamese sometimes omit them in writing for various reasons such as difficulty in typing diacritics on keyboards or digitizing electronic text (Scannell, 2011).

Arabic, on the other hand, considers diacritics as an optional choice in writing even in formal settings,[1] and familiarity with the language is relied upon to derive the meaning based on context. Although people can extrapolate missing diacritics with near perfect accuracy in such languages, missing diacritics pose a challenge for computational models due to increased ambiguity.

Diacritization is the process of automatically restoring missing diacritics for each character in written text. It is important in many NLP applications such as automatic speech recognition (Vergyri and Kirchhoff, 2004) and speech synthesis (Ungurean et al., 2008). Most state-of-the-art diacritization models use Bidirectional Long Short Term Memory (BiLSTM) (Hochreiter and Schmidhuber, 1997) as a sequential classification problem, or as a sequence-to-sequence transduction problem to convert the original text into diacritized form (Orife, 2018; Zalmout and Habash, 2017; Belinkov and Glass, 2015). Generally speaking, LSTM has shown great success for sequential data, leveraging long range dependencies and preserving the temporal order of the sequence (Cho et al., 2014; Graves, 2013). However, LSTM requires intensive computational resources both for training and inference due to its sequential nature.

As an alternative, recent NLP technologies such as machine translation (Gehring et al., 2017) and language modeling (Dauphin et al., 2016) have investigated other models such as convolutional neural networks (CNN). Convolutional-based architectures utilize hierarchical rather than sequential relationships between the input elements. Tem-

[*]The work was done while the author was an intern at AWS, Amazon AI.

[1]With the exception of religious scripture and educational books for children, which are always diacritized.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1442–1448, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

poral Convolutional Networks (TCN) is a generic family of architectures that has been developed to alleviate the problem of training deep sequential models and is shown to provide significant improvement over LSTMs across different benchmarks (Bai et al., 2018; Lea et al., 2017). TCNs integrate *causal* convolutions where output at a certain time is convolved only with elements from earlier times in the previous layers. In addition, it is possible to train deep sequential models in parallel and use lower computational requirements rendering TCNs scalable to larger datasets.

In this study, we evaluate the application of the TCN architecture as described in (Bai et al., 2018) but devised as a character-level sequence model for diacritization since character-based models generalize better to unseen data compared to word-based models for most languages. Because diacritization is dependent on both past and future states, we further apply a variant of TCNs, namely *Acausal* Temporal Convolutional Network (A-TCN) (Lea et al., 2017), allowing the model to learn from previous as well as future context. We evaluate the architectures on three very different languages: Arabic, Vietnamese, and Yoruba.

To the best of our knowledge, TCN and A-TCN have not been investigated before for diacritization. In this paper, we show that A-TCN outperforms TCN while yielding comparable performance to BiLSTM but with the added advantage of being more efficient (speed and less computational footprint, i.e. decreased need for significant computational resources).

2 Related Work

A fair number of studies have been developed for the task of diacritization for different languages that include diacritics (Yarowsky, 1994; De Pauw et al., 2007; Scannell, 2011; Alqahtani et al., 2016, 2019). Feature engineering and classical machine learning algorithms such as Hidden Markov Models, Maximum Entropy Models, and Finite State Transducer were the dominant approaches (Nelken and Shieber, 2005; Zitouni et al., 2006; Elshafei et al., 2006). However, recent studies show significant improvement using deep neural networks (Belinkov and Glass, 2015; Pham et al., 2017; Orife, 2018). While these deep models achieve state-of-the-art performance, they mainly rely on the use of recurrent architectures such as BiLSTM, which are relatively inefficient.

Pham et al. (2017) view the task of diacritization for Vietnamese as a machine transduction problem from undiacritized to diacritized text at the word level. Orife (2018) addresses the problem on Yoruba in a similar way and compares soft- and self- attention sequence-to-sequence performance on the word level empirically showing that self-attention significantly outperforms BiLSTM.

Náplava et al. (2018) uses BiLSTM models with residual connections to train deeper models at the character level in several languages, including Vietnamese. For inference, they use beam search coupled with a language model to select among the possible diacritic patterns from the output. Zalmout and Habash (2017) develops a morphological disambiguation model to determine Arabic morphological features including diacritization. They train the model using BiLSTM while leveraging a LSTM-based language model as well as other morphological features to rank and score the output analyses.

3 Approach

We evaluate the performance of convolutional sequence models, TCN and A-TCN, in the context of diacritization and compare that to the recurrent sequential models, LSTM and BiLSTM. The task is formulated as a sequence classification such that we predict a diacritic for each character in the input.[2]

3.1 Convolutional Neural Network (TCN)

As TCN is a generic family of models, multiple architectures have been successfully developed (Dauphin et al., 2016; Kalchbrenner et al., 2016; Oord et al., 2016; Gehring et al., 2017; Lea et al., 2017; Bai et al., 2018). We choose the TCN architecture described in (Bai et al., 2018) [BAI18] as it integrates best techniques from the previous architectures while maintaining simplicity.

BAI18's TCN model satisfies the two main characteristics that allows sequential modeling: 1. Using 1-D fully convolutional network (Long et al., 2015) to ensure that the length of each layer is the same as the input by zero padding; 2. Using causal convolutions, which convolve output at time t with elements from time $t-1$ and earlier in the previous layers. As Bai et al. (2018) indicated,

[2]We have also investigated BiLSTM-CRF, the model training time has been greatly increased without substantial improvement in terms of accuracy.

developing a TCN architecture that only considers these two characteristics restricts how far the model can utilize previous information. Thus, to ensure learning from longer effective history, BAI18 further integrate dilated convolutions (Yu and Koltun, 2015), enabling an exponentially large receptive field correlated with the depth of the network. To enable deeper learning, they integrate a residual block (He et al., 2016), in which each block includes two layers of dilated causal convolution as fully illustrated in (Bai et al., 2018).

3.2 Acausal Convolutional Neural Network (A-TCN)

TCN is beneficial for applications that restrict information flow from the past, such as language modeling (Bai et al., 2018; Dauphin et al., 2016); however, this is not sufficient for diacritization. Incorporating future and past context has been previously integrated in different versions of TCN (Lea et al., 2017; Gehring et al., 2017) but it either did not enhance the performance of their tasks or it was evaluated on convolutional sequence-to-sequence models rather than sequential models as in the case of our study.

To incorporate both future and past context, we relax the causality constraint by integrating acausal convolution rather than causal convolution, hence A-TCN, as illustrated in Figure 1. A-TCN is a tweaked variant of TCN such that the model convolves information from x_{t-d} to x_{t+d} (previous and following states) instead of x_{t-d} to x_t (previous states) only.[3] In our implementation, we use layer normalization (Ba et al., 2016) rather than weight normalization. The extent in which context is considered is influenced by the number of layers as well as the kernel size. Each character is constructed from itself and $k-1$ characters, where *(k: kernel size)* . Additionally, as we go deeper, the model further incorporates different additional $k-1$ characters, skipping $d-1$ characters, where *(d: dilation factor)*, to incorporate the character at the d^{th} position from both sides (see Figure 1).

4 Experimental Setup

Dataset: For Arabic, we use the Arabic Treebank (ATB) dataset: parts 1, 2, and 3 and follow the same data division as (Diab et al., 2013).

[3]Lea et al. (2017) investigated acausal convolution in their architecture but reported insignificant improvement over causal convolution in their problem space.

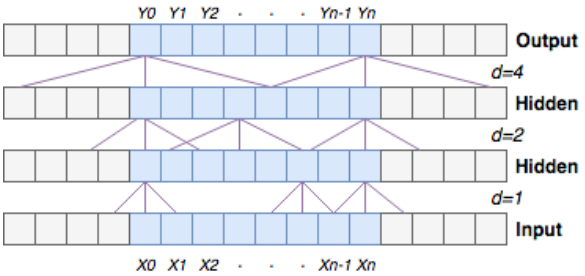

Figure 1: A dilated acausal convolution with 3 as a filter size and dilation factors equals to 1,2, and 4. White slots represent zero padding while colored slots represent characters. The remaining components of A-TCN are fully explained in (Bai et al., 2018).

Data	Arabic	Vietnamese	Yoruba
Train	502,938	800,022	800,771
Test	63,168	786,236	44,598
Dev	63,126	408,093	44,314
OOV	7.3%	1.3%	2.6%

Table 1: Number of word tokens as well as Out-Of-Vocabulary (OOV) rate. OOV rate indicates the percentage of undiacritized words in the test set not observed during training.

We use datasets provided by Orife (2018) and Jakub Nplava (2018) for Yoruba and Vietnamese, respectively. Most languages, especially those that are severely impacted by diacritics, rarely have such amounts of diacritized datasets. Thus, we sample a moderate size subset of the training data for Vietnamese, roughly 3.7% to train the models. In the process, we remove from the training set all sentences that have at least one word of more than 10 characters,[4] or that do not have at least one diacritic, or that contain more than 70 words. Table 1 illustrates the dataset statistics.

To augment the dataset without requiring additional annotated dataset, we segment each sentence into space tokenized units;[5] each unit is further segmented into its characters and passed through the model along with a specific number of previous and future words. We add the special word boundary "<w>" between words with a window size of 10 words before and after the target word (21 words in total).[6]

Parameter Setting: The character embedding vectors are of dimension size 45, randomly ini-

[4]Vietnamese is characterized by having short word length.

[5]We did not investigate different types of tokenization. Relying on white space is simple and avoids additional preprocessing steps.

[6]We empirically tuned the window size on dev data.

tialized with a uniform distribution between [-0.1,0.1]. We use Adam optimization (Kingma and Ba, 2014) with 0.001 learning rate. For LSTM and BiLSTM, we use 3 layers and 250 hidden units. For TCN and A-TCN, we use 3 layers, 500 hidden units, and a kernel size of 5. Hidden units are initialized randomly using Xavier (Glorot and Bengio, 2010) with a magnitude of 3. For regularization, the dropout is set to 0.5 (Srivastava et al., 2014). We increase the dilation factor in TCN exponentially with the depth of the network.

5 Results

System	DER	WER	OOV
Arabic			
Pasha et al. (2014)	-	12.3%	29.8%
Zalmout and Habash (2017)	-	8.3%	**20.2%**
LSTM	19.2%	51.9%	86.6%
TCN	17.5%	47.6%	87.2%
BiLSTM	**2.8%**	**8.2%**	33.6%
A-TCN	3.0%	10.2%	36.3%
Vietnamese			
Náplava et al. (2018)	11.2%	44.5%	-
LSTM	13.3%	39.5%	33.1%
TCN	11.1%	32.9%	32.4%
BiLSTM	2.6%	7.8%	**15.3%**

LSTM	13.4%	37.2%	84.9%
TCN	12.7%	35.5%	83.8%
BiLSTM	**3.6%**	**12.1%**	**69.3%**
A-TCN	**3.8%**	12.6%	70.2%

Table 2: Models' performance on all words and OOV words per language. For Vietnamese, Náplava et al. (2018) reports 2.45% for WER on a much larger dataset (∼25M words), which is significantly better than our model.

We use two standard accuracy measures for evaluation: Diacritic Error Rate (DER) and Word Error Rate (WER). Table 2 shows the performance of the considered architectures across the sample languages.

Importance of modeling past and future context: A-TCN yields significant improvement over TCN, which indicates the importance of considering future and previous context for diacritization. Similarily BiLSTM significantly outperforms LSTM across all three languages. Overall, architectures that allow only unidirectional information flow provide lower performance than those that utilize context from both directions.

Recurrent vs. convolutional architectures: In line with prior work, across all three languages, TCN outperforms LSTM in the unidirectional architectures. A-TCN yields comparable results to BiLSTM except in the case of Arabic where the WER drops by ∼2%.

OOV rate performance To evaluate the model's robustness beyond observed training data, we specifically compare their WER performance on Out-Of-Vocabulary (OOV) words. BiLSTM has better ability to generalize on unseen data compared to A-TCN in Arabic and Yoruba, whereas both architectures are comparable in Vietnamese.

Qualitative Analysis: For Arabic, we further examine the impact of both BiLSTM and A-TCN on syntactic diacritics, aka inflectional diacritics which reflect syntactic case and mood primarily. These inflectional diacritics typically occur word finally in broken plurals and singular nouns as diacritics indicating syntactic case. Verbal mood is also marked word finally on verbs. We approximate the inflectional diacritics by computing the percentage of incorrectly predicted diacritics for the last characters of each word. BiLSTM yields a better performance (5.1% WER) compared to A-TCN (5.9% WER).

In addition, we randomly choose 20 sentences (605 words) to examine their categorical errors. We found similar errors in both architectures which include passive and active voice (e.g. نَشَرَت / na$arat[7] "spread" and نُشِرَت / nu$irat "been spread"), inflectional diacritics (e.g. وُصُولَ / wuSuwla and وُصُولُ / wuSuwlu, both mean "arrival" but have different syntactic positions), and named entities.[8] Thus, incorporating information from longer history in TCN architectures such as A-TCN compared to recurrent models such BiLSTM did not enhance learning inflectional diacritics.

We analyzed the confusion matrix and found that both architectures BiLSTM and A-TCN exhibit similar trends in the types of generated errors. In Arabic, the top two diacritics that are in-

[7]We adopt Buckwalter Transliteration encoding into Latin script for rendering Arabic text http://www.qamus.org/transliteration.htm.

[8]Diacritics in named entities are usually not consistent even among native speakers.

Lang	BiLSTM	A-TCN	Difference	
			Time	Efficiency
AR	376.85	132.55	-64.8%	+284%
VI	4187.81	1542.34	-63.2%	+271%
YO	461.19	138.45	-70.0%	+334%

Table 3: Inference time in seconds for each architecture across languages. *Efficiency* is defined in terms of text diacritization rate (amount of text diacritized per minute).

correctly diacritized by both A-TCN and BiLSTM (normalized by their frequencies) are N and $\sim N$ which represent indefiniteness with and without doubling the consonants. The least diacritics that are incorrectly diacritized are no diacritics, sukun which represents the absence of diacritics, and two short vowels *i* and *a*. This is consistent with the frequency of diacritics in Arabic except that in the diacritic *u* which is also frequent but falls in the middle range of errors; this diacritic usually represents passive voice in Arabic which relies on syntactic relations between words. The same behavior can be found in Vietnamese and Yoruba where top and least erroneous diacritics are shared between both architectures.

Efficiency Comparison: We provide a comparative analysis of models' training and inference runtime (Table 3). During training time, A-TCN yields similar efficiency gains across all three languages with comparable performance in terms of accuracy. The convergence criteria was set as at least 1% improvement in accuracy from the previous epoch. During inference time, A-TCN was 2.7$\sim$3.3X faster in diacritizing text while providing comparable accuracy. This leads to 271$\sim$334% improvement in terms of text diacritization rate in the amount of text diacritized per minute. This supports our overall observation that A-TCN is a solid alternative to BiLSTM for this problem space due to its efficient performance especially for industrial settings where time is a crucial factor. All experiments were carried out on a single Tesla P100 GPU.

For Arabic, for instance, BiLSTM took $\sim$19 hours to converge while A-TCN took $\sim$14 hours. The DER were 2.8% and 3.0% respectively. Thus, A-TCN was 24% faster than BiLSTM while being marginally lower by 0.2% in terms of DER.

Comparison to Prior Work: Table 2 shows the performance of previous models trained on the same data. For Arabic, both A-TCN and BiLSTM provide significantly better performance than MADAMIRA (Pasha et al., 2014), which is a morphological disambiguation tool for Arabic. The performance of Zalmout and Habash (2017)'s model falls in between BiLSTM and A-TCN. As opposed to our character-based models, both previous models use other morphological features along with a language model to rank all possible diacritic choices. We believe that this additional semantic and morphological information help their models perform better on OOV words.

For Vietnamese, when we re-train Náplava et al. (2018) model on the same sample discussed in Section 4, both A-TCN and BiLSTM provide significantly better results. Náplava et al. (2018) also use BiLSTM but with different parameter settings and different dataset preparation.[9] For Yoruba, both character-based architectures provide lower performance than Orife (2018)'s model. However, Orife (2018) uses seq2seq modeling which generate diacritized sentences that are not of the same length as the input and can generate words not present in the original sentence (hallucinations). This is unpleasant behaviour for diacritization especially if used in text-to-speech applications.

6 Conclusion

In this study, we show that character-based convolutional architectures for diacritization yield comparable performance to both word and character based RNN ones for multiple languages, albeit at a significantly lower computational cost. Moreover, character based modeling yields better performance overall for the diacritization task.

In all cases, A-TCN performs much better than TCN, with a reduction of up to 40% in error rate, which means that using future information is crucial in diacritization. All in all, the decision whether to use A-TCN or BiLSTM is a trade-off between accuracy and efficiency. A-TCN provides efficient solutions with comparable accuracy and comes in more handy for applications that need predicting diacritics on the fly such as text-to-speech applications and simultaneous machine translation. A-TCN was 2.7$\sim$3.3X faster than BiLSTM at inference time (271%$\sim$334% improvement in the amount of text diacritized per minute), crucially at comparable accuracies, making it a very attractive solution for industrial applications in particular.

[9] We augment the dataset as explained in Section 4.

Improving Generative Visual Dialog by Answering Diverse Questions

Vishvak Murahari[1] **Prithvijit Chattopadhyay**[1]

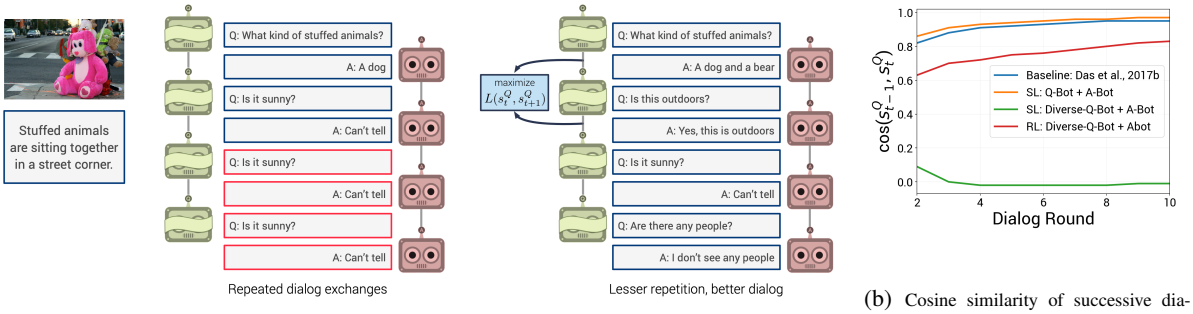
Abstract

Prior work on training generative Visual Dialog models with reinforcement learning (Das et al., 2017b) has explored a Q-BOT-A-BOT image-guessing game and shown that this 'self-talk' approach can lead to improved performance at the downstream dialog-conditioned image-guessing task. However, this improvement saturates and starts degrading after a few rounds of interaction, and does not lead to a better Visual Dialog model. We find that this is due in part to repeated interactions between Q-BOT and A-BOT during self-talk, which are not informative with respect to the image. To improve this, we devise a simple auxiliary objective that incentivizes Q-BOT to ask diverse questions, thus reducing repetitions and in turn enabling A-BOT to explore a larger state space during RL *i.e.* be exposed to more visual concepts to talk about, and varied questions to answer. We evaluate our approach via a host of automatic metrics and human studies, and demonstrate that it leads to better dialog, *i.e.* dialog that is more diverse (*i.e.* less repetitive), consistent (*i.e.* has fewer conflicting exchanges), fluent (*i.e.* more human-like), and detailed, while still being comparably image-relevant as prior work and ablations.

1 Introduction

Our goal is to build agents that can *see* and *talk i.e.* agents that can perceive the visual world and communicate this understanding in natural language conversations in English. To this end, Das et al. (2017a); de Vries et al. (2017) proposed the task of Visual Dialog – given an image, dialog history consisting of a sequence of question-answer pairs, and a follow-up question about the image, predict a free-form natural language answer to the question – along with a dataset and evaluation metrics[1].

Posing Visual Dialog as a supervised learning problem is unnatural. This is because at every round of dialog, the agent's answer prediction is thrown away and it gets access to ground-truth dialog history, thus disabling it from steering conversations during training. This leads to compounding errors over long-range sequences at test time, a problem also common in training recurrent neural networks for language modeling (Bengio et al., 2015; Ross et al., 2011; Ranzato et al., 2016).



To overcome this, Das et al. (2017b) devised a goal-driven approach for training Visual Dialog agents with deep reinforcement learning. This is formulated as a game between two agents – Q-BOT (that asks questions) and A-BOT (that answers questions). Q-BOT is shown a one-line description of an unseen image that A-BOT has access to and Q-BOT is allowed to ask questions (in natural language) to A-BOT for a fixed number of rounds and simultaneously make predictions of the unseen image. Both agents are rewarded for Q-BOT's image-guessing performance and trained with REINFORCE (Williams, 1992) to optimize this reward. Thus, there is incentive for Q-BOT to ask questions informative of the hidden image, and for A-BOT to provide meaningful answers.

While this reinforcement learning approach leads to improved performance on the image-guessing task than supervised learned agents, it has a few shortcomings – 1) image-guessing performance degrades after a few rounds of dialog (Fig. 2e), and 2) these improvements over supervised learning do not translate to an improved A-BOT, *i.e.* responses from this Visual Dialog agent are not necessarily better (on automatic metrics or human judgements), just that the Q-BOT-A-BOT pair is sufficiently in sync to do well at image-guessing.

We begin by understanding why this is the case, and find that Q-BOT-A-BOT dialog during 'self-talk' often tends to be repetitive *i.e.* the same question-answer pairs get repeated across rounds (Fig. 1a left). Since repeated interactions convey no additional information, image-guessing perfor-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1449–1454, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

(a) **Left**. Prior work on training generative Visual Dialog models with RL on an image-guessing task between Q-BOT and A-BOT (Das et al., 2017b) leads to repetitive dialog. **Right**. We devise an auxiliary objective that incentivizes Q-BOT to ask diverse questions, thus reducing repetitions and enabling A-BOT to be exposed to more varied questions during RL, overall leading to better dialog, as measured by automatic metrics and human studies.

(b) Cosine similarity of successive dialog state embeddings within Q-BOT. Prior work (Das et al., 2017b) has high similarity. Our approach explicitly minimizes this similarity leading to more diverse dialog.

Figure 1

mance saturates, and even starts to degrade as the agent forgets useful context from the past.

These repetitions are due to high similarity in Q-BOT's context vectors of successive rounds driving question generation (Fig. 1b). To address this, we devise a smooth-L1 penalty that penalizes similarity in successive state vectors (Section 3). This incentivizes Q-BOT to ask diverse questions, thus reducing repetitions and in turn enabling A-BOT to explore a larger part of the state space during RL *i.e.* be exposed to more visual concepts to talk about, and varied questions to answer (Section 6).

Note that a trivial failure mode with this penalty is for Q-BOT to start generating diverse but totally image-irrelevant questions, which are not useful for the image-guessing task. A good balance between diversity and image-relevance in Q-BOT's questions is necessary to improve at this task.

We extensively evaluate each component of our approach against prior work and baselines:

- Q-BOT on diversity and image-relevance of generated questions during Q-BOT-A-BOT self-talk. We find that diverse-Q-BOT asks *more novel questions* while still being image-relevant.

- Q-BOT-A-BOT self-talk on consistency, fluency, level of detail, and human-interpretability, through automatic metrics and human studies. We find that diverse-Q-BOT-A-BOT dialog after RL is *more consistent, fluent, and detailed*.

- A-BOT on precision and recall of generated answers on the VisDial dataset (Das et al., 2017a) *i.e.* quality of answers to human questions. Training diverse-Q-BOT + A-BOT with RL does not lead to a drop in accuracy on VisDial.

2 Preliminaries

We operate in the same setting as Das et al. (2017b) – an image-guessing task between a questioner (Q-BOT) and an answerer (A-BOT) – where Q-BOT has to guess the image A-BOT has access to by asking questions in multi-round dialog.

We adopt the same training paradigm[2] consisting of 1) a supervised pre-training stage where Q-BOT and A-BOT are trained with Maximum Likelihood Estimation objectives on the VisDial dataset (Das et al., 2017a), and 2) a self-talk RL finetuning stage where Q-BOT and A-BOT interact with each other and the agents are rewarded for each successive exchange based on incremental improvements in guessing the unseen image. We learn parameterized policies $\pi_{\theta_Q}(q_t|s_{t-1}^Q)$ and $\pi_{\theta_A}(a_t|s_t^A)$ for Q-BOT and A-BOT respectively which decide what tokens to utter (*actions*: question q_t and answer a_t at every dialog round t) conditioned on the context available to the agent (*state* representations: s_{t-1}^Q, s_t^A). Q-BOT additionally makes an image feature prediction $\hat{y}_t$ at every dialog round, and the reward is $r_t = ||y^{gt} - \hat{y}_{t-1}||_2^2 - ||y^{gt} - \hat{y}_t||_2^2$, *i.e.* change in distance to the true representation y^{gt} before and after a dialog round. We use REINFORCE (Williams, 1992) to update agent parameters, *i.e.* Q-BOT and A-BOT are respectively updated with $\mathbb{E}_{\pi_Q,\pi_A}[r_t \nabla_{\theta_Q} \log \pi_Q(q_t|s_{t-1}^Q)]$ and $\mathbb{E}_{\pi_Q,\pi_A}[r_t \nabla_{\theta_A} \log \pi_A(a_t|s_t^A)]$ as gradients.

Our transition from supervised to RL is gradual – we supervise for N rounds and have policy-gradient updates for the remaining $10-N$, starting from $N = 9$ till $N = 4$, one round at a time. After reaching $N = 4$, repeating this procedure from $N = 9$ led to further (marginal) improvements.

[2] github.com/batra-mlp-lab/visdial-rl

Both Q-BOT and A-BOT are modeled as Hierarchical Recurrent Encoder-Decoder architectures (Serban et al., 2016). Q-BOT's fc7 (Simonyan and Zisserman, 2015) feature prediction of the unseen image ($\hat{y}$) is conditioned on the dialog history so far (s^Q_{t-1}) via a regression head[3].

3 Smooth-L1 Penalty on Question Repetition

Our goal is to encourage Q-BOT to ask a diverse set of questions so that when A-BOT is exposed to the same during RL finetuning, it is better able to explore its state space[4]. Furthermore, asking diverse questions allows Q-BOT-A-BOT exchanges across rounds to be more informative of the image, thus more useful for the image-guessing task.

We observe that agents trained using the paradigm proposed by Das et al. (2017b) suffer from repetition of *context* across multiple rounds of dialog – similar dialog state embeddings across multiple rounds leading to repeated utterances and similar predicted image representations, which consequently further increases similarity in state embeddings. Fig. 1b shows increasing $\cos(s^Q_{t-1}, s^Q_t)$ across dialog rounds for Das et al. (2017b).

To encourage Q-BOT to ask diverse questions, we propose a simple auxiliary loss that penalizes similar dialog state embeddings. Specifically, given Q-BOT states – s^Q_{t-1}, s^Q_t – in addition to maximizing likelihood of question (during supervised pretraining), or image-guessing reward (during self-talk RL finetuning), we maximize a smooth-L1 penalty on $\Delta_t = \texttt{abs}(\left\|s^Q_{t-1}\right\|_2 - \left\|s^Q_t\right\|_2)$,

$$f(\Delta_t) = \begin{cases} 0.5\Delta_t^2 & \text{if } \Delta_t < 0.1 \\ 0.1(\Delta_t - 0.05) & \text{otherwise} \end{cases} \quad (1)$$

resulting in $\sum_{t=2}^{N} f(\Delta_t)$ as an additional term in the overall objective (N = no. of dialog rounds).

Note that in order to maximize this penalty, Q-BOT has to push s^Q_{t-1} and s^Q_t further apart, which can only happen if s^Q_{t-1} is updated using a question-answer pair that is different from the previous exchange, thus overall forcing Q-BOT to ask different questions in successive dialog rounds. Similar diversity objectives have also been explored in Li et al. (2016b) as reward heuristics.

[3]Please refer to appendix for architecture details.

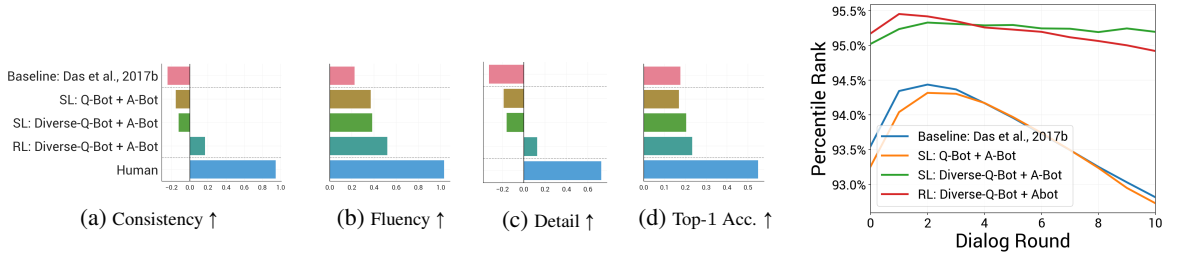
[4]A-BOT's state-space is characterized by a representation of the question, image, and the dialog history so far.

Before arriving at (1), and following Fig. 1b, we also experimented with directly minimizing cosine similarity, $\cos(s^Q_{t-1}, s^Q_t)$. This led to the network learning large biases to flip the direction of successive s^Q_{t-1} vectors (without affecting norms), leading to question repetitions in alternating rounds.

4 Experiments

Baselines and ablations. To understand the effect of the proposed penalty, we compare our full approach – '`RL: Diverse-Q-bot + A-bot`' – with the baseline setup in Das et al. (2017b), as well as several ablations – 1) '`SL: Q-bot + A-bot`': supervised agents (*i.e.* trained on VisDial data under MLE, no RL, no smooth-L1 penalty). Comparing to this quantifies how much our penalty + RL helps. 2) '`SL: Diverse-Q-bot + A-bot`': supervised agents where Q-BOT is trained with the smooth-L1 penalty. This quantifies gains from RL.

Automatic Metrics. To evaluate Q-BOT's *diversity* (Table 1), we generate Q-BOT-A-BOT dialogs (with beam size = 5) for 10 rounds on VisDial v1.0 val and compute 1) Novel Questions: the number of new questions (via string matching) in the generated dialog not seen during training, 2) Unique Questions: no. of unique questions per dialog instance (so $\leqslant 10$), 3) Dist-n and Ent-n (Zhang et al., 2018; Li et al., 2016a): the number and entropy of unique n-grams in the generated questions normalized by the total number of tokens, and 4) Mutual Overlap (Deshpande et al., 2019): BLEU-4 overlap of every question in the generated 10-round dialog with the other 9 questions, followed by averaging these 10 numbers. To measure Q-BOT's *relevance*, we report the negative log-likelihood under the model of human questions from VisDial. We evaluate A-BOT's answers to human questions from the VisDial dataset on the retrieval metrics introduced by Das et al. (2017a) (Table 2). Finally, we also evaluate performance of the Q-BOT-A-BOT pair at image-guessing (Fig. 2e), which is the downstream task they are trained with RL for.



Human Studies. To evaluate how human-understandable Q-BOT-A-BOT dialogs are, we conducted a study where we showed humans these dialogs (from our agents as well as baselines), along with a pool of 16 images from the VisDial v1.0 test-std split – consisting of the unseen image, 5 nearest neighbors (in fc7 space), and 10 random images – and asked humans to pick their top-5 guesses for the unseen image. Our hypothesis

(e) Q-BOT-A-BOT image-guessing task performance

Figure 2: (**a-d**): Human evaluation of Q-BOT-A-BOT dialog over 50 images and 200 human subjects for each model variant. (**e**): Percentile rank (higher is better) of the true image (shown to A-BOT) as retrieved using fc7 feature predictions from Q-BOT.

was that if questions are more diverse, the dialog will be more image-informative, and so humans should be able to better guess which image was being talked about. We report top-1 accuracy of true image in human guesses. We also asked humans to rate Q-BOT-A-BOT dialog on consistency, fluency, and level of detail on a 5-point Likert scale.

5 Implementation Details

We used beam search with a beam size of 5 during self-talk between all Q-BOT-A-BOT variants. NDCG scores on the v1.0 val split and the total SL loss (on the same split) were used to select the best SL A-BOT and Q-BOT checkpoints respectively. We used a dropout rate of 0.5 for all SL-pretraining experiments and no dropout for RL-finetuning. We used Adam (Kingma and Ba, 2015) with a learning rate of 10^{-3} decayed by $\sim$0.25 every epoch, upto a minimum of 5×10^{-5}.

The objective for training Diverse-Q-BOT was a sum of the smooth-L1 penalty (introduced in Section 3), cross entropy loss, and L2 loss between the regression head output and the fc7 (Simonyan and Zisserman, 2015) embedding of the image. We observed that coefficients in the range of $1e^{-3}$ to $1e^{-5}$ worked best for the smooth-L1 penalty. We also observed that training for a large number of epochs ($\sim$80) with the above mentioned range of coefficient values led to the best results.

6 Results

- **Q-BOT's diversity** (Table 1): The question-repetition penalty consistently increases diversity (in both SL and RL) over the baseline! `RL: Diverse-Q-bot` asks ~1.5 more unique questions on average than Das et al. (2017b) (6.70 → 8.19) for every 10-round dialog, ~6.3x more novel questions (71 → 449), and a higher fraction and entropy of unique generated n-grams, while still staying comparably relevant (NLL).
- **A-BOT on VisDial** (Table. 2): `RL: A-bot` outperforms `SL: A-bot`, but does not statistically improve over the baseline on answering human questions from VisDial[5] (on v1.0 val & test-std).
- **Image-guessing task** (Fig. 2e): `Diverse-Q-bot + A-bot` (SL and RL) significantly outperform the baseline on percentile rank of ground-truth image as retrieved using Q-BOT's fc7 prediction. Thus, the question-repetition penalty leads to a more informative communication protocol.
- **Human studies** (Fig. 2): Humans judged `RL: Diverse-Q-bot + A-bot` dialog significantly more consistent (fewer conflicting exchanges), fluent (fewer grammatical errors), and detailed (more image-informative) over the baseline and supervised learning. This is an important result. Performance on GuessWhich, together

[5]This is consistent with trends in Das et al. (2017b).

with these dialog quality judgements from humans show that agents trained with our approach develop a more effective communication protocol for the downstream image-guessing task, while still not deviating off English, which is a common pitfall when training dialog agents with RL (Kottur et al., 2017; Lewis et al., 2017).

Note that since our penalty (Eqn. 1) is structured to avoid repetition across successive rounds, one possible failure mode is that Q-BOT learns to ask the same question every alternate dialog round (at t and $t+2$). Empirically, we find that this happens $\sim$15% of times (2490 times out of $\sim$16.5k question pairs) on v1.0 val for RL: Diverse Q-BOT + A-BOT compared to $\sim$22% for SL: Q-BOT + A-BOT. This observation, combined with the fact that Diverse-Q-BOT asks $\sim$1.6 more unique questions relative to SL: Q-BOT across 10 rounds suggests that simply incentivizing diversity in successive rounds works well empirically. We hypothesize that this is because repeating questions every other round or other such strategies to game our repetition penalty is fairly specific behavior that is likely hard for models to learn given the large space of questions Q-BOT could potentially ask.

7 Related Work

Our work is related to prior work in visual dialog (Das et al., 2017a; de Vries et al., 2017) and modeling diversity in text-only dialog (Zhang et al., 2018; Li et al., 2016a,b).

Closest to our setting is work on using conditional variational autoencoders for self-talk in visual dialog (Massiceti et al., 2018), where diversity is not explicitly modeled but is measured via metrics specific to the proposed architecture.

Adding constraints to generate a diverse set of natural language dialog responses have previously been explored in Zhang et al. (2018) via adversarial information maximization, in Gao et al. (2019) by jointly modeling diversity and relevance in a shared latent space, and in Li et al. (2016a) using a maximum mutual information criterion. In contrast, we are interested in diversity at the level of the entire dialog (instead of a single round) – reducing repetitions in QA pairs across multiple rounds. Our repetition penalty is partly inspired by the 'Information Flow' constraint in Li et al. (2016b). As detailed in Section 2, we experimented with similar forms of the penalty and eventually settled on smooth-L1. To the best of our knowledge, we are the first to explicitly model diversity as a constraint in visual dialog.

8 Conclusions & Future Work

We devised an auxiliary objective for training generative Visual Dialog agents with RL, that incentivizes Q-BOT to ask diverse questions. This reduces repetitions in Q-BOT-A-BOT dialog during RL self-talk, and in turn enables A-BOT to be exposed to a larger state space. Through extensive evaluations, we demonstrate that our Q-BOT-A-BOT pair has significantly more diverse dialog while still being image-relevant, better downstream task performance, and higher consistency, fluency, and level of detail than baselines. Our code will be publicly released, and we hope this will serve as a robust base for furthering progress on training visual dialog agents with RL for other multi-agent grounded language games, adapting to learn to talk about novel visual domains, *etc*.

Cross-lingual Transfer Learning with Data Selection for Large-Scale Spoken Language Understanding

Abstract

A typical cross-lingual transfer learning approach boosting model performance on a resource-poor language is to pre-train the model on *all* available supervised data from another resource-rich language. However, in large-scale systems, this leads to high training times and computational requirements. In addition, characteristic differences between the source and target languages raise a natural question of whether *source-language data selection* can improve the knowledge transfer. In this paper, we address this question and propose a simple but effective language model based source-language data selection method for cross-lingual transfer learning in large-scale spoken language understanding. The experimental results show that with data selection i) the source data amount and hence training speed is reduced significantly and ii) model performance is improved.

1 Introduction

Spoken Language Understanding (SLU) plays an important role in spoken language technology and is typically divided into two sub-tasks: Intent Classification (IC) and Slot Filling (SF). While the former identifies a speaker's intent, the latter extracts semantic constituents from the natural language query. Recently, there have been emerging efforts on Cross-Lingual Transfer Learning (CLTL) methods to reduce data requirements in deep neural network (DNN) based SLU. A typical approach is to pre-train the model on labeled data from a richly resourced language, and then either apply it directly on a target language (Upadhyay et al., 2018) or fine-tune it on a smaller amount of supervised data from a target language (Do and Gaspers, 2019). However, both in SLU and other NLP tasks, prior work on CLTL typically utilized all available source data to transfer knowledge, as it has been mainly investigated in rather small Academic settings. However, in large-scale settings with millions of utterances, this would lead to costly training times, high computational requirements and optimization difficulties. Moreover, the different characteristics between the source and target languages raise a natural question of whether source-language data selection in which only the most relevant source instances are picked for pre-training can improve CLTL performance, as a considerable amount of source utterances might be "irrelevant" to the target language or even yield negative transfer.

Addressing these questions, in this paper we explore source-language data selection for CLTL in SLU, focusing especially on large-scale settings in which we assume the existence of a *large* amount (millions) of source data and a *moderate* amount (thousands) of target data. Since the effectiveness of pre-training in CLTL depends on the similarity of the source data distribution and the real distribution of the target language, we propose a source-language data selection method which computes the relevance score of each source instance to the target language by using several N-gram language model based metrics. Our method is designed to satisfy *both* IC and SF sub-tasks in a multi-task training scenario, and to select data from *multiple* source languages, which have been rarely studied in the literature.

Our experimental results show that our proposed data selection method: i) improves CLTL performance in large-scale settings, while reducing the amount of source data significantly ii) brings higher gains to SF but does not hurt IC, and iii) can select data efficiently from multiple source languages for a single target language.

2 Related work

Prior work on CLTL for SLU has mainly focused on using machine translation (e.g. García et al. (2012); He et al. (2013); Gaspers et al. (2018)). Until recently, few approaches based on cross-lingual joint training and cross-lingual supervised pre-training for DNNs have been proposed. The former takes advantage of the knowledge transferring in a SLU system by jointly training (relatively balanced) source and target data (e.g. Li et al. (2018)). Meanwhile, the latter is usually used when the amount of source data is significantly larger than the amount of target data. In particular, the SLU model is pre-trained on a large amount of supervised source data, and then either tested directly on the target language (e.g. Upadhyay et al. (2018)), or fine-tuned on a smaller amount of supervised target data (e.g. Do and Gaspers (2019)). Our CLTL method follows the line of Do and Gaspers (2019), but instead of utilizing all available source data, we aim at selecting the most relevant subset of the source data for the target language.

Data selection has been studied in the field of domain adaptation with most of the work targeting machine translation (Axelrod et al., 2011; van der Wees et al., 2017). These approaches usually rank sentence pairs in a large bitext from a source domain according to their difference in cross-entropy or perplexity with respect to a target domain corpus and then select the top n sentence pairs to train a machine translation system for the target domain. Although this task also deals with multiple languages, it is not a CLTL problem. The application of data selection on other tasks are relatively rare, e.g., dependency parsing (Plank and van Noord, 2011), sentiment analysis (Remus, 2012), POS tagging (Ruder and Plank, 2017).

Several common data metrics have been proposed to rank the relevance of the source instances to the target domain, e.g, word similarity measures, diversity. However, to the best of our knowledge, data selection has *not yet* been explored for DNN-based CLTL in SLU. In addition, two challenges tackled in this paper, i.e. applying data selection for a multi-task training scenario and dealing with multiple source languages, have been rarely studied in the literature.

3 Spoken language understanding

3.1 Task definition

Suppose for a language l with word vocabulary $\mathcal{V}_l$, intent vocabulary $\mathcal{I}_l$ and slot vocabulary $\mathcal{S}_l$, we have a set of utterances which are annotated with an intent label and each word is annotated with a slot label. The task of SLU is divided into two sub-tasks: i) *Intent classification*, which learns a function mapping each unlabeled utterance to a proper intent label $\in \mathcal{I}_l$, and ii) *Slot filling*, which learns a function mapping each unlabeled token to a proper slot label $\in \mathcal{S}_l$.

3.2 Model

Our multi-task SLU model consists of: i) A shared embedding layer which is the concatenation of a 1-dimensional convolution neural network based character embedding and a word embedding. ii) A shared encoder which is a two-layers bi-directional highway Long-short Term Memory network (Srivastava et al., 2015) served by the embedding layer as inputs, learning a contextual, fixed-dimensional representation for each token. ii) Two decoders for SF and IC sub-tasks; each consists of a stack of two dense layers and a softmax layer on top.

The two sub-tasks are trained jointly via a weighted loss function: $L = \alpha_i \hat{L}_i + \alpha_s \hat{L}_s$, where $\hat{L}_i, \hat{L}_s$ are the normalized cross-entropy losses with label smoothing (Szegedy et al., 2016) of IC and SF, respectively.

3.3 Cross-lingual transfer learning

Given a target language l^t with a limited supervised data set $\mathbf{D}_{l^t}$ divided into a training set $\mathbf{D}_{l^t}^T$ and a validation set $\mathbf{D}_{l^t}^V$, CLTL aims at improving the SLU performance on l^t by leveraging the larger supervised data sets $\mathbf{D}_{l_1^s}, \ldots, \mathbf{D}_{l_N^s}$ from N source languages $l_1^s, \ldots, l_N^s$. A common idea behind CLTL methods is to map the source and target data into a shared space, so that the knowledge can be transferred in-between languages.

In this paper, we assume the availability of a multi-lingual word embedding function which maps a word in any language into a shared space: $\mathcal{W} : \mathcal{V}_{l_1^s} \bigcup \ldots \mathcal{V}_{l_N^s} \bigcup \mathcal{V}_{l^t} \rightarrow \mathbb{R}^d$, where $\mathcal{V}_l$ is the vocabulary of language l. In addition, for a source language l_i^s in which a bilingual dictionary $\mathcal{D}_{l_i^s, l^t} : \mathcal{V}_{l_i^s} \rightarrow \mathcal{V}_{l^t}$ is available, a word w can be alternatively mapped into the shared space by using $\mathcal{W}(\mathcal{D}_{l_i^s, l^t}(w))$ [1]. The word embedding layer in our

[1] Experiments on the development data shows that

SLU model is fixed to the mapping from the word vocabulary to this shared space, without being updated during training. In contrast, the character embedding layer in our model is initialized randomly and updated during training. Our CLTL training strategy consists of two phases: First, the model is *pre-trained* on the source data $\mathbf{D}_{l_1^s} \cup \ldots \cup \mathbf{D}_{l_N^s}$ for T_w^s epochs, and validated on $\mathbf{D}_{l^t}^V$. Second, the model is *fine-tuned* on the target data $\mathbf{D}_{l^t}^T$ for T_w^t epochs and validated on $\mathbf{D}_{l^t}^V$.

4 Data selection

The effectiveness of pre-training in CLTL depends on the similarity of the source data distribution and the real distribution of the target language. Let us consider each component in our model. First, for the word embedding layer, obtaining similar distributions of the source data and the target language can be considered as an "easy" task by using multilingual word embedding. Second, for the character embedding layer and the encoder, it depends on how similar the character patterns and the word patterns of the source data and the target language are, respectively. Finally, for the decoders, the similar distributions could be expected given the good distributions provided by the encoder.

We, therefore, propose a relevance metric for the source utterances w.r.t. the target language: $R(u) = \sum_{k=1}^{M} \alpha_k f_k(u)$, where f_k and α_k are respectively an attribute value and its importance weight, and M is the total number of attributes. Each attribute is associated with an N-gram word- or character- based language model trained on the target language which can be used to estimate the similarity of a pattern to the target language. Let us consider an attribute f_k and its N-gram language model LM_k trained on the target language l_t. Given an utterance $u = w_1 \ldots w_n$ in a source language l_i^s and the bilingual dictionary $\mathcal{D}_{l_i^s, l^t} : \mathcal{V}_{l_i^s} \rightarrow \mathcal{V}_{l^t}$ mapping a word in l_i^s to another word in l^t, we call $\mathbf{S}$ the set of N-grams generated from $\mathcal{D}_{l_i^s, l^t}(w_1) \ldots \mathcal{D}_{l_i^s, l^t}(w_n)$. The attribute value f_k is computed as the average language model score of the elements in $\mathbf{S}$:

$$f_k(u) = \sum_{g \in \mathbf{S}} \mathrm{LM}_k(g) * \frac{1}{|\mathbf{S}|} \qquad (1)$$

$\mathcal{W}(\mathcal{D}(w))$ works well for French as target language, while $\mathcal{W}(w)$ is better for German.

20K-DE	EN 5M, DE 1.1M, ES 114,702	20K	5K	58K

Table 1: Supervised data statistics.

We then normalize $f_k(u)$ at intent level:

$$\bar{f}_k(u) = \frac{f_k(u)}{\max_{u' \in \mathbf{I}_u} f_k(u')} \qquad (2)$$

where $\mathbf{I}_u$ is the set of utterances (from all source languages) having the same intent as u. By using the proposed relevance metric, the source data can be ranked in descending order, and only the top-K utterances will be selected for the pre-training.

5 Experiments

5.1 Data

Supervised data For large-scale experiments, we extracted random samples from a large-scale SLU system. The data are representative of user requests to voice-enabled devices and are labeled with intents and slots. We include four languages into our experiments, i.e. English (EN), German (DE), French (FR) and Spanish (ES). DE and FR are used as the target languages in our experiments. Data statistics can be found in Table 1.

Unlabelled data sets For each of the target languages (DE and FR), we build N-gram language models on unlabelled data sets in that language. We make use of 3M DE sentences and 1M FR sentences which are freely available from the Leipzig unlabelled corpus collection (Goldhahn et al., 2012). In addition, we collect 500K DE and 2.5K FR unlabelled utterances with a similar nature as labelled utterances from the SLU system.

Pre-trained resources We use pre-trained 300-dimensional multilingual word embeddings and bilingual dictionaries provided by Conneau et al. (2017) and Lample et al. (2017), respectively.

5.2 Setup

We carry out four experiments with 10K and 20K target data in DE and FR (see Table. 1 for the experiment names and the labelled data statistics). We conduct experiments with transferring from one source language (EN) to another (DE) and from

three source languages (EN, DE, ES) to one target language (FR). In each experiment, we compare four different training strategies: i) Mono (w.o. CLTL): an SLU model is trained on *only* the supervised *target* data. ii) CLTL: *all* supervised source data is used for pre-training, and we fine-tune on target language data. iii) CLTL-RD: random K% utterances of the original source data are used for pre-training. iv) CLTL-DS: the K% most relevant source utterances are selected by using our proposed relevance metric for pre-training.

Settings The convolutions used for character embeddings have window sizes of 2, 3, 4, each consisting of 64 filters. The sizes of LSTM and dense layers are set to 300. All dropout keep probabilities are set to 0.9. The hyper-parameter tuning on the development set results in $\alpha_i = 0.2, \alpha_s = 0.8$, label smoothing rate $= 0.1$. We use Adam optimizer with learning rate $= 0.001$. Exponential decay is applied to the learning rate with decay steps $= 500$, and decay rate $= 0.95$. For CLTL, the number of training epochs T_w^s and T_w^t are set to 6 and 25, respectively. For data selection, we use four N-gram language models, i.e. word-based bi-gram and tri-gram language models and character-based bi-gram and tri-gram language models. The four importance weights are set to 1.0 each. For evaluation we use the standard metrics, i.e. F1, precision and recall for slot filling (computed using the CoNLL 2002 script) and accuracy for intent classification.

Table 2: Performance of CLTL on large-scale data sets. K is set to 50 (%) in CLTL-RD and CLTL-DS. Reported results are the mean and std. values of 3 runs.

Is 100% better than 50%? Table 2 shows the performances of the different training strategies in our experiments. In CLTL-RD and CLTL-DS settings, K is set to 50 (%). It helps to answer the question that whether using the full source data (100%) is better than using just 50%. Interestingly, although 100% (CLTL) is better than random 50% (CLTL-RD) in 3 out of 4 experiments, it is surpassed by our selected 50% in all of the experiments. These results do not only prove the effectiveness of our proposed data selection metric but also suggest a potentially powerful application of source-language data selection on cross-lingual transfer learning.

Slot filling vs. intent classification As shown in Table 2source-language, our data selection method tends to bring higher gains to SF than to IC. One possible reason is that IC is the easier between the two sub-tasks (less categories, single label vs. sequence label decoding etc.). However, it is important to stress that our data selection does not hurt IC, meaning that the method is useful for joint learning.

One vs several source languages The similar trends in experiments with DE as target and FR as target show that our proposed data selection method can be applied in both single-source and multi-source transfer learning. In order to compare the utility of multiple vs a single source, we ran an experiment on 10K-FR using only English as the source language. The means of slot F1 and IC dropped from 81.0% and 91.2% to 79.9% and 90.8%, respectively, when using only English, potentially because it is not the closest language to French. Hence, the model could probably choose better source utterances from multiple sources. This indicates that our method works for both settings with higher gains for using multiple source languages.

Value of K and importance weights of the language models? One may question whether it is possible to optimize the importance weights of the language models and choose K automatically. A possible solution could be using Bayesian optimization (Ruder and Plank, 2017). Instead of selecting the top K% utterances, we define a threshold θ: u is selected if $R(u) >= \theta$. θ and α_k become hyper-parameters which can be optimized using Bayesian Optimization with the score of the CLTL model on a development set as the objective. However, while

this could improve performance, it is expensive, especially in large-scale settings, i.e. optimization would likely add more computation time than what we can gain by training on a subset.

Performance on a small-scale benchmark dataset While we are mainly interested in large-scale SLU, we also strive for further understanding of CLTL by conducting a similar experiment on a small-scale widely-used SLU benchmark data set, i.e. ATIS (Tür et al., 2010). It contains audio recordings and corresponding annotated transcriptions in English of people making flight reservations.

To compare with the state-of-the-art systems, we apply our monolingual model on ATIS. The model reaches 95.6% F1 for slot filling and 96.8% accuracy for intent classification which are *comparable* to the state-of-the-art results reported on the same data set (Do and Gaspers, 2019).

We then perform a cross-lingual transfer learning experiment from English to German on ATIS. To construct the training sets of the target language, we select two random subsets of 200 and 400 English utterances from the training part of ATIS and translate them into German. The development set of the target language is formed by the German translation of a random subset of 144 English utterances selected from the validation part of ATIS. The test set of the target language is the German translation version of the ATIS test set which includes 893 utterances. The annotated source data comprise 4015 English training utterances from ATIS.

Exp.	Model	Slot			Intent
		P	*R*	*F1*	*Acc.*
200-DE	Mono	79.8 ± 0.3	80.6 ± 0.6	80.2 ± 0.6	85.8 ± 0.6
	CLTL	81.8 ± 0.5	82.8 ± 0.9	82.3 ± 0.6	85.3 ± 1.6
	CLTL-RD	83.0 ± 1.6	83.3 ± 1.7	83.1 ± 1.6	86.8 ± 1.4
	CLTL-DS	84.8 ± 2.7	85.3 ± 2.3	**85.0 ± 2.5**	**87.2 ± 1.9**
400-DE	Mono	86.8 ± 1.1	87.7 ± 0.6	87.2 ± 0.8	88.2 ± 0.7
	CLTL	88.0 ± 0.5	87.8 ± 0.7	87.9 ± 0.6	88.0 ± 0.3
	CLTL-RD	87.8 ± 1.3	87.4 ± 1.1	87.6 ± 1.1	87.9 ± 0.8
	CLTL-DS	88.3 ± 0.1	88.0 ± 0.3	**88.2 ± 0.2**	**88.2 ± 0.2**

Table 3: Performance of CLTL on ATIS. K is set to 50 (%) in CLTL-RD and CLTL-DS. Reported results are the mean and std. values of 3 runs.

Table 3 shows the performance of CLTL on the small-scale ATIS data set. As can been seen, in general, CLTL with data selection (CLTL-DS) is still beneficial in a small-scale setting.

6 Conclusions

We presented an efficient approach to select source data for cross-lingual transfer learning in large-scale SLU. Our results indicate that by using data selection we can both improve performance and reduce source data significantly without a negative effect on system performance, which can reduce training time and computational requirements in large-scale systems greatly. This suggests an interesting future research direction toward data selection for cross-lingual transfer learning problems.

Abstract

With the aim of promoting and understanding the multilingual version of image search, we leverage visual object detection and propose a model with diverse multi-head attention to learn grounded multilingual multimodal representations. Specifically, our model attends to different types of textual semantics in two languages and visual objects for fine-grained alignments between sentences and images. We introduce a new objective function which explicitly encourages attention diversity to learn an improved visual-semantic embedding space. We evaluate our model in the German-Image and English-Image matching tasks on the Multi30K dataset, and in the Semantic Textual Similarity task with the English descriptions of visual content. Results show that our model yields a significant performance gain over other methods in all of the three tasks.

1 Introduction

Joint visual-semantic embeddings (VSE) are central to the success of many vision-language tasks, including cross-modal search and retrieval (Kiros et al., 2014; Karpathy and Fei-Fei, 2015; Gu et al., 2018), visual question answering (Antol et al., 2015; Goyal et al., 2017), multimodal machine translation (Huang et al., 2016; Elliott and Kádár, 2017), etc. Learning VSE requires extensive understanding of the content in individual modalities and an in-depth alignment strategy to associate the complementary information from multiple views.

With the availability of large-scale parallel English-Image corpora (Lin et al., 2014; Young et al., 2014), a rich line of research has advanced learning VSE under the monolingual setup. Most recent works (Kiros et al., 2014; Vendrov et al., 2015; Karpathy and Fei-Fei, 2015; Klein et al., 2015; Wang et al., 2016, 2018; Huang et al., 2019b) leverage triplet ranking losses to align English sentences and images in the joint embedding space. In VSE++ (Faghri et al., 2018), Faghri *et al.* improve VSE by emphasizing hard negative samples. Recent advancement in VSE models explores methods to enrich the English-Image corpora. Shi et al. (2018) propose to augment dataset with textual contrastive adversarial samples to combat adversarial attacks. Recently, Huang et al. (2019a) utilize textual semantics of regional objects and adversarial domain adaptation for learning VSE under low-resource constraints.

An emerging trend generalizes learning VSE in the multilingual scenario. Rajendran et al. (2016) learn M-view representations when parallel data is available only between one pivot view and the rest of views. PIVOT (Gella et al., 2017) extends the work from Calixto et al. (2017) to use images as the pivot view for learning multilingual multimodal representations. Kádár et al. (2018) further confirms the benefits of multilingual training.

Our work is motivated by Gella et al. (2017) but has important differences. First, to disentangle the alignments in the joint embedding space, we employ visual object detection and multi-head attention to selectively align salient visual objects with textual phrases, resulting in visually-grounded multilingual multimodal representations. Second, as multi-head attention (Vaswani et al., 2017) is appealing for its efficiency and ability to jointly attend to information form different perspectives, we propose to further encourage the diversity among attention heads to learn an improved visual-semantic embedding space. Figure 1 illustrates our gradient updates promoting diversity. The proposed model achieves state-of-the-art performance in the multilingual sentence-image matching tasks in Multi30K (Elliott et al., 2016) and the semantic textual similarity task (Agirre et al., 2012, 2014, 2015).

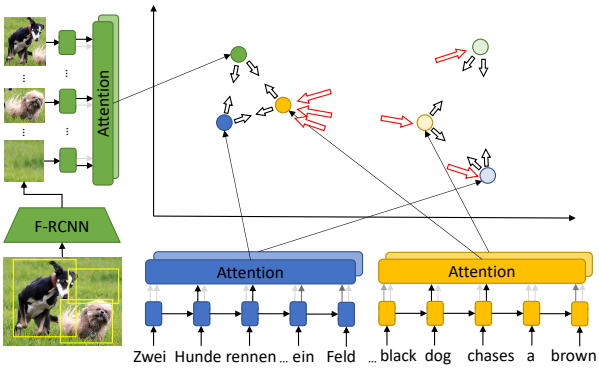

Figure 1: Multi-head attention with diversity for learning grounded multilingual multimodal representations. (A two-headed example with a part of diversity loss l_θ^D colored in red.)

2 Related Works

Classic attention mechanisms have been addressed for learning VSE. These mechanisms can be broadly categorized by the types of {*Query*, *Key*, *Value*} as discussed in Vaswani et al. (2017). For intra-modal attention, {*Query*, *Key*, *Value*} are within the same modality. In DAN (Nam et al., 2017), the content in each modalities is iteratively attended through multiple steps with intra-modal attention. In SCAN (Lee et al., 2018), inter-modal attention is performed between regional visual features from Anderson et al. (2018) and text semantics. The inference time complexity is $O(MN)$ (for generating M query representations for a size N datatset). In contrast to the prior works, we leverage intra-modal multi-head attention, which can be easily parallelized compared to DAN and is with a preferred $O(M)$ inference time complexity compared to SCAN.

Inspired by the idea of attention regularization in Li et al. (2018), for learning VSE, we propose a new margin-based diversity loss to encourage a margin between attended outputs over multiple attention heads. Multi-head attention diversity within the same modality and across modalities are jointly considered in our model.

3 The Proposed Model

Figure 1 illustrates the overview of the proposed model. Given a set of images as the pivoting points with the associate English and German[1] descriptions or captions, the proposed VSE model aims to learn a multilingual multimodal embedding space in which the encoded representations (v, e, g) of a paired instance (i, x^e, x^g) are closely aligned to each other than non-paired ones.

Encoders: For a sampled (i, x^e, x^g) pair, we first encode the tokens in the English sentence $x^e = \{x_1^e, \ldots, x_N^e\}$ and the tokens in the German sentence $x^g = \{x_1^g, \ldots, x_N^g\}$ through the word embedding matrices followed by two bi-directional LSTMs. The outputs of the textual encoders are $e = \{e_1, \ldots, e_N\}, e_n \in \mathbb{R}^H$ for English and $g = \{g_1, \ldots, g_N\}, g_n \in \mathbb{R}^H$ for German, where N is the max sentence length and H is the dimension of the shared embedding space. For the image, we leverage a Faster-RCNN (Ren et al., 2015) network with a ResNet (He et al., 2016) backbone to detect and encode salient visual objects in the image. With a trainable one-layered perceptron to transform visual features into the shared embedding space, we encode the image as $v = \{v_1, \ldots, v_M\}, v_m \in \mathbb{R}^H$, where M is the maximum amount of visual objects in an image.

Multi-head attention with diversity: We employ K-head attention networks to attend to the visual objects in an image as well as the textual semantics in a sentence then generate fixed-length image/sentence representations for alignment. Specifically, the k-th attended German sentence representation g^k is computed by:

$$a_i^k = \text{softmax}(\tanh(W_{c_g}^k c_g^k)^\top \tanh(W_g^k g_i)) \quad (1)$$

$$g^k = \sum_{i=1}^{N} a_i^k g_i, \quad (2)$$

where a_i^k is the attention weight, $W_g^k \in \mathbb{R}^{H \times H_{attn}}, W_{c_g}^k \in \mathbb{R}^{H_c \times H_{attn}}$ is the learnable transformation matrix for German. $c_g^k \in \mathbb{R}^{H_c}$ is the learnable H_c-dimensional contextual vector for distilling important semantics from German sentences. The final German sentence representation is the concatenation of K-head attention outputs $g = [g^0 \| g^1 \| \ldots \| g^K]$. Similar for encoding the English sentence $e = [e^0 \| e^1 \| \ldots \| e^K]$ and the image $v = [v^0 \| v^1 \| \ldots \| v^K]$.

With $\{V, E, G\}$ where $v \in V, e \in E, g \in G$ as the set of attended fixed-length image and sentence representations in a sampled batch, we use the widely-used hinge-based triplet ranking loss with hard negative mining (Faghri et al., 2018) to align instances in the visual-semantic embedding space. Taking Image-English instances $\{V, E\}$ as

[1]For clarity in notation, we discuss only two languages. The proposed model can be intuitively generalized to more languages by summing additional terms in Eq. 4 and Eq. 6-7.

an example, we leverage the triplet correlation loss defined as:

$$l_\theta(V,E) = \sum_p \left[\alpha - s(v_p, e_p) + s(v_p, \hat{e}_p)\right]_+ + \sum_q \left[\alpha - s(v_q, e_q) + s(\hat{v}_q, e_q)\right]_+, \quad (3)$$

where α is the correlation margin between positive and negative pairs, $[.]_+ = \max(0, .)$ is the hinge function, and $s(a,b) = \frac{a^T b}{\|a\|\|b\|}$ is the cosine similarity. p and q are the indexes of the images and sentences in the batch. $\hat{e}_p = \text{argmax}_q s(v_p, e_{q\neq p})$ and $\hat{v}_q = \text{argmax}_p s(v_{p\neq q}, e_q)$ are the hard negatives. When the triplet loss decreases, the paired images and German sentences are drawn closer down to a margin α than the hardest non-paired ones. Our model aligns $\{V, E\}$, $\{V, G\}$ and $\{E, G\}$ in the joint embedding space for learning multilingual multimodal representations with the sampled $\{V, E, G\}$ batch. We formulate the overall triplet loss as:

$$l_\theta(V,E,G) = l_\theta(V,G) + l_\theta(V,E) + \gamma l_\theta(G,E). \quad (4)$$

Note that the hyper-parameter γ controls the contribution of $l_\theta(G,E)$ since (e, g) may not be a translation pair even though (e, v) and (g, v) are image-caption pairs.

One of the desired properties of multi-head attention is its ability to jointly attend to and encode different information in the embedding space. However, there is no mechanism to support that these attention heads indeed capture diverse information. To encourage the diversity among K attention heads for instances within and across modalities, we propose a new simple yet effective margin-based diversity loss. As an example, the multi-head attention diversity loss between the sampled images and the English sentences (*i.e.* diversity across-modalities) is defined as:

$$l^D_\theta(V,E) = \sum_p \sum_k \sum_r \left[\alpha_D - s(v^k_p, e^{k\neq r}_p)\right]_+ \quad (5)$$

As illustrated with the red arrows for update in Figure 1, the merit behind this diversity objective is to increase the distance (up to a diversity margin α_D) between attended embeddings from different attention heads for an instance itself or its cross-modal parallel instances. As a result, the diversity objective explicitly encourage multi-head attention to concentrate on different aspects of information sparsely located in the joint embedding space to promote fine-grained alignments between multilingual textual semantics and visual objects. With the fact that the shared embedding space is multilingual and multimodal, for improving both intra-modal/lingual and inter-modal/lingual diversity, we model the overall diversity loss as:

$$l^D_\theta(V,E,G) = l^D_\theta(V,V) + l^D_\theta(G,G) + l^D_\theta(E,E) + l^D_\theta(V,E) + l^D_\theta(V,G) + l^D_\theta(G,E), \quad (6)$$

where the first three terms are intra-modal/lingual and the rest are cross-modal/lingual. With Eq. 4 and Eq. 6, we formalize the final model loss as:

$$l^{All}_\theta(V,E,G) = l_\theta(V,E,G) + \beta l^D_\theta(V,E,G), \quad (7)$$

where β is the weighting parameter which balances the diversity loss and the triple ranking loss. We train the model by minimizing $l^{All}_\theta(V,E,G)$.

4 Experiments

Following Gella et al. (2017), we evaluate on the multilingual sentence-image matching tasks in Multi30K (Elliott et al., 2016) and the semantic textual similarity task (Agirre et al., 2012, 2015).

4.1 Experiment Setup

We use the model in Anderson et al. (2018) which is a Faster-RCNN (Ren et al., 2015) network pre-trained on the MS-COCO (Lin et al., 2014) dataset and fine-tuned on the Visual Genome (Krishna et al., 2016) dataset to detect salient visual objects and extract their corresponding features. 1,600 types of objects are detectable. We then pack and represent each image as a 36×2048 feature matrix where 36 is the maximum amount of salient visual objects in an image and 2048 is the dimension of the flattened last pooling layer in the ResNet (He et al., 2016) backbone of Faster-RCNN.

For the text processing, we lower-case, tokenize, and then truncate the maximum sentence length to 100. We use 300-dim word embedding matrices initialized either randomly or with pre-trained multilingual embeddings. (We use the multilingual version of FastText (Mikolov et al., 2018)). We also experiment incorporating the last layer of contextualized multilingual BERT embeddings (Devlin et al., 2018) to replace the word embedding matrices as the textual input features for the bi-directional LSTMs.

Table 2: Results on the image and video datasets of Semantic Textual Similarity task. (Pearson's $r \times 100$).

For training, we sample batches of size 128 and train 20 epochs on the training set of Multi30K. We use the Adam (Kingma and Ba, 2014) optimizer with 2×10^{-4} learning rate then 2×10^{-5} after 15-*th* epoch. Models with the best summation of validation R@1,5,10 are selected to generate image and sentence embeddings for testing. Weight decay is set to 10^{-6} and gradients larger than 2.0 are clipped. We use 3-head attention ($K = 3$) and the embedding dimension $H = 512$. The same dimension is shared by all the context vectors in the attention modules. Other hyperparameters are set as follows: $\alpha = 0.2, \alpha_D = 0.1, \beta = 1.0$ and $\gamma = 0.6$.

4.2 Multilingual Sentence-Image Matching

We evaluate the proposed model in the multilingual sentence-image matching (retrieval) tasks on Multi30K: (i) Searching images with text queries (Sentence-to-Image). (ii) Ranking descriptions with image queries (Image-to-Sentence). English and German are considered.

Multi30K (Elliott et al., 2016) is the multilingual extension of Flickr30K (Young et al., 2014). The training, validation, and testing split contain 29K, 1K, and 1K images respectively. Two types of annotations are available in Multi30K: (i) One parallel English-German translation for each image and (ii) five independently collected English and five German descriptions/captions for each image. We use the later. Note that the German and English descriptions are *not* translations of each other and may describe an image differently.

As other prior works, we use recall at k (R@k) to measure the standard ranking-based retrieval performance. Given a query, R@k calculates the percentage of test instances for which the correct one can be found in the top-k retrieved instances. Higher R@k is preferred.

Table 1 presents the results on the Multi30K testing set. The VSE baselines in the first five rows are trained with English and German descriptions independently. In contrast, PIVOT (Gella et al., 2017) and the proposed model are capable of handling multilingual input queries with single model. For a fair comparison with PIVOT, we also report the result of swapping Faster-RCNN with VGG as the visual feature encoder in our model.

As can be seen, the proposed models successfully obtain state-of-the-art results, outperforming other baselines by a significant margin. German-Image matching benefit more from joint training with English-Image pairs. The models with pre-trained multilingual embeddings and contextualized embeddings achieve better performance in comparison to randomly initialized word embeddings, especially for German. One explanation is that the degradation from German singletons is alleviated by the multi-task training with English and the pre-trained embeddings. While the model with BERT performs better in English, FastText is preferred for German-Image matching.

Figure 2: Qaulitative text-to-image matching results on Multi30K. Correct (colored in green) if ranked first.

4.3 Semantic Textual Similarity Results

For semantic textual similarity (STS) tasks, we evaluate on the video task from STS-2012 (Agirre et al., 2012) and the image tasks from STS-2014-15 (Agirre et al., 2014, 2015). The video descriptions are from the MSR video description corpus (Chen and Dolan, 2011) and the image descriptions are from the PASCAL dataset (Rashtchian et al., 2010). In STS, a system takes two input sentences and output a semantic similarity ranging from [0,5]. Following Gella et al. (2017), we directly use the model trained on Multi30K to generate sentence embeddings then scaled the cosine similarity between the two embeddings as the prediction.

Table 2 lists the standard Pearson correlation coefficients r between the system predictions and the STS gold-standard scores. We report the best scores achieved by paraphrastic embeddings (Wieting et al., 2017) (text only) and the VSE models in the previous section. Note that the compared VSE models are all with RNN as the text encoder and *no* STS data is used for training. Our models achieve the best performance and the pre-trained word embeddings are preferred.

4.4 Qualitative Results and Grounding

In Figure 2 we samples some qualitative multilingual text-to-image matching results. In most cases our model successfully retrieve the one and only one correct image. Figure 3 depicts the t-SNE visualization of the learned visually grounded multilingual embeddings of the (v, e, g) pairs pivoted on v in the Multi30K testing set. As evidenced,

Figure 3: t-SNE visualization and grounding of the learned multilingual multimodal embeddings on Multi30K. Note the sentences are *not* translation pairs.

although the English and German sentences describe different aspects of the image, our model correctly aligns the shared semantics (*e.g.* ("*man*", "*mann*"), ("*hat*", "*wollmtze*")) in the embedding space. Notably, the embeddings are visually-grounded as our model associate the multilingual phrases with exact visual objects (*e.g. glasses* and *ears*). We consider learning grounded multilingual multimodal dictionary as the promising next step.

As limitations we notice that actions and small objects are harder to align. Additionally, the alignments tends to be noun-phrase/object-based whereas spatial relationships (*e.g.* "*on*", "*over*") and quantifiers remain not well-aligned. Resolving these limitations will be our future work.

5 Conclusion

We have presented a novel VSE model facilitating multi-head attention with diversity to align different types of textual semantics and visual objects for learning grounded multilingual multimodal representations. The proposed model obtains state-of-the-art results in the multilingual sentence-image matching task and the semantic textual similarity task on two benchmark datasets.

Decoupled Box Proposal and Featurization with Ultrafine-Grained Semantic Labels Improve Image Captioning and Visual Question Answering

Abstract

Object detection plays an important role in current solutions to vision and language tasks like image captioning and visual question answering. However, popular models like Faster R-CNN rely on a costly process of annotating ground-truths for *both* the bounding boxes *and* their corresponding semantic labels, making it less amenable as a primitive task for transfer learning. In this paper, we examine the effect of decoupling box proposal and featurization for down-stream tasks. The key insight is that this allows us to leverage a large amount of labeled annotations that were previously unavailable for standard object detection benchmarks. Empirically, we demonstrate that this leads to effective transfer learning and improved image captioning and visual question answering models, as measured on publicly-available benchmarks.

1 Introduction

Object detection has been employed extensively as a primitive task for vision and language tasks such as image captioning and visual question answering (VQA); see (Anderson et al., 2018) and the work that follows it. One motivation is that the ability to recognize salient regions and objects may be too difficult to learn from weakly-supervised *top-down* signals, in the form of captions and question-answer pairs. Indeed, *bottom-up* signals provided by object detection often correspond to semantic units of language such as words or phrases, making them suitable for text generation and image-text alignment.

However, object detection itself can be broken down into multiple subtasks (Liu et al., 2018). A family of "two-stage" object detectors first proposes category-agnostic bounding box candidates and then featurizes and classifies the cropped regions into one of the available semantic labels.

Figure 1: Ultrafine-grained semantic labels (at "instance level") provide transfer learning power to down-stream tasks like visual question answering.

Even "one-stage" object detection approaches, where these boxes become category-specific, can be formulated in a *bottom-up* manner as detecting and grouping extreme and center points (Zhou et al., 2019). Can we take advantage of this observation to learn to transfer more effectively? In this work, we take a step in this direction by examining the effect of decoupling box proposal and featurization *on downstream vision and language tasks*. In particular, we consider a two-stage object detector and set a goal of pushing the "featurization" aspect of the task further than before.

Our choice to break free from "featurization by object detection models" has at least two advantages. First, there is a larger amount of labeled data that can be leveraged to train a better featurization module, even if such data do not support learning box proposals. To put it another way, the quality of features directly provided by object detectors is limited by the fact that annotating ground-truths for *both* the bounding boxes *and* their corresponding semantic labels is costly and scales poorly. By separating them, we reintroduce the freedom to annotate for object-agnostic box segmentation, without the burden of baking in an-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1468–1474, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

notation decisions related to the granularity level of the semantic labels (i.e., do we use as semantic labels "money", "euro", or "20 euro"?). As illustrated in Figure 1, the granularity level of the semantic labels plays a crucial role for downstream tasks such as VQA.

Second, this approach is better suited to downstream tasks whose domains are different from the one the object detector is trained on. In other words, it allows us to benefit from transfer learning, which is a great advantage given the relatively modest amount of available supervised data for these downstream vision and language tasks.

We empirically demonstrate the above-mentioned advantages through a focused study of the effect of improved featurization on image captioning and VQA in transfer learning settings. In particular, we (i) leverage ultra-fine-grained semantic labels (e.g., "golden gate bridge" vs. "bridge") for featurization (Juan et al., 2019); and, (ii) focus on scenarios in which object detection modules trained on Visual Genome (VG) (Krishna et al., 2017) are applied to out-of-domain images: image captioning on the Conceptual Captions dataset (Sharma et al., 2018), and VQA on the VizWiz dataset (Gurari et al., 2018). Our results indicate that there are ways to incorporate low-level pre-training tasks that benefit vision and language models via higher-quality bottom-up signals.

2 Related Work

Attention-based deep models are popular in image captioning and VQA. Early work used fixed partitions of images as candidate regions (Xu et al., 2015). However, variable sized regions that are better correlated with object boundaries have gained momentum (Fu et al., 2017; Pedersoli et al., 2017; Anderson et al., 2018). Indeed, Anderson et al. (2018) established new state-of-the-art performance over both image captioning and VQA tasks on the MSCOCO and VQA2 benchmarks using a Faster R-CNN detector trained on Visual Genome. As both Visual Genome and VQA2 were built on images from MSCOCO, the object detector was applied largely to in-domain images. In contrast, our work focuses on more realistic settings in which domains of different tasks may not be perfectly aligned (Chen et al., 2018).

We leverage image representations extracted from a network pre-trained over large amounts of labeled data. Prior work demonstrated the power of pre-training with image classification at scale (Sun et al., 2017; Mahajan et al., 2018; Wu et al., 2019). However, we consider downstream vision *and language* tasks (image captioning and visual question answering), in contrast to less complex vision-only tasks explored in such work: object detection and in some cases semantic segmentation and human pose estimation. Furthermore, our transfer learning technique is based on decoupled region proposal and ultra-finegrained featurization, not fine-tuning the pre-trained network.

Another set of closely related work utilized additional data for scaling up either vision tasks (Hoffman et al., 2016; Tang et al., 2017; Redmon and Farhadi, 2017) or vision and language tasks (Venugopalan et al., 2017; Lu et al., 2018; Noh et al., 2019). For instance, YOLO9000 (Redmon and Farhadi, 2017) built a "WordTree" hierarchy based on the WordNet synsets (Miller et al., 1990), mapped categories in both COCO object detection and ImageNet classification datasets into the hierarchy, and proposed a joint detection and classification training framework. Our approach to transfer learning with ultrafine-grained featurization can similarly address the long-tail nature of target vocabulary (see Figure 2) while being simpler (e.g., not require carefully merging different sets of vocabulary as in YOLO9000). The number of classes we consider is also several orders of magnitude larger.

Incorporating object detection signals in downstream tasks appropriately is non-trivial and an active subject for research (Santoro et al., 2017; Zhang et al., 2018). In this work, we ask the orthogonal question of whether it is necessary to accept the object detector's output as-is.

3 Features and Experimental Setup

Our starting point is a two-stage object detector, which consists of two core modules. One is responsible for category-agnostic box proposal, and the other for featurizing each cropped region for semantic label prediction. In this paper, we select Faster R-CNN (Ren et al., 2015b), a widely-used object detector in image captioning and VQA.

Faster R-CNN Model We reimplement the Faster R-CNN model, training it to predict both 1,600 object and 400 attribute labels in Visual Genome (Krishna et al., 2017), following the standard setting from Anderson et al. (2018). ResNet-

101 (He et al., 2016) pre-trained on ImageNet (Russakovsky et al., 2015) is used as the core featurization network[1]. We achieve a mAP@50 of 10.96 for object detection and 1.5 for attribute detection. Given an image, Faster R-CNN proposes K bounding box regions, each of which comes with a D-dimensional feature vector as well as object/attribute class predictions (along with their scores). K is set to 100 and D to 2048 in our experiments. Using output features on the task of VQA and our model described in Section 5, we obtain an accuracy of 66.9% on the validation set of the VQA2 dataset (Goyal et al., 2017). For comparison, this number already surpasses all validation accuracy numbers in Table 2 for a strong model by Peng et al. (2019), suggesting that our Faster R-CNN features are of high-quality.

Decoupled Box Proposal and Featurization with Ultra-finegrained Semantic Labels In standard use of object detectors following Anderson et al. (2018), downstream tasks receive "knowledge" merely about a few thousand classes and four hundred attributes. Here, we exploit the fact that box proposal and featurization can be decoupled, and work on improving the object representation (featurization).

More concretely, we conduct a study toward understanding the utility of improved featurization on downstream tasks. To this end, we exploit a graph-based, semi-supervised representation learning approach called Graph-Regularized Image Semantic Embedding (Graph-RISE) (Juan et al., 2019). Specifically, Graph-RISE is based on ResNet-101 where the 10x10x2K feature map is first average pooled to 4x4x2K, and then flattened and projected to a 64-dimensional embedding before the softmax layer. Learned from $\mathcal{O}$(260M) web images and $\mathcal{O}$(40M) (noisy) semantic labels, these compact 64-dimensional feature vectors are trained to capture a whole spectrum of semantic similarity, ranging from coarse-grained / category-level (e.g., "bridge"), fine-grained level (e.g., "steel red bridge"), to ultrafine-grained / instance-level (e.g., "golden gate bridge").

Our Objective The main goal is to compare two approaches in using bottom-up signals: 1) FRCNN: use the default visual features from the Faster R-CNN detector; 2) Ultra: use bounding boxes from the Faster R-CNN detector, then featurize them using the much more compact representation from Graph-RISE that potentially reflects differentiation of ultrafine-grained semantic labels. Next, we evaluate this setup on downstream tasks for image captioning and visual question answering.

[1] See further details in the supplementary material.

4 Image Captioning

Dataset We use the Conceptual Captions (CC) dataset (Sharma et al., 2018), consisting of 3.3 million training and 15,000 validation images/caption pairs. Another 12,000 image/caption pairs comprise the hidden test set. Official scores on the test set are obtained by submitting models to the CC Challenge server[2]. Unlike other image captioning datasets, images from CC are pulled from across the web and thus exhibit a wide variety of both images and image-caption styles. Most notably, the domain of images can be very different from Visual Genome, unlike in popular benchmarks such as MSCOCO (Lin et al., 2014).

Model We adopt the encoder-decoder model from (Sharma et al., 2018), whose basic building block is a Transformer Network (Vaswani et al., 2017). To convert multi-modal inputs to a sequence of encoder feature vectors, we use up to three types of image features:

G : Global features by Graph-RISE, a dense 64D vector extracted from the whole image;

B : Box-region features by Faster R-CNN (FRCNN, sparse 2048D), or Graph-RISE (Ultra, dense 64D), extracted from each cropped image region resized to 224x224 (cf. Sec. 3);

L : Label embeddings, obtained by embedding predicted object semantic labels from Google Cloud Vision APIs[3] into a 512D feature vector. These semantic labels are then mapped to embeddings using an embedding layer pre-trained to predict label co-occurrences in web documents using a word2vec model (Mikolov et al., 2013).

For both **B** and **L**, we select the inputs with highest scores and order the sequence inputs based on such scores from high to low. Additionally for **B**, we remove box regions whose scores are lower than 0.001. We use beam search with width 5 for the decoder in all of our experiments[4].

Table 1: Automatic metric scores for the image captioning task on Conceptual Captions. Ablation results are reported for our model using different sets of visual features. The top two baselines are from the Conceptual Captions Leaderboard as of August 30, 2019.

Metrics We adopt the standard automatic metrics for image captioning: CIDEr (Vedantam et al., 2015), ROUGE-L (Lin and Och, 2004), and SPICE (Anderson et al., 2016), as implemented in the COCO-caption evaluation toolkit[5].

Results We report results on both the dev and test sets for Conceptual Captions in Table 1. "Base" uses the **G** feature only. We first compare the Base **G** against each of the feature types (**B**-FRCNN, **B**-Ultra, and **L**). We then perform ablations under the **+B** condition (FRCNN/Ultra) to the Base **G** or stronger **G** + **L** models.

According to dev CIDEr scores, global or box Graph-RISE features **G** and **B**-Ultra are (individually) clearly stronger than box features by Faster R-CNN **B**-FRCNN or label embeddings **L** features. Nevertheless, these features are considerably complementary. Specifically, box features **B**-Ultra complements the Base **G**, pushing the score from 0.868 to 0.912. It is also worth noting that, albeit their low individual scores, **B**-FRCNN or **L** improves upon each model they are added to.

Our models with Ultra features clearly outperform the ones with FRCNN. This is demonstrated in three conditions: when they are on their own, when they are added to the simple **G** model, and when they are added to the stronger **G** + **L** model. Manual inspection of the models' predictions further supports this; a qualitative comparison of **B**-Ultra vs. **B**-FRCNN in Figure 2 suggests that ultra-finegrained featurization leads to an improved correspondence between visual inputs and caption tokens of *unfamiliar* objects (such as "monks" and "staircase").

[5]https://github.com/tylin/coco-caption.

To get test scores, we submit our best model using FRCNN and our best model using Ultra (based on dev CIDEr) to the CC Challenge server. Test scores for other models were not obtained due to the limited number of submissions per time period. As of August 30, 2019, the **G** + **B**-Ultra + **L** model outperforms all other single baselines[6], for both CIDEr and SPICE (and tie on ROUGE-L).

5 Visual Question Answering

Dataset We use the recently-proposed VizWiz dataset (Gurari et al., 2018), in which both images and questions originate from visually-impaired or blind people. It consists of 20,000/3,173 ⟨image, question, answers⟩ triplets in the train/val splits, and additional 8,000 triplets for the test split. Each question is independently annotated with 10 answers. We choose the VizWiz benchmark specifically because it is a more suitable benchmark for measuring transfer learning effects. Other VQA datasets, including VQA1.0 (Antol et al., 2015), VQA2.0 (Goyal et al., 2017), Visual7W (Zhu et al., 2016), COCOQA (Ren et al., 2015a), and GQA (Hudson and Manning, 2019) are completely or partly based on MSCOCO or Visual Genome. As such, they may not provide unbiased grounds for measuring the impact of object-detection features based on Visual Genome versus alternative featurization techniques.

Model We follow the setting described in Pythia v0.1 (Jiang et al., 2018), the winning entry to the VQA challenge 2018. In particular, the architecture is a *simplified* "up-down" model from (Anderson et al., 2018)[7]. The featurization of the bounding boxes follows the description from Section 4. For the base condition, we use the box features based on Faster R-CNN (**B**-FRCNN), following the majority of previous work. For the test condition, we replace them with the Ultra-based features (**B**-Ultra).

Metrics As commonly done in previous work (Antol et al., 2015), we use as our accuracy metric the average score over 9 subsets of the ground-truth 10 answers, where each score is computed by the formula: min(# humans that provided that answer / 3, 1). Accuracy on the test-dev and test-standard splits is obtained by submitting the mod-

Ground-truth "monks clean a garden at a temple ."
Box FRCNN (VG) "a woman walks through the streets ."
Box Ultra "monks walking in front of a temple"

"black sesame seeds on a white background"
"a pile of dried flowers"
"black chia seeds on a white background"

Ground-truth "a photo of a staircase inside a historic house"
Box FRCNN (VG) "the interior of the church"
Box Ultra "the staircase of the house"

"car & tree ornament this heart of mine"
"digital art selected for the #"
"christmas tree in a toy car"

Figure 2: Qualitative results from our image captioning models using **B**-FRCNN vs. **B**-Ultra (see text for details), along with ground-truth captions. Ultra is more capable than FRCNN of dealing with images with unfamiliar objects, those that do not perfectly fall into the domain where the Faster R-CNN object detector is trained on.

	all	y/n	num	unans	other
VizWiz	46.9	59.6	21.0	80.5	27.3
BAN	51.6	**68.1**	17.9	**85.3**	31.5
Ours (FRCNN)	51.9	66.7	24.3	85.0	32.1
Ours (Ultra)	**53.7**	**68.1**	**28.8**	84.0	**35.4**

Table 2: Accuracy (%) on the test-standard split for the VQA task on the VizWiz dataset. Additionally, we provide accuracy per answer type: yes/no (y/n), number (num), unanswerable (unans), and the rest (other). The baselines include VizWiz (Gurari et al., 2018) and BAN (Kim et al., 2018).

els to the VizWiz Challenge server[8].

Results We report results on the VizWiz benchmark in Table 2. Our model with FRCNN provides a strong baseline, slightly outperforming the previous-best model, BAN (Kim et al., 2018), a different architecture that also uses the FRCNN-based features for object bounding boxes. The model using Ultra features further improves upon this; at 53.7%, it outperforms the one using FRCNN by a significant margin (1.8% accuracy on "all" question types). Moreover, this 1.8% improvement is a weighted average across answer types; the per-answer-type numbers indicate that our approach achieves even better improvements on two of the more difficult answer types, "number" (+4.5%) and "rest" (+3.3%). These improvements are illustrated by the examples provided in Figure 1.

This illustrates the effectiveness of decoupling bounding box proposal and featurization, and quantifies the impact of using transfer learning via large amounts of training data and ultrafine-grained semantic labels used for object representations.

6 Conclusion

In this work, we propose to (re)decouple box proposal and featurization. We show that this allows us to leverage additional signals and annotations, leading to more effective transfer learning for downstream vision and language tasks: image captioning and visual question answering. This result suggests that large-scale datasets with fine-grained image-level semantic labels, even when they do not dissect complex visual scenes, can benefit current state-of-the-art models – especially when applied to benchmarks where images are from diverse domains.

Abstract

Popular metrics used for evaluating image captioning systems, such as BLEU and CIDEr, provide a single score to gauge the system's overall effectiveness. This score is often not informative enough to indicate what specific errors are made by a given system. In this study, we present a fine-grained evaluation method REO for automatically measuring the performance of image captioning systems. REO assesses the quality of captions from three perspectives: 1) **R**elevance to the ground truth, 2) **E**xtraness of the content that is irrelevant to the ground truth, and 3) **O**mission of the elements in the images and human references. Experiments on three benchmark datasets demonstrate that our method achieves a higher consistency with human judgments and provides more intuitive evaluation results than alternative metrics.[1]

1 Introduction

Image captioning is an interdisciplinary task that aims to automatically generate a text description for a given image. The task is fundamental to a wide range of applications, including image retrieval (Rui et al., 1999) and vision language navigation (Wang et al., 2019). Though remarkable progress has been made (Gan et al., 2017; Karpathy and Li, 2015), the automatic evaluation of image captioning systems remains a challenge, particularly with respect to quantifying the generation errors made by these systems (Bernardi et al., 2016).

Existing metrics for caption evaluation can be grouped into two categories: 1) rule-based metrics (Papineni et al., 2002; Vedantam et al., 2015) that are based on exact string matching, and 2) learning-based metrics (Cui et al., 2018; Sharif et al., 2018) that predict the probability of a testing caption as a human-generated caption by using a learning model. In general, prior work has shown that description adequacy with respect to the ground truth data is a main concern for evaluating text generation systems (Gatt and Krahmer, 2018). Though this aspect has been emphasized by prior work for assessing image captions (Papineni et al., 2002; Banerjee and Lavie, 2005; Gao et al., 2019), one common limitation of existing metrics is the lack of interpretability to the description errors because existing metrics only provide a composite score for the caption quality. Without fine-grained analysis, the developers may not be able to understand the specific description errors made by their developed captioning systems.

To fill this gap, we propose an evaluation method called **REO** that considers three specific pieces of information for measuring each caption with respect to: 1) **R**elevance: relevant information of a candidate caption with respect to the ground truth, 2) **E**xtraness: extra information of a

REO_R: 0.28	REO_E: 9.39	REO_O: 10.64	REO_R: 0.26	REO_E: 10.40	REO_O: 9.32

Figure 1: An example of caption evaluation. Given two caption candidates, even though Caption A covers more image information than Caption B (e.g., missing "kids"), Caption A contains extra irrelevant description (highlighted in red). Prior metrics (e.g., BLEU4) only provide an overall quality score, which is difficult to infer specific description mistakes in a caption. In contrast, REO provides three indicators (i.e., relevance, extraness, and omission) that can properly achieve a fine-grained assessment for each caption.

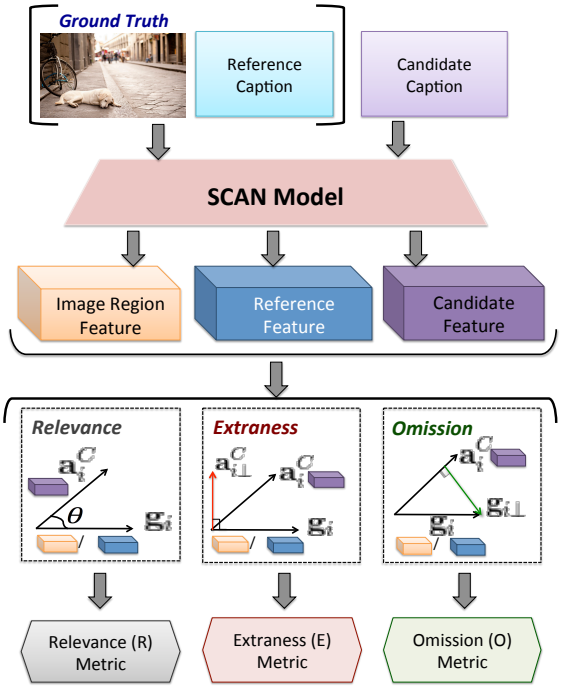

Figure 2: Overview of REO evaluation for image captioning: (1) Feature Extraction; (2) Metric Measurement.

candidate caption beyond ground truth data, and 3) **O**mission: missing information that a candidate fails to describe from an image and human-generated reference captions. Figure 1 shows a comparison between existing metrics and our proposed metrics that measure caption quality at a fine-grained level. If we view caption generation as a process of decoding the information embedded in an image, we can evaluate an image captioning system by measuring the effectiveness of the decoding process in terms of the relevance of the decoded information regarding the image content, and the amount of missing or extra information. Using both the images and reference captions as ground truth information for evaluation, our approach is built based on a shared image-text embedding space defined by a grounding model that has been pre-trained on a large benchmark dataset. Given a pair of vectors representing a candidate caption and its ground truth (i.e., the target image and associated reference captions), respectively, we compute the relevance of the candidate caption and ground truth based on vector similarities. By applying vector orthogonal projection, we identify the extra and missing information carried by the candidate caption. Each aspect that we consider here (i.e., relevance, extraness, omission) is measured by an independent score.

We test our method on three datasets. The experimental results show that our proposed metrics are more consistent with human evaluations than alternative metrics. Interestingly, our study finds that human annotators pay more attention to extra or missing information in a caption (i.e., false positive and false negatives) than the caption's relevance for the given image (true positives). We also find that considering both image and references as ground truth information is more helpful for caption evaluation than considering image or references individually.

2 Methods

Figure 2 provides an overview for the calculation of REO, which happens in two stages. The first stage is *feature extraction*, where we aim to obtain feature vectors to encode the candidate caption C and corresponding ground truth $\mathbf{G}$ for further comparisons. The second stage is to measure *three metric scores*. Specifically, we measure relevance using standard cosine similarity. To measure irrelevance (i.e., extraness and omissions), we compare the information carried by C and $\mathbf{G}$, respectively. We will give a detailed description of our method in the following two subsections.

2.1 Feature Extraction

Following Lee et al., we leverage a pre-trained Stacked Cross Attention Neural Network (SCAN) to build a multi-modal semantic space. Specifically, we obtain word features $\mathbf{H}^\tau = [\mathbf{h}_1^\tau; \cdots; \mathbf{h}_M^\tau] \in \mathbb{R}^{M \times D}$ by averaging the forward and backward hidden states per word from a bidirectional GRU (Bahdanau et al., 2014), where $\tau = \{C, R\}$ denotes either a candidate C or a reference R sentence of M words. Based on Anderson et al., we achieve image features $\mathbf{U} \in \mathbb{R}^{N \times D'}$ by detecting N salient regions per image ($N = 36$ in this paper). A linear layer is applied to transform image features to D-dimensional features $\mathbf{V} = [\mathbf{v}_1; \cdots; \mathbf{v}_N] \in \mathbb{R}^{N \times D}$.

Based on the SCAN model, we further extract the context information from the caption words for each detected region. To this end, we compute a context feature $\mathbf{a}_i^\tau$ for the i^{th} region by a weighted sum of caption word features in Eq. (1). Notice that $\mathbf{A}^\tau = [\mathbf{a}_1^\tau; \cdots; \mathbf{a}_N^\tau] \in \mathbb{R}^{N \times D}$ extracts the context information of the caption τ with respect to all regions in the image.

$$\mathbf{a}_i^\tau = \sum_{j=1}^{m} \alpha_{ij} \mathbf{h}_j^\tau \tag{1}$$

$$\alpha_{ij} = \frac{\exp(\lambda \text{sim}(\mathbf{v}_i, \mathbf{h}_j^\tau))}{\sum_{k=1}^{m} \exp(\lambda \text{sim}(\mathbf{v}_i, \mathbf{h}_k^\tau))} \tag{2}$$

where λ is a smoothing factor, and $\text{sim}(\mathbf{v}, \mathbf{h}^\tau)$ is a normalized similarity function defined as

$$\text{sim}(\mathbf{v}_i, \mathbf{h}_j^\tau) = \frac{\max(0, \text{cosine}(\mathbf{v}_i, \mathbf{h}_j^\tau))}{\sqrt{\sum_{k=1}^{n} \max(0, \text{cosine}(\mathbf{v}_k, \mathbf{h}_j^\tau))^2}} \tag{3}$$

2.2 Metric Scores

In order to explore the impact of image data on evaluation, we focus on comparing context features $\mathbf{A}^C$ of the candidate caption C to ground-truth references $\mathbf{G} \equiv [\mathbf{g}_1; \cdots; \mathbf{g}_N] = \{\mathbf{V}, \mathbf{A}^R\}$, where $\mathbf{G}$ denotes either image features $\mathbf{V}$ or the context features of R (i.e., $\mathbf{A}^R$).

Relevance : The relevance between a candidate caption and a ground-truth reference based on the i-th region is computed by the cosine similarity of $\mathbf{a}_i^C$ and $\mathbf{g}_i$. We average similarity over all regions to get the relevance score of a candidate caption with respect to an image.

$$\mathcal{R} = \frac{1}{N} \sum_{i=1}^{N} \text{sim}(\mathbf{a}_i^C, \mathbf{g}_i) \tag{4}$$

Extraness : The extraness of C is captured by performing an orthogonal projection of $\mathbf{a}_i^C$ to $\mathbf{g}_i$, which returns the vertical context vector $\mathbf{a}_{i\perp}^C$ to represent the irrelevant content of C to the ground truth at the i^{th} region.

$$\mathbf{a}_{i\perp}^C = \mathbf{a}_i^C - \frac{\mathbf{a}_i^C \cdot \mathbf{g}_i}{\| \mathbf{g}_i \|^2} \mathbf{g}_i. \tag{5}$$

To avoid potential disturbance due to correlated feature vectors, we measure the Mahalanobis distance between the vertical context vector $\mathbf{a}_{i\perp}^C$ and its original context vector $\mathbf{a}_i^C$ (see Eq. (7)). Notice that a small distance value indicates that the irrelevant context vector $\mathbf{a}_{i\perp}^C$ is closed to the original context vector $\mathbf{a}_i^C$. In other words, the original context contains a large amount of extra information. Therefore, the higher this metric is, the less extra information the caption contains.

$$\mathcal{E} = \frac{1}{N} \sum_{i=1}^{N} d(\mathbf{a}_i^C, \mathbf{a}_{i\perp}^C) \tag{6}$$

$$d(\mathbf{p}, \mathbf{q}) = \sqrt{(\mathbf{p} - \mathbf{q}) S^{-1} (\mathbf{p} - \mathbf{q})} \tag{7}$$

Omission : The measurement of omission is similar to that of extraness, where we capture the missing information of C by the vertical context features $\mathbf{g}_{i\perp}$ based on the orthogonal projection of $\mathbf{g}_i$ to $\mathbf{a}_i^C$. The omission score is denoted as $\mathcal{O}$. Similarly, the higher the omission score is, the less missing information the caption contains.

$$\mathbf{g}_{i\perp} = \mathbf{g}_i - \frac{\mathbf{g}_i \cdot \mathbf{a}_i^C}{\| \mathbf{a}_i^C \|^2} \mathbf{a}_i^C \tag{8}$$

$$\mathcal{O} = \frac{1}{N} \sum_{i=1}^{N} d(\mathbf{g}_i, \mathbf{g}_{i\perp}) \tag{9}$$

Considering that each image may have multiple reference captions, we further average the score of the aforementioned three aspects over all reference captions while considering $\mathbf{A}^R$ as ground truth.

3 Experiments

3.1 Experimental Setup

We perform experiments on three human-evaluated caption sets. ***Composite Dataset*** (Aditya et al., 2015) contains the candidate captions of images from MS-COCO, Flickr8k, and Flickr30k. Captions were generated by humans and two caption models (11,985 instances in total). Human judgments for these candidate captions was provided on a 5-point scale rating that represents description correctness. ***PublicSys Dataset*** has 2,500 captions collected by Rohrbach et al., which were generated by five state-of-the-art captioning systems on 500 MS-COCO images, respectively. Human grading was done on a 5-point scale based on annotators' preferences to descriptions. ***Pascal-50S Dataset*** (Vedantam et al., 2015) includes 4000 caption pairs that describe images from the UIUC PASCAL Sentence dataset. Each annotator was asked to select one sentence per pair that is closer to the expression of the given reference sentence. Candidate pairs were grouped into four categories: 1) human-human correct (HC, i.e., a pair of captions are written by humans for the same image), 2) human-human incorrect (HI, i.e., Two human-written captions of which one describes another image instead of the target image), 3) human-machine (HM, i.e., two captions are generated by a human and a machine, respectively.), and 4) machine-machine (MM, i.e., both machine-generated caption).

Following standard practice (Anderson et al., 2016; Elliott and Keller, 2014), we compared with

Ground Truth	Metric	Composite (τ)	PublicSys (τ)	Pascal-50S ($accuracy\%$)

Table 1: Caption-level correlation between metrics and human grading scores in Composite and PublicSys dataset by using Kendall tau (τ). All p-values < 0.01. For PASCAL-50S, we display the accuracy of metrics at matching human judgments with 5 reference captions per image. The highest value per column is in bold font. Column titles are explained in Section 3.1. Ground truth refers to two points of information: human-written references and images.

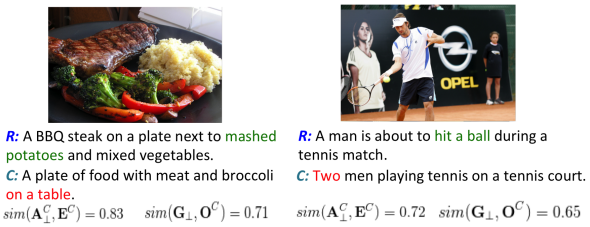

Figure 3: Examples of validating error identification. Text in red is extra information, while text in green is missing information. $sim(x, y)$ is the average similarity between machine-identified and true error vectors over image regions.

rule-based metrics (see Table 1). All existing metrics were implemented with the MS-COCO evaluation tool [2]. The performance of metrics was assessed via Kendall's tau (τ) rank correlation for the scoring-based datasets (i.e., Composite & PublicSys) and accuracy of the pairwise comparison for the Pascal-50S dataset.

3.2 Experimental Results

Can extra & missing information be captured? In order to measure the effectiveness of error identification (i.e., extraness and omission), we randomly sampled a subset of data, and manually identify the actual extraness (i.e., $\mathbf{E}^C$) and true omission (i.e., $\mathbf{O}^C$) of each candidate caption. We conduct validation based on the average cosine similarity between the machine-identified error (i.e., $\mathbf{a}^C_{i\perp}$ &$\mathbf{g}_{i\perp}$) and true error description.

Figure 3 provides two illustrative examples of the validation process. Phrases highlighted in red (e.g.,"on a table") are extra information (more text in the candidate caption than in the ground truth). Meanwhile, phrases in green (e.g., "mashed potatoes") are missing from the candidate description, but occur in the image and the reference caption. We observe that machine-identified errors are highly similar to the true error information in both cases (≥ 0.65). This result suggests that our method can capture extraness and omission from an image caption.

Do error-aware evaluation metrics help? The results of metric performance in Table 1 show that overall, using the three metrics proposed in REO, especially extraness and omission, led to a noticeable improvement in Kendall tau's correlation compared to the best reported results based on prior metrics. Our results suggest that human evaluation tends to be more sensitive to the irrelevance than the relevance of a candidate caption regarding ground truth. We also find that jointly considering both images and human-written references contributes more to caption evaluation than each of the two data sources alone - except for the case of HC pair comparison. This exception can be explained by the phenomenon that human-written descriptions are flexible in terms of word

[2] https://github.com/tylin/coco-caption

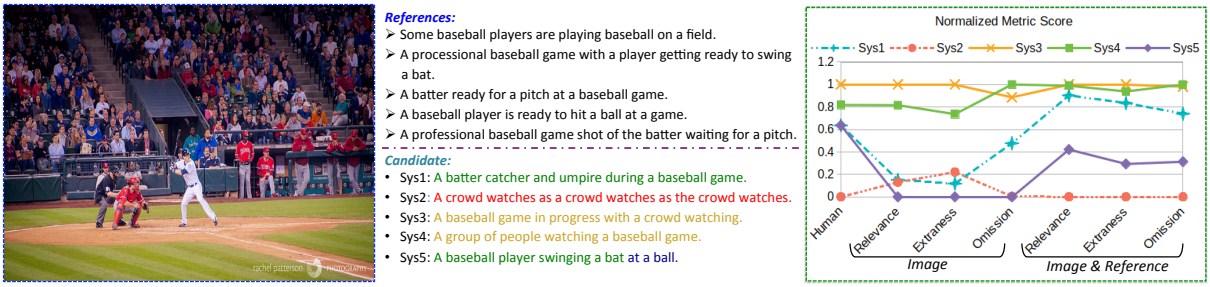

Figure 4: Case study of REO metric scores. Candidates are highlighted in: 1) green: a detailed but incompleted caption, 2) red: repetition, 3) yellow: high-level description, and 4) blue: extra information not shown in the image.

choice and sentence structure, and such diversity may lead to the challenge of comparing a reference to a candidate in cases where both captions were provided by humans. By further looking into each considered aspect in REO, we find that extranesss metric is more appropriate to evaluate machine-generated captions (e.g., the PublicSys dataset and the MM pairs of Pascal-50S dataset), while the omission metric can be a better choice to access caption quality when the testing data consists of human-written descriptions.

What can we learn from the metric outputs? To analyze our metric scores more in depth, we compare the outputs of five captioning systems on a set of images in the PublicSys dataset. Figure 4 shows an illustrative example. To make the scale of human grading and REO metrics comparable, we normalize scores per metric by using max-min normalization.

We find that metrics calculated in cases where the ground truth contained both the target image and human references are more likely to identify expression errors. For example, though the phrase "a crowd watches" in the caption of system 2 is relevant to the image, this phrase is repeated by three times in a sentence. As a result, the scores for relevance and extraness are decreasing when the ground truth involves references. Also, metrics focusing only on image content return higher values when the testing captions provide a high-level description of the whole image (e.g., captions of system 3 and 4) compared to the detailed captions for a specific image part (e.g., captions of system 1 and 5 focus on the baseball player). By comparing the herein considered three aspects of each caption, we observe that a caption that mainly focuses on describing a part of image in detail boosts relevance, but the sentence achieves a reduced metric score in terms of omission.

4 Conclusion

This paper presents a fine-grained, error-aware evaluation method REO to measure the quality of machine-generated image captions according to three aspects of descriptions: relevance regarding ground truth, extra description beyond image content, and omitted ground truth information. Comparing these metrics to alternative metrics, we find that our proposed solution produces evaluations that are more consistent with the assessment of human judges. Moreover, we find that human judgment tends to penalize extra and missing information (false positives and false negatives) more than it appreciates relevant content. Finally, and to no surprise, we conclude that using a combination of image content and human-written references as ground truth data allows for a more comprehensive evaluation than using either type of information separately. Our method can be extended to evaluate other text generation tasks.

Acknowledgments

We appreciate anonymous reviewers for their constructive comments and insightful suggestions. This work was partly performed when Ming Jiang was interning at Microsoft Research. The authors would like to thank Pengchuan Zhang for his help with pre-training the grounding model.

WSLLN: Weakly Supervised Natural Language Localization Networks

Abstract

We propose weakly supervised language localization networks (WSLLN) to detect events in long, untrimmed videos given language queries. To learn the correspondence between visual segments and texts, most previous methods require temporal coordinates (start and end times) of events for training, which leads to high costs of annotation. WSLLN relieves the annotation burden by training with only video-sentence pairs without accessing to temporal locations of events. With a simple end-to-end structure, WSLLN measures segment-text consistency and conducts segment selection (conditioned on the text) simultaneously. Results from both are merged and optimized as a video-sentence matching problem. Experiments on *ActivityNet Captions* and *DiDeMo* demonstrate that WSLLN achieves state-of-the-art performance.

1 Introduction

Extensive work has been done on temporal action/activity localization (Shou et al., 2016; Zhao et al., 2017; Dai et al., 2017; Buch et al., 2017; Gao et al., 2017c; Chao et al., 2018), where an action of interest is segmented from long, untrimmed videos. These methods only identify actions from a pre-defined set of categories, which limits their application to situations where only unconstrained language descriptions are available. This more general problem is referred to as natural language localization (NLL) (Hendricks et al., 2017; Gao et al., 2017a). The goal is to retrieve a temporal segment from an untrimmed video based on an arbitrary text query. Recent work focuses on learning the mapping from visual segments to the input text (Hendricks et al., 2017; Gao et al., 2017a; Liu et al., 2018; Hendricks et al., 2018; Zhang et al., 2018) and retrieving segments based on the alignment scores. However, in order to successfully train a NLL model, a large number of diverse language descriptions are needed to describe different temporal segments of videos which incurs high human labeling cost.

We propose Weakly Supervised Language Localization Networks (WSLLN) which requires only video-sentence pairs during training with no information of where the activities temporally occur. Intuitively, it is much easier to annotate video-level descriptions than segment-level descriptions. Moreover, when combined with text-based video retrieval techniques, video-sentence pairs may be obtained with minimum human intervention. The proposed model is simple and clean, and can be trained end-to-end in a single stage. We validate our model on *ActivityNet Captions* and *DiDeMo*. The results show that our model achieves the state-of-the-art of the weakly supervised approach and has comparable performance as some supervised approaches.

2 Related Work

Temporal Action Localization in long videos is widely studied in both offline and online scenarios. In the offline setting, temporal action detectors (Shou et al., 2016; Buch et al., 2017; Gao et al., 2017c; Chao et al., 2018) predict the start and end times of actions after observing the whole video, while online approaches (De Geest et al., 2016; Gao et al., 2017b; Shou et al., 2018b; Xu et al., 2018; Gao et al., 2019) label action class in a per-frame manner without accessing future information. The goal of temporal action detectors is to localize actions in pre-defined categories. However, activities in the wild is very complicated and it is challenging to cover all the activities of interest by using a finite set of categories.

Natural Language Localization in untrimmed videos was first introduced in (Gao et al., 2017a; Hendricks et al., 2017), where given an arbitrary text query, the methods attempt to localize the text (predict its start and end times) in a video. Hendricks *et al.* proposed MCN (Hendricks et al., 2017) which embeds the features of visual proposals and sentence representations in the same space and ranks proposals according their similarity with the sentence. Gao *et al.* proposed CTRL (Gao et al., 2017a), where alignment and regression are conducted for clip candidates. Liu *et al.* introduced TMN (Liu et al., 2018) which measures the clip-sentence alignment guided by the semantic structure of the text query. Later, Hendricks *et al.* proposed MLLC (Hendricks et al., 2018) that explicitly reasons about temporal clips of a video. Zhang *et al.* proposed MAN (Zhang et al., 2018) which utilizes Graph Convolutional Networks (Kipf and Welling, 2016) to model temporal relations among visual clips. Although these methods achieve considerable success, they need segment-level annotations for training. Duan *et al.* proposed WSDEC to handle weakly supervised dense event captioning in (Duan et al., 2018) by alternating between language localization and caption generation iteratively. WSDEC generates language localization as intermediate results and can be trained using video-level labels. Thus, we set it as a baseline, although it is not designed for NLL.

Weakly Supervised Localization has been studied extensively to use weak supervisions for object detection on images and action localization in videos (Oquab et al., 2015; Bilen and Vedaldi, 2016; Tang et al., 2017; Gao et al., 2018; Kantorov et al., 2016; Li et al., 2016; Jie et al., 2017; Diba et al., 2017; Papadopoulos et al., 2017; Duchenne et al., 2009; Laptev et al., 2008; Bojanowski et al., 2014; Huang et al., 2016; Wang et al., 2017; Shou et al., 2018a). Some methods use class labels to train object detectors. Oquab *et al.* discussed that object locations may be freely obtained when training classification models (Oquab et al., 2015). Bilen *et al.* proposed WSDDN (Bilen and Vedaldi, 2016), which focuses on both object recognition and localization. Their proposed two-stream architecture inspired several weakly supervised approaches (Tang et al., 2017; Gao et al., 2018; Wang et al., 2017) including our method. Li *et al.* presented an adaptation strategy in (Li et al., 2016) which uses the output of a weak detector as pseudo groundtruth to train a detector in a fully supervised way. OICR (Tang et al., 2017) integrates multiple instance learning and iterative classifer refinement in a single network. Some works use other types of weak supervisions to optimize detectors. In (Papadopoulos et al., 2017), Papadopoulos *et al.* used clicks to train detectors. Gao *et al.* utilized object counts for weakly supervised object detection (Gao et al., 2018). Instead of using temporally labeled segments, weakly supervised action detectors use weaker annotations, *e.g.*, movie script (Duchenne et al., 2009; Laptev et al., 2008), the order of the occurring action classes in videos (Bojanowski et al., 2014; Huang et al., 2016) and video-level class labels (Wang et al., 2017; Shou et al., 2018a).

3 Weakly Supervised Language Localization Networks (WSLLN)

3.1 Problem Statement

Following the setting of its strongly supervised counterpart (Gao et al., 2017a; Hendricks et al., 2017), the goal of a weakly supervised language localization (WSLL) method is to localize the event that is described by a sentence query in a long, untrimmed video. Formally, given a video consisting of a sequence of image frames, $\mathbf{V}_i = [I_i^1, I_i^2, ..., I_i^T]$, and a text query Q_i, the model aims to localize a temporal segment, $[I_i^{st}, ..., I_i^{ed}]$, which semantically aligns best with the query. st and ed indicate the start and end times, respectively. The difference is that WSLL methods only utilize video-sentence pairs, $\{\mathbf{V}_i, Q_i\}_{i=1}^N$, for training, while supervised approaches have access to the start and end times of the queries.

3.2 The Proposed Approach

Taking frame sequences, $[I_i^1, I_i^2, ..., I_i^T]$, as inputs, the model first generates a set of temporal proposals, $\{p_i^1, p_i^2, ..., p_i^n\}$, where p_i^j consists of temporally-continuous image frames. Then, the method aligns the proposals with the input query and outputs scores for proposals, $\{s_i^1, s_i^2, ..., s_i^n\}$, indicating their likelihood of containing the event.

Feature Description. Given a sentence query Q_i of arbitrary length, sentence encoders can be used to extract text feature, fq_i, from the query. For a video, $\mathbf{V}_i = [I_i^1, I_i^2, ..., I_i^T]$, features, $\mathbf{fv}_i = [fv_i^1, fv_i^2, ..., fv_i^T]$, are extracted from each frame. Following (Hendricks et al., 2017), the visual fea-

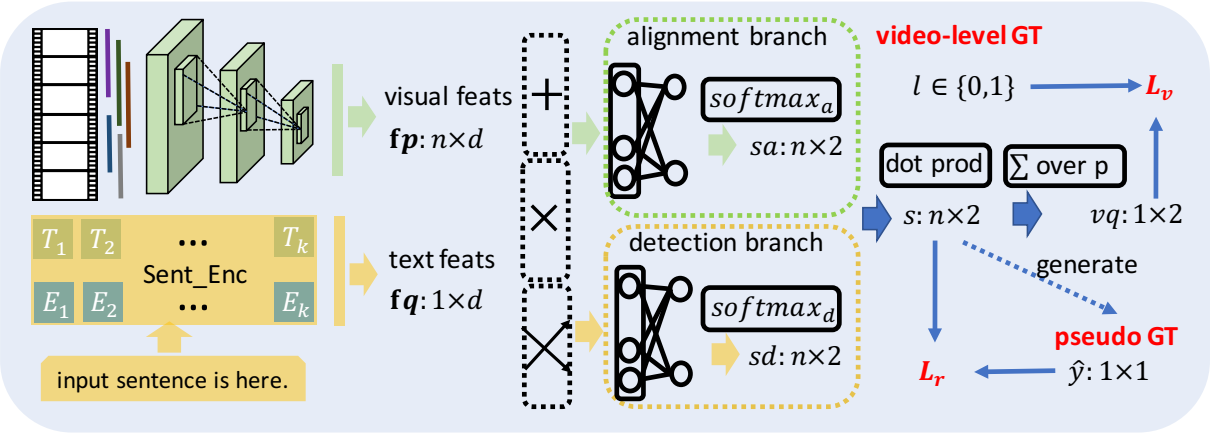

Figure 1: The workflow of our method. Visual and text features are extracted from n video proposals and the input sentence. Fully-connected (FC) layers are used to transform the features to the same length, d. The two features are combined by multi-modal processing (Gao et al., 2017a) and input to the two-branch structure. Scores from both parts are merged. Video-level scores, vq, are obtained by summing s over proposals. The whole pipeline is trained end-to-end using video-level and pseudo segment-level labels. $x \times z$ indicates dimensions.

ture, fp_i^j, of a proposal p_i^j is obtained using Eq. 1, where $pool(x, t_1, t_2)$ means average pooling features x from time t_1 to t_2, $||$ indicates concatenation, j_{st}/j_{ed} indicates start/end times of the proposal and $\bar{j}$ means time is normalized to $[0, 1]$.

$$pool(\mathbf{fv}_i, j_{st}, j_{ed})||pool(\mathbf{fv}_i, 0, T)||[\bar{j}_{st}, \bar{j}_{ed}] \quad (1)$$

We see that the feature of each proposal contains the information of its visual pattern, the overall context and its relative position in the video.

Following (Gao et al., 2017a), features of the sentence and a visual proposal are combined as in Eq. 2. The feature, fm, will be used to measure the matching between a candidate proposal and the input query.

$$fm = (fp + fq)||(fp \cdot fq)||FC(fp||fq) \quad (2)$$

The workflow of WSLLN is illustrated in Fig. 1. Inspired by the success of the two-stream structure in the weakly supervised object and action detection tasks (Bilen and Vedaldi, 2016; Wang et al., 2017), WSLLN consists of two branches, *i.e.*, alignment branch and selection branch. The semantic consistency between the input text and each visual proposal is measured in the alignment branch. The proposals are compared and selected in the detection branch. Scores from both branches are merged to produce the final results.

Alignment Branch produces the consistency scores, $sa_i \in \mathrm{R}^{n\times 2} = [sa_i^1, sa_i^2, ..., sa_i^n]$, for proposals of the video-sentence pair. sa_i in Eq. 3, measures how well each proposal matches the text. Different proposal scores are calculated independently where $softmax_a$ indicates applying the softmax function over the last dimension.

$$sa_i = softmax_a(\mathbf{W}_a fm_i) \quad (3)$$

Detection Branch performs proposal selection. The selection score, $sd_i \in \mathrm{R}^{n\times 2} = [sd_i^1, sd_i^2, ..., sd_i^n]$ in Eq. 4, is obtained by applying softmax function over proposals. Through softmax, the score of a proposal will be affected by those of other proposals, so this operation encourages competition among segments.

$$sd_i = softmax_d(\mathbf{W}_d fm_i) \quad (4)$$

Score Merging is applied to both parts to obtain the results by dot production, *i.e.*, $s_i = sa_i \cdot sd_i$, for proposals. s_i is used as the final segment-sentence matching scores during inference.

Training Phase. To utilize video-sentence pairs as supervision, our model is optimized as a video-sentence matching classifier. We compute the matching score of a given video-sentence pair by summing s_i^j over proposals, $vq_i = \sum_{j=1}^{n} s_i^j$. Then, L_v is obtained in Eq. 5 by measuring the score with the video-sentence match label $l_i \in \{0, 1\}$. Positive video-sentence pairs can be obtained directly. We generate negative ones by pairing each video with a randomly selected sentence in the training set. We ensure that the positive pairs are not included in the negative set.

$$L_v = loss(vq_i, l_i) \quad (5)$$

Results can be further refined by adding an auxiliary task L_r in Eq. 6 where $\hat{y}_i = \{0, 1, ..., n-1\}$ indicates the index of the segment that best matches the sentence during training. The real segment-level labels are not available, thus we generate pseudo labels by setting $\hat{y}_i = \text{argmax}_j s_i^j[:, 1]$. This loss further encourages competition among proposals.

$$L_r = loss(s_i^j, \hat{y}_i) \tag{6}$$

The overall objective is minimizing L in Eq. 7, where λ is a balancing scalar. $loss$ is cross-entropy loss.

$$L = loss(vq_i, l_i) + \lambda loss(s_i^j, \hat{y}_i). \tag{7}$$

4 Experiments

4.1 Experimental Settings

Implementation Details. BERT (Devlin et al., 2018) is used as the sentence encoder, where the feature of '[CLS]' at the last layer is extracted as the sentence representation. Visual and sentence features are linearly transformed to have the same dimension, $d = 1000$. The hidden layers for both branches have 256 units. For *ActivityNet Captions*, we take the $n = 15$ proposals over multiple scales of each video provided by (Duan et al., 2018) and use the C3D (Tran et al., 2015) features provided by (Krishna et al., 2017). For *DiDeMo*, we use the $n = 21$ proposals and VGG (Simonyan and Zisserman, 2014) features (RGB and Flow) provided in (Hendricks et al., 2017).

Evaluation Metrics. Following (Gao et al., 2017a; Hendricks et al., 2017), *R@k,IoU=th* and *mIoU* are used for evaluation. Proposals are ranked according to their matching scores with the input sentence. If the temporal IoU between at least one of the top-k proposals and the groundtruth is bigger or equal to th, the sentence is counted as matched. *R@k,IoU=th* means the percentage of matched sentences over the total sentences given k and th. *mIoU* is the mean IoU between the top-1 proposal and the groundtruth.

4.2 Experiments on ActivityNet Captions

Dataset Description. *ActivityNet Captions* (Krishna et al., 2017) is a large-scale dataset of human activities. It contains 20k videos including 100k video-sentences in total. We train our models on the training set and test them on the validation set.

Model	WS	IoU=0.1	IoU=0.3	IoU=0.5	mIoU
CTRL	F	49.1	28.7	14.0	20.5
ABLR	F	73.3	55.7	36.8	37.0
WSDEC-S	F	70.0	52.9	37.6	40.4
WSDEC-W	T	62.7	42.0	23.3	28.2
WSLLN	T	75.4	42.8	22.7	32.2

Table 1: Comparison results based on $R@1$ on *ActivityNet Captions*. All baseline numbers are reprinted from (Duan et al., 2018). WS: weakly supervised.

$\lambda \rightarrow$	0.0	0.1	0.2	0.3	0.4	0.5
IoU=0.1	64.9	75.4	75.5	75.5	75.5	66.6
IoU=0.3	36.2	42.8	42.9	42.9	42.9	38.3
IoU=0.5	19.4	22.7	22.7	22.8	22.7	20.7
mIoU	27.4	32.2	32.3	32.3	32.3	28.8

Table 2: R@1 results of our method on *ActivityNet Captions* when λ in Eq. 7 is set to be different values.

Although the dataset provides segment-level annotation, we only use video-sentence pairs during training.

Baselines. We compare with strongly supervised approaches, *i.e.*, CTRL (Gao et al., 2017a), ABLR (Yuan et al., 2018) and WSDEC-S (Duan et al., 2018) to see how much accuracy it sacrifices when using only weak labels. Originally proposed for dense-captioning, WSDEC-W (Duan et al., 2018) achieves state-of-the-art performance for weakly supervised language localization. Although showing good performance, WSDEC-W involves complicated training stages, and alternates between sentence localization and caption generation for iterations.

4.2.1 Comparison Results

Comparison results are displayed in Tab. 1. It shows that WSLLN largely outperforms WSDEC-W by $\sim 4\%$ $mIoU$. When comparing with strongly supervised methods, WSLLN outperforms CTRL by over 11% $mIoU$. Using the $R@1, IoU = 0.1$ metric, our model largely outperforms all the baselines including strongly and weakly supervised methods which means that when a scenario is flexible with the IoU coverage, our method has great advantage over others. When th =0.3/0.5, our model has comparable results as WSDEC-W and largely outperforms CTRL. The overall results demonstrate good performance of WSLLN, even though there is still a big gap between weakly supervised methods and

some supervised ones, *i.e.*, ABLR and WSDEC-S. $mIoU$ (mean±std) of WSLLN across 3 runs is 32.2 ± 0.05 which demonstrates the robustness of our method.

4.2.2 Ablation Study

Effect of λ. We evaluate the effect of λ (see Eq. 7) in Tab. 2. As it shows, our model performs stable when λ is set from 0.1 to 0.4. When $\lambda = 0$, the refining module is disabled and the performance drops. When λ is set to a big number, *e.g.*, 0.5, the contribution of L_v is reduced and the model performance also drops.

Effect of Sentence Encoder. WSDEC-W uses GRU (Cho et al., 2014) as its sentence encoder, while our method uses BERT. It seems an unfair comparison, since BERT is powerful than GRU in general. However, we uses pretrained BERT model without fine tuning on our dataset, while WSDEC-W uses GRU but performed an end-to-end training. So, it is unclear which setting is better. To resolve this concern, we replace our BERT with GRU following WSDEC-W. The $R@1$ results when IoU is set to be 0.1, 0.3 and 0.5 are 74.0, 42.3 and 22.5, respectively. The mIoU is 31.8. It shows that our model with GRU has comparable results as that with BERT.

Effect of Two-branch Design. We create two baselines, *ie*, *Align-only* and *Detect-only*, to demonstrate the effectiveness of our design. To perform fair comparison, both of them are trained using only video-sentence pairs.

Align-only contains only the alignment branch. For positive video sentence pair, we give positive labels to all proposals. Negative pairs have negative labels for all the proposals. Loss is calculated between proposal scores and the generated segment-level labels.

Detect-only contains only the detection branch. Loss is calculated using the highest detection score over proposals and the video-level label at each training iteration.

Comparison results are displayed in Tab. 3. It shows that the two baselines underperform WSLLN by a large margin, which demonstrates the effectiveness of our design.

4.3 Experiments on DiDeMo

Dataset Description. *DiDeMo* was proposed in (Hendricks et al., 2017) for the language localization task. It contains 10k, 30-second videos including 40k annotated segment-sentence pairs.

Model	IoU=0.1	IoU=0.3	IoU=0.5	mIoU
Align-only	40.0	18.9	7.5	13.4
Detect-only	33.7	18.3	10.4	13.6

Table 3: Ablation study based on $R@1$ on *ActivityNet Captions*. Both methods are trained using weak supervisions.

Model	WS	Input	R@1	R@5	mIoU
Chance	–	–	3.75	22.50	22.64
LOR	F	RGB	16.2	43.9	27.2

MCN	F	Flow	25.8	75.4	38.9
WSLLN	T	RGB	19.4	53.1	25.4
WSLLN	T	Flow	18.4	54.4	27.4

Table 4: Comparison results on *DiDeMo*. Following MCN, we set $th = 1.0$ for the IoU threshold. All baseline numbers are reprinted from (Hendricks et al., 2017). WS: weakly supervised.

Our models are trained using video-sentence pairs in the train set and tested on the test set.

Baselines. To the best of our knowledge, no weakly supervised method has been evaluated on *DiDeMo*. So, we compare with some supervised methods, *i.e.*, MCN (Hendricks et al., 2017) and LOR (Hu et al., 2016). MCN is a supervised NLL model. LOR is a supervised language-object retrieval model. It utilizes much more expensive (object-level) annotations for training. We follow the same setup of LOR as in (Hendricks et al., 2017) to evaluate LOR for our task.

Comparison Results are shown in Tab. 4. WSLLN performs better than LOR in terms of $R@1/5$. We also observe that the gap between our method and the supervised NLL model is much larger on *DiDeMo* than on *ActivityNet Captions*. This may be due to the fact that *DiDeMo* is a much smaller dataset which is a disadvantage for weakly supervised learning.

5 Conclusion

We propose WSLLN– a simple language localization network. Unlike most existing methods which require segment-level supervision, our method is optimized using video-sentence pairs. WSLLN is based on a two-branch architecture where one branch performs segment-sentence alignment and the other one conducts segment selection. Experiments show that WSLLN achieves promising results on *ActivityNet Captions* and *DiDeMo*.

Abstract

Grounding is crucial for natural language understanding. An important subtask is to understand modified color expressions, such as *"dirty blue"*. We present a model of color modifiers that, compared with previous additive models in RGB space, learns more complex transformations. In addition, we present a model that operates in the HSV color space. We show that certain adjectives are better modeled in that space. To account for all modifiers, we train a hard ensemble model that selects a color space depending on the modifier-color pair. Experimental results show significant and consistent improvements compared to the state-of-the-art baseline model.[1]

1 Introduction

Grounded color descriptions are employed to describe colors which are not covered by basic color terms (Monroe et al., 2017). For instance, *"greenish blue"* cannot be expressed by only *"blue"* or *"green"*. Grounded learning of modifiers, as a result, is essential for grounded language understanding problems such as image captioning (Karpathy and Fei-Fei, 2015), visual question answering (Goyal et al., 2017) and object recognition (van de Sande et al., 2010).

In this paper, we present models that are able to predict the RGB code of a target color given a reference color and a modifier. For example, as shown in Figure 1, given a reference color code $\vec{r} = \begin{bmatrix}101 & 55 & 0\end{bmatrix}^\top$ and a modifier $m =$ *"greenish"*, our models are trained to predict the target color code $\vec{t} = \begin{bmatrix}105 & 97 & 18\end{bmatrix}^\top$. The state-of-the-art approach for this task (Winn and Muresan, 2018) represents both colors and modifiers as vectors in RGB space, and learns a vector representation of modifiers $\vec{m}$ as part of a simple additive model, $\vec{r} + \vec{m} \approx \vec{r}$, in RGB color space. For instance, given the reference color $\vec{r} = \begin{bmatrix}229 & 0 & 0\end{bmatrix}^\top$, the target color $\vec{t} = \begin{bmatrix}132 & 0 & 0\end{bmatrix}^\top$, the modifier $m =$ *"darker"* is learned as a vector $\vec{m} = \begin{bmatrix}-97 & 0 & 0\end{bmatrix}^\top$. This model works well when the modifier is well represented as a single vector independent of the reference color,[2] but fails to model modifiers with more complex transformations, for example, color related modifiers, like *"greenish"*, which are better modelled through color interpolation.

Reference	Modifier	Target
$[101 \quad 55 \quad 0]^T$	greenish	$[105 \quad 97 \quad 18]^T$
$[229 \quad 0 \quad 0]^T$	darker	$[132 \quad 0 \quad 0]^T$
$[3 \quad 67 \quad 223]^T$	more neon	$[4 \quad 217 \quad 255]^T$

Figure 1: Examples of the grounded modifier modelling task, shown in RGB space. Given the reference and modifier, the system must predict the target color.

To fit a better model, we assume that there are approximate intersection points for the extension lines of modifier vectors, for instance, Figure 2c shows the *"darker"* related vectors in RGB space and we can see that the intersection point is approximately $\begin{bmatrix}0 & 0 & 0\end{bmatrix}^\top$. On the basis of this, we introduce an RGB model which can learn a transformation matrix and an interpolation point for each modifier.

There are many other color spaces besides RGB, e.g., HSL and HSV (Joblove and Greenberg, 1978; Hanbury, 2008), and mapping between such

[1] Code available at https://github.com/HanXudong/GLoM

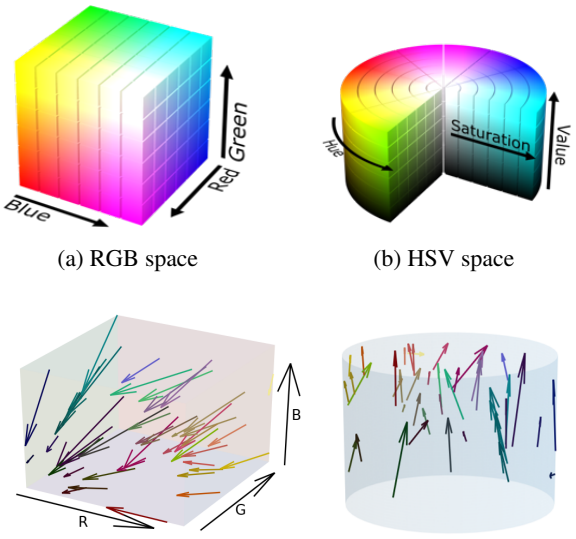
[2] Winn and Muresan (2018) parameterize $\vec{m}$ as a function of m and $\vec{r}$, such that the modifier vectors can adapt to the different reference colors, but showed that this had limited effect in practise.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1488–1493, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

spaces can be done via invertible transformations (Agoston, 2005). As shown in Figure 2d, for some modifiers, color vectors can be approximately parallel in HSV space, thus simplifying the modeling problem. We propose a HSV model using a von-Mises loss, and show that this model outperforms the RGB method for many modifiers. We also present an ensemble model for color space selection, which determines for each modifier the best color space model. Overall our methods substantially outperform prior work, achieving state-of-the-art performance in the grounded color modelling task.

2 Methods

Here we describe the methods employed for color modeling. Formally, the task is to predict a target color vector $\vec{t}$ in RGB space from a reference color vector $\vec{r}$ and a modifier string m.



2.1 Modeling in RGB space

Baseline Model Winn and Muresan (2018) present a model (WM18) which represents a vector $\vec{m} \in \mathbb{R}^3$ as a function of $(m,\ \vec{r})$ pointing from a reference color vector $\vec{r}$ to the target color vector $\vec{t}$, such that $\vec{t} = \vec{r} + \vec{m}$. In the simplest case the modifier m is irrelevant to the reference color $\vec{r}$. This assumption, however, does not hold in all situations. For example, when predicting an instance with the reference vector $\vec{r} = \begin{bmatrix}193 & 169 & 106\end{bmatrix}^\top$ and the modifier *"greenish"*, the outcome $\hat{t}$ is expected to be $\begin{bmatrix}177 & 183 & 102\end{bmatrix}^\top$, however, WM18 predicts $\hat{t} = \begin{bmatrix}195 & 156 & 95\end{bmatrix}^\top$. The cosine similarity between $(\hat{t} - \vec{r})$ and $(\vec{t} - \vec{r})$ is -0.76, i.e., $\vec{m}$ points in the opposite direction to where it should.

RGB Model As shown in Figure 2c, pairs of vectors for the same modifier are often not parallel. In theory, such vectors can even be orthogonal: compare *"darker red"* vs *"darker blue"*, which fall on different faces of the RGB cube. To model this, we propose a model in RGB space as follows:

$$\vec{t} = M\vec{r} + \vec{\beta} \tag{1}$$

Where $M \in \mathbb{R}^{3\times3}$ is a transformation matrix and $\vec{\beta}$ is a modifier vector which is designed to capture the information of m. Given an error term $\varepsilon \sim \mathcal{N}(\vec{0}, \sigma I_3)$, the RGB model is trained to minimize the following loss for the log Gaussian likelihood:

(a) RGB space (b) HSV space

(c) "dark" in RGB (d) "dark" in HSV

Figure 2: 2a: RGB color space. 2b: HSV color space. Arrows in 2c and 2d show vectors staring from reference colors to target colors in RGB and HSV color spaces. Images 2a and 2b by Michael Horvath, available under Creative Commons Attribution-Share Alike 3.0 Unported license.

$$\mathcal{L} = \frac{1}{n}\sum_{i=1}^{n}(\vec{t_i} - \hat{t_i})^\top(\vec{t_i} - \hat{t_i}) \tag{2}$$

where $\vec{t_i}$ is the target vector in each instance and $\hat{t}_i$ is the prediction.[3]

Specific Settings Our model generalizes WM18, which can be realized by setting $M = I_3$ and $\vec{\beta} = \vec{m}$.

Another interesting instance of the model is obtained by setting $M = (1 - \alpha_m)I_3$ and $\vec{\beta} = \alpha_m\vec{m}$, which we call the Diagonal Covariance (DC) model. In contrast to the RGB model and WM18, which model $\vec{m}$ as a function of $\vec{r}$ and m, $\vec{m}$ in the DC model does not depend on $\vec{r}$. Given $\vec{r}$ and m, to predict the $\vec{t}$, our DC model predicts $\vec{m}$ first and then applies a linear transformation to get the target color vector as follows: $\vec{t} = \vec{r} + \alpha_m \times (\vec{m} - \vec{r})$, where $\alpha_m \in [0, 1]$ is a scalar which only depends on m and measures the distance from $\vec{r}$ to $\vec{m}$. In the DC model $\vec{m}$ is the interpolation point for modifiers, such as $\begin{bmatrix}0 & 0 & 0\end{bmatrix}^\top$ for the modifier *"darker"*.

2.2 Modeling in HSV space

Compared with the RGB color space, when modeling modifiers in HSV, there are two main differ-

[3] Although other distributions, such as Beta distribution, may model uncertainties better, as focusing on mean value prediction, Gaussian models provide similar performances.

ences: hue is represented as an angular dimension, and the modifier vectors are more frequently parallel (see Fig 2d). As shown in Figure 2b, HSV space forms a cylindrical geometry with *hue* as its angular dimension, with the value red occurring at both 0 and 2π. For this reason, modelling the hue with a Gaussian regression loss is not appropriate. To account for the angularity, we model *"hue"* with a von-Mises distribution, with the following *pdf*:

$$f(h) = \frac{\exp\left(k\cos\left(h-\hat{h}\right)\right)}{2\pi I_0(k)}. \quad (3)$$

The mean value $\hat{h}$ represents the center of *hue* dimension, k indicates the concentration about the mean, and $I_0(k)$ is the modified Bessel function of order 0.

When training the model, the parameter k is assumed constant, and thus the loss function is:

$$\mathcal{L} = 1 - \frac{1}{n}\sum_{i=1}^{n}\cos\left(h_i - \hat{h}_i\right), \quad (4)$$

where h_i is the *hue* value of the target color in each instance and $\hat{h}_i$ is the prediction.

The second difference to modeling in RGB space is that the modifier behavior is simpler in HSV. For modifiers, vectors from reference colors to target colors are more likely to be parallel (see Figure 2d). As a result, we present an additive model in HSV space where a modifier m will be modeled as a vector from $\vec{r}$ to $\vec{t}$:

$$\vec{t} = \vec{r} + \vec{m} \quad (5)$$

Here $\vec{m}$ is a function of both m and $\vec{r}$. In addition, modifier modeling will be split into two parts: modeling *"hue"* dimension as von-Mises distribution and other dimensions together as a bivariate normal distribution (See Equation 2). Notice that Equation (5) is the same equation as used by WM18, however, here it is applied in a color space that better fits its assumptions.

WM18 is presented and evaluated only in RGB color space. To compare its performance with our models, we transform output into RGB space.

2.3 Ensemble model

An ensemble model is trained to make the final prediction, which we frame as a hard binary choice to select the color space appropriate for the given modifier. This works by applying the general RGB model and HSV model (Equations 1 and 5) to get their predictions, and converting the HSV predictions into RGB space. Then the hard ensemble is trained to predict which color space should be used based on the modifier m and the reference vector $\vec{r}$, using as the learning signal which model prediction had the smallest error against the reference colour for each instance (measured using Delta-E distance, see §3.2). The probability of the RGB model being selected is: $p = \sigma(f(m, \vec{r}))$, where σ is the logistic sigmoid function and $f(m, \vec{r})$ is a function of modifier m and reference color $\vec{r}$.

3 Experiments

3.1 Dataset

The dataset[4] used to train and evaluate our model includes 415 triples (reference color label, r, modifier, m, and target color label, t) in RGB space presented by Winn and Muresan (2018). Munroe (2010) collected the original dataset consisting of color description pairs collected in an open online survey; the dataset was subsequently filtered by McMahan and Stone (2015). Winn and Muresan processed color labels and converted pairs to triples with 79 unique reference color labels and 81 unique modifiers.

We train models in both RGB and HSV color space, but samples in WM18 are only presented in RGB space. Because modifiers encode the general relationship between r and t we use the same approach presented by Winn and Muresan (2018): using the mean value of a set of points to represent a color. A drawback of this approach is that it does not account for our uncertainty about the appropriate RGB encoding for a given color word.

3.2 Experiment Setup

Model configuration: The model presented by Winn and Muresan (2018) is initialized with Google's pretrained 300-d word2vec embeddings (Mikolov et al., 2013b,a) which are not updated during training. To perform comparable experiments, all models in paper are designed with the same pre-trained embedding model. Other pre-trained word embeddings, such as GloVe (Pennington et al., 2014) and BERT (Devlin et al., 2019), were also tested but there was no significant

Table 1: Average cosine similarity score and Delta-E distance over 5 runs. A smaller Delta-E distance means a less significant difference between two colors. **Bold**: best performance. Hard: the hard ensemble model. WM18*: the performance from WM18 paper. See *Supplementary Material* for example outputs and ensemble analysis.

difference in performance compared to word2vec. Single models are trained over 2000 epochs with batch size 32 and 0.1 learning rate. The hyperparameters for the ensemble model are as follows: 600 epochs, 32 batch size, and 0.1 learning rate.

Architecture: An input modifier is represented as a vector by word2vec pretrained embeddings and followed by two fully connected layers(FC_1 and FC_2) with size 32 and 16 respectively. Let h_1 be the hidden state of FC_2 then $h_1 = FC_2(FC_1(\vec{r}, E_m, \vec{r})$ where E are fixed, pretrained word2vec embeddings. $\vec{r}$ is used as an input for both FC_1 and FC_2. After FC_2, all the other layers are based on hidden state h_1.

Evaluation: Following Winn and Muresan (2018), we evaluate the performance in 5 distinct input conditions: (1) *Seen Pairings:* The triple (r, m, t) has been seen when training models. (2) *Unseen Pairings:* Both r and m have been seen in training data, but not the triple (r, m, t). (3) *Unseen Ref. Color:* r has not been seen in training, while m has been seen. (4) *Unseen modifiers:* m has not been seen in training, while r has been seen. (5) *Fully Unseen:* Neither r nor m have been seen in training.

Because of the small size of the dataset, we report the average performance over 5 runs with different random seeds. Two scores, cosine similarity, and Delta-E are applied for evaluating the performance. Cosine similarity measures the difference in terms of vector direction in color space and Delta-E is a non-uniformity metric for measuring color differences. Delta-E was first presented as the Euclidean Distance in CIELAB color space (McLaren, 1976). Lower Delta-E values are thus preferable as they indicate better matching of the target color. Luo et al. (2001) present the latest and most accurate CIE color difference metrics, Delta-E 2000, which improve the original formula by taking into account weighting factors and fixing the lightness inaccuracies. Our models are evaluated with Delta-E 2000.

3.3 Results

Table 1 shows the results. Compared with WM18, our RGB model outperforms under all conditions. As we have stated, our model is a generalization of their approach. The more complex transformation matrix in our RGB model is able to learn more information, such as the effects of covariance between color channels, and thus achieves a better performance than WM18. Note that our reimplementation of the original WM18 system lead to significantly better performance.[5]

According to the cosine similarity, the HSV model is superior for most test conditions (con-

[5]We train the model for many more epochs, which is required for a good to the training data. This can be observed in terms of the 'seen pairings', where the WM18 reported results appear to be underfitting.

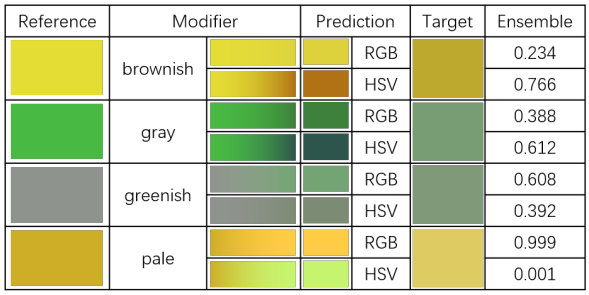

Figure 3: Examples of predictions from RGB, HSV and Ensemble model. The Ensemble column reports the predicted probability of the RGB and HSV models being selected.

firming our hypothesis about simpler modifier behaviour in this space). However for Delta-E, the RGB model and ensemble perform better. Unlike cosine, Delta-E is sensitive to differences in vector length, and we would argue it is the most appropriate metric because lengths are critical to measuring the extent of lightness and darkness of colors. Accordingly the HSV model does worse under this metric, as it more directly models the direction of color modifiers, but as a consequence this leads to errors in its length predictions. Overall the ensemble does well according to both metrics, and has the best performance for several test conditions with Delta-E.

Error Analysis We first focused error analysis on prediction of "Unseen Modifiers" and "Fully Unseen" instances. As shown in Table 1, our models are able to predict target colors given seen modifiers but fail to make predictions for instances with unseen modifiers. All modifiers are represented by word2vec embeddings, and we expect that predictions of unseen modifiers should be close to instances with similar seen modifiers. For example, the prediction of a reference color $\vec{r}$ and modifier *"greeny"* should be similar to the prediction of the same reference color $\vec{r}$ and a similar seen modifier, e.g. *"green"* and *"greenish"*. However, the prediction of *"greeny"* is more similar to *"bluey"*, a consequence of these terms having highly similar word embeddings (as do other colour modifiers with a *-y* suffix, irrespective of their colour). This is related to the problem reported in Mrkšić et al. (2016), whereby words and their antonyms often have similar embeddings, as a result of sharing similar distributional contexts. Accordingly for the *unseen modifier* condition, our model is often misled by attempting to generalise from nearest neighbour modifiers which have a different meaning.

4 Related Work

Baroni and Zamparelli (2010) was the first work to propose an approach to adjective-noun composition (AN) for corpus-based distributional semantics which represents nouns as vectors and adjectives as matrices nominal vectors. However it is hard to gain an intuition for what the transformation does since these embeddings generally live on a highly structured but unknown manifold. In our case, we operate on colors and we actually know the geometry of the colour spaces we use. This makes it easier for us to interpret the learned mapping (see Figure 2c and 2d that show convergence to a point in RGB and parallelism in HSV space).

5 Conclusion and Future Work

In this paper, we proposed novel models of predicting color based on textual modifiers, incorporating a matrix transformation than the previous largely linear additive method. As well as our more general approach, we exploit the properties of another color space, namely HSV, in which the modifier behaviours are often simpler. Overall our method leads to state of the art performance on a standard dataset.

In future work, we intend to develop more accurate modifier representations to allow for better generalisation to unseen modifiers. This might be achieved by using a composition sub-word representation for modifiers, such as character-level encoding. Finally, we also strive to acquire larger datasets. This is a crucial step towards comparing the generalization performance of different color-modifier models. Models trained on larger data sets are likely to be more applicable to real-world problems since they learn representations for more color terms.

Abstract

Core to the vision-and-language navigation (VLN) challenge is building robust instruction representations and action decoding schemes, which can generalize well to previously unseen instructions and environments. In this paper, we report two simple but highly effective methods to address these challenges and lead to a new state-of-the-art performance. First, we adapt large-scale pretrained language models to learn text representations that generalize better to previously unseen instructions. Second, we propose a stochastic sampling scheme to reduce the considerable gap between the expert actions in training and sampled actions in test, so that the agent can learn to correct its own mistakes during long sequential action decoding. Combining the two techniques, we achieve a new state of the art on the Room-to-Room benchmark with 6% absolute gain over the previous best result (47% → 53%) on the *Success Rate weighted by Path Length* metric.

1 Introduction

The vision-and-language navigation (VLN) task, learning to navigate in visual environments based on natural language instructions, has attracted interest throughout the artificial intelligence research community (Hemachandra et al., 2015; Anderson et al., 2018; Chen et al., 2019; Savva et al., 2019). It fosters research on multimodal representations and reinforcement learning, and serves as a test bed for many real-world applications such as in-home robots.

In the recent Room-to-Room (R2R) VLN challenge (Anderson et al., 2018), most state-of-the-art methods are developed based on an encoder-decoder framework (Cho et al., 2014; Sutskever et al., 2014), where a natural language instruction is represented as a sequence of words, and a navigation trajectory as a sequence of actions, enhanced with attention (Anderson et al., 2018; Wang et al., 2019; Fried et al., 2018; Ma et al., 2019a). Two important components are shared by all VLN agents: (i) an *Instruction Encoder* that employs a language model (LM) for instruction understanding; and (ii) an *Action Decoder*, where an appropriate sequence-level training scheme is required for sequential decision-making. Each component faces its own challenges (see Figure 1).

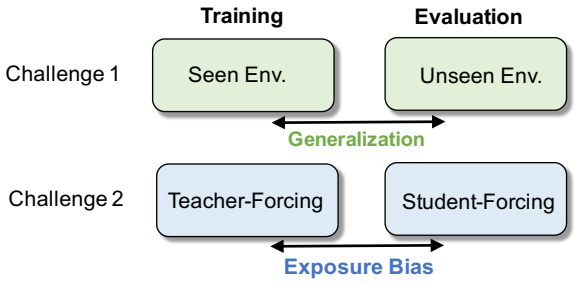

Figure 1: Two challenges in VLN.

The first challenge is generalizing grounded natural language instruction understanding from seen to unseen environments. Specifically, in the R2R task, only 69% of bigrams are shared between training and evaluation.[1] Existing work leverages pretrained GloVe embeddings (Pennington et al., 2014) to help generalize. In computer vision, it has been shown that large-scale models pretrained on ImageNet can transfer the knowledge to downstream applications (Yosinski et al., 2014), thus improving generalization. Comparable language-based transfer learning has not been shown for instruction understanding in VLN.

The second challenge is *exposure bias* (Ranzato et al., 2016) for the action decoder, due to the discrepancy between training and inference. This problem is common to many tasks where decoding is needed, including text generation, abstractive summarization, and machine translation (Ben-

[1]Table 1 shows n-gram overlap statistics between training seen and validation seen/unseen environments.

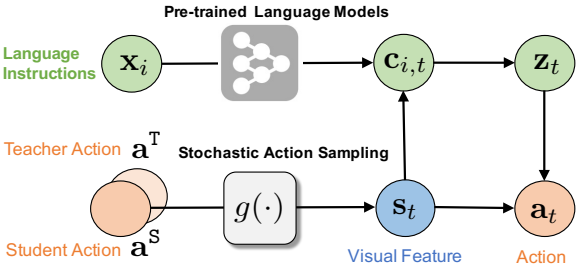

Figure 2: Illustration of proposed methods.

gio et al., 2015). Two widely used training strategies are *student-forcing* and *teacher-forcing* (described in detail in Section 2.2). It is well-known that the sequence length determines which training strategy is more effective. In the VLN literature, student-forcing has been widely used, as early work (Anderson et al., 2018) used long trajectories (up to 20 steps) with a simple discrete action space. Most recent work, however, has relied on a panoramic action space (Fried et al., 2018) in which most trajectories are only up to seven steps long. In such cases, teacher-forcing is preferable (Tan et al., 2019). Neither strategy is perfect: teacher-forcing has exposure bias, while student-forcing's random actions can cause an agent to deviate far from the correct path, rendering the original instruction invalid.[2]

To tackle these challenges, we have developed two techniques to enable the agent to navigate more efficiently. For the first challenge, we leverage the recent large-scale pretrained language models, BERT (Devlin et al., 2019) and GPT (Radford et al., 2018), to improve the agent's robustness in unseen environments. We show that large-scale *language-only* pretraining improves generalization in grounded environments. For the second challenge, we propose a stochastic sampling scheme to balance teacher-forcing and student-forcing during training, so that the agent can recover from its own mistakes at inference time. As a result of combining both techniques, on the R2R benchmark test set, our agent (PRESS)[3] achieves 53% on SPL, an absolute 6% gain over the current state of the art.

2 Method

In the VLN task, instructions are represented as a set $\mathcal{X} = \{\boldsymbol{x}_i\}_{i=1}^{M}$ of M instructions per trajectory. Each instruction $\boldsymbol{x}_i$ is a sequence of L_i words, $\boldsymbol{x}_i = [x_{i,1}, x_{i,2}, ..., x_{i,L_i}]$. Given $\mathcal{X}$, the goal is to train an agent to navigate from a starting position $\boldsymbol{s}_0$ to a target position, via completing a T-step trajectory $\tau = [\boldsymbol{s}_0, \boldsymbol{a}_0, \boldsymbol{s}_1, \boldsymbol{a}_1, \cdots, \boldsymbol{s}_T, \boldsymbol{a}_T]$, where $\boldsymbol{s}_t$ and $\boldsymbol{a}_t$ are the visual state and navigation action, respectively, at step t. The training dataset $\mathcal{D}_E = \{\boldsymbol{\tau}, \mathcal{X}\}$ consists of example pairs of instruction set $\mathcal{X}$ and a corresponding expert trajectory $\boldsymbol{\tau}$. Our goal is to learn a policy $\pi_{\boldsymbol{\theta}}(\boldsymbol{\tau}|\mathcal{X})$ that maximizes the log-likelihood of the target trajectory $\boldsymbol{\tau}$ given instructions $\mathcal{X}$:

$$\log \pi_{\boldsymbol{\theta}}(\boldsymbol{\tau}|\mathcal{X}) = \sum_{t=1}^{T} \log \pi_{\boldsymbol{\theta}}(\boldsymbol{a}_t|\boldsymbol{s}_t, \mathcal{X}), \quad (1)$$

where $\boldsymbol{\theta}$ are trainable parameters. The policy is usually parameterized as an attention-based seq2seq model, with a language encoder $\boldsymbol{z}_t = f_{\theta_E}(\boldsymbol{x})$, and an action decoder $\boldsymbol{a}_t = f_{\theta_D}(\boldsymbol{z}_t, \boldsymbol{s}_t)$. Successful navigation depends on (i) precisely grounding the instructions $\mathcal{X}$ in τ in various environments, and (ii) correctly making the current decision $\boldsymbol{a}_t$ based on previous actions/observations $\tau_{<t} = [\boldsymbol{s}_0, \boldsymbol{a}_0, \cdots, \boldsymbol{s}_{t-1}]$. To address these concerns, we propose PRESS, illustrated in Figure 2.

2.1 Instruction Understanding with Pretrained Language Models

At each step t, the agent decides where to navigate by updating a dynamic understanding of the instructions $\boldsymbol{z}_t$, according to its current visual state $\boldsymbol{s}_t$. Given instruction $\boldsymbol{x}$, the language encoder proceeds in two steps, end-to-end, by considering a function decomposition $f_{\theta_E} = f_{\boldsymbol{\theta}_{x\to e}} \circ f_{\boldsymbol{\theta}_{e\to z}}$:

- $f_{\boldsymbol{\theta}_{x\to e}} : \boldsymbol{x} \to \boldsymbol{e}$, where $\boldsymbol{x} = [x_1, \cdots, x_L]$ is represented as its (contextualized) word embedding form $\boldsymbol{e} = [e_1, \cdots, e_L]$, with e_i as the representation for word x_i;
- $f_{\boldsymbol{\theta}_{e\to z}} : \boldsymbol{e} \to \boldsymbol{z}_t$: For each embedded instruction $\boldsymbol{e}$, we ground its representations as $\boldsymbol{c}_{i,t}$ for state $\boldsymbol{s}_t$ via neural attention. To handle

[2] To compensate, beam search is often used to improve success rates. Recent work, e.g., using search strategies (Ke et al., 2019) or progress monitors (Ma et al., 2019b), has focused on mitigating the cost of computing top-k rollouts.

[3] **PRE**TRAINED LMS AND **S**TOCHASTIC **S**AMPLING

language variability, one may aggregate features of multiple instructions $\mathcal{C}_t = \{\boldsymbol{c}_{i,t}\}_{i=1}^{M}$ into a single joint feature $\boldsymbol{z}_t = \frac{1}{M}\sum_{i=1}^{M}\boldsymbol{c}_{i,t}$.[4]

Previous methods in VLN learn $\boldsymbol{e}$ either from pretrained word embeddings (Pennington et al., 2014) which do not take into account word context, or from scratch. As a result, their representations do not capture contextual information within each instruction. More importantly, they tend to overfit the training instructions associated with seen environments, limiting their utility in unseen environments. To remedy these issues, we propose to represent $\boldsymbol{e}$ with contextualized word embeddings produced using large-scale pretrained language models, such as BERT and GPT.

Instruction Encoder. The agent's memory vector $\boldsymbol{h}_{t-1}$ captures the perception and action history and is used to attend to the instruction $\boldsymbol{x}$. A pretrained LM $f_{\boldsymbol{\theta}_{x\to e}}$ encodes the instruction $e = [\boldsymbol{e}_1, \cdots, \boldsymbol{e}_L]$; $\boldsymbol{e}_i$ where the representation for word x_i, is built with $f_{\boldsymbol{\theta}_{x\to e}} \in \{$ GPT, BERT $\}$, and $\boldsymbol{\theta}_{x\to e}$ are fine-tuned parameters. The embedded words $e = [\boldsymbol{e}_1, \cdots, \boldsymbol{e}_L]$ are passed through an LSTM $f_{\boldsymbol{\theta}_{e\to z}}$ to produce a sequence of textual features $[\boldsymbol{h}_1^e, \cdots, \boldsymbol{h}_L^e]$. At each time step t, the *textual context* for the instruction $\boldsymbol{x}$ is computed as weighted sum of textual features in the sequence:

$$\boldsymbol{c}_{i,t} = \sum_{l=1}^{L} \alpha_l \boldsymbol{h}_l^e \tag{2}$$

where $\alpha_l = \text{Softmax}(\boldsymbol{h}_t^\top \boldsymbol{h}_l^e)$, α_l places more weight on the word representations that are most relevant to the agent's current status.

Decoder. At each step, the agent takes an action a_t, and the environment returns new visual observations; the agent first performs one-hop visual attention $f(\cdot)$ to all the visual image features s_t, based on its previous memory vector $\boldsymbol{h}_{t-1}$. Then, the agent updates its visual state $\boldsymbol{s}_t$ as the weighted sum of the panoramic features, $\boldsymbol{s}_t = \sum_j \gamma_{t,j}\boldsymbol{s}_{t,j}$. The attention weight $\gamma_{t,j}$ for the j-th visual feature $\boldsymbol{s}_{t,j}$ represents its importance with respect to the previous history context $\boldsymbol{h}_{t-1}$, computed as $\gamma_{t,j} = \text{Softmax}((\mathbf{W}_h\boldsymbol{h}_{t-1})^\top \mathbf{W}_s\boldsymbol{s}_{t,j})$ (Fried et al., 2018) where $\text{Softmax}(r_j) = \exp(r_j)/\sum_{j'}\exp(r_{j'})$, $\mathbf{W}_h$ and $\mathbf{W}_s$ are trainable projection matrices.

$$\boldsymbol{h}_t = f_{\boldsymbol{\theta}_D}([\boldsymbol{s}_t, \boldsymbol{a}_{t-1}], \boldsymbol{h}_{t-1}) \tag{3}$$

where $\boldsymbol{a}_{t-1}$ is the action taken at previous step, and $\boldsymbol{\theta}_D$ are the LSTM decoder parameters.

Two-stage learning. The parameters of our agent are $\boldsymbol{\theta} = \{\boldsymbol{\theta}_{x\to e}, \boldsymbol{\theta}_{e\to z}, \theta_D\}$. In practice, we find that the agent overfits quickly, when the full model is naively fine-tuned, with $\boldsymbol{\theta}_{x\to e}$ initialized by pretrained LMs (*e.g.,* BERT). In this paper, we consider a two-stage learning scheme to facilitate the use of pretrained LMs for VLN. (i) Embedding-based stage: We fix $\boldsymbol{\theta}_{x\to e}$, and use BERT or GPT to provide instruction embeddings. Only $\{\boldsymbol{\theta}_{e\to z}, \boldsymbol{\theta}_D\}$ are updated (while tuning on validation). (ii) Fine-tuning stage: We train all model parameters $\boldsymbol{\theta}$ with a smaller learning rate, so that $\boldsymbol{\theta}_{x\to e}$ can adapt to our VLN task.

2.2 Stochastic Action Sampling

A core question is how to learn useful state representations $\boldsymbol{s}_t$ in Eq. (1) during the trajectory rollout. In other words, which action should we use to interact with the environment to elicit the next state? As noted, most existing work uses one of two schemes: (i) *Teacher-forcing (TF)*, where the agent takes ground-truth actions $\boldsymbol{a}^{\text{T}}$ only. Though TF enables efficient training, it results in "exposure bias" because agents must follow learned rather than gold trajectories at test time. In contrast, (ii) *Student-forcing (SF)*, where an action $\boldsymbol{a}^{\text{S}}$ is drawn from the current learned policy, allows the agent to learn from its own actions (aligning training and evaluation), however, it is inefficient, as the agent explores randomly when confused or in the early stages of training.

In this work, we consider a stochastic scheme (*SS*) to alternate between choosing actions from $\boldsymbol{a}^{\text{T}}$ and $\boldsymbol{a}^{\text{S}}$ for state transition $\boldsymbol{s} \leftarrow g(\boldsymbol{a}^{\text{T}}, \boldsymbol{a}^{\text{S}})$, inspired by scheduled sampling (Bengio et al., 2015). As illustrated in Figure 2, at each step, the agent "flips a coin" with some probability ϵ to decide whether to take the teacher's action a^{T} or a sampled one a^{S}:

$$\boldsymbol{a} = \delta\boldsymbol{a}^{\text{T}} + (1-\delta)\boldsymbol{a}^{\text{S}}, \tag{4}$$

where $\delta \sim \text{Bernoulli}(\epsilon)$. This allows the agent to leverage the advantages of both TF and SF, yielding a faster and less biased learner. We fix ϵ as a constant during learning, which is different from the decaying schedule in (Bengio et al., 2015).

[4] This recovers $\boldsymbol{z}_t = \boldsymbol{c}_t$ when only a single instruction is available.

3 Experiments

3.1 Dataset

We use the Room-to-Room dataset for the VLN task, built upon the Matterport3D dataset (Chang et al., 2017), which consists of 10,800 panoramic views and 7,189 trajectories. Each trajectory is paired with three natural language instructions. The R2R dataset consists of four splits: train seen, validation seen, validation unseen, and test unseen. There is no overlap between seen and unseen environments. At the beginning of each episode, the agent starts at a specific location, and is given natural instructions, the goal of the agent is to navigate to the target location as quickly as possible.

3.2 Baseline Systems

We compare our approach with eight recently published systems:

- RANDOM: an agent that randomly selects a direction and moves five step in that direction (Anderson et al., 2018).
- SEQ2SEQ: sequence-to-sequence model proposed by Anderson *et al.* as a baseline for the R2R benchmark (Anderson et al., 2018) and analyzed in (Thomason et al., 2019).
- RPA (Wang et al., 2018): is an agent which combines model-free and model-based reinforcement learning, using a look-ahead module for planning.
- SPEAKER-FOLLOWER (Fried et al., 2018): an agent trained with data augmentation from a speaker model with panoramic actions.
- SMNA (Ma et al., 2019a): an agent trained with a visual-textual co-grounding module and progress monitor on panoramic actions.
- RCM+SIL(TRAIN) (Wang et al., 2019): an agent trained with cross-modal grounding locally and globally via reinforcement learning.
- REGRETFUL (Ma et al., 2019b): an agent with a trained progress monitor heuristic for search that enables backtracking.
- FAST (Ke et al., 2019): an agent which combines global and local knowledge to compare partial trajectories of different lengths, enabling efficient backtrack after a mistake.
- ENVDROP (Tan et al., 2019): proposed an environment dropout method, which can generate more environments based on the limited seen environments.

Setting	Agent	Validation Seen SR ↑	Validation Seen SPL ↑	Validation Unseen SR ↑	Validation Unseen SPL ↑
S	seq2seq	51	46	32	25
	PRESS	47 (-4)	43 (-3)	43 (+11)	38 (+13)
M	seq2seq	49	44	33	26
	PRESS	56 (+7)	53 (+9)	56 (+23)	50 (+24)

Table 2: Comparison of PRESS and seq2seq.

3.3 Evaluation Metrics

We benchmark our agent on the following metrics:

TL **Trajectory Length** measures the average length of the navigation trajectory.

NE **Navigation Error** is the mean of the shortest path distance in meters between the agent's final location and the target location.

SR **Success Rate** with which the agent's final location is less than 3 meters from the target.

SPL **Success weighted by Path Length** trades-off SR against TL.

SPL is the recommended primary metric, other metrics are considered as auxiliary measures.

3.4 Implementation

We use a LSTM/GPT/BERT for the language encoder, and a second single-layer LSTM for the action decoder (h=1024). We use Adamax and batch sizes of 24/16 for pretraining/finetuning. The learning rates for MLE are $1e^{-4}$, during finetuning BERT the learning rate is $5e^{-5}$. Following (Fried et al., 2018), we use a panoramic action space and the ResNet image features provided by (Anderson et al., 2018). The code is publicly available here: https://github.com/xjli/r2r_vln.

3.5 Results

Robust Generalization. First, we compare PRESS to a baseline seq2seq model[5] in two evaluation settings on the validation splits: (1) **S**: A single instruction is provided to the agent at a time. Thus, three separate navigation trajectories are generated corresponding to three alternative instructions in this setting. We report the averaged performance over three separate runs. (2) **M**: All three instructions are provided to the agent at once. The seq2seq baseline does not have an aggregation strategy so we report its performance for the single trajectory with maximum likelihood. For PRESS, we aggregate the instructions via context

[5]The baseline seq2seq agent is the FOLLOWER of SPEAKER-FOLLOWER (Fried et al., 2018).

Table 3: Comparison with the state-of-the-art methods. **Blue** indicates best value overall.

mean-pooling and generate a single trajectory. No data augmentation is applied to either model.

The results are summarized in Table 2. (*i*) PRESS drastically outperforms the seq2seq models on unseen environments in both settings, and (*ii*) Interestingly, our method shows a much smaller gap between seen and unseen environments than seq2seq. It demonstrates the importance of pretrained LMs and stochastic sampling for strong generalization in unseen environments.

Comparison with SoTA. In Table 3, we compare the performance of our agent against all the published methods, our PRESS agent outperforms the existing models on nearly all the metrics.

Ablation Analysis. Key to this work is leveraging large-scale pretrained LMs and effective training strategies for action sequence decoding. Table 4 shows an ablation of these choices. (1) BERT and GPT are better than LSTM on both seen and unseen environments, and BERT generalizes better than GPT on unseen environments. (2) Teacher-forcing performs better than student-forcing on validation unseen environments, while an opposite conclusion is drawn on validation seen environments. SS performs the best on unseen environments.

Qualitative Examples. We provide two navigation examples of PRESS on the validation unseen environments with the step-by-step views and top-down views in Appendix.

(1) Figure 3 shows how the agent with LSTM instruction encoder performs compared with our PRESS agent. There are two rare words "**mannequins**" and "**manikins**" which are not in the training dataset and confuse the LSTM agent, while, PRESS successfully maps these two "mannequins" and "manikins" to the correct objects.

LM		Validation Seen TL	NE	SR	SPL	Validation Unseen TL	NE	SR	SPL
LSTM	TF	10.50	5.74	44	42	9.86	6.23	42	39
	SF	11.87	3.97	59	53	13.23	6.17	40	31

	SF	12.39	2.71	73	64	13.12	5.06	51	42
	SS	10.35	3.09	71	67	10.06	4.31	**59**	**55**

Table 4: Ablation results of different language pretrainings and training strategies: Teacher Forcing (TF), Student Forcing (SF) and Stochastic Sampling (SS).

(2) The second set in Figure 4 shows how the agents trained with different training strategies performs in an unseen environment. The agents trained with teacher-forcing and student-forcing both fail, while PRESS succeeds.

4 Conclusion

We present PRESS, a navigation agent based on two previously underexplored techniques in VLN: pretrained language models and stochastic action sampling. Our PRESS demonstrates robust generalization in the unseen environments, leading to a new state-of-the-art performance over many of the much more complex approaches previously proposed. As both the components of PRESS can be easily integrated, future models can consider building upon them as a strong baseline system.

Abstract

We explore whether it is possible to leverage eye-tracking data in an RNN dependency parser (for English) when such information is only available during training – i.e. no aggregated or token-level gaze features are used at inference time. To do so, we train a multi-task learning model that parses sentences as sequence labeling and leverages gaze features as auxiliary tasks. Our method also learns to train from disjoint datasets, i.e. it can be used to test whether already collected gaze features are useful to improve the performance on new *non-gazed* annotated treebanks. Accuracy gains are modest but positive, showing the feasibility of the approach. It can serve as a first step towards architectures that can better leverage eye-tracking data or other complementary information available only for training sentences, possibly leading to improvements in syntactic parsing.

1 Introduction

Eye trackers and gaze features collected from them have been recently applied to natural language processing (NLP) tasks, such as part-of-speech tagging (Duffy et al., 1988; Nilsson and Nivre, 2009; Barrett and Søgaard, 2015a), named-entity recognition (Tokunaga et al., 2017) or readability (González-Garduño and Søgaard, 2018). Eye-movement data has been also used for parsing. For example, Barrett and Søgaard (2015b) rank discriminative features to predict syntactic categories (e.g. subject vs. object) and use them to improve a transition-based parser, trained on a structured perceptron with discrete features (Collins, 2002; Zhang and Nivre, 2011). However, the experiments were carried out on a parallel toy treebank and the performance was relatively low. Lopopolo et al. (2019) follow the inverse path, and use dependency parsing features to predict eye-regression during training, i.e. cases where the reader goes back to a word of the sentence.

In this context, how to retrieve and leverage eye-tracking data has become an active area of research in different NLP fields. Previous studies (Barrett and Søgaard, 2015b; Barrett et al., 2016) suggest that real-time eye-tracking data can be collected at inference time, so that *token-level* gaze features are used during training but also at test time. However, even if in the near future every user has an eye tracker on top of their screen – a scenario which is far from guaranteed, and raises privacy concerns (Liebling and Preibusch, 2014) – many running NLP applications that process data from various Internet sources will not expect to have any human being reading massive amounts of data. Other studies (Barrett and Søgaard, 2015a; Hollenstein and Zhang, 2019) instead derive gaze features from the training set: in particular, they collect *type-level* gaze features from the vocabulary in the training set; which are then aggregated to create a lookup table and used as a sort of pre-computed gaze input when a given word in the test set matches an entry, otherwise, a token has an unknown gaze feature value. In this manner, the influence of gaze features on unseen data depends on the vocabulary encountered during training. For instance, Hollenstein et al. (2019) report that unknown tokens make up 41.09% on new data for their research on named-entity recognition (NER) with eye-tracking data. To our knowledge, this kind of approaches have not been applied to syntactic parsing.

More in the line of our work, Barrett et al. (2018) is one of the few approaches that does not rely on the assumption of using gaze features as input. Instead, the human data is used as an inductive bias to guide the attention weights in a recurrent neural network for sequence classification (used for tasks such as binary sentiment anal-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1500–1506, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ysis a the sentence level). Moreover, it has been shown that both constituency (Vilares et al., 2019) and dependency (Strzyz et al., 2019a) parsing can benefit from multi-task learning. Also related to our work with human data, González-Garduño and Søgaard (2017) show that gaze features learned in a multi-task (MTL) setup can lead to improvements in readability assessment.

Contribution In this work we leverage gaze learning for dependency parsing assuming that gaze features are likely to be only available during training – and no gaze features are given, in any form, at inference time. Our approach learns eye-movement features as auxiliary tasks in a multitask framework where both parsing and gaze prediction are addressed as sequence labeling. To test its effect on syntactic analysis, we experiment on parallel and disjoint datasets with dependency parsing and gaze annotations. The source code can be found at `https://github.com/mstrise/dep2label-eye-tracking-data`.

2 Methods and materials

This section describes in detail the data and the models used in our work.

2.1 Data

We will use both *parallel* data (containing dependency and gaze annotations) and *disjoint* data (where one dataset contains only parsing annotations and the other one just gaze data).

***Parallel* data** The Dundee corpus (Kennedy et al., 2003) contains recordings of measurements for eye movements of ten English-speaking participants during reading 20 newspaper articles from *The Independent* making in total 2368 unique sentences. This dataset was used as the starting point to create a corpus that fits the purpose of dependency parsing, the Dundee treebank (Barrett et al., 2015). This treebank augments sentences from the Dundee corpus with syntactic annotations according to the Universal Dependencies (UD) guidelines (Nivre et al., 2016). We will use this treebank as the parallel data for our models. We split the data $(80-10-10)$ into training, development and test. Sentences were randomly shuffled with assurance that the same sentence coming from the 10 participants is included only in one of the sets.[1]

***Disjoint* data** Most of dependency treebanks do not contain gaze annotations. With this setup, in addition to the assumption that eye-movement data is available during training, we aim to show whether we improve the performance of a dependency parser with gaze-annotated data coming from a different corpus. We will use two datasets: one with dependency annotations and another one labeled with eye-movement data. For the former we use the Penn Treebank (PTB) (Marcus et al., 1993), which contains sentences from *The Wall Street Journal* annotated with phrase-structure trees. We convert it into Stanford Dependencies (de Marneffe et al., 2006) and apply the standard splits for dependency parsing: sections $2-21$ for training, 22 for development set and 23 for testing, whereas PoS tags are predicted by the Stanford tagger (Toutanova et al., 2003). For gaze-annotated data, we will employ the eye-movement annotations from the Dundee Treebank but using a different split $(90-10-0)$.[2]

2.2 Gaze-averaged sequence labeling parsing

During training we opt to emulate recent cognitive studies that suggest that human sentence understanding recruits the same brain regions for lexical and syntactic processing, consistent with a sequence-tagging-like process (Fedorenko et al., 2018), which is also a natural and intuitive way to learn to predict eye-movement information. To do so, we rely on standard bidirectional long short-term memory networks (BILSTMs) (Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997).

We denote $\text{LSTM}_\theta(\mathbf{w})$ as the abstraction of a long short-term memory network, that processes an input sentence w=$[w_1, ..., w_n]$ to generate an output of hidden representations $\mathbf{h}$=$[\mathbf{h}_1, ..., \mathbf{h}_n]$. Thus, a BILSTM can be seen as $\text{BILSTM}_\theta(\mathbf{w})$ = $\text{LSTM}^l_\theta(\mathbf{w_{i:m}}) \cdot \text{LSTM}^r_\theta(\mathbf{w_{m:n}}) = \mathbf{h}^l \cdot \mathbf{h}^r$.[3] In this work we will stack two layers of BILSTMs before decoding the output. BILSTMs are commonly used for sequence labeling tasks (Reimers

[1] In addition we removed 40 sentences (4 unique sentences read by the 10 participants) that contained cases of incoherence in their syntactic dependency annotation resulting in 23640 sentences in total (2364 unique sentences).

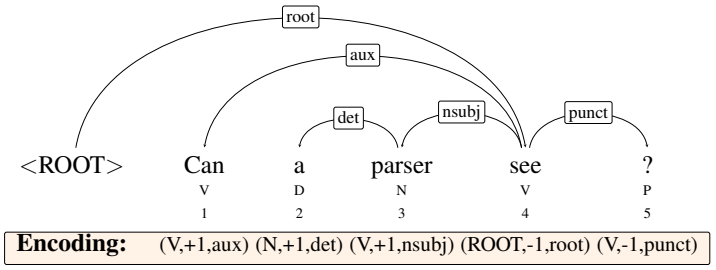
[2] During testing we will be just testing the performance on the PTB test set.

[3] LSTM^l processes the sentences from left-to-right and LSTM^r from right-to-left. '$\cdot$' is the concatenation operator.

and Gurevych, 2017), where a word-level prediction can be generated for each token, by adding a feed forward network to predict an output label at each time step, using a $softmax(\mathbf{W} \times \mathbf{h}_i + \mathbf{b})$. In this paper we propose to learn to leverage eye-movement data as a sequence labeling task. To jointly learn dependency parsing in a common framework, we also cast parsing as sequence labeling and learn both tasks in a multitask learning (MTL) setup (Caruana, 1997). The main components are described in the following paragraphs.

Dependency parsing as sequence labeling We proceed similarly to Strzyz et al. (2019b). Given a linearization function $F_w : T_{|w|} \rightarrow L^w$, for each word w_i, Strzyz et al.'s approach generates a label $l_i \in (o_i, p_i, d_i)$ that encodes the binary relationship between w_i and its head, where: d_i encodes the dependency relation, and the sub-pair (o_i, p_i) the index of such head term, with $o_i \in \mathbb{N}$ and $p_i \in P$ (a part-of-speech set). If o_i is positive, then the head of w_i is the o_i-th token to the right that has the part-of-speech tag p_i. If o_i is negative, then the head of w_i is the $|o_i|$-th token to the left whose PoS tag is p_i.

This parser obtains similar results to competitive transition- and graph-based parsers such as BIST (Kiperwasser and Goldberg, 2016) and can be taken as a strong baseline to test the effect of eye-movement data for dependency parsing.



Gaze information In previous studies the choice of number of gaze features used in the experiments has varied, seemingly, depending on the NLP task of interest. For instance, Barrett et al. (2016) distinguish 31 features (where 22 are gaze features) for part-of-speech tagging while Hollenstein and Zhang (2019) use 17 features in the NER task. In another piece of work, 5 gaze features are used for relation classification and sentiment analysis (Hollenstein et al., 2019). Finally, Singh et al. (2016) use gaze features in order to automatically predict reading times for a new text. However, the model predicts only 4 features that are then used as features for readability assessment.

We have chosen 12 gaze features and based on the previous work (Barrett et al., 2016; Hollenstein and Zhang, 2019) we have divided them into 4 groups. In particular, we explore the informativeness of the *basic gaze features*: total fixation duration on a word w (`total fix dur`), mean fixation duration on w (`mean fix dur`, number fixations on w (n `fix`) and fixation probability on w (`fix prob`). As *early gaze features* we consider: first fixation duration on w (`first fix dur`) and first pass duration (`first pass dur`), while as *late gaze features*: number of re-fixations on w (n `re-fix`) and reread probability of w (`reread prob`). We also take account of the neighboring words and treat them as *context features*: fixation probability on the previous and next word ($w-1$ and $w+1$ `fix prob`) as well as fixation duration on the previous and next word ($w-1$ and $w+1$ `fix dur`). Figure 1 depicts an exemplary (linearized) dependency tree with some of the gaze features used in the experiments. Following previous work (Hollenstein and Zhang, 2019), we discretize gaze features.[4]

Multitask learning We previously argued that gaze-annotated data is unlikely to be available at inference time. However, previous related work for dependency parsing usually assumes that such information will be collected during testing and fed as input features to the model (Barrett and Søgaard, 2015b; Hollenstein and Zhang, 2019). What we propose instead is to leverage such information during training. To do so, we rely on MTL and auxiliary tasks. Our work focuses on exploiting the utility of gaze information using just a standard BILSTM, directly building on top of previous work of dependency parsing as sequence labeling (Strzyz et al., 2019b), and ignoring extra tools such as attention. In this line, a future possible solution could be to apply the approach by Barrett et al. (2018) to structured prediction and word-level classification. In their work they used human data as an inductive bias to update the attention weights of the network.

In our setup, dependency parsing as sequence labeling is addressed through two main tasks: one to predict the index of the head term, i.e. the sub-index (o_i, p_i), and another one to predict the dependency relation (d_i). Eye-movement discrete labels are learned as auxiliary tasks. We use a hard-sharing architecture where the BILSTMs are fully shared and followed by an independent feed-forward layer (followed by a softmax) to predict the corresponding label for each of the tasks. The main idea is that the eye-movement signal(s) will

[4] `Total fix dur`, `mean fix dur`, `first fix dur`, `first pass dur`, $w-1$ and $w+1$ `fix dur` are used as a discrete variable whose values are represented as percentile intervals with a bin size of 20, while for the other features we use their raw values.

Gaze features:

`mean fix`	60-80	0-20	60-80	80-100	20-40
`nb fix`	2	0	3	5	1
w `fix prob`	0	0	1	1	0
$w+1$ `fix prob`	0	0	1	1	0

Figure 1: A dependency tree with its encoding and some of the corresponding gaze features.

be back-propagated to update the weights of the shared BILSTM, building a model that latently encodes such information and helps dependency parsing.

For the parallel data setup, the model is trained in a standard way, and the cross-entropy loss is computed as $\mathcal{L} = \mathcal{L}_{(o,p)} + \mathcal{L}_d + \sum_a \beta_a * \mathcal{L}_a$. For the disjoint setup, during the training process for each batch we randomly pick all its samples from one of the treebanks (samples that have not been yet taken, either from the dependency parsing corpus or the gaze-annotated one) and run the network to make the predictions. Then, we back-propagate the loss for the outputs associated to that treebank and ignore the rest, i.e. $\mathcal{L} = \tau(\mathcal{L}_{(o,p)} + \mathcal{L}_d) + (1-\tau)\sum \beta_{aux}\mathcal{L}_{aux}$, where τ is a binary flag set to 1 when the batch contains dependency parsing samples, and to 0 otherwise.

For both setups we will test: (i) predicting *one* of the gaze features as an auxiliary task (ii) predicting multiple gaze labels as multiple auxiliary tasks.

3 Experiments

We conduct an explanatory study for the general viability of our method. We will compare results on the development and test set to verify whether the improvements are consistent. In particular, we carry out two experiments:

- Experiment 1 (on parallel data): Tests how eye-tracking data influences the performance when both gaze features and syntactic dependencies are extracted from the same data (in this case the Dundee treebank). The baseline is a model where no gaze features were used.
- Experiment 2 (on disjoint data): As previously said, we wish to test whether we can leverage existing gaze-annotated datasets to improve the performance in other non-gazed annotated dependency treebanks. Also, note that the Dundee treebank is relatively small (∼2k sentences) and results from the previous Experiment can be not as representative as those obtained in larger corpora. In this setup, we train models using gaze information from the Dundee treebank and dependency relations from PTB, evaluating on the latter.[5] The baseline is obtained by training a model only on the dependency relations retrieved from PTB.

Metrics We evaluate the parsers with Unlabeled and Labeled Attachment Score (UAS and LAS) excluding punctuation (following the standard methodology for experiments on the PTB).

3.1 Results

Table 1 shows the results for Experiment 1 (on the Dundee treebank, i.e. on parallel data), suggesting that the degree of informativeness of the gaze features that a parser can leverage differ among each other. In particular, we observe that the improvements across different models and the development and test sets are unstable. The evaluation on the dev set shows that gaze features from *early* and *context* group used as multiple auxiliary tasks (`early` and `context feats aux`) modestly improve the model in comparison with the baseline. With respect to the results on the test set, the most informative features are: `mean fix dur`,

[5] Note that the set of fine-tuned embeddings can be slightly different from that of Experiment 1, since words not occurring in Experiment 1 might be present in Experiment 2 due to the use of a different corpus.

	Gaze features	dev set		test set	
		UAS	LAS	UAS	LAS

Table 2: Results for dependency parsing evaluated on PTB treebank with gaze features as auxiliary task(s) learned from the disjoint dataset: Dundee treebank.

which improves the LAS by $+0.46$, and first fix dur by $+0.33$.

Table 2 shows the results for Experiment 2 (using Dundee gaze data and PTB dependencies). Under this setup, the gains decrease in comparison with the results on the parallel setup. This could be partially caused by not using parallel data. The improvements seem to be more consistent between the development and test sets. This could be related to the fact that we use a larger (more representative) treebank. When looking at the dev set scores, the most discriminative gaze feature is mean fix dur that increases LAS by $+0.17$ and first fix dur by $+0.14$. On the other hand, evaluation on the test set shows that the most informative gaze features are from the *context* group learned as multiple auxiliary tasks (context feats aux) and they improve the LAS score by $+0.18$, followed by fix prob and $w-1$ fix prob with $+0.13$, total fix dur with $+0.12$ and late feats aux with $+0.10$. Results from both datasets suggest that grouping gaze features and treating them as multiple auxiliary tasks can improve the model's learning.

Discussion The experiments show that our method can give moderate gains for dependency parsing when leveraging gaze information.[6] However, the experiments also show that there is room for improvement, especially coming from generalization capabilities across different treebanks. This also opens the question of whether a different architecture could better suit the purpose of leveraging the gaze information in a consistent way. In this context, a potential line of work could adapt human-attention approaches (Barrett et al., 2018) for structured prediction and word-level classification, although it would come at a cost of speed for parsing as sequence labeling (Strzyz et al., 2019b).

4 Conclusion

This paper has explored how to leverage human data with a competitive dependency parser during training. This contrasts with most of previous work on parsing and gaze annotations, which worked under the assumption that eye-tracking data would be available at inference time. We address this problem and propose a method of leveraging gaze features by using it as an auxiliary task both with and without parallel data. We obtain modest but positive improvements, which opens the question about how to increase the leverage of eye-tracking or other complementary data that is only available during training or comes from a different dataset.

Acknowledgements

This work has received funding from the European Research Council (ERC), under the European Union's Horizon 2020 research and innovation programme (FASTPARSE, grant agreement No 714150), from the ANSWER-ASAP project (TIN2017-85160-C2-1-R) from MINECO, and from Xunta de Galicia (ED431B 2017/01).

[6] Nevertheless, our approach can be employed also to leverage other types of data than eye measurements, i.e. NER or chunking data.

Abstract

Understanding text often requires identifying meaningful constituent spans such as noun phrases and verb phrases. In this work, we show that we can effectively recover these types of labels using the learned phrase vectors from deep inside-outside recursive autoencoders (DIORA). Specifically, we cluster span representations to induce span labels. Additionally, we improve the model's labeling accuracy by integrating latent code learning into the training procedure. We evaluate this approach empirically through unsupervised labeled constituency parsing. Our method outperforms ELMo and BERT on two versions of the Wall Street Journal (WSJ) dataset and is competitive to prior work that requires additional human annotations, improving over a previous state-of-the-art system that depends on ground-truth part-of-speech tags by 5 absolute F1 points (19% relative error reduction).

1 Introduction

The deep inside-outside recursive autoencoder (Drozdov et al., 2019, DIORA) is part of a recent trend in fully unsupervised neural constituency parsers (Shen et al., 2018; Williams et al., 2018a; Htut et al., 2018; Shen et al., 2019; Kim et al., 2019). However, these works and nearly all previous research (Klein and Manning, 2002; Seginer, 2007; Ponvert et al., 2011; Spitkovsky et al., 2013) have focused on *unlabeled* constituency parsing.

In this paper, we instead focus on *labeled* constituency parsing for English. The small number of previous works that exist in this area suffer from substantial weaknesses: 1) the models depend on ground-truth part-of-speech tags, which are not always available and known to boost constituency parsing scores (Kitaev and Klein, 2018), 2) none can simultaneously identify and label constituents (instead they typically depend on an external latent parser), and 3) they ignore sentences longer than ten tokens because previous latent parsers do not scale to longer sentences (Haghighi and Klein, 2006; Borensztajn and Zuidema, 2007; Reichart and Rappoport, 2008).

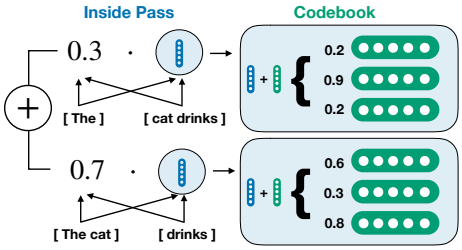

Figure 1: The left half of this figure depicts the inside-pass of the DIORA model as described in (Drozdov et al., 2019). We are interested in clustering the learned vectors $a(i, j)$ such that each span may be mapped to a phrase type. To enhance this clustering based approach, we augment the DIORA architecture with latent codes, shown in the right half of the figure.

Unlike previous work, we achieve strong results in unlabeled constituency parsing using a single model for both bracketing and labeling. Our approach relies on clustering span representations, which are fixed-length continuous vectors learned end-to-end using DIORA and do not require external resources such as part-of-speech tags. Furthermore, we enhance the DIORA architecture with latent codes: the model learns a distribution over these codes that loosely aligns with the ground-truth assignment of phrase types and, more importantly, improves the quality of the clusters.

Our code-enhanced DIORA architecture outperforms DIORA and achieves a new state of the art of 76.7 F1 on WSJ-10 when labeling a gold bracketing (19% relative error reduction over the previous best model, Haghighi and Klein 2006, which unlike our approach uses gold part-of-speech tags). Furthermore, we show DIORA is competitive when a ground truth bracketing is not provided, and instead must be induced. On

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1507–1512, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the full WSJ test set, DIORA outperforms two strong baselines, ELMo (Peters et al., 2018a) and BERT (Devlin et al., 2019). We analyze the clustered constituents and observe they are separated syntactically (i.e. past tense vs. present participle verbs) and semantically (i.e. time-related phrases vs. references to people).

2 DIORA: Deep Inside-Outside Recursive Autoencoders

DIORA is a recursive autoencoder that learns to reconstruct an input sentence. A fundamental step in the reconstruction is to build a chart using the inside-outside algorithm (Baker, 1979), which represents a soft weighting over all possible binary trees of the input sentence. For all the model details, we refer the reader to Drozdov et al. (2019). For this work, it is key to understand two capabilities that DIORA provides: each span in a sentence is represented as a vector and DIORA induces a maximally likely binary tree for the sentence.

We can directly label the constituents of a sentence by clustering the learned span vectors from DIORA and assigning a label to each cluster. DIORA's autoencoder objective incentivizes the model to learn representations that compress the sentence well in order to reconstruct the input leading to the discovery of syntactic structure.

To encourage phrase representations to be easily clusterable into a small set of phrase types, we add an additional component to DIORA that forces phrase vectors to be representable by a small number of latent codes. Recent models have integrated ideas from vector quantization into variational autoencoders (Kingma and Welling, 2013) and key-value memory layers (Lample and Conneau, 2019), forcing the model to compress inputs into a single discrete latent embedding (van den Oord et al., 2017; Kaiser et al., 2018). Given a trained model, one could then assign labels to each of the latent variables and use this to label inputs directly.

We instead use a less restrictive modeling approach by assigning each input to a soft weighting over the K latent embeddings. This is similar to the soft EM training used by Roy et al. (2018) and can be thought of analogously to fuzzy/soft K-means clustering (Dunn, 1974; Bezdek, 1981) rather than hard K-means clustering.

Implementation and training details for our model are described in Appendix A.1.

2.1 DIORA with Codebook

DIORA is constrained to binary trees and its composition is represented as:

$$a(i,j) = \text{Compose}(\bar{a}(i), \bar{a}(j)), \quad (1)$$

where i and j are neighboring spans, $\bar{a}$ is summary vector for all possible parses over a span, and Compose is a function such as tree-LSTM or multi-layer perceptron.

To add the latent codebook into the model, we modify Eq. 1 to combine each constituent vector with a weighted summation over latent codes:

$$f_{cb}(x) = C^T \sigma(CWx),$$

where C is a codebook in $\mathbb{R}^{N \times M}$, x is a constituent vector in $\mathbb{R}^M$, and W is a bi-linear matrix used to compute the affinity between the constituent vector and the latent codes. One way to think of this equation is that each code (row in C) is a centroid, and the vector of affinity scores, $\sigma(CWx)$,[1] is a soft assignment of the constituent vector over the latent codes. The modified DIORA equation when incorporating the codebook is:

$$a'(i,j) = a(i,j) + f_{cb}(a(i,j)) \quad (2)$$

This codebook-enhanced architecture is visually depicted in Fig. 1. We use 70 codes when training this model (representing the 25 phrase types, 45 part-of-speech types, and ignoring the ROOT label), although we explore different configurations in §4.4.

3 Unsupervised Labeled Parsing

We perform unsupervised labeled constituency parsing with a multi-step approach.

Tree assignment. Assign a tree to each input sentence where the leaves of the tree are the words in the sentence. The tree is not labeled. This may be derived from the ground truth parse or induced using DIORA. When induced, we extract a binary tree by running the CKY algorithm[2] over DIORA's learned compatibility scores.

[1] More details about the equation $C^\top \sigma(CWx)$ are discussed in Appendix A.3. It's worth noting that σ can be an arbitrary function, in this work we use the identity function.

[2] The CKY algorithm is an efficient dynamic programming approach for recognizing constituency trees using exact inference (Kasami, 1966; Younger, 1967; Rush et al., 2010).

– WSJ (Test) –	Gold		Induced	
Model	**F1**$_\mu$	**F1**$_{max}$	**F1**$_\mu$	**F1**$_{max}$
Upper Bound	76.3	76.3	59.7	59.7
Majority (NP)	30.6	30.6	24.5	24.5
ELMo	58.5	59.4	43.5	48.2

– WSJ-10 –	Gold		Induced	
Model	**F1**$_\mu$	**F1**$_{max}$	**F1**$_\mu$	**F1**$_{max}$
Upper Bound	86.0	86.0	64.6	64.6
Majority (NP)	32.0	32.0	25.2	25.2
ELMo	67.8	68.9	50.1	53.0
ELMo$_{CI}$	65.9	67.3	46.0	47.6
BERT	54.6	57.8	44.5	45.2
DIORA	72.7 $\pm$1.5	76.2	55.2 $\pm$0.7	56.3
DIORA$_{CB}$	73.2 $\pm$1.7	75.7	54.5 $\pm$1.2	56.6
DIORA$^*_{CB}$	**74.9** $\pm$1.1	**76.7**	53.9 $\pm$0.8	55.1
PCFG†	-	51.6	-	35.3
BMM†	-	(76.8)	-	59.5
Proto†	-	71.1	-	65.2

Table 2: WSJ-10 unsupervised labeled constituency parsing with punctuation removed. † indicates that the model relies on gold part-of-speech tags, and results in parentheses are related but not comparable to others in the table. Proto (Haghighi and Klein, 2006) uses additional hand written rules. BMM (*Gold*) (Borensztajn and Zuidema, 2007) is evaluated using more than K clusters (where K is the size of the tag set) by mapping ground truth labels to induced labels, therefore it is not strictly comparable to the other results. Neither BMM (Reichart and Rappoport, 2008) nor Proto are effective at inducing unlabeled structured, so depend on external latent parsers for the *Induced* evaluation, either CCM (Klein and Manning, 2002) or CCL (Seginer, 2007). ELMo and BERT do not induce structure whatsoever and depend on DIORA for the *Induced* evaluation. ELMo$_{CI}$ uses only the context-insensitive character embeddings produced by ELMo.

Vector assignment. Assign the corresponding span vector to each constituent in these trees over the entire dataset. For DIORA without the codebook, this will be the concatenation of inside and outside vector. When using the codebook, this will be one of two options: the same as for DIORA, except using the output of Eq. 2, or it will be the soft score assignment of the codebook $\sigma(CWx)$. The first option is referred to as DIORA$_{CB}$ and the soft score assignment as DIORA$^*_{CB}$.

Cluster and label assignment. Cluster the collection of constituent vectors using K centroids learned with K-means. Finally, we use the ground truth phrase labels to assign each cluster to a phrase type — each constituent is mapped to the most common label within its cluster. We set K equal to the number of distinct phrase types in order to match previous work.

4 Experiments and Results

4.1 DIORA

We compare multiple configurations of DIORA. The first is the original model DIORA using the concatenation of the inside and outside vectors to represent a phrase. We also look at the codebook-enhanced architecture DIORA$_{CB}$, and when clustering the codebook scores we refer to the model as DIORA$^*_{CB}$.

4.2 Baselines

While ELMo (Peters et al., 2018a) and BERT (Devlin et al., 2019) do not produce phrase vectors or induce recognizable constituency parse structure,[3] we show that they can still be used for unsupervised labeled parsing. When a reference parse is provided, it is only necessary to derive ad-hoc phrase vectors using the contextualized token vectors from these models. Peters et al. (2018b) describe an effective way to do so for ELMo, which involves concatenating the token vectors at the beginning and end of the phrase.[4] For BERT, it is critical to look at all layers as lower layers tend to be more syntactic in nature (Tenney et al., 2019). For both models, we report the max F1 and mean F1, and for the *Induced* evaluation we use the parses extracted from DIORA.

4.3 WSJ

Unsupervised constituency parsing has often been evaluated on different splits of the WSJ. For *labeled* constituency parsing, models that produce

[3] BERT does not strictly output word-level vectors. Rather, the output are subword vectors which we aggregate with mean-pooling to achieve a word-level representation.

[4] We tried many combinations (4 variants for ELMo and nearly 200 for BERT). They are described in Appendix A.2.

binary trees as output have a performance ceiling on this n-ary data — unary-chains limit recall[5] and more-than-binary nodes limit precision.

In some cases, an unlabeled tree structure over a sentence can be readily accessed. The algorithm described in §3 is robust to this case — simply replace the first step with the ground truth parse. We evaluate our model using the ground truth parse (Gold) and when inducing a parse (Induced). These results, comparison to baseline methods, and an upper-bound on binary tree performance are shown in Tables 1 and 2.

The Upper Bound in the *Induced* column of these tables represents a perfect labeling of the most accurate induced binary tree from DIORA, and the Majority (NP) row is the same tree labeled with the most common tag.

4.4 Model Ablations

As an alternative to clustering the constituent vectors with K-means, one can treat the codebook affinity scores, $\sigma(C^\top Wx)$, as a soft assignment over the clusters represented by each code. To examine this alternative, we replace K-means in the algorithm from §3 with the $\arg\max$ over the affinity scores. A model trained with 25 codes[6] achieves greater than 60% recall at labeling the ground truth trees for WSJ-10, indicating the codes represent some syntactic patterns although not as effectively as when using K-means.

Given these results, we are curious to see how model performance changes as the number of codes varies. We train codebook DIORA with $\{25, 70, 100, 200, 300, 400\}$ codes and evaluate each configuration using the procedure from §3 on the WSJ validation set. We compare the performance to non-codebook DIORA trained with $\{2, 3, 4, 5\}$ layers.[7] Results are shown in Fig. 2.

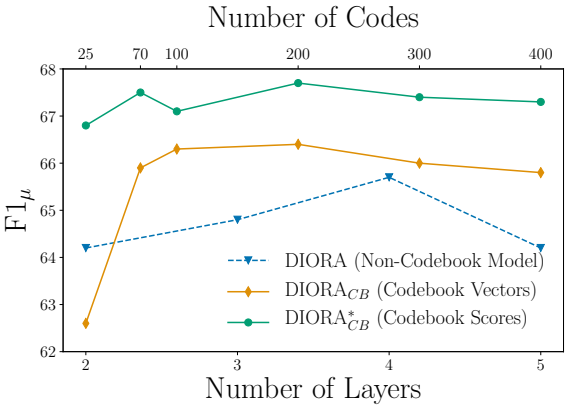

Figure 2: WSJ validation set results for different DIORA variants. The non-codebook DIORA sees improved performance as layers are added, but its average F1 never exceeds that of the codebook-enhanced architecture. Both clustering of codebook cells $a'(i, j)$ and codebook scores $\sigma(CWx)$ see performance improvements then diminishing returns as the number of codes increases. The dashed line uses the bottom x-axis and the solid lines use the top x-axis.

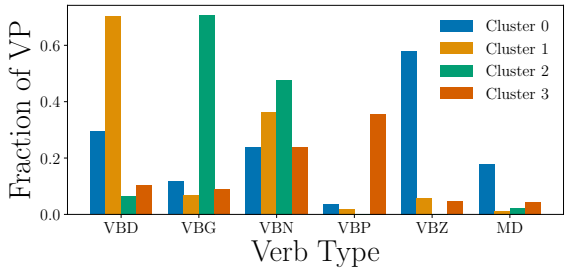

Figure 3: $DIORA_{CB}$ cluster assignment analyzed on WSJ-10 using part-of-speech tags. The four clusters shown were all assigned the VP label, yet seem to have finer-grained properties related to verb tense.

5 Qualitative Analysis of Clusters

We investigate phrase clusters from a single experiment ($DIORA_{CB}$ on WSJ-10), which are assigned to 9 NP, 5 VP, 5 S, 4 PP, 1 ADJP and 1 QP, according to the majority gold labels in that cluster. These 6 assigned phrase types correspond with the 6 most frequent labels.

We find some semantic properties are evident in the clusters. For example, a 100% correct NP cluster (all phrases in this cluster have gold label NP) are all *possessive NPs*. One of the NP clusters consists of NPs that are mostly related to *time* (15 minutes, last year, this fall), even the incorrectly labeled phrases are time-related such as the ADVP 'no longer' and 'so far'. Another NP cluster identifies *people*, which includes "ms. parks 's mother" but excludes "mr. noriega 's proposal" even though both phrases have the same part-of-speech tag sequence [NNP NNP POS NN].

One of the five VP clusters completely takes the form *to + verb* — 7 out of 11 mislabeled cases contain "to" in the phrase, for example, "not

[5] Labeled parsing is usually evaluated on whether a span has the correct label. An NP prediction for a span would be correct if there is an NP-QP or QP-NP unary-chain over this span. A binary tree could only ever get one of QP or NP correct in this case, hence limiting recall.

[6] We use 25 codes here instead of 70 so that the model may be fairly compared with previous systems.

[7] Elsewhere in this paper, DIORA uses two layers.

to mention" (CONJP). The four other VP clusters present some degree of tense and singular/plural properties. A bar-chart showing the finer-grained properties of the VP clusters is shown in Fig. 3. Cluster 0 includes the majority of VBZ and MD (will, won't, can, could), Cluster 1 is mainly composed of past tense VPs (VBD), Cluster 2 has many VBG, and Cluster 3 consists of 86% VBP.

One of the S clusters captures instances of S that do not cover the whole sentence. Another starts with coordinating conjunctions such as "and" or "but", yet another captures phrases beginning with personal pronouns or determiners.

6 Conclusions

In this paper, we show that DIORA can be used for unsupervised *labeled* constituency parsing. We also introduce a new codebook-enhanced variant of DIORA that improves labeling performance. Our model outperforms the previous state of the art in unsupervised labeled constituency parsing for the WSJ-10 dataset, even though the previous best uses ground truth part-of-speech tags and ours does not, and introduces the first results on the full WSJ test set. The results indicate that grammar induction with types is viable using recent neural-network-based models, and our analysis warrants further exploration in this area.

Abstract

Dependency parsing of conversational input can play an important role in language understanding for dialog systems by identifying the relationships between entities extracted from user utterances. Additionally, effective dependency parsing can elucidate differences in language structure and usage for discourse analysis of human-human versus human-machine dialogs. However, models trained on datasets based on news articles and web data do not perform well on spoken human-machine dialog, and currently available annotation schemes do not adapt well to dialog data. Therefore, we propose the Spoken Conversation Universal Dependencies (SCUD) annotation scheme that extends the Universal Dependencies (UD) (Nivre et al., 2016) guidelines to spoken human-machine dialogs. We also provide ConvBank, a conversation dataset between humans and an open-domain conversational dialog system with SCUD annotation. Finally, to demonstrate the utility of the dataset, we train a dependency parser on the ConvBank dataset. We demonstrate that by pre-training a dependency parser on a set of larger public datasets and fine-tuning on ConvBank data, we achieved the best result, 85.05% unlabeled and 77.82% labeled attachment accuracy.

1 Introduction

Syntactic parsing (Chen et al., 2018) and semantic parsing (Kollar et al., 2018; Gupta et al., 2018) have been used in dialog systems to disambiguate the relationships between noun phrases in understanding tasks. Compared to constituency parsing and semantic role labeling, dependency parsing provides more clear relationships between predicates and arguments (Johansson and Nugues, 2008). Constituency parsers provide information about noun phrases in a sentence, but provide only limited information about relationships within a noun phrase. For example, in the sentence "What do you think about Google's privacy policy being reviewed by journalists from CNN?," a constituency parser would place "Google's privacy policy being reviewed by journalists from CNN" under a single phrasal node. Similarly, a semantic role labeling system would tend to label the same phrase as an argument of the verb, but it would not disambiguate the relationships within the phrase. Finally, NER only provides information about named entities which may or may not be the key semantic content of the sentence. Dependency parsers, by contrast, can provide information about relationships when a sentence contains multiple entities, even when those entities are within the same phrase.

Identifying relationships between entities in a user utterance can help a dialog system formulate a more appropriate response. For instance, in the sentence about "Google's privacy policy" mentioned above, there are multiple entities for the system to consider. The system must determine the most important entity in the utterance in order to model the topic and generate an appropriate response. A dependency graph facilitates this process by providing information about the syntactic relationships between entities.

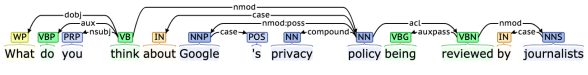

Figure 1: Example dependency-parsed sentence. Stanford CoreNLP visualizer (Manning et al., 2014).

A dependency parse of the sentence, shown in Figure 1, demonstrates that the key element of the sentence, "policy", is directly linked to the root "think" as a *nmod*. The other entities in the sentence are modifiers of the central element, and are clearly labeled as such. These structures make it

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1513–1519,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

easier for a dialog system to identify core semantic content and formulate an appropriate response.

Dependency parsing is a well studied (Dozat and Manning, 2016; Clark et al., 2018) task. However, most dependency parsers are trained on well-written text datasets, such as news articles and web-scrape data. In a conversational setting, dialog systems deal with transcripts that are produced by automated speech recognition (ASR) systems. ASR systems are prone to produce errors, such as dropped and mis-transcribed words, and prematurely terminated utterances. Such errors, in our experience, make building an automated dependency parser harder.

Additional data is needed to train parsers for the dialog system domain. Due to limitations in the UD scheme for parsing speech data, we propose an extension of the UD standard, SCUD, designed specifically for dialog systems. SCUD considers unique issues in automated speech transcription and what is useful for dialog systems to generate appropriate responses. We then use SCUD to annotate a corpus of open-domain human-system conversations with automated speech transcripts. We finally leverage this data, along with previously annotated UD datasets, to build a dependency parser. Since the training data used is collected with an open-domain dialog system, the trained dependency parser can be applied to dialog systems with any task.

In addition to its use in dialog systems, dependency parsed dialog data could be used in discourse analysis to assist in understanding the syntactic patterns people use when interacting with a computer. While researchers have investigated such differences in task-oriented dialog systems (Doran et al., 2003), we believe that ConvBank and SCUD present an opportunity for expanded discourse analysis of open-domain dialog systems.

2 Related Work

Dependency parsing on text such as the Universal Dependencies English Web Treebank (UD-EWT) (Silveira et al., 2014), is a well-developed field in NLP; however, the parsing of automated speech transcripts remains an open problem (Bechet et al., 2014). As has been well-documented, speech, and the resulting ASR transcipts, is a very different domain from written text (Biber and Conrad, 1999; Leech, 2000; Carter and McCarthy, 2017). Adams (2017) focuses on adapting a parser trained on UD-EWT to the speech domain without annotating new training data. For example, she attempts to create additional speech domain training data by parsing raw speech transcripts with Google's SyntaxNet. She then uses the resulting parsed output as training data for MaltParser (Nivre et al., 2006). However, the resulting models do not show consistent improvement over a baseline parser. Based on these results, and the apparent need for new training data for the speech domain, we chose to annotate a new human-system dialogs dataset to facilitate building dependency parsers for automated speech transcription and dialog systems.

Previous work has demonstrated that expanding the UD annotation scheme can result in successful parsers for other domains. For example, Liu et al. (2018) expand the UD scheme to train a parser for Twitter data. Thus we take a similar approach in expanding the UD scheme to encompass issues common to automated speech transcription.

Unlike written discourse, speech is full of disfluencies which make discovering the underlying syntactic structure challenging, as such disfluencies interrupt the syntactic structure of the utterance (Nasr et al., 2014; Caines et al., 2017). For example, according to Meteer and Taylor (1995), 17% of tokens in the Switchboard telephone conversations are various disfluencies. Frequent types of disfluencies include hesitations and false starts. When dealing with ASR-based systems, one must also contend with ASR errors. According to Nasr et al. (2014), such disfluencies must either be integrated into the syntactic parse of the utterance or removed prior to parsing. We choose to take the former approach, integrating speech disfluencies and speech transcription errors into the dependency graph produced by our annotation scheme and the resultant parser.

3 Annotation Scheme

When we initially began to annotate speech transcript data using the UD 2.0 (Nivre et al., 2017) scheme, our annotators repeatedly complained of constructions which they were unable to annotate given the limitations of UD 2.0. We developed SCUD in response to these issues. SCUD closely follows UD 2.0 so that we may leverage larger UD-compliant datasets of text data, such as UD-EWT. We extend the UD annotation scheme to encompass specific features peculiar to the speech domain, namely the use of non-syntactic discourse

markers, speech disfluencies, and ASR errors.

One major difference between speech and text is the fact that speech contains a fairly large number of discourse markers which do not serve a syntactic role in the utterance. This is similar to the difference between text and tweets pointed out by Liu et al. (2018). We make use of the UD relation *discourse* to indicate discourse markers which are not part of the syntactic structure of an utterance; for example, the word "like" in "I have like three dogs", where "like" plays a pragmatic, rather than a syntactic, role.

Another goal of our annotation scheme is to handle disfluencies common to both human and ASR-generated speech transcripts. We expand the scope of extant UD relation tags to tag common speech disfluencies. For example, the UD tag *reparandum* is applicable to situations in which a user self-corrects his or her speech. We use the UD tag *flat* to link repeated words and stutters to indicate that these headless multi-word expressions are a single syntactic unit. Handling non-syntactic tokens is particularly important because, while ASR may improve, the way people speak is less likely to change.

We are also able to expand the existing UD annotation scheme to handle some common errors in ASR output. In cases where an ASR system incorrectly splits words, we utilize the UD relation *goeswith* to link the two words in a dependency graph. We also provide a means to insert nodes at locations where an ASR system has dropped words necessary for formation of a grammatical structure. We do this by expanding the enhanced UD 2.0 standard, which provides a method to insert nodes in graphs as place-holders for words omitted through ellipsis. An example of using such a place-holder node is shown in Table 1, where the subject of the sentence in question has been omitted due to an ASR error. We also create one new relation tag to deal with a common error in ASR system output: prematurely terminated user utterances. Many conversational agents are turn-based (Kepuska and Bohouta, 2018) , and depend on pauses in user speech to detect the end of the user's dialog turn. As a result, hesitations by the user can result in the system prematurely terminating the user's turn. In reviewing our dialog system output data, we found that the ASR system prematurely terminates as many as 5% of user turns. We created the dependency label *preterm* to annotate such occurrences in our dataset.

2	got	VERB	0	root
3	two	NUM	4	nummod
4	dogs	NOUN	2	obj

Table 1: Example of omitted word node insertion

We must also consider the issue of incorrectly transcribed words. ASR systems are prone to mistranscribing words in the input signal; such errors can significantly change the meaning of the underlying utterance or result in a transcription which is ungrammatical or semantically nonsensical (Errattahi et al., 2018). While error correction methods for dialog systems have been developed (Choi et al., 2016), preprocessing our data with such a system is beyond the scope of this study. We instructed annotators to annotate all words as they were transcribed by the system. The alternative would involve annotators trying to infer user intent from context, which makes predictable annotation far less likely.

In total, SCUD has 37 primary relation tags. The relation tagset closely follows the UD 2.0 annotation standards with the exception of domain-specific extensions as noted above.

4 Dataset and Annotation Process

We collected a corpus of humans conversing with an open-domain dialog chatbot based on the Alexa platform (Chen et al., 2018). Users were asked to come into a lab and have an undirected conversation with our system. The automated speech transcripts of the users' utterances were collected and selected at random for inclusion in this corpus. We recruited two annotators who are experienced with dependency grammars and annotation projects to annotate 1,500 sentences. As is common with other UD annotation projects, we asked each annotator to correct the work of the other. Once this round of corrections was complete, we measured agreement as the percentage of tokens which remained unchanged between the original annotations and the corrected version. The two annotators agreed on 86.4% of unlabeled dependencies and 80.5% of labeled dependencies. These numbers are comparable to those reported on Tweebank (Liu et al., 2018), another challeng-

ing annotation problem. Once annotator agreement was assessed, a third annotator reviewed the annotations to improve compliance with the annotation scheme. We found that ASR errors, such as ungrammatical sentences resulting from mistranscription and word omission are a major contributing factor to annotator disagreement in our dataset.

The result of our annotation project is ConvBank, a corpus of 1,500 ASR-generated text utterances from a human-machine spoken dialog system with SCUD annotation. The corpus is compliant with UD 2.0 standards with the exception of extensions made to the UD standard as noted above. All data, code, and pre-trained models related to this project are publicly available via the project webpage[1].

ConvBank uses 32 of the 37 possible primary relations in SCUD, described above. A comparison of the ten most common tags in ConvBank and UD-EWT is presented in Table 2. *punct* is the most common relation in UD-EWT but is absent from ConvBank; this is because our automated speech transcripts do not contain punctuation. Other differences in relation distribution, such as the higher relative frequencies of *root* and *nsubj* can be explained by the shorter sentences in ConvBank compared to UD-EWT. Since each sentence must have a root, and most have a subject, the fewer other words in each sentence, the higher the frequencies of these two tags will tend to be.

5 Parsing Experiments

To demonstrate the utility of the ConvBank dataset, we use the data to train a dependency parser for ASR-based spoken dialog systems.

5.1 Training Data

We use three datasets in training our dependency parser. We use the publicly available UD-EWT (Silveira et al., 2014) and Tweebank v.2 (Liu et al., 2018) to train baseline models. We also combine UD-EWT and Tweebank to create a larger UD dataset for pre-training. Finally, we use our own ConvBank dataset to fine-tune our best-performing baseline model. We hold out 500 annotated ConvBank sentences for testing.

We considered using the constituency parsed Switchboard corpus (Godfrey et al., 1992), which is a human-human telephone corpus, due to its similarity to our domain. However, no fully UD-compliant version of the dependency parsed corpus is publicly available. Although conversion from constituency to dependency graphs is possible, we found the resulting dependency graphs unusable due to the error-prone conversion process. Peng and Zeldes (2018) point out that conversion systems particularly struggle with attaching nominal modifiers and oblique arguments.

5.2 Methods

We build all models using the biaffine parser as described in Dozat and Manning (2016) and Qi et al. (2019). We use the open-source implementations of Dozat's biaffine parser code[2] for training our models. We use Glove (Pennington et al., 2014) for pre-trained word embeddings. We train three baseline models to compare how models trained on text data compare with our model, which leverages both annotated text and automated speech transcripts. First, we train a parsing model on UD-EWT (Silveira et al., 2014) alone. We also train a separate model on Tweebank v.2 (Liu et al., 2018) alone to determine how a parser trained on tweets, which are arguably more similar to conversational speech, will perform. We also train a model on combined UD-EWT and Tweebank data. Our final baseline is a model trained on a 1,000 utterance subset of ConvBank. This model is used to determine how a parser trained on our data performs without pre-training on a larger text dataset.

Our fine-tuning approach is based on the idea that, by providing the system with additional domain-specific examples from ConvBank, we are able to build upon the system's baseline knowl-

[1] https://gitlab.com/ucdavisnlp/dialog-parsing

[2] https://github.com/tdozat/Parser-v3

edge to create a final system which performs substantially better than baseline. Stymne et al. (2018) demonstrate that this type of fine-tuning is an effective way to leverage multiple treebanks to train a single dependency parser. Our fine-tuning process consists of initializing our network weights using the weights from our baseline model trained on the UD English Web Treebank. As demonstrated by our results, the baseline model trained on UD-EWT alone performs reasonably well in assigning many UD labels and dependencies; however the system does not handle well issues specific to the dialog domain. To improve performance on the dialog domain, we resume training the pre-trained model with our annotated ConvBank data, using identical training parameters, until perplexity stabilizes.

5.3 Results and Discussion

We present the parsing accuracy on the ConvBank test set in Table 3. Training only using 1,000 annotated in-domain ConvBank data reaches 75.65% and 58.29% accuracy on unlabeled and labeled edges respectively. This suggests that 1,000 utterances are not enough to achieve optimal results. However, human annotations are expensive to obtain, limiting the size of our dataset. The model trained on EWT or Tweebank or EWT and Tweebank combined achieved similar results that are better than the model trained on ConvBank alone. As these three models had similar results, we fine-tune on the slightly better-performing EWT model. Fine-tune achieves the best best result on both unlabeled and labeled edges (85.05% and 77.82% respectively). Fine-tuning on EWT with ConvBank data improves parsing accuracy on the test data by over 7 points on unlabeled dependency edges and by nearly 12 points on labeled edges. These results suggest leveraging both a large set of out-of-domain data and in-domain data achieves the best performance.

There are some clear differences between our fine-tuned model and the baseline model trained on text data. In speech, discourse markers such as "but", "so", and "and" frequently begin utterances. These items can be difficult to parse correctly, as they more frequently serve grammatical functions. Our baseline model generally tags such items as coordinating conjunctions or adverbs, while in the fine-tuned model such items are more often appropriately tagged as discourse markers. Another clear example is the correct use of the *reparandum* tag. For example in the utterance "you know you my name", the baseline model tags the second "you" as an indirect object, while the fine-tuned model correctly tags the item as *reparandum*. The baseline model tags only three items in our test data as *reparandum*, while the fine-tuned model identifies thirty-one such instances. These results indicate that our fine-tuned model is more closely aligned to the speech domain than our baseline model. However, our best model still struggles when faced with fixed expressions common in conversational speech, such as "Top Gun" and "Kitchen Table Wisdom". The model also performs poorly on ungrammatical utterances, as expected.

Fine-tune	85.05	77.82

Table 3: Parsing Accuracy Results

6 Conclusion

Dependency parsing can effectively identify the relationships between entities in a user utterance to improve speech language understanding. However, dependency parsing for speech data does not perform well when trained on out-of-domain text data. To solve this problem, we present ConvBank, a new dataset of annotated automated speech transcripts, annotated with the Spoken Conversation Universal Dependencies (SCUD) annotation scheme to build UD-compatible parses. We demonstrate the utility of ConvBank by fine-tuning a dependency parser with a large dataset, reaching 85.05% on labeled dependency edges and 77.82% on unlabeled dependencies.

In future work, we hope to expand the size of ConvBank to improve its utility to researchers in training parsing models and studying conversational systems. We also hope to improve the performance of our parsing system by jointly training dependency parsing with semantic role labeling.

Abstract

We propose a semantic parser for parsing compositional utterances into Task Oriented Parse (TOP), a tree representation that has intents and slots as labels of nesting tree nodes. Our parser is span-based: it scores labels of the tree nodes covering each token span independently, but then decodes a valid tree globally. In contrast to previous sequence decoding approaches and other span-based parsers, we (1) improve the training speed by removing the need to run the decoder at training time; and (2) introduce edge scores, which model relations between parent and child labels, to mitigate the independence assumption between node labels and improve accuracy. Our best parser outperforms previous methods on the TOP dataset of mixed-domain task-oriented utterances in both accuracy and training speed.

1 Introduction

Most commercial conversational AI systems parse task-oriented utterances using intent classification and slot-filling models (He and Young, 2003; Raymond and Riccardi, 2007; Mesnil et al., 2015), where the intent is the task of the utterance (e.g., `IN:GET_DIRECTION`) and the slots are the parameters needed to complete the task (e.g., `SL:DESTINATION`). This limited representation typically allows only a single intent per utterance and at most one slot label per token. Dialog systems using such a flat representation would struggle to handle compositional tasks that involve invoking multiple backend services (e.g., "direction to John's party": find John's address, and then find the direction to that address).

To support compositional utterances, the hierarchical Task Oriented Parsing (TOP) representation has recently been introduced (Gupta et al., 2018). As illustrated in Figure 1, the TOP representation

$$T = \{(0,5) : (\texttt{IN:GET_DIRECTION}),$$
$$(2,5) : (\texttt{SL:DESTINATION}, \texttt{IN:FIND_EVENT}),$$
$$(2,3) : (\texttt{SL:ORGANIZER}),$$
$$(4,5) : (\texttt{SL:CATEGORY}),$$
$$(0,1) : \varnothing, \quad (0,2) : \varnothing, \quad (0,3) : \varnothing, \quad \dots\}$$

Figure 1: An example TOP tree and its mapping representation T. (`IN:` = intent; `SL:` = slot)

is a tree where intents and slots are nested alternatively to model composition. The values inside intent and slot subtrees can then be used by downstream dialog modules to invoke appropriate services in a hierarchical fashion.

We propose a span-based semantic parser for parsing utterances into the TOP representation. In its most basic form, the parser embeds each token span (e.g., $x_{2:5}$ = *"John 's party"* in Figure 1) as a vector, and then uses it to predict the labels of the tree nodes covering the span (e.g., `SL:DESTINATION` and `IN:FIND_EVENT`). While the label prediction is done independently for each span, a CKY decoding algorithm is used to decode a valid tree with the maximum tree score.

Our main contributions are twofold. First, we reinterpret the ad-hoc tree score in previous span-based parsing work (Stern et al., 2017; Gaddy et al., 2018; Kitaev and Klein, 2018) as a joint distribution over the labels. Under this new framework, the loss function factors nicely, which allows us to train the model in a highly parallelized fashion instead of having to run the computation-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1520–1526, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ally expensive decoder during training. Second, we introduce *edge scores* to model the relationship between parent and child nodes in the tree. This mitigates the independence assumption and allows the decisions at child nodes to influence the parent node.

We evaluate our models on the TOP dataset (Gupta et al., 2018) of compositional utterances on events and navigation domains. Most utterances have nested intents, with some utterances containing intents from different domains. We demonstrate that our model is fast to train and outperforms previous models on the dataset.[1]

2 Related work

Neural tree generation. Previous work on syntactic and semantic parsing employs different strategies for generating trees. Approaches such as transition-based parsers (Dyer et al., 2016; Liu and Zhang, 2017) and top-down tree generation (Vinyals et al., 2015; Choe and Charniak, 2016; Dong and Lapata, 2016; Krishnamurthy et al., 2017; Yin and Neubig, 2018) frame tree generation as predicting a sequence of actions for generating the tree. The decoding processing generally consists of local decisions, and beam search is used to retain uncertainty. In contrast, global decoding methods (Durrett and Klein, 2015; Lee et al., 2016) can incorporate non-local features and decode a tree with the maximum global score.

Span-based models. Span-based models use the embeddings of token spans to perform prediction. By capturing the properties of the whole phrase instead of individual words, span embeddings can be suitable for tasks where phrases are the basic unit. Indeed, span-based models have recently shown great promise by achieving state-of-the-art results for segmentation and tagging (Kong et al., 2016), coreference resolution (Lee et al., 2017) and semantic role labeling (He et al., 2018).

For syntactic parsing, span embeddings have been used to score actions in shift-reduce parsing (Cross and Huang, 2016), or to score the existence and labels of tree nodes in bottom-up and top-down parsing (Stern et al., 2017; Kitaev and Klein, 2018). The analysis by Gaddy et al. (2018) shows that the span embeddings can learn to capture various information, such as label correlation and structural agreement, which was traditionally modeled by grammars or lexical features.

[1] The code is available at `https://github.com/ppasupat/factored-span-parsing`.

3 Setup

Given an utterance $x = (x_0, \ldots, x_{n-1})$ with n tokens, the task is to predict a TOP parse tree, as illustrated in Figure 1. Each leaf node corresponds to a token x_i, while each non-terminal node covers some *span* (i, j) with tokens $x_{i:j} = (x_i, x_{i+1}, \ldots, x_{j-1})$. The label l of each non-terminal node is either an intent (prefixed with `IN:`) or a slot (prefixed with `SL:`). Two type constraints for TOP trees include: (1) intents can only have slots as children and vice versa, and (2) the tree root covering span $(0, n)$ must be an intent.

For our span-based parser, it is helpful to view the tree as a *mapping* T from each span (i, j) to a *chain* $c = (l_1, \ldots, l_k)$ which lists the $k \geq 0$ labels in the unary chain covering the span (i, j). For instance, the span $(2, 5)$ in Figure 1 has $T[2, 5] =$ (`SL:DESTINATION`, `IN:FIND_EVENT`). If no non-terminal node covers the span, we denote the empty chain as $c = \varnothing$.

Following previous span-based parser work (Cross and Huang, 2016; Stern et al., 2017), we only consider unary chains that appear in the training data to be valid chains. (In our experiments, the training data has 57 distinct labels and 135 distinct chains. Only a single chain in the test data is not covered in training data.)

4 Model

Our parser is based on a joint distribution over the chain at each span. Let the probability of span (i, j) having chain c be a softmax over the possible chains:

$$p(T[i, j] = c) = \frac{\exp\left[f_{\mathrm{n}}(x_{i:j}, c)\right]}{\sum_{c'} \exp\left[f_{\mathrm{n}}(x_{i:j}, c')\right]}. \quad (1)$$

(The conditioning on x is omitted.) Here, the *node score* $f_{\mathrm{n}}(x_{i:j}, c)$ is a real-valued function with $f_{\mathrm{n}}(x_{i:j}, \varnothing)$ fixed as 0. To compute the node scores for a span $x_{i:j}$, we embed the span using an LSTM-based span embedder[2] from Lee et al. (2017), and then apply a feedforward network to produce a real-valued score for each chain $c \neq \varnothing$.

We now make a simplifying assumption that the values of $T[i, j]$ are independent. The log-

[2] Refer to Appendix A for modeling details.

likelihood of the entire mapping T becomes

$$\begin{aligned}\log p(T) &= \sum_{i<j} \log p(T[i,j]) \\ &= \sum_{i<j} \begin{bmatrix} f_{\mathrm{n}}(x_{i:j}, T[i,j]) \\ -\log \sum_{c'} \exp\left[f_{\mathrm{n}}(x_{i:j}, c')\right] \end{bmatrix}.\end{aligned} \tag{2}$$

The log-sum-exp term $\log \sum_{c'} \exp f_{\mathrm{n}}(x_{i:j}, c')$ does not depend on T. During inference, maximizing the log-likelihood $\log p(T)$ is thus equivalent to maximizing the *tree score*:

$$s(T) := \sum_{i<j} f_{\mathrm{n}}(x_{i:j}, T[i,j]). \tag{3}$$

At test time, we use CKY chart parsing to decode a valid TOP tree T with the maximum score $s(T)$.

Training. The tree score $s(T)$ turns out to be the same scoring function used in previous span-based constituency parsing models (Stern et al., 2017; Gaddy et al., 2018; Kitaev and Klein, 2018). To train the model, these previous works use margin loss:

$$\max\left\{0, -s(T^*) + \max_T \left[\Delta(T, T^*) + s(T)\right]\right\} \tag{4}$$

where T^* is the gold tree, T is the predicted tree and Δ is a distance function. Computing the $\max_T$ term requires running a cost-augmented CKY decoder, which is computationally expensive and difficult to parallelize, especially when we add edge scores as described in the next section.

Instead, we propose to directly maximize the log-likelihood in Equation 2 of the gold trees in the training data. Concretely, given a gold tree T^*, our loss function is the negative log-likelihood $-\log p(T^*)$, which decomposes into a cross-entropy loss for each span (i, j) according to Equation 2. We train our model by directly minimizing these cross-entropy loss terms; in other words, we treat the model as a multiclass classification model where the input is the span $x_{i:j}$ and the classes are the possible chains for the span.

Our training method is faster than using margin loss since it does not require running the CPU-bound CKY decoder during training. Moreover, the cross-entropy loss terms can be computed in parallel for all spans of *multiple examples* at once, which leads to further speed-up.

Class weight for empty chains. In practice, the number of spans (i, j) with gold chains $T^*[i,j] = \varnothing$ (i.e., no subtree covering the span) is large compared to the total number of spans. To avoid the class imbalance problem, we scale the cross-entropy loss terms for spans with $T^*[i,j] = \varnothing$ by a hyperparameter $\alpha < 1$.

5 Edge scores

The model so far scores each span independently, which can be sub-optimal. For example, the prediction of the top intent only depends on the embedding of $x_{0:n}$, which is equivalent to standard intent classification or the first decision of a top-down tree generation. Similarly, ontology constraints (which intents can take which slots) are also not captured by the model.

To allows child nodes to influence the decision of the parent at inference time, we introduce *edge scores*. For a span (i, j) with $T[i,j] = c = (l_1, \ldots, l_k)$, consider the parent node of the top-most non-terminal l_1, and define $\pi[i,j]$ to be its label. We model the conditional distribution of $\pi[i,j]$ as a softmax over all possible labels:

$$\begin{aligned}&p(\pi[i,j] = l \mid T[i,j] = c) \\ &\quad = \frac{\exp\left[f_{\mathrm{e}}(x_{i:j}, c, l)\right]}{\sum_{l'} \exp\left[f_{\mathrm{e}}(x_{i:j}, c, l')\right]}\end{aligned} \tag{5}$$

where $f_{\mathrm{e}}(x_{i:j}, c, l)$ is the *edge score*. Similar to node scores, we compute $f_{\mathrm{e}}(x_{i:j}, c, l)$ by applying a feed-forward network on the concatenation of the embeddings of $x_{i:j}$ and c. For convenience of notation, we let $\pi[i,j] = \varnothing$ when the parent does not exist (i.e., when $T[i,j] = \varnothing$ or $(i,j) = (0,n)$). In those situations, we let $f_{\mathrm{e}}(x_{i:j}, c, l)$ be 0 for $l = \varnothing$ and $-\infty$ otherwise.

We define the joint log-likelihood of T and π:

$$\begin{aligned}&\log p(T, \pi) \\ &= \sum_{i<j} \Big[\log p(T[i,j]) + \log p(\pi[i,j] \mid T[i,j])\Big] \\ &= \sum_{i<j} \begin{bmatrix} f_{\mathrm{n}}(x_{i:j}, T[i,j]) \\ -\log \sum_{c'} \exp\left[f_{\mathrm{n}}(x_{i:j}, c')\right] \\ +f_{\mathrm{e}}(x_{i:j}, T[i,j], \pi[i,j]) \\ -\log \sum_{l'} \exp\left[f_{\mathrm{e}}(x_{i:j}, T[i,j], l')\right] \end{bmatrix}.\end{aligned} \tag{6}$$

Unlike in the original model, the last log-sum-exp term in Equation 6 *does* depend on the tree T, and thus has to be included in the tree score. Our

new tree score is

$$s(T) := \sum_{i<j} \left[\begin{array}{l} f_{\mathrm{n}}(x_{i:j}, T[i,j]) \\ + \log p(\pi[i,j] \mid T[i,j]) \end{array} \right] \quad (7)$$

where $p(\pi[i,j] \mid T[i,j])$ is the softmax over edge scores as defined in Equation 5. Note that we cannot replace node scores $f_{\mathrm{n}}(x_{i:j}, T[i,j])$ with their log-softmax this way since we want dummy nodes to contribute a score of 0 to the tree score.

To train the model, we again directly minimize the negative log-likelihood of the gold tree T^*. The loss function factors into a cross-entropy loss term for each span (i,j) and for each edge in T^*.

Discussion. The joint modeling of $T[i,j]$ and $\pi[i,j]$ is closely related to the parent annotation technique in syntactic parsing (Johnson, 1998; Klein and Manning, 2003; Petrov et al., 2006), where certain non-terminal labels are split into multiple labels based on their parents in the grammar rule (e.g., `VP` with parent `S` becomes `VP^S`). In our framework, we can view the label and edge scores (Equation 7) as a score over parent-annotated labels $(T[i,j], \pi[i,j])$:

$$s(T) = \sum_{i<j} f_{\mathrm{a}}(x_{i:j}, T[i,j], \pi[i,j]) \quad (8)$$

where $f_{\mathrm{a}}(x_{i:j}, \varnothing, \varnothing) = 0$. From our preliminary experiments, we found that modeling f_{a} as a combination of label and edge scores, as in Equation 7, is empirically better than directly applying a softmax over possible pairs $(T[i,j], \pi[i,j])$.

One analysis in Gaddy et al. (2018) shows that the span embedding of $x_{i:j}$ is powerful enough to identify the parent label $\pi[i,j]$ with high accuracy. However, in TOP semantic trees, parent and child nodes can have span boundaries that are far apart (e.g., the top intent covering span $(0, 15)$ might have a child slot covering span $(7, 9)$). As an alternative to increasing the power of the span embedder to handle long-range relations, which could lead to overfitting, adding edge scores is a simpler way to model relations between labels.

6 Experiments

We evaluate our models on the TOP dataset (Gupta et al., 2018) of hierarchical intent-slot annotations for utterances in navigation and event domains.[3] We use the dataset version with the noisy `IN:UNSUPPORTED_*` intents excluded, which contains 28410 training, 4032 development, and 8241 test examples. The main evaluation metric is exact match accuracy: the fraction of predicted parses that *exactly* match the annotated parses. We also report the labeled bracket F1 score for the parse tree constituents (Black et al., 1991).

Training details. We highlight crucial modeling decisions of our models and defer other details to Appendix B.

- For a fair comparison, we use the same token and sequence embedders as Gupta et al. (2018): 200-dimensional GloVe embeddings and 2-layer 164-dimensional biLSTMs. We expect contextual embeddings (Peters et al., 2018; Devlin et al., 2018) and a transformer-based sequence embedder (Kitaev and Klein, 2018) to further improve the results, as observed in Einolghozati et al. (2018).

- The class weight α for empty chains is tuned on the development data: $\alpha = 0.4$ for the basic model and $\alpha = 0.2$ for the model with edge scores. We will later demonstrate how different choices of α affect the results.

Baselines. We compare our method to existing approaches proposed for this task in Gupta et al. (2018): a shift-reduce parser based on Recurrent Neural Network Grammars (RNNG) (Dyer et al., 2016), and the best sequence-to-sequence model that produces linearization of the trees based on CNN utterance embeddings (Gehring et al., 2017).[4] We also consider the span-based parsers by Stern et al. (2017) with the additional improvements from Gaddy et al. (2018).[5] The parsers were designed for constituency parsing, are trained with cost-augmented margin loss, and use either a bottom-up CKY decoder (Stern-chart) or a top-down greedy decoder (Stern-greedy).

Accuracy. Table 1 shows the exact match accuracy and bracket scores on the test data. The span-based model without edge scores is comparable to the baseline RNNG model. With edge scores, the span-based model outperforms the baselines in both exact match accuracy and labeled F1 scores.

ours (+ f_e)	**81.80**	**93.63**	9m

Table 1: The test exact match accuracy, labeled bracket F1, and training time per epoch of different methods.

Error type	no f_e	+ f_e
wrong top intent	106	99
wrong label except top intent	381	367
wrong non-terminal boundary	133	133
missing a non-terminal	153	154
spurious non-terminal	198	185
joining two gold non-terminals	20	26
splitting a gold non-terminal	27	36
other errors	6	4

Table 2: The error breakdown on the development data of our span-based models. Note that an example can have multiple errors.

Training speed. Our span-based models can be trained in a highly parallelized fashion without having to run the computationally expensive decoder. Table 1 shows the average wall-clock time used to train the model for one epoch over the training data.

Error analysis. We compare the errors made by the span-based parsers on the development set. Table 2 provides a breakdown of the error counts of the models on development data.

Recall trade-off. As described in Section 4, the hyperparameter α controls the weight of the loss terms for the class $c = \varnothing$ (i.e., not building a subtree for the span). As such, we can use α to trade off two types of errors: missing non-terminals (over-predicting $c = \varnothing$) and spurious non-terminals (under-predicting $c = \varnothing$). As shown in Figure 2, higher α encourages the model to predict $c = \varnothing$ more frequently, leading to more missing non-terminals (intents and slots) and fewer spurious ones. We can also tune α based on the downstream tasks. For instance, getting a higher slot recall using a small α is arguably better for dialog systems since other downstream modules (e.g., entity linker) can detect and discard spurious slots.

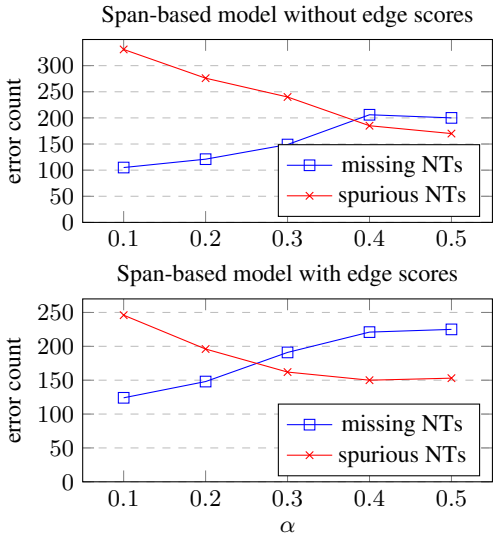

Figure 2: Trade-off between missing and spurious non-terminals with different α (weight for class $c = \varnothing$).

When α is low, one common type of errors is when the models incorrectly split a non-terminal. This usually happens when the gold slot consists of two sub-phrases that can be interpreted as slots on their own (e.g., a `SL:CATEGORY_EVENT` slot *"holiday concerts"* is split into a `SL:DATE_TIME` slot *"holiday"* and a `SL:CATEGORY_EVENT` slot *"concerts"*). As the tree score is the sum of span scores, the parser is biased toward creating two non-terminal nodes instead of one. Luckily, in the context of task-oriented dialogs, this type of errors tends to have small effects on the semantic interpretation, and sometimes even provides more useful information for downstream modules.

7 Conclusion

We presented the first span-based parser for parsing utterances into the hierarchical intent-slot representation. The log-likelihood objective allows us to train the model without having to decode a tree in a highly parallelized fashion, while edge scores can explicitly capture the parent-child relationship even when their boundaries are far apart.

Apart from standard accuracy improvement techniques such as better token embeddings and ensembling, possible future directions include a more fine-grained control of the recall trade-off, modeling the tokens outside the non-terminals instead of ignoring them, incorporating the parent's embedding in edge scores, and a more efficient or approximate decoder similar to the greedy decoder from Stern et al. (2017).

Abstract

Context modeling is essential to generate coherent and consistent translation for Document-level Neural Machine Translations. The widely used method for document-level translation usually compresses the context information into a representation via hierarchical attention networks. However, this method neither considers the relationship between context words nor distinguishes the roles of context words. To address this problem, we propose a query-guided capsule networks to cluster context information into different perspectives from which the target translation may concern. Experiment results show that our method can significantly outperform strong baselines on multiple data sets of different domains.

1 Introduction

The encoder-decoder based Neural machine translation (NMT) models (Sutskever et al., 2014; Bahdanau et al., 2014; Wu et al., 2016; Vaswani et al., 2017; Zhang et al., 2019) have made great progresses and drawn much attention in recent years. In practical applications, NMT systems are often fed with a document-level input which requires reference resolution, the consistency of tenses and noun expressions and so on. Many researchers have proven that contextual information is essential to generate coherent and consistent translation for document-level translation (Hardmeier, 2012; Meyer and Webber, 2013; Sim Smith, 2017; Jean et al., 2017; Maruf and Haffari, 2018; Miculicich et al., 2018; Zhang et al., 2018a; Voita et al., 2018; Wang et al., 2017; Tu et al., 2018; Maruf et al., 2019). Despite the great success of the above models, they are designed for sentence-level translation tasks and exclude contextual information in the model architecture.

On these grounds, the widely used hierarchical attention networks (HAN) was proposed to integrate contextual information in document-level translation (Miculicich et al., 2018). In this method, the context sentences are considered in the form of hierarchical attentions retrieved by the current generation. That is, it utilizes a word-level attention to represent a sentence and then a sentence-level attention to represent all the involved context. In this way, the final attention representation has to encode all the information needed for coherent and consistent translation, including reference information, tenses, expressions and so on. To get the multi-perspective information, it is necessary to distinguish the role of each context word and model their relationship especially when one context word could take on multiple roles (Zhang et al., 2018b). However, this is difficult to realize for the HAN model as its final representation for the context is produced with an isolated relevance with the query word which ignores relations with other context words.

To address the problem, we introduce Capsule Networks into document-level translation which have proven good at modelling the *parts-wholes* relations between low-level capsules and high-level capsules (Hinton et al., 2011; Xiao et al., 2018; Sabour et al., 2017; Hinton et al., 2018; Gu and Feng, 2019). With capsule networks, the words in a context source sentence is taken as low-level capsules and the information of different perspectives is treated as high-level capsules. Then in the dynamic routing process of capsule networks, all the low-level capsules trade off against each other and consider over all the high-level capsules and drop themselves at a proper proportion to the high-level capsules. In this way, the relation among low-level capsules and that between low-

level capsules and high-level capsules are both explored. In order to make sure high-level capsules indeed cluster information needed by the target translation, we apply capsule networks to both sides of the current sentence and add a regularization layer using Pearson Correlation Coefficients to force the high-level capsules on the two sides to approach to each other. In addition, we still need to ensure the final output of capsule networks is relevant to the current sentence. Therefore we propose a Query-guided Capsule Network (QCN) to have the current source sentence to take part in the routing process so that high-level capsules can retain information related to the current source sentence.

To the best of our knowledge, this is the first work which applies capsule networks to document-level translation tasks and QCN is also the first attempt to customize attention for capsule networks in translation tasks. We conducted experiments on three English-German translation data sets in different domains and the results demonstrate that our method can significantly improve the performance of document-level translation compared with strong baselines.

2 Background

2.1 Sentence-level NMT and Transformer Model

Sentence-level NMTs are generally based on an encoder-decoder framework (Sutskever et al., 2014; Bahdanau et al., 2014; Wu et al., 2016; Vaswani et al., 2017; Zhang et al., 2019; Meng and Zhang, 2019). In this framework, the encoder encodes the source sentence $\boldsymbol{x} = \{x_1, x_2, \cdots, x_M\}$ into a sequence of continuous representations $\boldsymbol{z} = \{z_1, z_2, \cdots, z_M\}$. Given $\boldsymbol{z}$, the decoder predicts target words in order and returns the target translation $\boldsymbol{y} = \{y_1, y_2, \cdots, y_N\}$. The objective function of NMT is to maximize the log-likelihood of a set of source-target language sentence pairs as

$$\mathcal{L}(\Theta; \boldsymbol{x}, \boldsymbol{y}) = \frac{1}{|\mathcal{S}|} \sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{S}} \log P(\boldsymbol{y}|\boldsymbol{x}; \Theta) \quad (1)$$

where $\mathcal{S}$ is the training set.

As we implement our approaches based on the Transformer architecture (Vaswani et al., 2017), which is a strong sentence-level NMT baseline, we give a brief description of the Transformer model. The encoder and decoder are composed of similar layers which consists of two general types of sub-layers: multi-head attention mechanism and point-wise fully connected feed-forward network (FFN).

Encoder: The encoder of the Transformer is composed of N identical layers. Each of these layers includes a multi-head self-attention mechanism that allows each position of the output of previous encoder layer to attend to all other positions, as well as a position-wise FFN, which is stacked on top of the multi-head self-attention, composed of two linear transformations and a ReLU activation function.

Decoder: The architecture of the decoder is similar to the encoder, however, it employs an additional multi-head attention sub-layer over the encoder output between the multi-head self-attention sub-layer and position-wise FFN sub-layer. The multi-head self-attention sub-layer needs to mask the input target tokens in the future.

2.2 Document-level NMT

The document-level translation task is to translate each source sentence with consideration of the previous context in the document. Formally, the translation of a document $\boldsymbol{D}$ containing $|\boldsymbol{D}| = J$ sentence pairs can be defined as given the source document $\boldsymbol{X}$ in order and the translation system generates each translation $\boldsymbol{y^j} \in \boldsymbol{Y}$ in order. The document translation probability can be defined as:

$$P(\boldsymbol{Y}|\boldsymbol{X}; \Theta) = \prod_{j=1}^{J} P(\boldsymbol{y}^j|\boldsymbol{x}^j, \boldsymbol{D}_{<j}; \Theta) \quad (2)$$

where $\boldsymbol{x}^j$, $\boldsymbol{y}^j$ denote the j_{th} source and target sentence respectively, and $\boldsymbol{D}_{<j}$ denotes all of the previous sentence pairs in document. For each sentence $\boldsymbol{x}^j$, each target word is generated according to the source representation and the generated target hypothesis, therefore the Eq. (2) can be formulated as:

$$P(\boldsymbol{Y}|\boldsymbol{X}; \Theta) = \prod_{j=1}^{J} \prod_{i=1}^{I^j} P(y_i^j|, \boldsymbol{y}_{<i}^j, \boldsymbol{x}^j, \boldsymbol{D}_{<j}; \Theta) \quad (3)$$

where y_i^j denotes the i_{th} word of the j_{th} translation $\boldsymbol{y}^j$ with the length as I^j and $\boldsymbol{y}_{<i}^j$ denotes the generated target hypothesis.

The training objective of document-level NMTs is to maximize the log-likelihood of translations in

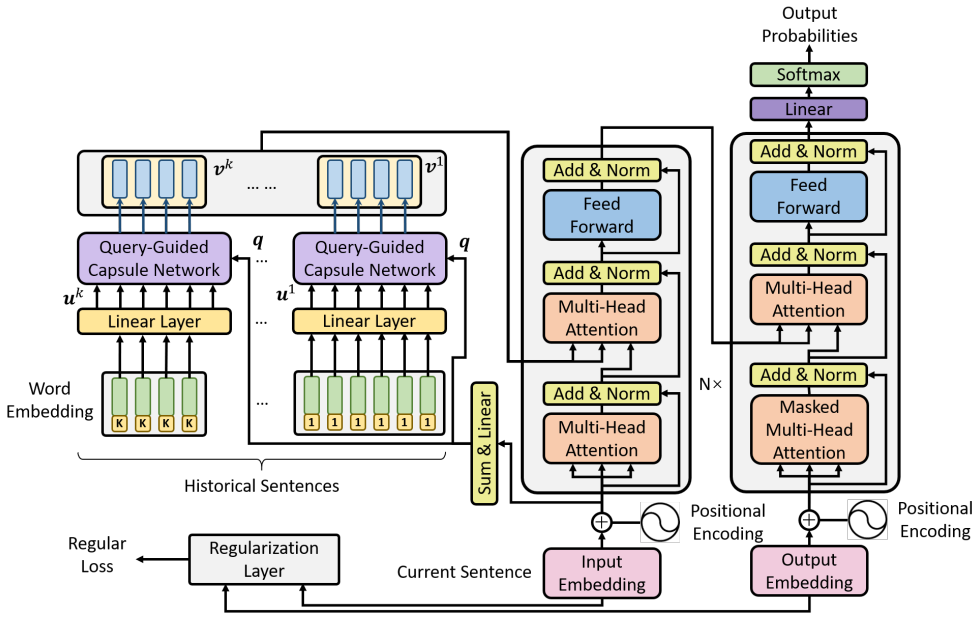

Figure 1: The overall architecture consists of three modules: the *Query-guided Capsule Network* in the upper left of this figure, the *Regularization Layer* in the lower left of this figure and the *Sub-layer-expanded Transformer* in the right of this figure.

document context as following:

$$\mathcal{L}(\Theta; \boldsymbol{X}, \boldsymbol{Y}) = \frac{1}{|\mathcal{D}|} \sum_{(\boldsymbol{X},\boldsymbol{Y})\in\mathcal{D}} \log P(\boldsymbol{Y}|\boldsymbol{X}; \Theta) \tag{4}$$

where $\mathcal{D}$ is the training set of the DocNMT.

Compared with the sentence-level NMTs, the critical part of document-level NMTs is to effectively capture and utilize the related contextual information when translating the to-be-translated source sentence.

3 Our Approach

In this section, we introduce the proposed Query-guided Capsule Network (QCN) for enhancing the document-level NMT. First, we present the overall architecture of the network, and then we describe the QCN in detail.

3.1 Overall Architecture

We aim to enhance the document-level NMT performance through effectively capturing and employing the contextual features in each historical sentence that related to the current sentence. We integrating a novel Query-guided Capsule Network into the sentence-level Transformer-based NMT (Vaswani et al., 2017) to capture the document-level contextual information for translating the current source sentence.

As shown in Figure 1, the overall architecture of our translation model is composed of three modules:

- **The Query-guided Capsule Network** takes the to-be-translated source sentence as the query to guide the procedure of retrieving related and helpful contextual features from historical sentences with a novel dynamic routing algorithm.

- **Sub-layer-expanded Transformer** contains a new sub-layer that attending the contextual features extracted from the QCN to effectively utilize them for translation.

- **Regularization Layer** contains two conventional Capsule Networks to unify the source sentence and the target sentence into an identical semantic space through computing an extra PCCs loss item at the training stage.

3.2 Query-guided Capsule Network

The Capsule Network (CapsNet) (Sabour et al., 2017) was proposed to build parts-wholes relationships in the iterative routing procedure, which can be used to capture features in historical sentences from low level to high level. Capsules in the lower layer vote for those in the higher layer by aggregating their transformations with iteratively updated

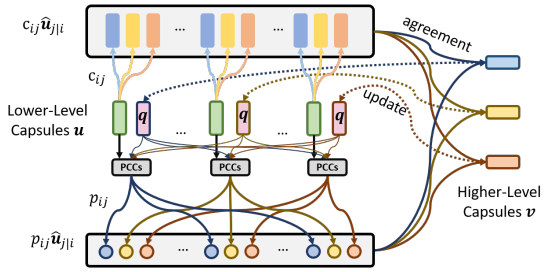

Figure 2: Query-guided Capsule Network, the green blocks in the middle of the figure are lower-level capsules $\boldsymbol{u}_i$, right-side blocks indicate the higher-level capsules $\boldsymbol{v}_j$ and the query vector $\boldsymbol{q}$ is initially tiled to length $|\boldsymbol{v}|$ and updated with corresponding higher-level capsules. Here shows a Query-guided Capsule Network with 3 high-level (feature) capsules. In each iteration, the PPCs is computed according to the input vector $\boldsymbol{u}_i$ and the query vector $\boldsymbol{q}_j$, then $p_{ij}\hat{\boldsymbol{u}}_{j|i}$ and $c_{ij}\hat{\boldsymbol{u}}_{j|i}$ are added to obtain the higher-level capsules which will be used to update corresponding query later.

coupling coefficients. However, there exists an obvious drawback of directly applying the Capsule Network into the document-level NMT for capturing contextual features. The reason is that the CapsNet can only extract internal features without considering whether features are related to the to-be-translated source sentence.

To address this issue, we proposed the Query-guided Capsule Network (QCN), which employ the representation of the to-be-translated source sentence as the query to guide the feature extraction procedure of the Capsule Network. In this way, contextual features that generated from the QCN are based on the internal semantic relations among each historical sentence and the external semantic relations between historical sentences and the to-be-translated source sentence. The QCN is based on an improved dynamic routing algorithm which will be detailed introduced in the next section.

Improved Dynamic Routing of QCN

Given a query vector $\boldsymbol{q}$ and a set of input capsules $\boldsymbol{u} = \{\boldsymbol{u}_1, \boldsymbol{u}_2, \cdots, \boldsymbol{u}_n\}$, the dynamic routing algorithm iteratively calculates the correlation between the query vector and each input capsule and updates output capsules. Specifically, query vector $\boldsymbol{q}$ is the representation of source to-be-translated sentence and input capsules $\boldsymbol{u}$ are all word embeddings in previous sentences, which can be formulated as:

$$\boldsymbol{q} = \mathrm{g}(\sum_{x \in \boldsymbol{x}} \mathrm{embedding}(x)) \quad (5)$$

$$\boldsymbol{u}_i^{-k} = \mathrm{f}([\mathrm{embedding}(x_i^{-k}); \mathrm{onehot}(k)]) \quad (6)$$

where f and g are both linear transformation functions and k indicates the distance of historical sentence from the to-be-translated sentence. Each word embedding in historical sentences is concatenated with a distance-determined one-hot vector to provide positional markers. Compared to the dynamic routing method proposed by (Sabour et al., 2017), our improved dynamic routing method of QCN can model information that related to the query among input capsules.

Algorithm 1 shows details of the algorithm and Figure 2 illustrates the interaction of the various components in the QCN. Initially, the improved dynamic routing algorithm of QCN recieves a sequence of lower-level capsules $\boldsymbol{u} = \{\boldsymbol{u}_1, \boldsymbol{u}_2, \cdots, \boldsymbol{u}_n\}$ and a query vector $\boldsymbol{q}$ and

Algorithm 1 Improved Dynamic Routing

Input: r , $\boldsymbol{q}$ and $\boldsymbol{u} = \{\boldsymbol{u}_1, \boldsymbol{u}_2, \cdots, \boldsymbol{u}_n\}$
Output: $\boldsymbol{v} = \{\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_m\}$

// Initialization

  for each input capsule $\boldsymbol{u}_i$ in lower-layer **do**
    $\hat{\boldsymbol{u}}_{j|i} \leftarrow \boldsymbol{W}_{ij}\boldsymbol{u}_i$
    $\alpha_{ij} \leftarrow 0$
    $\boldsymbol{q}_j \leftarrow \boldsymbol{q}$
    $p_{ij} \leftarrow \tanh(\mathrm{PCCs}(\boldsymbol{u}_i, \boldsymbol{q}_j))$
    ▷ PCCs computes Eq 7
  end for
end for

// Iteration
$itr \leftarrow 0$
repeat
  for each input capsule $\boldsymbol{u}_i$ in lower-layer **do**
    $\boldsymbol{c}_i \leftarrow \mathrm{softmax}(\boldsymbol{\alpha}_i)$
  end for

  for each output capsule $\boldsymbol{v}_j$ in higher-layer **do**
    $\boldsymbol{s}_j \leftarrow \sum_{i=1}^{n}(c_{ij} + p_{ij})\hat{\boldsymbol{u}}_{j|i}$
    $\boldsymbol{v}_j \leftarrow \mathrm{squash}(\boldsymbol{s}_j)$
    ▷ squash computes Eq 8
  end for

  for each output capsule $\boldsymbol{v}_j$ in higher-layer **do**
    for each input capsule $\boldsymbol{u}_i$ in lower-layer **do**
      $\alpha_{ij} \leftarrow \alpha_{ij} + p_{ij}\hat{\boldsymbol{u}}_{j|i}\boldsymbol{v}_j$
    end for
    $\boldsymbol{q}_j \leftarrow \frac{\boldsymbol{q}_j + \boldsymbol{v}_j}{2}$
    for each input capsule $\boldsymbol{u}_i$ in lower-layer **do**
      $p_{ij} \leftarrow \tanh(\mathrm{PCCs}(\boldsymbol{u}_i, \boldsymbol{q}_j))$
    end for
  end for
  $itr \leftarrow itr + 1$
until $itr = r$

then calculates a Pearson Correlation Coefficients (PCCs) between $\boldsymbol{q}$ and each input capsule $\boldsymbol{u}_i$ (line 7). The PCCs is a measure of the linear correlation between two variables. When PCCs is close to +1, it means they have very strong positive linear correlation, and close to -1 means total negative correlation. Given a pair of variables $(\boldsymbol{A}, \boldsymbol{B})$, the formula for computing PPCs is

$$\begin{aligned}\text{PCCs}(\boldsymbol{A}, \boldsymbol{B}) &= \frac{\text{Cov}(\boldsymbol{A}, \boldsymbol{B})}{\sigma_{\boldsymbol{A}}\sigma_{\boldsymbol{B}}} \\ &= \frac{(\boldsymbol{A} - \frac{1}{n}\sum_{i=1}^{n} a_i)^T(\boldsymbol{B} - \frac{1}{n}\sum_{i=1}^{n} b_i)}{\|\boldsymbol{A}\| \cdot \|\boldsymbol{B}\|} \end{aligned} \quad (7)$$

where $\boldsymbol{A}$ and $\boldsymbol{B}$ are both n-dimension vectors, Cov is the covariance and $\sigma_{\boldsymbol{A}}, \sigma_{\boldsymbol{B}}$ is the standard deviation of $\boldsymbol{A}$ and $\boldsymbol{B}$ respectively.

The routing iteration process then computes coupling coefficients, denoted as $\boldsymbol{c}_i$(line 16), with regard to a input capsule $\boldsymbol{u}_i$ and all the higher-level capsules $\boldsymbol{v}$. In the original dynamic routing algorithm (Sabour et al., 2017), coupling coefficients are only determined by the cumulative "agreement", which are the prior probabilities that capsule $\boldsymbol{u}_i$ should be coupled to capsule $\boldsymbol{v}_j$. However, in DocNMT situation, it is far from enough to cluster the high-level information from the capsules in lower-level that related to query vector according to a naive "agreement". To address this issue, we reduce the "agreement", when PCCs show a negative linear correlation between the query vector $\boldsymbol{q}$ and the input vector $\boldsymbol{u}_i$. Instead, we increase the "agreement", when PCCs are positive (line 27). The query vector $\boldsymbol{q}$ is initially tiled to length $|\boldsymbol{v}|$ and updated with the corresponding higher-level capsules $\boldsymbol{v}_j$ in each iteration (line 29).

Our routing iteration updates higher-level capsules by adding $\sum_{i=1}^{n} p_{ij}\hat{\boldsymbol{u}}_{j|i}$ to $\boldsymbol{s}_j$. This step can add more information related to the query vector and cut off the unrelated features (line 20). It is necessary to get different length of output capsules shrunk into the 0 to 1 interval using "squash" function (line 21) proposed by Sabour et al. (2017) which is shown in Eq.(8).

$$\text{squash}(\boldsymbol{t}) = \frac{||\boldsymbol{t}||^2}{1 + ||\boldsymbol{t}||^2}\frac{\boldsymbol{t}}{||\boldsymbol{t}||} \quad (8)$$

where $\boldsymbol{t}$ can be the initial input capsule $\boldsymbol{u}_i$ or the vector $\boldsymbol{s}_j$ for predicting the output capsule.

3.3 Sub-layer-expanded Transformer

To effectively utilize contextual features extracted from each historical sentence by QCN, we introduce an additional context-aware multi-head attention sub-layer in each layer of the Transformer encoder. The multi-head attention can attend to all the positions of the contextual features with outputs of the previous sub-layer as a query. Then the output of the context-aware multi-head attention sub-layer is fed into the point-wise feed-forward sub-layer in each layer of the encoder. The right part in Figure 1 shows details of the Sub-layer-expanded Transformer. Specifically, the equation of multi-head attention computing procedure is as following:

$$\begin{aligned}\text{MultiHead}(Q,K,V) &= \text{Concat}(H_1,\cdots,H_h)W^O \\ H_i &= \text{Attention}(QW_i^Q, KW_i^K, VW_i^V) \end{aligned} \quad (9)$$

where W_i^Q, W_i^K and W_i^V are the parameter matrices, Q, K and V indicates the query, key and value representations. The computation of the attention function is as following:

$$\text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}})V \quad (10)$$

where d_k indicates the dimension of queries Q and keys K.

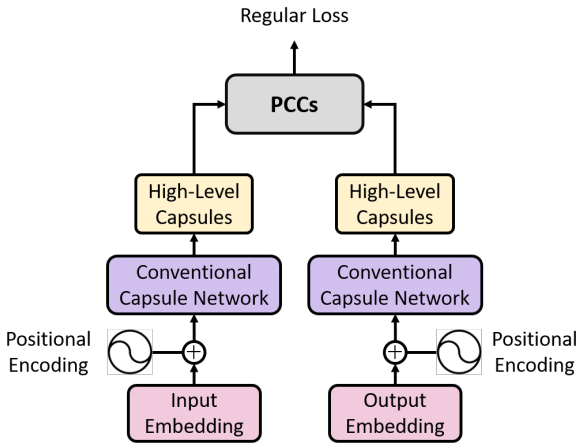

Figure 3: Regularization Layer. In the training stage, this layer takes the inputs of the encoder (left part of the figure) and decoder (right part of the figure) as the input capsules of two capsule networks separately, and computes the PCCs between the high-level capsules of two networks.

3.4 Regularization Layer

To better modeling the document-level translation task, we incorporate a regularization layer (Figure 3) into the whole architecture to restrict the source sentence and target sentence to an identical semantic space. This layer separately feeds the inputs

of encoder and decoder into two capsule networks Caps_{enc} and Caps_{dec}, and computes the PCCs between the outputs of two networks. We regard the PCCs as an extra regularization term in the final objective at the training stage. The loss function of our model can be formulated as:

$$\mathcal{L}(\Theta; \boldsymbol{X}, \boldsymbol{Y}) = \frac{1}{|\mathcal{D}|} \times \sum_{j=1}^{J} \sum_{i=1}^{I^j} \{\log P(y_i^j | , \boldsymbol{y}_{<i}^j, \boldsymbol{x}^j, \boldsymbol{D}_{<j}; \Theta) + \text{PCCs}(\text{Caps}_{enc}(\boldsymbol{x}^j), \text{Caps}_{dec}(\boldsymbol{y}^j))\} \quad (11)$$

where Θ are parameters of the model, $\boldsymbol{D}_{<j}$ are historical sentences of the to-be-translated source sentence, $\boldsymbol{x}^j$ is the to-be-translated sentence and $\boldsymbol{y}_{<i}^j$ denotes the generated target hypothesis.

4 Experiments

4.1 Settings

Datasets and Evaluation Metrics

We carry out experiments on English-German translation tasks in three different domains: talks, news, and speeches. The corpora statistics are shown in Table 1.

- **TED.** This corpus is a Machine Translation part of the IWSLT 2017 (Cettolo et al., 2012) evaluation compaigns[1], each TED talk is considered to be a document. we take the *tst2016-207* as the test set, and other as our development set.
- **News.** We take the sentence-aligned document-delimited News Commentary v11 corpus[2] as our training set. The WMT'16 *news-test2015* and *news-test2016* are used for development and testing respectively.
- **Europarl.** The corpus are extracted from the Europarl v7 (Koehn, 2005) according to the method mentioned in Maruf and Haffari (2018). The training, development and test sets are obtained through randomly splitting the corpus.

We download all of above extracted corpora[3] from Maruf et al. (2019). The tokenization and truecase pre-processing are implemented on all datasets using the scripts of the Moses Toolkit[4] (Koehn et al., 2007). We also apply segmentation into BPE subword units[5] (Sennrich et al., 2016) with 30K merge operations.

We use two metrics: BLEU (Papineni et al., 2002) and Meteor (Lavie and Agarwal, 2007) to evaluate the translation quality.

Models and Baselines

We use the Transformer architecture as our context-agnostic baseline and adopt three context-aware baselines (Zhang et al., 2018a; Miculicich et al., 2018; Maruf and Haffari, 2018).

We performed the same configuration on our models according to the settings of the Maruf and Haffari (2018). Specifically, for the Transformer, we set the hidden size and point-wise FFN size as 512 and 2048 respectively. We use 4 layers and 8 attention heads in both encoder and decoder. All dropout rates are set to 0.1 for context-agnostic model and 0.2 for context-aware model.

In the training phase, we use the default Adam optimizer (Kingma and Ba, 2014) with a fixed learning rate of 0.0001. The batch size is 1500 on TED dataset and 900 on both News and Europarl datasets.

4.2 Results and Analysis

Main Results

Table 2 shows that our model surpasses all the context-agnostic(Vaswani et al., 2017) and context-aware(Zhang et al., 2018a; Miculicich et al., 2018; Maruf and Haffari, 2018) baselines on TED and Europarl datasets. For TED dataset, the performance of our model greatly exceeds that of all other baselines, and is better than Miculicich et al. (2018) with a gain of +0.59 BLEU and +0.61 Meteor. For Europarl dataset, our model got improvements with a gain of +0.07 on BLEU metric, but the Meteor score is +0.64 higher than Maruf et al. (2019) which utilize the whole document as the contextual information, whereas we only using 3 previous sentences.

Results on the sequence-level Transformer and our DocNMTs show that the captured contextual features provide helpful semantic information for enhancing the translation quality. The regularization term that we proposed can effectively

Table 2: BLEU and Meteor scores of models. There exists three context-aware baseline models and a context-agnostic model. "Regularization Term" denotes integrating the regularization layer into the Transformer model and "QCN" denotes incorporating Query-guided Capsule Network in the Transformer model.

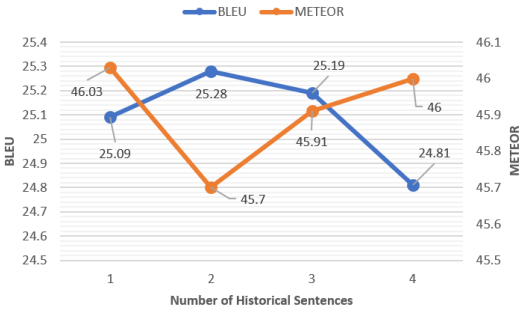

Figure 4: Effect of Contextual Information Scope. It is not that the more historical sentences we utilize, the better translation performance is. Effect of scope on BLEU and Meteor scores are inconsistent to some degree.

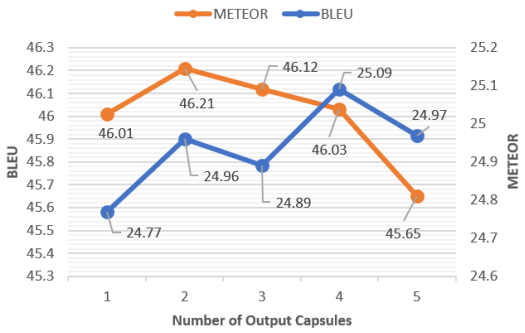

Figure 5: Effect of Feature Capsule Number. Appropriate capsule number is important for model performance.

further improve the model performance on TED and Europarl datasets. For the restriction of the GPU memory, we have to filter long sentences to keep our model running. Although, it hurts the model performance on the "News" dataset (contains many long sentences), the QCN module and regularization term still bring improvements.

Effect of Contextual Information Scope

To investigate the effect of contextual information scope, we carry on the number of historical sentences hyper-parameter experiments on the TED talk dataset. We fix the hyper-parameters of the QCN by setting both the number of higher-level capsules and routing iteration to four, and investigating the impact of changes in the number of historical sentences on BLEU and Meteor scores. Figure 4 shows that using one historical sentence in QCN can obtain the best Meteor score while the highest BLEU score is presented when we utilize two historical sentences. We found that the growth of Meteor and BLEU scores are opposite. Therefore, the choice of utilizing how many historical sentences is a trade-off between both scores. We choose three historical sentences as our final setting. Through experimentation, we also found it is not that the more historical sentences we utilize, the better translation performance is.

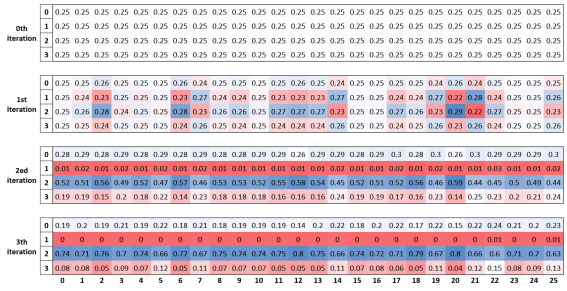

Figure 6: Agreement distribution of a sentence (26 words) as inputs of the QCN and 4 contextual features as output. Blue color means higher agreement and the red means lower. From top to bottom are four heat maps in 0_{th} to 3_{th} iterations.

Effect of Feature Capsule Number

QCN is the crucial part of our overall architecture and the positive and negative impact depends on the configuration of the QCN. Therefore, We also investigate the effect of the hyper-parameter of QCN: the number of feature capsules.

We set the number of historical sentence as 3 according to the previously experimental results, and the number of routing iteration is set to 4. Figure 5 shows that Meteor score become highest when the number of higher-level capsules is set as 2, but BLEU score can obtain best score at 4. We finally choose 4 as the final setting because both BLEU and Meteor can obtain relatively good results.

Visualization of Agreement and PCCs

Coupling Coefficients (CCs) can indirectly reflect the variation of the "agreement", so we visualize the coefficients in each routing iteration at the stage of decoding as shown in Figure 6. In the first iteration, all coupling coefficients are initialized in a uniform distribution, all higher-level capsules are voted by lower-level capsules equally. Then, lower-level capsules are iteratively trained to send more information to the proper higher-level capsule. Figure 6 shows that most of input capsules are tend to vote the 2_{ed} feature capsule finally.

Different from the CCs, PCCs show the linear correlation between query and inputs. Initially, the query vector is tiled with the number of feature capsules and is used to calculate the PCCs with each input capsules, as the Figure 7 shows that the color of every column is identical. As the iterative routing begins, each query is updated according to the higher-level capsules. The function of the PPCs is to increase or decrease the coupling coefficients value according to the positive or negative

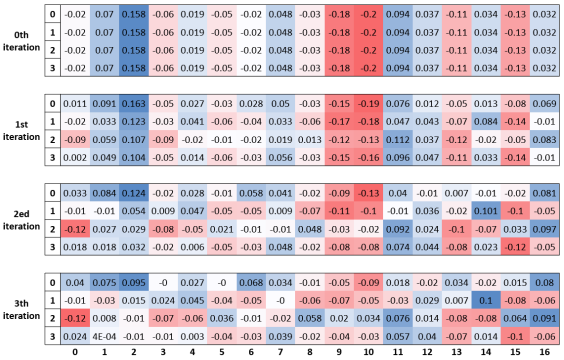

Figure 7: PCCs distribution of a sentence has 17 words as inputs of the QCN and 4 duplicated query. Blue color denotes positive correlation and red means negative. From top to bottom are four heat maps in 0_{th} to 3_{th} iterations.

value. See Figure 7, we can find that PCCs varies as iteration changes.

5 Related Work

Document-level Machine Translation

Document-level machine translation became a hot research direction in the later stage of statistical machine translation era. Hardmeier and Federico (2010) represented the links between word pairs in the context using a word dependency model for SMT to improve the translation of anaphoric pronouns. Hardmeier et al. (2012, 2013) first proposed a new document-level SMT paradigm that translates whole documents as units. However, in this period, most of the work has not achieved too many compelling results or has been only focused on a part of difficulties.

With the coming of the era of Neural Machine Translation, many works began to focus on Document-level NMT tasks. Xiong et al. (2019) trained a reward teacher to refine the translation quality from a document perspective. Tiedemann and Scherrer (2017) simply concatenated sentences in one document as models' input or output. Jean et al. (2017) used additional context encoder to capture larger-context information. Kuang et al. (2017); Tu et al. (2018) used a cache to memorize most relevant words or features in previous sentences or translations.

Recently, several studies integrated additional modules into the Transformer-based NMTs for modeling contextual information. (Voita et al., 2018; Zhang et al., 2018a), Maruf and Haffari (2018) proposed a document-level NMT using a

memory-networks, and Wang et al. (2017) and Miculicich et al. (2018) integrated hierarchical attention network in RNN-based NMT or Transformer to model the document-level information. Maruf et al. (2019) used the whole document as the contextual information and firslty divided document-level translation tasks into two types: offline and online.

Capsule Networks

Hinton et al. (2011) proposed the capsule conception to use vector for describing the pose of an object. The dynamic routing algorithm was proposed by Sabour et al. (2017) to build the part-whole relationship through the iterative routing procedure. Hinton et al. (2018) designed a new routing style based on the EM algorithm. Some researchers investigated to apply the capsule network for various tasks. Wang et al. (2018) investigated a novel capsule network with dynamic routing for linear time NMT. Yang et al. (2018) explored capsule networks for text classification with strategies to stabilize the dynamic routing process. Gu and Feng (2019) introduces capsule networks into Transformer to model the relations between different heads in multi-head attention. We specifically investigated dynamic routing algorithms for the document-level NMT.

6 Conclusion

We have proposed a novel Query-guided Capsule Network with an improved dynamic routing algorithm for enhancing context modeling for the document-level Neural Machine Translation Model. Experiments on English-German in different domains showed our model significantly outperforms sentence-level NMTs and achieved state-of-the-art performance on two of three datasets, which proved the effectiveness of our approaches.

Simple, Scalable Adaptation for Neural Machine Translation

Ankur Bapna **Orhan Firat**

Abstract

Fine-tuning pre-trained Neural Machine Translation (NMT) models is the dominant approach for adapting to new languages and domains. However, fine-tuning requires adapting and maintaining a separate model for each target task. We propose a simple yet efficient approach for adaptation in NMT. Our proposed approach consists of injecting tiny task specific adapter layers into a pre-trained model. These lightweight adapters, with just a small fraction of the original model size, adapt the model to multiple individual tasks simultaneously.

We evaluate our approach on two tasks: (i) Domain Adaptation and (ii) Massively Multilingual NMT. Experiments on domain adaptation demonstrate that our proposed approach is on par with full fine-tuning on various domains, dataset sizes and model capacities. On a massively multilingual dataset of 103 languages, our adaptation approach bridges the gap between individual bilingual models and one massively multilingual model for most language pairs, paving the way towards universal machine translation.

1 Introduction

Recent developments in deep learning have led to significantly improved quality on Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2014; Vaswani et al., 2017). While NMT performance on sentence level translation for high resource languages seems to be dramatically improved (Wu et al., 2016; Hassan et al., 2018), performance on out-of-domain data or low resource languages, still remains pretty poor (Duh et al., 2013; Koehn and Knowles, 2017; Farajian et al., 2017; Dong et al., 2015; Zoph et al., 2016). This has generated significant interest in adaptation approaches, that can leverage the huge amounts of parallel data available for high resource languages, to improve translation performance on low resource tasks. In this work we focus on two adaptation tasks: (i) Domain Adaptation, to improve the performance of in-domain translation by leveraging out-of-domain datasets (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016), and (ii) Multilingual NMT, to improve the translation quality on low resource languages via co-training with similar languages (Dong et al., 2015; Firat et al., 2016; Johnson et al., 2016; Zoph et al., 2016; Neubig and Hu, 2018; Aharoni et al., 2019; Arivazhagan et al., 2019).

While several approaches have been explored in literature (Chu and Wang, 2018), full fine-tuning of model parameters remains the dominant approach for adapting to new domains and languages (Luong and Manning, 2015; Neubig and Hu, 2018). However, fine-tuning requires training and maintaining a separate model for every language, for every domain. As the number of languages and domains grow, training, maintaining and serving a separate model for every task becomes infeasible. This is further exacerbated by the increasing model capacity of state-of-the-art NMT models (Shazeer et al., 2018; Bapna et al., 2018; Huang et al., 2018); full fine-tuning is just too parameter inefficient. In addition to the growing number of models, fine-tuning requires very careful hyper-parameter tuning (eg. learning rate, regularization knobs etc.) during adaptation, and is prone to rapid over-fitting (Sennrich et al., 2016; Miceli Barone et al., 2017). This sensitivity to hyper-parameters and over-fitting to the adaptation corpus become worse in the setting of high capacity models.

These weaknesses beckon the need for parameter-efficient, scalable and hyper-parameter insensitive approaches for adaptation. The ideal adaptation approach should also offer the flexi-

bility to adapt to tasks of varying complexity and adaptation corpus sizes, within a single model.

In this work we propose using light-weight adapter layers, which are transplanted between the layers of a pre-trained network and fine-tuned on the adaptation corpus. Adapting only the light-weight layers enables our approach to be parameter efficient, and eases the scalability of the approach to large models. The capacity of these adapters can be adjusted to match the requirements of the target task, making them suitable for a variety of adaptation tasks. By separating the parameters of the original network and each adaptation task, our approach circumvents catastrophic interference (McCloskey and Cohen, 1989) with the original model parameters, and allows us to simultaneously adapt a single model to multiple domains and languages, while retaining the quality on the source languages and domains.

We make three major contributions in this work: (i) we propose a formulation of adapter layers for NMT adaptation that enables us to tune their capacity according to the target task complexity and corpus size, (ii) we evaluate our approach on domain adaptation, and demonstrate that light-weight adapters match the performance of full fine-tuning based adaptation at a fraction of the per-domain parameter cost, and (iii) we use adapters to train a massively multilingual model on 103 languages, and demonstrate that it is possible to train a single model that significantly improves transfer performance on low resource languages, without huge regression on high resource language pairs.

By demonstrating the effectiveness of adapters on domain adaptation and massively multilingual translation, we make progress towards a flexible universal translation model for all languages and domains.

2 Related Work

Several approaches have been proposed in recent literature that try to address the shortcomings of full fine-tuning when applied to domain adaptation (Chu and Wang, 2018). Michel and Neubig (2018) proposed a space efficient approach to adaptation that introduces domain-specific biases to the output vocabulary, enabling extreme personalization in settings where small amounts of data are available for a lot of different domains. Thompson et al. (2018) fine-tune selected components of the base model architecture, in order to determine how much fine-tuning each component contributes to the final adaptation performance. Wuebker et al. (2018) propose introducing sparse offsets from the base model parameters for every domain, reducing the memory complexity of loading and unloading domain specific parameters in real world settings. Bapna and Firat (2019) train the base model to utilize neighboring samples from the training set, enabling the model to adapt to new domains without the need for additional parameter updates. Learning Hidden Unit Contribution (LHUC) (Vilar, 2018) is perhaps closest to our work in spirit.

They introduce domain specific gates that control the contribution of hidden units feeding into the next layer. However, they introduce a limited amount of per-domain capacity which doesn't scale well when a lot of domain specific data is available.

Residual Adapters were first introduced for adapting vision models in Rebuffi et al. (2017), but their formulation used a single projection layer, without any tunable hyper-parameters that could be used to adjust capacity based on the target domain. Houlsby et al. (2019) utilized a new formulation of adapters to adapt BERT (Devlin et al., 2018) to multiple tasks simultaneously. Our formulation of adapters is motivated by theirs, but differs in a few respects. Houlsby et al. (2019) introduce adapters after every sub-layer (self-attention, feed-forward) within a transformer layer, and re-train existing layer normalization parameters for every new domain. We simplify this formulation by leaving the parameters frozen, and introducing new layer normalization parameters for every task, essentially mimic-ing the structure of the transformer feed-forward layer.

3 Approach

Our approach consists of two phases: (i) Training a generic base model, and (ii) adapting it to new tasks with added small network modules. We first take a standard NMT model which is trained on a large source corpus. Following convergence,[1] all model parameters are frozen, preserving the information learned during this pre-training phase. Next, per-task light-weight adapter layers (see Fig. 1 right pane) are introduced after every layer in the encoder and the decoder (see Fig. 1 left pane). We fine-tune the parameters of these task-specific adapters on the adaptation corpus. This procedure can be followed for every additional task, allowing us to train a single model for all tasks simultaneously, with a small set of task-specific adapters.

Adapter Modules Our design principles for adapter modules are simplicity and flexibility. We propose a simple single hidden-layer feed-forward network formulation for adapters, with a non-linear activation function between the two projection layers. The inner dimension of these two projections is the only knob to tune. This allows us to adjust the capacity of the adapter module easily, depending on the complexity of the target task or domain. Additionally, we normalize the input of the adapters, in order to make the module plug-able into any part of the base network, irrespective of the variations in the activation patterns/distributions. This parametrized normalization layer allows the module to learn the activation pattern of the layer it's injected into. Finally, to allow the adapter module to represent a no-op if necessary, we wrap it with a residual connection.

Formulation Let z_i be the output of the i-th layer, of dimension d. We first apply layer-normalization (Ba et al., 2016) to the inputs of the adapter corresponding to task T.

$$\tilde{z}_i^T = LN_T(z_i). \tag{1}$$

This is followed by a projection layer of dimension b. The dimension of the projection can be tuned based on the task complexity and the size of the adaptation corpus. This now allows us to make it a bottleneck layer for compression, or over-parametrize it with a dimension larger than the input dimension.[2]

$$h_i^T = relu(W_{bd}^T \tilde{z}_i^T). \tag{2}$$

Lastly, the inner representation is projection back to the input dimension d, and combined with a residual connection (He et al., 2015):

$$x_i^T = W_{db}^T h_i^T + z_i. \tag{3}$$

Our proposed formulation for adapters, and their incorporation into Transformers (Vaswani et al., 2017) is illustrated in Figure 1. This self-contained adapter module can be injected between any two layers of the network, without disrupting the original operation.

4 Domain Adaptation

We first compare the adaptation performance of the light-weight residual adapters against full fine-tuning and LHUC (Vilar, 2018) on a large scale English-French domain adaptation task.

[1] We leave the methodology for defining convergence task specific, e.g. early stopping on validation set accuracy or number of training steps.

[2] Following the wiring choices of Transformer feed-forward network (Vaswani et al., 2017).

4.1 Dataset

We use the WMT En-Fr training set (36M pairs) as our out-of-domain (source) training corpus. NMT models trained on WMT are then adapted to the IWSLT'15 En-Fr corpus, consisting of 237k sentence pairs. We also evaluate adaptation performance on the JRC-Acquis dataset [3], which is an extremely narrow domain dataset containing 797k sentence pairs in the training split. For IWSLT, we use the test corpora from 2012-14 for validation, and the test corpus from 2015 as the test set. For JRC-Acquis the test and validation set contain 6574 and 5121 sentence pairs respectively. We also evaluate the translation performance of the non-adapted base model on newstest-2014.

Dataset	Base	FT	LHUC	Adap.
WMT'14	42.80	-	-	-
IWSLT'15	41.33	**44.59**	43.33	**44.63**
JRC	54.60	**64.13**	57.10	63.48

Table 1: Domain adaptation performance with different adaptation strategies. Base refers to the baseline NMT model trained on the WMT'14 En-Fr training corpus. FT refers to the fine-tuning upper bound, adapting all the model parameters by incrementally training on in-domain training data. LHUC adds additional task-specific gating parameters to the pre-trained model, which are trained on the in-domain data, as described in Vilar (2018). Adap. is the proposed adaptation approach, adding domain specific adapter layers trained on the in-domain training corpus.

4.2 Using Adapters for Domain Adaptation

When using adapters for domain adaptation, we follow the following two step approach:

- Pre-training: Pre-train the NMT model on a large open-domain corpus. Freeze all the parameters of this pre-trained model.
- Adaptation: Inject a set of domain-specific adapter layers for every target domain. These adapters are then fine-tuned to maximize performance on the corresponding domains. This step can be applied any time a new domain is added to the model.

As discussed in Section 5.2, we follow a slightly different approach when using adapters for multilingual NMT.

[3] http://opus.nlpl.eu/JRC-Acquis.php

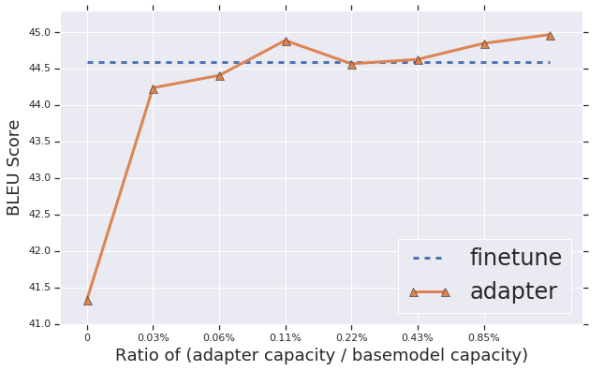

Figure 2: IWSLT Adaptation performance vs adapter capacity in terms of percentage of the base model's capacity. The range of model capacity plotted here corresponds to adapter bottleneck dimensions of 4, 8...256 respectively.

4.3 Models and Hyper-parameters

We use a larger version of Transformer Big containing 375M parameters as our base model. Our model is identical to Vaswani et al. (2017), having 6 encoder and decoder layers (12 in total), except that we use hidden layers of size 8192 instead of 4096, and a learning rate schedule of (3.0, 40K)[4], following Chen et al. (2018).

For full fine-tuning, we continue training on the in-domain corpus without resetting the optimizer accumulators or the learning rate schedule. This allows us to fine-tune gradually, avoiding rapidly over-fitting to the target domain. We also conducted fine-tuning experiments with SGD, but report results with the approach described above, based on better performance on the validation sets. When adapting with LHUC or lightweight adapters, we train using the same learning rate schedule and optimizer used during pre-training, but restart from the 0-th step, resetting the optimizer accumulators. BLEU scores are computed on the checkpoint with the best validation performance, on tokenized, true-cased output and references using *multi-bleu.perl* from Moses. All our experiments were performed using the open source Tensorflow Lingvo (Shen et al., 2019) framework.

4.4 Results and Analysis

The results of our adaptation experiments are documented in Table 1. On both, IWSLT and JRC-

[4] (3.0, 40K) schedule is the shorthand for a learning rate of 3.0, with 40K warm-up steps for the schedule, which is decayed with the inverse square root of the number of training steps after warm-up.

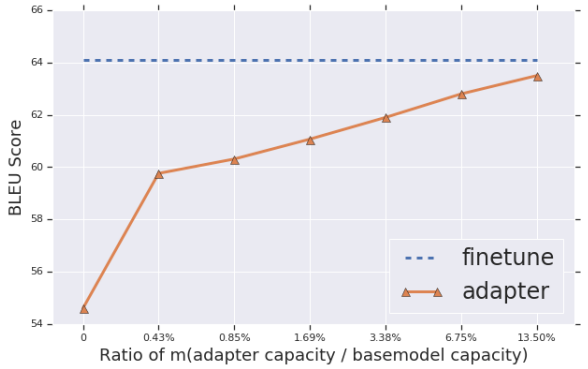

Figure 3: JRC-Acquis Adaptation performance vs adapter capacity in terms of percentage of the base model's capacity. The range of model capacity plotted here corresponds to adapter bottleneck dimensions of 64, 128...2048 respectively.

Acquis, full model fine-tuning (Full-FT columns in Table 1) on in-domain data significantly improves translation performance compared to the base, non-adapted Transformer Big by a huge margin, 3 BLEU points for IWSLT and 9 BLEU points for JRC. LHUC also improves performance over the base model, but lags behind a fully fine-tuned model for both domains and model capacities.

On IWSLT, adapters match the performance of the fine-tuning upper bound within error margins, while adding less than 0.11% of the original model parameters. On JRC-Acquis adapters recover around 90% of fine-tuning improvements without updating any existing parameters, while adding around 13.5% additional parameters.

To demonstrate the flexibility of our approach, we quantify the trade-off between adapter capacity and adaptation performance on both IWSLT and JRC-Acquis. In Figures 2 and 3, we plot the adaptation performance on IWSLT and JRC-Acquis respectively, while varying adapter capacity. On IWSLT, we notice that residual adapters reach within 0.5 BLEU of the full fine-tuning upper bound with just 0.03% of the model capacity, corresponding to a hidden dimension of size 4. By increasing capacity further we were able to improve over the full fine-tuning baseline by around 0.5 BLEU. On the other hand, on JRC-Acquis, adapter capacity had to be increased up to 13.5% of the total model capacity, corresponding to a hidden dimension of size 2048, before we were within 0.5 BLEU of the full fine-tuning performance. This highlights a key strength of the approach: by varying adapter capacity it is possible to adapt the same model to domains of varying complexity and amounts of data.

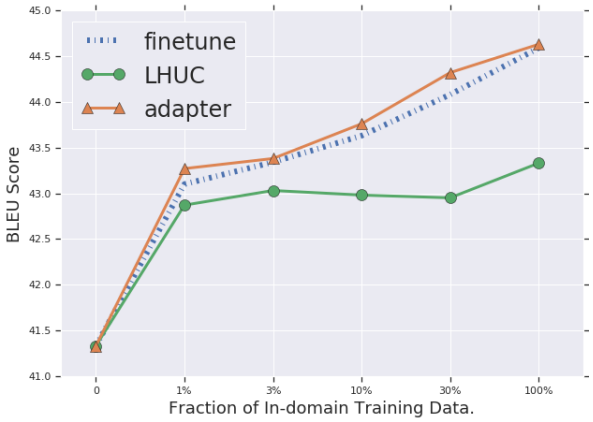

Figure 4: IWSLT Adaptation performance vs fraction of the in-domain training corpus used for adaptation. The blue solid line plots the performance of fine-tuning. The red dotted line tracks the performance of LHUC, while the yellow dashed line tracks the performance of the proposed residual adapter based approach with varying amounts of training data.

To evaluate the effectiveness of adapters when adapting with small in-domain corpora, we further compare the performance of adapters with fine-tuning on varying amounts of training data. In Figure 6 we plot the adaptation performance on IWSLT, when using different fractions of the training corpus for adaptation. While LHUC is competitive with full fine-tuning and light-weight adapters for extremely small fractions, the lack of capacity limits the applicability of the approach when larger quantities of adaptation data are available. On the other hand, by tuning the capacity of adapters to match the requirements for the adaptation corpus size, we are able to match and outperform fine-tuning on almost all evaluated datapoints.

In order to monitor the learning behavior of light-weight adapters, we compare the validation BLEU scores during the course of the fine-tuning process. Figure 5 illustrates the comparison of the two approaches, full fine-tuning and light-weight adapters. We notice that for a reasonably small adapter size, adapter performance gradually converges to its peak and stays steady, with almost no over-fitting for a long enough period, easing final model selection. On the other hand, with full fine-tuning, optimal model selection becomes challenging due to rapid over-fitting on the adaptation corpus. This, in fact, can be remedied by care-

fully tuning the learning rate (and/or batch size) during adaptation, but is not trivial and needs to be done individually for every different domain, model and corpus size, favoring the simplicity of our proposed approach.

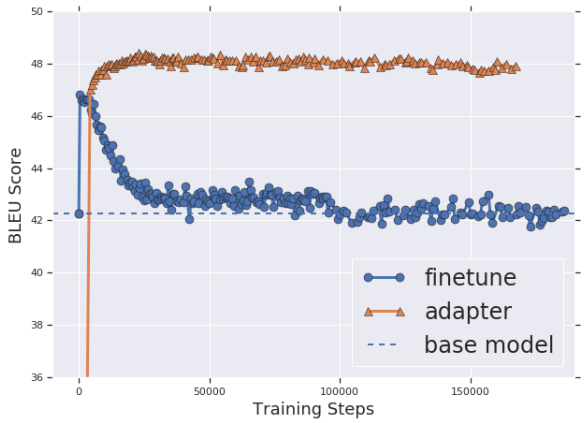

Figure 5: IWSLT dev performance vs number of in-domain adaptation steps when adapting with fine-tuning vs adapters.

5 Massively Multilingual Machine Translation

To stress test our adapters based approach, we apply this to a massively multilingual translation task on a real world dataset (Arivazhagan et al., 2019). Most previous literature in multilingual NMT focuses on improving the performance of low resource languages (Zoph et al., 2016; Firat et al., 2016; Neubig and Hu, 2018), often ignoring the source language performance of the adapted model. However, the goal of our work is to enable training a single model for all language pairs, in order to get benefits of transfer on low resource language pairs, without losing performance in the high resource setting.

5.1 Dataset

To highlight the flexibility of an adapters based approach, we study multilingual NMT on a massive scale, using a corpus generated by crawling and extracting parallel sentences from the web. Our corpus contains parallel documents for 102 languages, to and from English, containing a total of 25 billion sentence pairs (Arivazhagan et al., 2019).[5] The number of parallel sentences per language in our corpus ranges from around 10s of thousands to almost 2 billion. Figure 6 illustrates the data distribution across languages for all 102 languages studied in this paper.

5.2 Using Adapters for multilingual NMT

Our approach to using adapters for multilingual NMT diverges from domain adaptation, owing to the differences in the two tasks.

In the domain adaptation setting, while the input and output distributions of the adaptation domain might differ from that of the base, the set of inputs and outputs is pretty much the same. In mathematical terms, both the base and adaptation domain distributions, D_S and D_T respectively, are defined on the same support set $\{X, Y\}$.

On the other hand, in multilingual NMT, the support sets of different language pairs have very little overlap. In this setting, adapting a model to a new language pair without learning the embeddings and softmax parameters (which correspond to the input and output support sets) would be an extremely difficult task. Following the approach used for domain adaptation in Section 4.2 might not be possible here. We modify our approach to expand the input-output distribution of our initial pre-trained model to all language pairs we are interested in supporting, i.e. we can't add any new language pairs to the model during adaptation, but we use the adaptation stage to improve performance on languages learnt during pre-training.

For multilingual NMT, we follow the following two step approach:

- Global training: Train a fully shared model on all language pairs, with the goal of maximizing transfer to low resource languages.
- Refinement: Fine-tuning language pair specific adapters for all high resource languages, to recover lost performance during step 1. This step can only be applied for language pairs learned during global training.

5.3 Models and Hyper-parameters

We first train dedicated bilingual models on all language pairs to ground our multilingual analyses. We perform all our experiments with variants of the Transformer architecture (Vaswani et al., 2017). For most bilingual experiments, we use a larger version of Transformer Big containing 375M parameters (Chen et al., 2018), and a shared source-target sentence-piece model (SPM) (Kudo

[5] Limited to approximately this amount for experimentation.

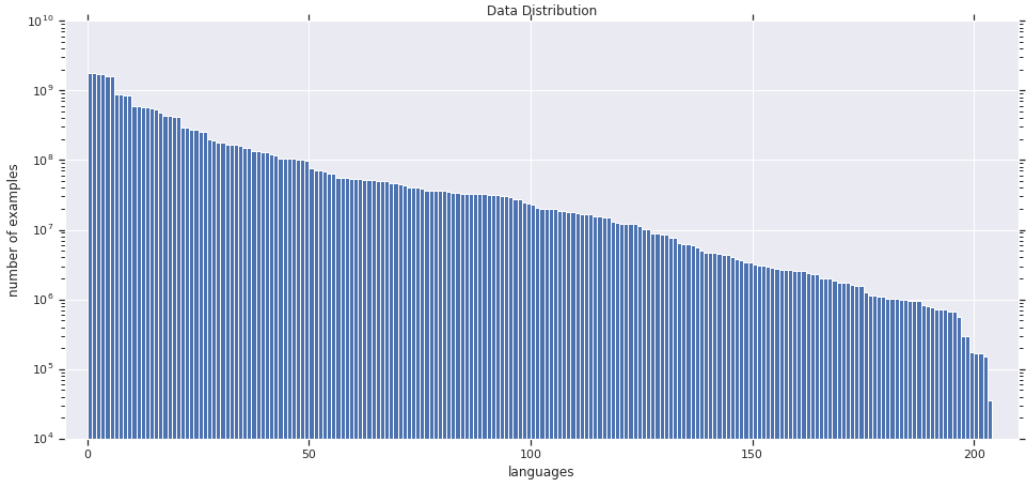

Figure 6: Per language pair data distribution of the dataset used for our multilingual experiments (for 102 languages, 204 language pairs to and from English). The y-axis depicts the number of training examples available per language pair on a logarithmic scale. Dataset sizes range from the order of 10^4 for the lowest resource language pairs to the order of 10^9 for the largest.

and Richardson, 2018) vocabulary with 32k tokens. We tune different values of dropout (Srivastava et al., 2014), depending on the dataset size for each language pair. For most medium and low resource languages we also experiment with Transformer Base. All our models are trained with Adafactor (Shazeer and Stern, 2018) with momentum factorization, a learning rate schedule of (3.0, 40K), and a per-parameter norm clipping threshold of 1.0. For Transformer Base models, we use a learning rate schedule of (2.0, 8K). BLEU scores are computed on the checkpoint with the best validation performance, on true-cased output and references.[6]

We now describe our approach for training the multilingual models. Due to the large imbalance in our training dataset (Figure 6), we first design a sampling strategy to simultaneously train a single model on all 204 language pairs. Sampling directly from the data distribution results in good performance on high resource languages, but low resource languages get starved. Sampling equally from all language pairs results in huge boost in low resource translation performance, but high resource languages perform significantly worse than their bilingual baselines.

To balance between high and low resource language pairs, we use a temperature based sampling strategy (Arivazhagan et al., 2019). For a given language pair, l_{12}, let D_{l12} be the size of the available parallel corpus. Then if we sample from the union of the datasets, the probability of the sample being from language pair l_{12} is $p_{l_{12}} = \frac{D_{l_{12}}}{\Sigma_{l_{12}} D_{l_{12}}}$. We set the probability of our sampled distribution to be proportional to $p_{l_{12}}^{\frac{1}{T}}$, where T is the sampling temperature. Now, $T = 1$ corresponds to true data distribution and $T = 100$ corresponds to an (almost) equal number of samples for each language. We use $T = 5$ for our multilingual model.

We train a single Transformer Big simultaneously on all 204 language pairs (102 languages to and from English), with the same hyper-parameter settings as the bilingual model. However, we use a shared SPM vocab with 64K tokens, generated using the same sampling distribution ($T = 5$) used during training. We additionally use character coverage of 0.999995 to ensure our vocab contains most of the alphabets for all 103 languages. Please refer (Arivazhagan et al., 2019) for additional training details for the base multilingual model.

Following global pre-training on all language pairs, we inject and fine-tune language pair specific adapters. The fine-tuning stage is performed separately for each language pair to reduce the device memory needed for the training process. The fine-tuned adapters can then be combined together into a single model after this stage. For fine-tuning, we use the same hyper-parameter used during global pre-training, but reset our optimizer

[6]We used an in-house implementation of mteval-v13a.pl from Moses to evaluate BLEU scores for our multilingual experiments.

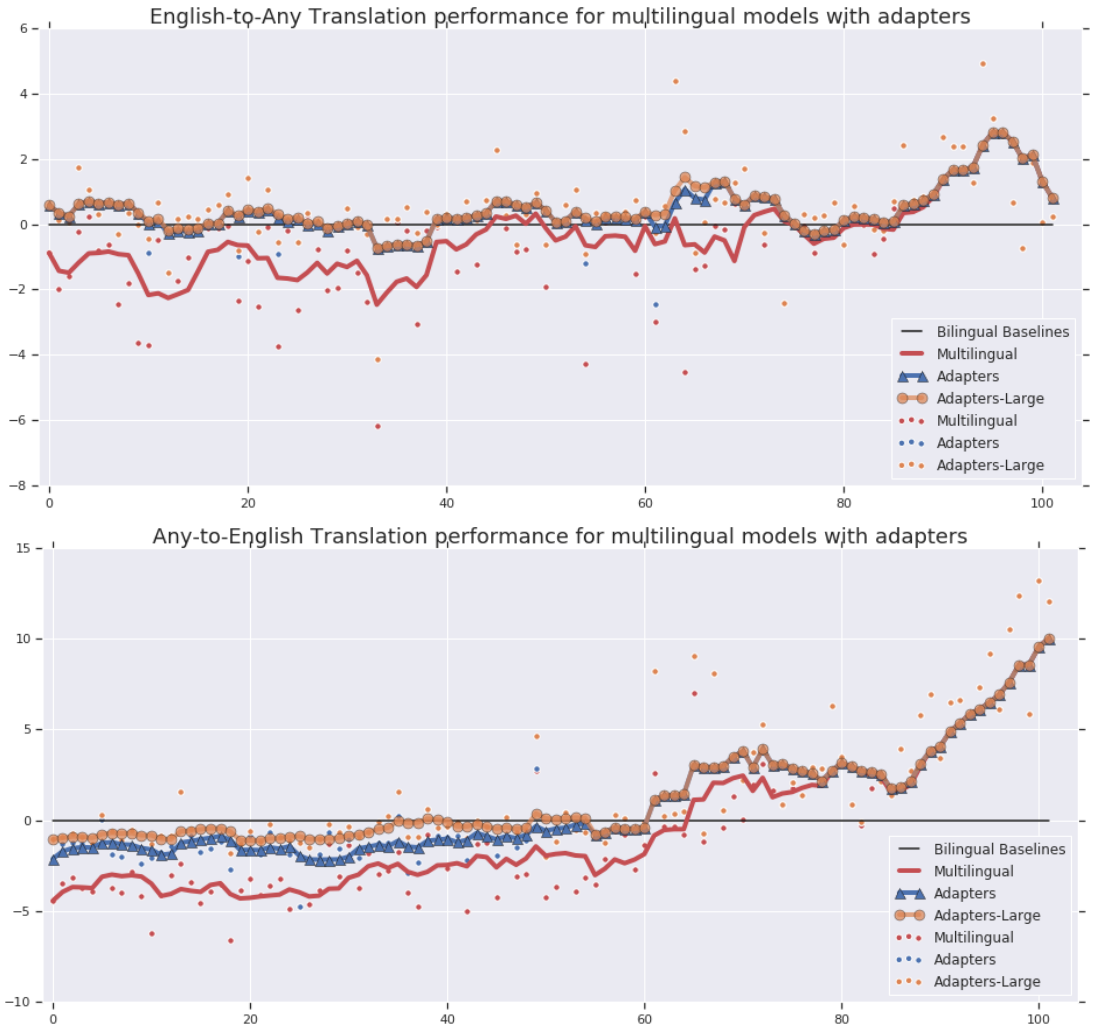

Figure 7: Trendlines depicting translation performance improvement in multilingual models with residual adapters. From left to right, languages are arranged in decreasing order of available training data. y-axis depicts the BLEU score relative to the bilingual baseline trained on the corresponding language pair. The plots correspond to the following models: (1.) Red: Multilingual model trained with sampling temperature, $T = 5$ (2.) Blue: Multilingual model + Small adapters, $b = 2048$ (3.) Pink: Multilingual model + Large adapters, $b = 4096$.
Note: For adapter experiments, we choose the best performance between $b = 0$, $b = 2048$ and $b = 4096$.

accumulators and restart from step 0. For our experiments we use the same bottle-neck dimension, $b = 2048$, for all language pairs. This was meant to reduce the number of experiments given the large number of language pairs in our setup. For language pairs that were worse than their bilingual models after adding adapters with $b = 2048$, we re-run fine-tuning with larger adapters, with $b = 4096$. In an ideal setting, the bottle-neck could be larger for the highest resource languages and $b = 0$ (no adapters) for the smallest languages.

5.4 Results and Analysis

We plot the translation quality on different language pairs in Figure 7. As we can see, the multilingual model significantly out-performs the bilingual baselines in the extremely low resource setting. These gains are even more amplified when translating into English, agreeing with previous work in multilingual NMT (Neubig and Hu, 2018; Aharoni et al., 2019). However, owing to the huge training corpus, we observe significant performance deterioration in the high resource languages. We attribute this deterioration to two factors: (i) Languages compete for capacity given the limited model size, and (ii) The model converges much before it trains on significant portions of the high resource datasets.

As is apparent from Figure 7, performance on high and medium resource languages improves

by huge margins after the second stage of training (adapter based refinement). Fine-tuning with adapters allows the model to see larger portions of the training data for high resource languages, and converges faster than training a model from scratch since it only updates a very small fraction of the model parameters (for most language pairs, the second stage converges within 20-50k steps, depending on the corpus size). For high resource languages, especially when translating into English, we observe further performance improvements when increasing adapter size. This again highlights the flexibility of adapters, it is possible to adjust the adapter capacity to match the complexity and resource size of the target task.

While adapters help us bridge most of the gap between bilingual and multilingual models, we still observe a minor regression for high resource languages translating into English, compared to the bilingual baselines. Although it might be possible to reduce this gap further by increasing the adapter size beyond $b = 4096$, there might be more efficient ways to approach this problem, including more expressive network architectures for adapters, joint fine-tuning of adapters and global model parameters, etc. However, we leave these studies to future work.

6 Conclusion

In this work, we proposed *light-weight adapters*, a simple yet efficient way for adapting large scale neural machine translation models. Our proposed approach, by injecting small task-specific adapter layers between the frozen base model layers during adaptation, enables the final network to adapt to multiple target tasks simultaneously, without forgetting the original parameters.

We evaluate light-weight adapters on two different adaptation tasks, domain adaptation and multilingual NMT. Experiments support the flexibility and scalability of *light-weight adapters*, (i) yielding comparable or better results when compared with the standard full fine-tuning or bilingual baselines, (ii) without the need for any hyper-parameter tuning across varying adaptation dataset sizes and model capacities.

With a large set of globally shared parameters and small interspersed task-specific layers, adapters allow us to train and adapt a single model for a huge number of languages and domains. We hope that this work would motivate further research into massively multitask and universal translation models.

Acknowledgments

We would like to thank the Google Translate and Lingvo development teams for their foundational contributions to this project. We would also like to thank Neil Houlsby, Anjuli Kannan and Yonghui Wu for helpful discussions early on in the project, and Wolfgang Macherey, Markus Freitag, Ciprian Chelba, Naveen Arivazhagan, Zhifeng Chen and the anonymous EMNLP reviewers for their insightful comments.

Abstract

This work introduces a machine translation task where the output is aimed at audiences of different levels of target language proficiency. We collect a high quality dataset of news articles available in English and Spanish, written for diverse grade levels and propose a method to align segments across comparable bilingual articles. The resulting dataset makes it possible to train multi-task sequence-to-sequence models that translate Spanish into English targeted at an easier reading grade level than the original Spanish. We show that these multi-task models outperform pipeline approaches that translate and simplify text independently.

1 Introduction

Generating text at the right level of complexity can make machine translation (MT) more useful for a wide range of users. As Xu et al. (2015) note, simplifying text makes it possible to develop reading aids for people with low-literacy (Watanabe et al., 2009; De Belder and Moens, 2010), for non-native speakers and language learners (Petersen and Ostendorf, 2007; Allen, 2009), for people who suffer from language impairments (Carroll et al., 1999; Canning et al., 2000; Inui et al., 2003), and for readers lacking expert knowledge of the topic discussed (Elhadad and Sutaria, 2007; Siddharthan and Katsos, 2010). Such readers would also benefit from MT output that is better targeted to their needs by being easier to read than the original.

Prior work on text complexity has focused on simplifying input text in one language, primarily English (Chandrasekar et al., 1996; Coster and Kauchak, 2011; Siddharthan, 2014; Xu et al., 2015; Zhang and Lapata, 2017; Scarton and Specia, 2018; Kriz et al., 2019; Nishihara et al., 2019). Simplification has been used to improve MT by restructuring complex sentences into shorter and simpler segments that are easier to translate (Gerber and Hovy, 1998; Štajner and Popovic, 2016; Hasler et al., 2017). Contemporaneously to our work, Marchisio et al. (2019) show that tagging the English side of parallel corpora with automatic readability scores can help translate the same input in a simpler or more complex form. Our work shares the goal of controlling translation complexity, but considers a broader range of reading grade levels and simplification operations grounded in professionally edited text simplification corpora.

Building a model for this task ideally requires rich annotation for evaluation and supervised training that is not available in bilingual parallel corpora typically used in MT. Controlling the complexity of Spanish-English translation ideally requires examples of Spanish sentences paired with several English translations that span a range of complexity levels. We collect such a dataset of English-Spanish segment pairs from the Newsela website, which provides professionally edited simplifications and translations. By contrast with MT parallel corpora, the English and Spanish translations at different grade levels are only comparable. They differ in length and sentence structure, reflecting complex syntactic and lexical simplification operations.

We adopt a multi-task approach to control complexity in neural MT and evaluate it on complexity-controlled Spanish-English translation. Our extensive empirical study shows that multitask models produce better and simpler translations than pipelines of independent translation and simplification models. We then analyze the strengths and weaknesses of multitask models, focusing on the degree to which they match the target complexity, and the impact of training data types and reading grade level annotation.[1]

2 Background

Given corpora of parallel complex-simple segments, text simplification can naturally be framed as a translation task, borrowing and adapting model architectures originally designed for MT. Xu et al. (2016) provide a thorough study of statistical MT techniques for English text simplification, and introduce novel objectives to measure simplification quality. Interestingly, they indirectly make use of parallel translation corpora to derive simplification paraphrasing rules by bilingual pivoting (Callison-Burch, 2007). Zhang and Lapata (2017) train sequence-to-sequence models to translate from complex to simple English using reinforcement learning to directly optimize the metrics that evaluate complexity (SARI) and fluency and adequacy (BLEU). Scarton and Specia (2018) address the task of producing text of varying levels of complexity for different target audiences. They show that neural sequence-to-sequence models informed by target-complexity tokens inserted in the input sequence perform well on this task. While the vast majority of text simplification work has focused on English, Spanish (Štajner et al., 2015), Italian (Brunato et al., 2016; Aprosio et al., 2019) and German (Klaper et al., 2013) have also received some attention.

While most MT approaches only indirectly capture style properties (e.g., via domain adaptation), a growing number of studies share the goal of considering source texts and their translation in their pragmatic context. Mirkin and Meunier (2015) introduce personalized MT. Rabinovich et al. (2016) and Vanmassenhove et al. (2018) suggest that the gender of the author is implicitly marked in the source text and that dedicated statistical and neural systems better preserve gender traits in MT output. Neural MT has enabled more flexible ways to control stylistic properties of MT output. Sennrich et al. (2016) first propose to append a special token to the source that neural MT models can attend to and to select the formal (Sie) or informal (du) version of second person pronouns when translating into German. Niu et al. (2018) show that multi-task models can jointly translate between languages and styles, producing formal and informal translations with broader lexical and phrasal changes than the local pronoun changes in Sennrich et al. (2016). Closest to our goal, Marchisio et al. (2019) address the task of producing either simple or complex translations of the same input, using automatic readability scoring of parallel corpora. They show that training distinct decoders for simple and complex language allows better complexity control than using the target complexity as a side-constraint. By contrast, our approach exploits text simplification corpora for richer supervision for both training and evaluation.

3 A Multi-Task Approach to Complexity Controlled MT

Task We define **complexity controlled MT** as a task that takes two inputs: an input language segment s_i and a target complexity c. The goal is to produce a translation s_o in the output language that has complexity c. For instance, given input Spanish sentences in Table 1, complexity controlled MT aims to produce English translations at a specific level of complexity, which might differ from the complexity of the original Spanish.

Model We model $P(s_o|s_i, c; \theta)$ as a neural encoder-decoder with attention (Bahdanau et al., 2015). This architecture has been used successfully for the two related tasks of text simplification (Wang et al., 2016; Zhang and Lapata, 2017; Nisioi et al., 2017; Scarton and Specia, 2018) and machine translation (Bahdanau et al., 2015). The encoder constructs hidden representation for each word in the input sequence, while the decoder generates the target sequence, conditioned on hidden source representations. We hypothesize that training a single encoder-decoder model to perform the two distinct tasks of machine translation and text simplification will yield a model that can perform complexity controlled MT. We adopt the multi-task framework proposed by Johnson et al. (2016) to train multilingual neural MT systems.

Representing target complexity Target complexity c can be incorporated in sequence-to-sequence models as a special token appended to the beginning of the input sequence, which acts as a side constraint. The encoder encodes this token in its hidden states as any other vocabulary token, and the decoder can attend to this representation to guide the generation of the output sequence. This simple strategy has been used in MT to control second person pronoun forms when translat-

at https://Newsela.com/data/. Scripts to replicate our model configurations and our cross-lingual segment aligner are available at https://github.com/sweta20/ComplexityControlledMT.

Table 1: Cross-lingual Newsela examples: the Spanish text s_i of complexity, or reading grade level, c_i is automatically aligned to English text s_o of c_o. Simplification transformations range from sentence splitting and deletions to paraphrasing and lexical substitution.

ing into German (Sennrich et al., 2016), to indicate the target language in multilingual MT (Johnson et al., 2016), and to obtain formal or informal translations of the same input (Niu et al., 2018). In monolingual text simplification tasks (Scarton and Specia, 2018), the reading grade level has been encoded as such a special token.

Training Data and Objectives Fully supervised training would ideally require translation samples with outputs representing different levels of complexity for the same input segment. However, constructing such data at the scale required to train deep neural networks is expensive and unrealistic. Our multi-task training configuration lets us exploit different types of training examples to train shared encoder-decoder parameters θ. We use the following samples/tasks:

- Complexity controlled MT samples (s_i, c_o, s_o): These are the closest samples to the task at hand, but are hard to obtain. They are used to defined the complexity-controlled MT loss

$$\mathcal{L}_{CMT} = \sum_{(s_i, c_o, s_o)} \log P(s_o|s_i, c_o; \theta) \quad (1)$$

- MT samples (s_i, s_o): These are sentence pairs drawn from parallel corpora. They are available in large quantities for many language pairs (Tiedemann, 2012) and are used to define the MT loss

$$\mathcal{L}_{MT} = \sum_{(s_i, s_o)} \log P(s_o|s_i; \theta) \quad (2)$$

- Text simplification samples in the MT target language $(s_o, c_{s'_o}, s'_o)$ where s'_o is a simplified version of complexity $c_{s'_o}$ for input s_o, which are likely to be available in much smaller quantities than MT samples.

$$\mathcal{L}_{Simplify} = \sum_{(s_o, c_{s'_o}, s'_o)} \log P(s_o|s'_o c_{s'_o}; \theta) \quad (3)$$

The multi-task loss is simply obtained by summing the losses from individual tasks: $\mathcal{L}_{CMT} + \mathcal{L}_{MT} + \mathcal{L}_{Simplify}$.

4 The Newsela Cross-Lingual Simplification Dataset

We build on prior work that used the Newsela dataset for English or Spanish text simplification by automatically aligning English and Spanish segments of different complexity to enable complexity-controlled machine translation.

The Newsela website provides high quality data to study text simplification. Xu et al. (2015) argue that text simplification research should be grounded in texts that are simplified by professional editors for specific target audiences, rather than more general-purpose crowd-sourced simplifications such as those available on Wikipedia. They show that Wikipedia is prone to sentence alignment errors, contains a non-negligible amount of inadequate simplifications, and does not generalize well to other text genres. By contrast, Newsela is an instructional content platform meant to help teachers prepare curriculum that match the language skills required at each grade level. The Newsela corpus consists of English articles in their original form, 4 or 5 different versions rewritten by professionals to suit different grade levels as well as optional translations of original and/or simplified English articles into Spanish resulting in 23,130 English and 5,320 Spanish articles with grade annotations respectively.

This section introduces our method to align English and Spanish segments across complexity levels, and the resulting bilingual dataset.

4.1 Cross-Lingual Segment Alignment

Extracting training examples from this corpus requires aligning segments within documents. This is challenging because text is neither simplified nor translated sentence by sentence, and as a result, equivalent content might move from one sentence to the next. Past work has introduced techniques to align segments of different complexity within documents of the same language (Xu et al., 2015; Paetzold et al., 2017; Štajner et al., 2018).

Complexity controlled MT requires aligning segments of different complexity in English and Spanish. Existing methods for aligning sentences in English and Spanish parallel corpora are not well suited to this task. For instance, the Gale-Church algorithm (Gale and Church, 1993) assumes that aligned sentences should have similar length. This assumption does not hold if the English article is a simplification of the Spanish article. Consider the following Spanish text and its English translation in Newsela:

Spanish: LA HAYA, Holanda - Te has tomado alguna vez una selfie?, Hoy en día es muy fácil. Solo necesitas un teléfono inteligente.

Google Translated English: THE HAGUE, Netherlands - Have you ever taken a selfie? Today is very easy. You only need a smart phone.

Original English Version: THE HAGUE, Netherlands - All you need is a smartphone to take a selfie. It is that easy.

As a result, we adapt a monolingual text simplification aligner for cross-lingual alignment. MASSAlign (Paetzold et al., 2017) is a Python library designed to align segments of different length within comparable corpora of the same language. It employs a vicinity-driven search approach, based on the assumption that the order in which information appears is roughly constant in simple and complex texts. A similarity matrix is created between the paragraphs/sentences of aligned documents/paragraphs using a standard bag-of-words TF-IDF model. It finds a starting point to begin the search for an alignment path, allowing long-distance alignment skips, capturing 1-N and N-1 alignments. To leverage this alignment flexibility, we apply MASSAlign to English articles and Spanish articles machine translated into English by Google translate.[2] An important property of Google translated articles is that they are aligned 1-1 at the sentence level. This lets us deterministically find the Spanish replacement for the aligned Google translated English version returned by MASSAlign. Translation quality is high for this language pair, and even noisy translated articles contain enough signal to construct the similarity matrix required by MASSAlign.

4.2 Resulting Dataset

We thus create: both samples for complexity controlled MT (s_i, c_o, s_o) and traditional monolingual text simplification samples $(s_o, c_{s'_o}, s'_o)$ that can be used by the multi-task model (Section 3). Since the properties of Newsela monolingual simplification samples have been studied thoroughly by Xu et al. (2015), we present key statistics for the cross-lingual simplification examples only. Table 2 contrasts Newsela parallel segments with bilingual parallel sentences drawn from the OPUS corpus (Tiedemann, 2009). We use Global Voices and News Commentary from OPUS corpus as it has the most similar domain to the Newsela data. Aligned segments in Newsela are about twice as long as segments in parallel corpora, and contain more than two sentences on each side on average. By contrast, parallel corpora samples align sentences one-to-one on average.

English				
Newsela	43.37	2.65	39,012	7,139,717
Global Voices	21.93	1.06	222,383	15,208,054
News	23.76	1.04	49,589	4,939,085

Table 2: Comparisons of the English-Spanish Newsela corpus with machine translation corpora from OPUS drawn from Global Voices and News Commentary.

Articles are distributed across reading levels spanning grades 2 to 12 for both English and English-Spanish pairs. Table 3 highlights the vocabulary differences among the different grade levels for the Newsela Spanish-English corpus. The vocabulary size of the corpus corresponding to lower grade level is smaller as compared to higher complexity levels. Also, complex sentences have more words per sentence on average but fewer sentences per segment compared to their simplified counterparts. Simple sentences differ from complex sentences in various ways, ranging from sentence splitting and content deletion to paraphrasing and lexical substitutions, as illustrated in Table 1.

5 Experiment Settings

We evaluate **complexity controlled MT** using a subset of the 150k Spanish-English segment pairs extracted from Newsela as described in Section 4. We select Spanish and English segments that have different reading grade levels, so that given a Spanish input, the task consists in producing an English translation which is simpler (lower reading grade level) than the Spanish input.The train/development/test split ensures that there is no overlap between articles held out for testing and articles used for training. We refer to the corresponding training examples as **MT+simplify** since it represents the joint task of translation and simplification.

5.1 Evaluation Metrics

We evaluate the truecased detokenized output of our models using three automatic evaluation metrics, drawing from both machine translation and text simplification evaluation.

BLEU (Papineni et al., 2002) estimates translation quality based on n-gram overlap between system output and references. However it does not separate mismatches due to meaning errors and mismatches due to simplification errors.

SARI (Xu et al., 2016)[3] is designed to evaluate text simplification systems by comparing system output against references and against the input sentence. It explicitly measures the goodness of words that are added, deleted and kept by the systems. Xu et al. (2016) showed that BLEU shows high correlation with human scores for grammaticality and meaning preservation and SARI shows high correlation with human scores for simplicity. In the cross-lingual setting, we cannot directly compare the Spanish input with English hypotheses and references, therefore we use the baseline machine translation of Spanish into English as a pseudo-source text. The resulting SARI score directly measures the improvement over baseline machine translation.

In addition to BLEU and SARI, we report Pearson's correlation coefficient (PCC) to measure the strength of the linear relationship between the complexity of our system outputs and the complexity of reference translations. Heilman et al. (2008) use it to evaluate the performance of reading difficulty prediction. Here we estimate the reading grade level complexity of MT outputs and reference translations using the Automatic Readability Index (ARI)[4] score, which combines evidence from the number of characters per word and number of words per sentence using hand-tuned

12	42,355	53.98	1.96	-	-	-

Table 3: Grade level Statistics of the Newsela Spanish-English corpus. Vocabulary size decreases with the reading grade level. Simpler segments contain fewer sentences and are often shorter that complex segments.

weights (Senter and Smith, 1967):

$$ARI = 4.71(\frac{chars}{words}) + 0.5(\frac{words}{sents}) - 21.43 \quad (4)$$

5.2 Training Data

In addition to the Newsela **MT+Simplify** training examples described above, which are of the form (s_i, c_o, s_o), we use monolingual English simplification data, bilingual parallel training data and Spanish simplification data.

Newsela Simplification provides training examples of the form $(s_o, c_{s'_o}, s'_o)$, where s_o and s'_o are in the same language. We refer to this data as **Simplify** data. It is used for training multi-task models and for auxiliary evaluation on English only. Our version of this corpus has 513k English segment pairs extracted using the method by Paetzold and Specia (2016). Similar to Scarton and Specia (2018), an original article 0 can be aligned to up to four simplified versions: 1,2,3 and 4. Here 4 denotes the least simplified level and 0 represents the most simplified level. The train split consists of 460k instance pairs whereas the development and test sets consist of roughly 20K instances, drawn from the same articles as the MT+preserve and MT+simplify test set. For Spanish, we have 110k segment pairs, which will be used to train the Spanish simplification baseline.

Bilingual Parallel Data (Newsela) We also extract parallel Spanish-English segments from Newsela based on aligned segments between Spanish and English articles that have the same reading grade level. We use this dataset to provide in-domain MT training examples which includes roughly 70k instances.

All datasets are pre-processed using Moses tools for normalization, tokenization and true-casing (Koehn et al., 2007). We further segment tokens into subwords using a joint source-target byte pair encoding model with 32,000 operations (Sennrich et al., 2015).

5.3 Sequence-to-Sequence Model Configuration

We use the standard encoder-decoder architecture implemented in the Sockeye toolkit (Hieber et al., 2017). Both encoder and decoder have two Long Short Term Memory (LSTM) layers (Bahdanau et al., 2015), hidden states of size 500 and dropout of 0.3 applied to the RNNs of the encoder and decoder which is same as what was used by Scarton and Specia (2018). We observe that dot product based attention works best in our scenario, perhaps indicating that the task of complexity controlled translation requires mostly local changes that do not lead to long distance reorderings across sentences. We train using the Adam (Kingma and Ba, 2014) optimizer with a batch size of 256 segments and checkpoint the model every 1000 updates. Training stops after 8 checkpoints without improvement of validation perplexity. The vocabulary size is limited to 50000. We decode with a beam size of 5. Grade side-constraints are defined using a distinct special token for each grade level (from 2 to 12). The constraint token corresponds to the grade level of the target instance.

5.4 Baseline

We contrast the multi-task system with pipeline based approaches, where translation and simplification are treated as independent consecutive steps. We train a neural MT model to perform translation from Spanish to English and other neural MT models to perform monolingual text simplification for Spanish and English respectively. In the first pipeline setup, the output from the translation model is fed as input to an English simplification model while in the other, the output from the Spanish simplification model is fed as input to an translation model. As Scarton and Specia (2018), we simply use grade level tokens as side constraints on English simplification examples to control output complexity.[5]

6 Evaluation of Complexity Controlled MT

We compare pipeline and multitask models on the Newsela complexity controlled MT task (Table 4). Overall, results show that compared to pipeline models, multitask models produce complexity controlled translations that better match human references according to BLEU. SARI suggests that multitask translations are simpler than baseline translations, and their resulting complexity correlates better with reference grade levels according to PCC.

The two pipeline models use the same MT system, therefore the difference between them comes from text simplification: using English simplification (first pipeline) outperforms Spanish simplification (second pipeline) according to BLEU and PCC, but not SARI. This can be explained by the smaller amount of Spanish simplification training data, which yields a model that generalizes poorly.

The "All tasks" model highlights the strengths of the multi-task approach: combining training samples from many tasks yields improvements over the "Translate and Simplify" multitask model which is trained on the exact same data as the pipelines. However, even without additional training data, the multitask "Translate and Simpify" model improves over baselines mainly by simplifying the output more, which suggests that the simplification component of the multitask model benefits from the additional MT training data.

[5] Additional constraints based on simplification operations were also used in that work but did not provide substantial benefits when operations are predicted based on the input.

Qualitative analysis suggests that the multi-task model is capable of distinguishing among different grade levels and the simplification operations performed for different grade levels are gradual. Table 5 illustrates simplification operations observed for a fixed grade 12 Spanish input into English with target grade levels ranging from 9 to 3. When translating to a nearby grade level, for example 9, the model roughly translates the entire input. For lower grade levels such as 7 and 5, lexical simplification and sentence splitting is observed. For the simplest grade level, the model deletes additional content. More examples are provided in the Appendix (Table 13).

Complexity cont. MT	BLEU	SARI	PCC
Pipeline Baselines			
Translate then Simplify	21.98	30.4	0.436
Simplify then Translate	17.09	37.4	0.275
Multitask Models			
Translate and Simplify	22.51	44.8	0.572
All Tasks	**22.75**	**45.0**	**0.608**

Table 4: Compared to pipeline models, multitask models produce complexity controlled translations that better match human references (BLEU), that are simpler (SARI), and whose resulting complexity correlates better with the target grade level (PCC). Pipeline models are trained on Newsela Simplification data and MT parallel data from Newsela and OPUS. "Translate and Simplify" uses the exact same data in a multi-task model. The "All tasks" model uses all data available, including Newsla MT+Simplify examples.

7 Analysis

7.1 Output Grade Analysis

We aim to better understand to what degree models simplify the input text: how often does the output complexity exactly matches that of the reference? Does this change depend on the distance between input and output complexity levels? Table 6 compiles Adjacency Accuracy scores (Heilman et al., 2008), which represent the percentage of sentences where the system output complexity is within 1 or 2 grades of the reference text. We derive the reading grade levels from ARI (Senter and Smith, 1967) and conduct this analysis for the best pipeline ("Translate then Simplify") and multitask models ("All Tasks"). These adjacency scores are broken down according to the distance between input and target grade levels.

12	Ahora el museo Mauritshuis está por inaugurar una exposición dedicada a los autorretratos del siglo XVII, que destaca las similitudes y diferencias entre las fotos modernas y las obras de arte históricas.
9	Now the museum Mauritois is launching an exhibition dedicated to the 18th century authoritations, highlighting the similarities and differences between modern photos and historical artworks.
7	The museum is **now set to open** an exhibition dedicated to the 18th century authoritations, highlighting the similarities and differences between modern photos and historical artworks.
5	The museum is now set to open an exhibit dedicated to the 18th century. **It highlights** the similarities and differences between modern photos and historical artworks.
3	The museum is now set to open an exhibit dedicated to the 18th century. It **shows** the similarities and differences between modern photos and art works.

Table 5: Example of multi-task model outputs when translating grade 12 Spanish into increasingly simpler English.

Adj.		Source Grade - Target Grade									
level	Model	1	2	3	4	5	6	7	8	9	10
1	Pipeline	**0.593**	**0.629**	0.594	0.556	0.524	0.493	0.472	0.457	0.448	0.444
	Multitask	0.59	0.626	0.594	**0.561**	**0.529**	**0.504**	**0.482**	**0.467**	**0.458**	**0.453**
2	Pipeline	**0.717**	**0.759**	**0.786**	0.747	0.713	0.678	0.654	0.637	0.626	0.621
	Multitask	0.711	0.755	0.784	**0.753**	**0.725**	**0.696**	**0.67**	**0.653**	**0.642**	**0.636**

Table 6: Adjacency ARI accuracy within grade level given by Adjacency level for the system output with respect to the target grade: Multitask model is able to better capture the target grade than the pipeline model when the difference between the source and the target grade is greater than 3.

When the source and target grades are close, roughly 60% of system outputs that are within a ± 1 window of the correct grade level. The pipeline model matches the target grade slightly better than the multitask model. However, in the more difficult case where the difference between source and target grades is larger than three, the multitask model outperforms the pipeline. Increasing the adjacency window to ± 2 pushes the percentage of matches in the 70s.

Overall these results show that multitask and pipeline models are able to translate and simplify, but that they do not yet fully succeed at precisely controlling the complexity of their output to match a specific target reading grade.

7.2 Ablation Experiments

Table 7 shows the impact of different training data types on the multitask model using ablation experiments. OPUS improves BLEU and SARI performance across the board. However, using OPUS without any Newsela MT data (Row 4) hurts the correlation score, indicating the importance of in-domain MT data to control complexity. The difference between the performance when using joint translation and simplification (MT+S) examples (Row 2) vs. simplification only (S in Row 3) is small in terms of BLEU (+0.11) and PCC (0.012), indicating that the monolingual simplification dataset can provide simplification supervision when MT+Simplify data is unavailable. The overall best performance for the task is obtained by using all types of training examples.[6]

7.3 Evaluation on Auxiliary Tasks

In addition to complexity controlled MT, the multi-task model can be used to simplify English text, and to translate from Spanish-to-English without changing the complexity. For completeness, we evaluate on these two auxiliary tasks.

Table 8 summarizes the results: the multitask model slightly outperforms a dedicated simplification model on English simplification, showing the benefits of the additional training data from other tasks. By contrast, on the resource-rich MT task, the standalone translation system performs better.

[6] A random sample of outputs from the best model configuration are provided in the Appendix (Table 14).

Newsela			OPUS	Evaluation Metrics		
S	MT+S	MT	MT	BLEU	SARI	PCC
✓	✓	✓	✓	22.75	45.0	0.608
	✓	✓	✓	22.62	44.5	0.584
✓		✓	✓	22.51	44.8	0.572
✓			✓	19.16	43.4	0.468
✓	✓	✓		14.65	41.4	0.521

Table 7: Data ablation experiments showing the impact of different types of training examples on multi-task model. The OPUS parallel corpus is essential to good performance. Simplification data (S) can be used for simplification supervision when joint translation and simplification examples (MT+S) are unavailable.

This can be explained by the fact that the standalone system is only responsible for text translation, while the multi-task model is exposed to samples of more diverse complexity levels during training which damage its ability to preserve complexity.

Task	BLEU	SARI	PCC
English Simplification			
Simplify	55.76	41.7	0.736
Translate and Simplify	**56.47**	41.3	0.730
All Tasks	56.05	**42.1**	0.736
Machine Translation			
Translate	**29.09**	-	**0.769**
Translate and Simplify	27.33	-	0.647
All Tasks	27.63	-	0.658

Table 8: Evaluation on auxiliary tasks: Multitask models trained on both the translation and simplification dataset improves the performance for the task of English Simplification.

7.4 Provenance of Reading Grade Level

Our models control complexity using the gold reading grade level assigned by professional Newsela editors. We investigate the impact of replacing these gold labels by automatic predictions from the ARI metric. ARI can be computed for any English segment, including for MT parallel corpora that are not annotated for complexity.

Table 9 shows that ARI provides an adequate substitute for manually annotated reading grade levels, as BLEU and SARI score remain close when Newsela reading grade levels are replaced by ARI-based tags. However, annotating all data with ARI grades, including the OPUS parallel corpus, hurts BLEU. We attribute this result to the differences in length and number of sentences per segment in OPUS vs. Newsela (Table 2): segments of vastly different lengths can have the same ARI score (Equation 4), thus confusing the multi-task model.

Complexity cont. MT	BLEU	SARI	PCC
Newsela reading grade	22.51	44.80	0.572
ARI on Newsela data	22.26	**45.12**	**0.581**
ARI on all data	20.91	44.75	0.577

Table 9: Complexity controlled MT with automatic vs. manual reading grade level tags: ARI provides an adequate substitute for manually assigned grade levels.

8 Conclusion

We introduce a new task that aims to control complexity in machine translation output, as a proxy for producing translations targeted at audiences with different reading proficiency levels. We construct a Spanish-English dataset drawn from the Newsela corpus for training and evaluation, and adopt a sequence-to-sequence model trained in a multitask fashion.

We show that the multitask model improves performance over translation and simplification pipelines, according to both machine translation and simplification metrics. The reading grade level of the multi-task outputs correlate better with target grade levels than with pipeline outputs. Analysis shows that these benefits come from their ability to combine larger training data from different tasks. Manual inspection also shows that the multi-task model successfully produces different translations for increasingly lower grades given the same Spanish input.

However, even when simplifying translations, multitask models are not yet able to exactly match the desired complexity level, and the gap between the complexity achieved and the target complexity increases with the amount of simplification required. Our datasets and models thus provide a foundation to investigate strategies for a tighter control on output complexity in future work.

Abstract

Multilingual Neural Machine Translation (NMT) models have yielded large empirical success in transfer learning settings. However, these black-box representations are poorly understood, and their mode of transfer remains elusive. In this work, we attempt to understand massively multilingual NMT representations (with 103 languages) using Singular Value Canonical Correlation Analysis (SVCCA), a representation similarity framework that allows us to compare representations across different languages, layers and models. Our analysis validates several empirical results and long-standing intuitions, and unveils new observations regarding how representations evolve in a multilingual translation model. We draw three major conclusions from our analysis, with implications on cross-lingual transfer learning: (i) Encoder representations of different languages cluster based on linguistic similarity, (ii) Representations of a source language learned by the encoder are dependent on the target language, and vice-versa, and (iii) Representations of high resource and/or linguistically similar languages are more robust when fine-tuning on an arbitrary language pair, which is critical to determining how much cross-lingual transfer can be expected in a zero or few-shot setting. We further connect our findings with existing empirical observations in multilingual NMT and transfer learning.

1 Introduction

Multilingual Neural Machine Translation (NMT) models have demonstrated great improvements for cross-lingual transfer, on tasks including low-resource language translation (Zoph et al., 2016; Nguyen and Chiang, 2017; Neubig and Hu, 2018) and zero or few-shot transfer learning for downstream tasks (Eriguchi et al., 2018; Lample and Conneau, 2019; Wu and Dredze, 2019). A possible explanation is the ability of multilingual models to encode text from different languages in a shared representation space, resulting in similar sentences being aligned together (Firat et al., 2016; Johnson et al., 2017; Aharoni et al., 2019; Arivazhagan et al., 2019b). This is justified by the success of multilingual representations on tasks like sentence alignment across languages (Artetxe and Schwenk, 2018), zero-shot cross-lingual classification (Eriguchi et al., 2018) and XNLI (Lample and Conneau, 2019). Although there exist empirical results that suggest that transfer is stronger across similar languages (Zoph et al., 2016; Neubig and Hu, 2018; Wu and Dredze, 2019), the mechanism of generalization in multilingual representations is poorly understood.

While interpretability is still a nascent field, there has been some work on investigating the learning dynamics and nature of representations learnt by neural models (Olah et al., 2018). Singular Value Canonical Correlation Analysis (SVCCA) is one such method that allows us to analyze the similarity between noisy, high-dimensional representations of the same datapoints learnt across different models, layers and tasks (Raghu et al., 2017). SVCCA has been used to understand the learning dynamics and representational similarity in a variety of computer vision (Morcos et al., 2018), language models (Saphra and Lopez, 2018) and NMT (Bau et al., 2018).

In this work, we attempt to peek into the black-box of massively multilingual NMT models, trained on 103 languages, with the lens of SVCCA. We attempt to answer:

- Which factors determine the extent of overlap in the learned representations?
- Is the extent of representational overlap similar throughout the model?

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1565–1575, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- How robust are multilingual NMT representations to fine-tuning on an arbitrary other language?

Answers to the above questions might have large implications on how we approach multilingual models and cross lingual transfer learning. Our work is the first that attempts to understand the nature of multilingual representations and cross-lingual transfer in deep neural networks, based on analyzing a model trained on 103 languages simultaneously.

We structure the study into these sections: In Section 2, we describe the experimental setup and tools used to train and analyze our multilingual NMT model. Following that, we attempt to answer each of the above questions in Sections 3 and 4. Finally in Section 5 we summarize our findings with a discussion of the potential implications.[1]

2 Experimental Setup

2.1 Data and Model

We study multilingual NMT on a massive scale, using an in-house training corpus (Arivazhagan et al., 2019b) generated by crawling and extracting parallel sentences from the web (Uszkoreit et al., 2010). Our dataset contains more than 25 billion sentence pairs for 102 languages to and from English, adding up to 204 direct language pairs.

Having being crawled from the web, our dataset has some important characteristics worth mentioning.

1. **Heavy imbalance between language pairs:** The number of parallel sentences per language pair ranges between 10^4 to 10^9. Figure 1 illustrates the data distribution for all the language pairs we study. Although this skew introduces optimization challenges (see Appendix A.1), it also creates a plausible setup for maximizing the positive language transfer from high-resource to low-resource language pairs, making it possible to study low-resource languages, that would otherwise have been very low quality.[2]

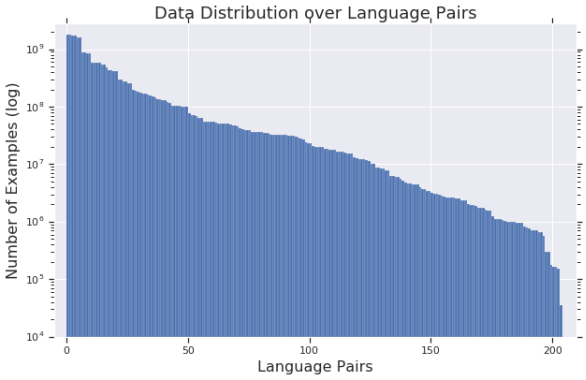

Figure 1: Per language pair data distribution of the dataset used to train our multilingual model. The y-axis depicts the number of training examples available per language pair on a logarithmic scale. Dataset sizes range from 10^4 for the lowest resource language pairs to 10^9 for the largest.

2. **Diversity:** Our corpus has languages belonging to a wide variety of scripts and linguistic families. These characteristics of our dataset make the problem that we study as realistic as possible. Models trained on this massive open-domain dataset are expected to yield rich, complex representations which we attempt to study in this paper.

To minimize confounding factors and control the evaluation set size and domain, we created a multi-way aligned evaluation set containing nearly 3k sentence pairs for all languages.[3] This also allows us to analyze the representational difference and similarity while controlling for semantics.

We use the Transformer-Big (Vaswani et al., 2017) architecture described in Artetxe and Schwenk (2018) for our experiments and share all parameters across language pairs including softmax layer and input/output word embeddings. For vocabulary, we use a Sentence Piece Model (Kudo and Richardson, 2018) with 64k tokens shared on both the encoder and decoder side.

Each set of parallel sentences has a `<2xx>` token prepended to the source sentence to indicate the target language, as in (Johnson et al., 2017). [4]

2.2 SVCCA

In this study we use Singular Value Canonical Correlation Analysis (SVCCA) (Raghu et al., 2017)

[1] Tools for online visualization and representation similarity used in our work will be open-sourced to facilitate further analysis.

[2] We provide baseline BLEU scores for all languages in Appendix A.2, notice the improvements for low-resource languages in our multilingual setup.

[3] Each sentence in our evaluation set is semantically identical across all other languages.

[4] Further details of the model and training routines are given in Appendix A.1.

as our investigation tool. SVCCA is a technique to compare vector representations in a way that is both invariant to affine transformations and fast to compute. We express a layer's representations as its activations on a set of n examples, $X = \{x_1, \ldots, x_n\}$. Let $l_1 \in \mathbb{R}^{n \times d_1}$ and $l_2 \in \mathbb{R}^{n \times d_2}$ be the representations of two neural network layers, with d_1 and d_2 being the dimensions of the layers corresponding to l_1 and l_2 respectively. Given layer activations over the set X, SVCCA does the following:

1. Computes SVD decompositions of l_1 and l_2 to get subspaces $l_1' \in \mathbb{R}^{n \times d_1'}$ and $l_2' \in \mathbb{R}^{n \times d_2'}$ that capture most of the variance in the subspace.[5]

2. Uses Canonical Correlation Analysis (CCA) (Hardoon et al., 2004) to linearly transform l_1' and l_2' to be as aligned as possible, i.e., CCA computes $\tilde{l_1} = W_1 l_1'$ and $\tilde{l_2} = W_2 l_2'$ to maximize the correlations $\bar{\rho} = \{\rho_1, ..., \rho_{min(d_1', d_2')}\}$ between the new subspaces.

As done in (Raghu et al., 2017), we use the mean of the correlations, $\bar{\rho}$, as an approximate measure of the relatedness of representations.

SVCCA for Sequences

Recent work on interpretability for NLU tasks uses methods such as diagnostic tasks (Belinkov et al., 2017; Tenney et al., 2019; Belinkov et al., 2018), attention based methods (Raganato and Tiedemann, 2018) or task analysis (Zhang and Bowman, 2018) and is primarily focused on understanding the linguistic features encoded by a trained model. Some recent work has applied SVCCA (or CCA) to language modeling (Morcos et al., 2018; Saphra and Lopez, 2018; Dalvi et al., 2019) and NMT (Bau et al., 2018; Dalvi et al., 2019). However, while Raghu et al. (2017) compare the learning dynamics of different classes in an image classifier, to the best of our knowledge, we are the first to apply SVCCA to a multilingual NMT or multitask setting. SVCCA was originally proposed for feed-forward neural networks, but our domain requires comparing unaligned sequences in different languages.

Sahbi (2018) proposes an alignment agnostic CCA approach to comparing unaligned data. However, the likelihood matrix D specifying alignment of datapoints across different datasets (say, language A and B) is application specific and infeasible to obtain in a multilingual setting. A simple heuristic is to summarize a set of activations by applying a pooling operation over the set. This is equivalent to assuming that a given token in a sentence from language A is equally likely to be aligned to each token in an equivalent sentence in language B. We perform SVCCA on the hidden representations of the model, averaged over sequence time-steps, for each sentence in our evaluation set. We compare this approach with a naive token level SVCCA strategy in A.3.

SVCCA Across Languages

In all known work using SVCCA, representations of the same data are used for analysis. However, in order to compare representations across languages, we leverage our multi-way parallel evaluation set to compare representations across different languages, since each data point is semantically equivalent across languages.

3 Multilingual NMT Learns Language Similarity

In this section, we use SVCCA to examine the relationship between representations of different languages learned by our massively multilingual NMT model. We compute SVCCA scores of layer-wise activations of a fully trained model between 103 languages pairs in both the Any-to-English and English-to-Any directions.[6]

Visualizing the Representations We first visualize the relationship between languages in their representation space for each layer using Spectral Embeddings (Belkin and Niyogi, 2003) [7]. In our case, we use mean SVCCA scores described in Section 2.2 as a similarity measure. Due to the differing nature of translating multiple languages to English and vice versa, the representation space of these two sets of languages, All-to-English and English-to-Any, behave differently and separate quite clearly (Figure 11 in the Appendix). We

[5] We retain 99% of the variance in our studies.

[6] Our multilingual NMT model is trained on the available training data which is English centric, hence an All-to-All multilingual model internally decomposes into All-to-English (X-En) and English-to-All (En-X) translation bundles, excluding zero-shot directions.

[7] We use the Laplacian Eigenmaps implementation of Spectral Embeddings in scikit-learn as of August 2019.

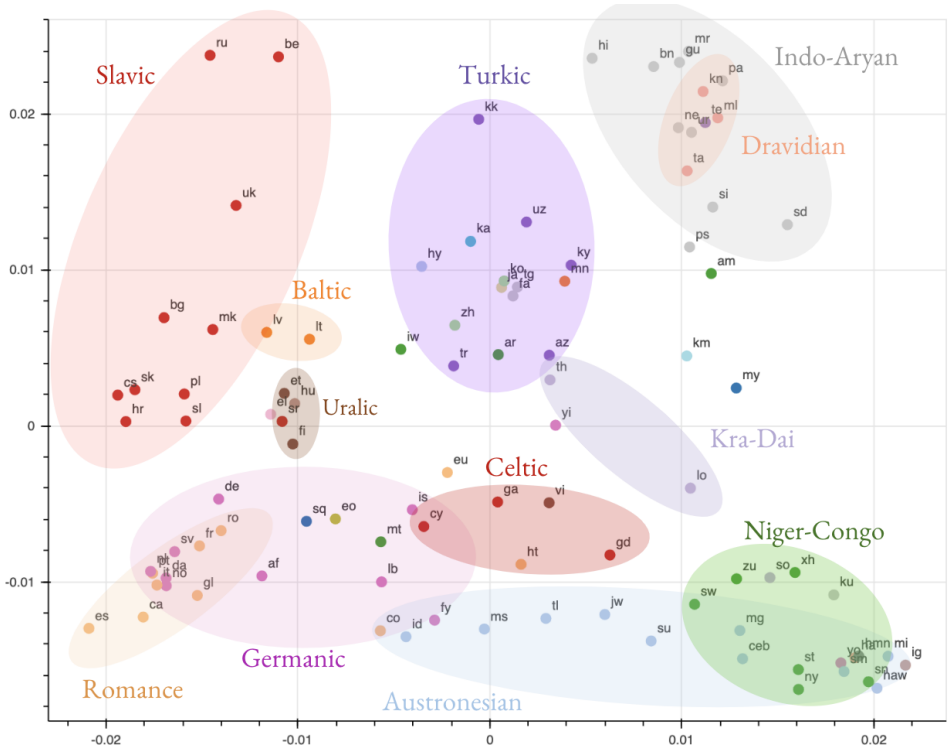

Figure 2: Visualizing clustering of the encoder representations of all languages, based on their SVCCA similarity. Languages are color-coded by their linguistic family. Best viewed in color.

first visualize the encoder representation of all languages in the All-to-English language pair set in Figure 2. For the sake of analysis, we then visualize subsets of the aforementioned 103 languages in Figures 3 and 4. We include visualizations of representations extracted from the embeddings and top layers of the encoder and decoder in the Appendix.

3.1 What is Language Similarity?

In the following sections we draw comparisons between the representational similarity of languages learned by our models, and the linguistic similarity between those languages. While there are entire sub-fields in linguistics devoted to studying similarity (e.g. Comparative Linguistics and Linguistic Typology (Ivić, 2011)), in this paper we define language similarity in terms of membership in the same language family (e.g. Turkic languages), or branch within that family (e.g. Oghuz Turkic languages). Families are groups of languages believed to share a common ancestor, and therefore tend to have similar vocabulary and grammatical constructs. An example phylogenetic language tree is given in Figure 3, on the right.

We also discuss writing systems, including scripts like Cyrillic, Roman, and Ge'ez. While similar languages frequently share the same script, that is not always true. Note that all of these categories[8] are muddled by various factors that are difficult to tease apart, and might be affected by the web-crawled data that we train on. For instance, languages sharing a script may also be part of the same political bloc, influencing what text is on the web. This and other confounding factors make a rigorous comparison exceedingly difficult. For brevity, we label languages in images with their BCP-47 language codes (Phillips and Davis, 2009), which are enumerated in the Appendix, Table 3.

3.2 Representations cluster by language similarity

We first visualize a clustering for all languages together in Figure 2. While there are a few outliers, we can observe some overlapping clusters, including the Slavic cluster on the top-left, the Germanic and Romance clusters on the bottom-left, the Indo-Aryan and Dravidian clusters on the top-right, etc. To analyze language clustering in more detail we

[8] When we refer to languages from a certain category, we only list those that are in our dataset. For example, when listing Turkic languages we exclude Bashkir, because we do not have English-Bashkir parallel data.

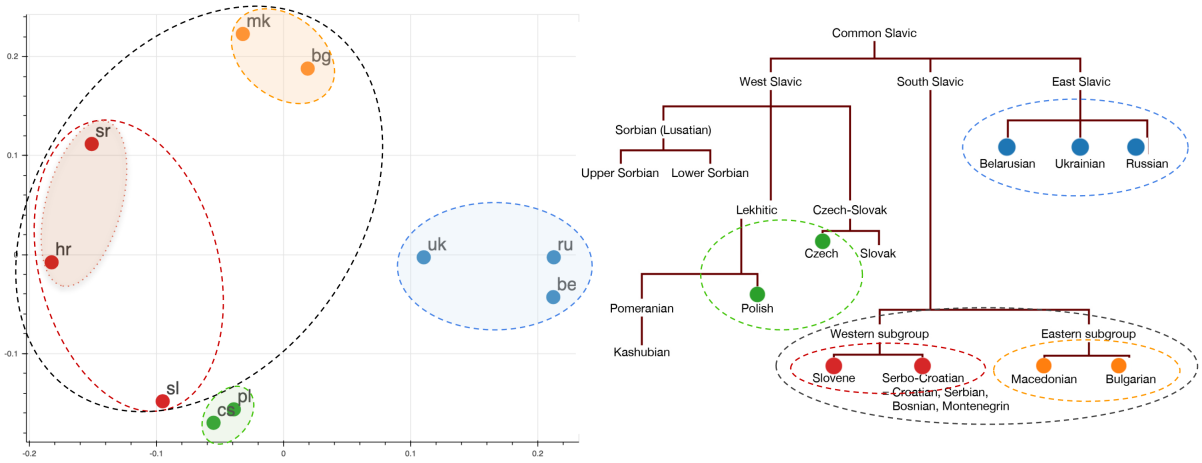

Figure 3: Comparing clusterings in the subword embeddings of the Slavic languages in our dataset with their family tree, which is the result of centuries of scholarship by linguists ((Browne and Ivanov)). Best seen in color.

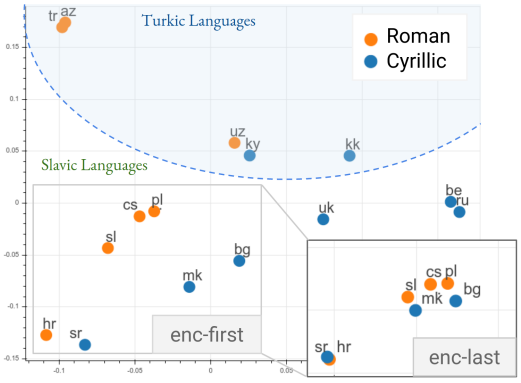

Figure 4: Representations of the Turkic and Slavic languages at the subword embeddings, compared with the top of the encoder, and colored by script. The inset shows a portion of the same image at the top of the encoder, focusing on the South-Western Slavic languages. Both images are at the same scale, see Appendix-Fig. 14 for more details. Best seen in color.

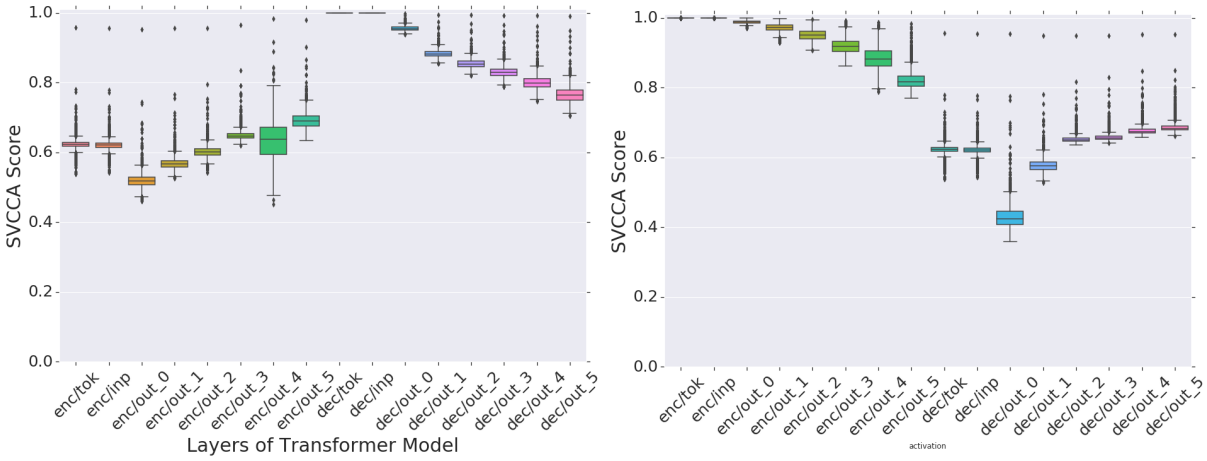


visualize sub-sets of the above languages.

In Figures 3 and 4, we visualize the Slavic and Turkic languages in our dataset. These languages come from two distinct families with very different linguistic properties, and within each family there are languages that are written in Cyrillic and Roman alphabets. This makes them ideal for understanding the interaction between superficial similarity (having the same alphabet and thus sharing many subwords) and linguistic similarity (sharing similar grammatical properties).

The first remarkable phenomenon we observe is that the clusters resulting from our model are grouped not only by family (Slavic), but branches within it (e.g. South Slavic), branches within those branches (e.g. Western Subgroup), and dialects within those (e.g. Serbo-Croatian). Figure 3 provides a more detailed look into the Slavic languages, and how this compositionality maps to the established family tree for Slavic languages. As can be seen in Figure 4, this phenomenon can also be observed for Turkic languages, with the Oghuz languages (Turkish and Azeri) forming one cluster, and the two Eastern branches Kipchak and Karluk (Uzbek, Kyrgyz, Kazakh) forming another.

A point worth special notice is the closeness between Serbian (sr) and Croatian (hr). Although these two are widely considered registers of the same language (Sussex and Cubberley), Serbian is written in Cyrillic, whereas Croatian is written in the Roman script. However, we see in both Figure 3 (middle left of plot) and Figure 4 (bottom left of plot) that they are each others' closest neighbors. Since they have no overlap in subword vocabulary, we conclude that they cluster purely based on distributional similarity – even at the level of sub-word embeddings.

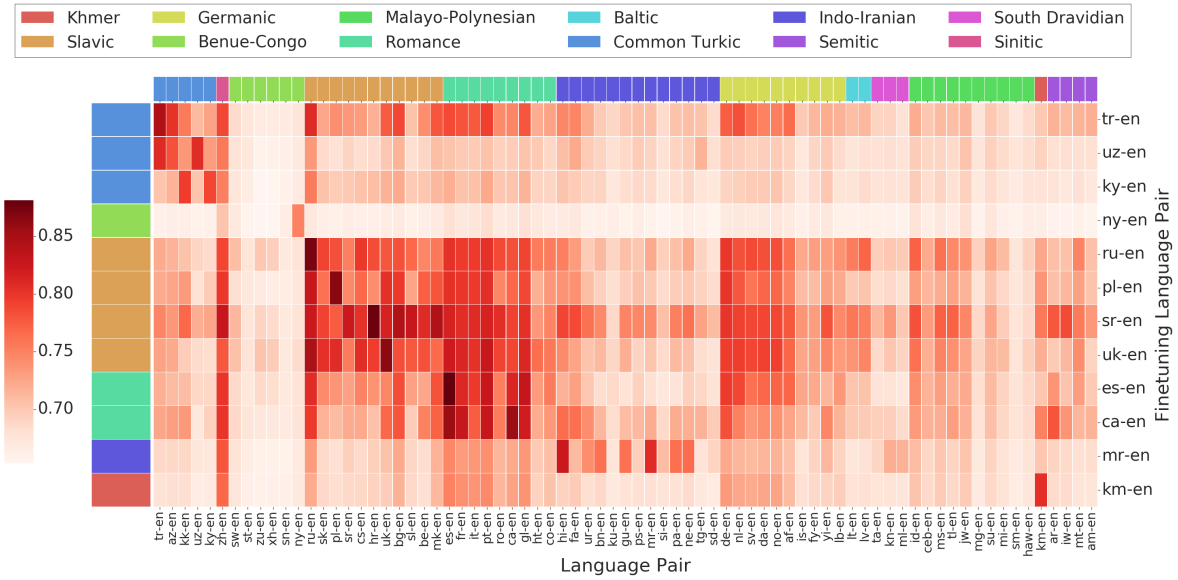
Although we see strong clustering by linguistic family, we also notice the importance of script and lexical overlap, especially (and unsurprisingly) in the embeddings. In Figure 4 we visualize the Turkic and Slavic languages, and color by script. Although the linguistic cluster is probably stronger, there is also a distinct grouping by script, with the Roman-scripted languages on the left and the Cyrillic-scripted languages on the right. However, as we move up the encoder, the script associations become weaker and the language family as-

(a) X-En Language Pairs

(b) En-X Language Pairs

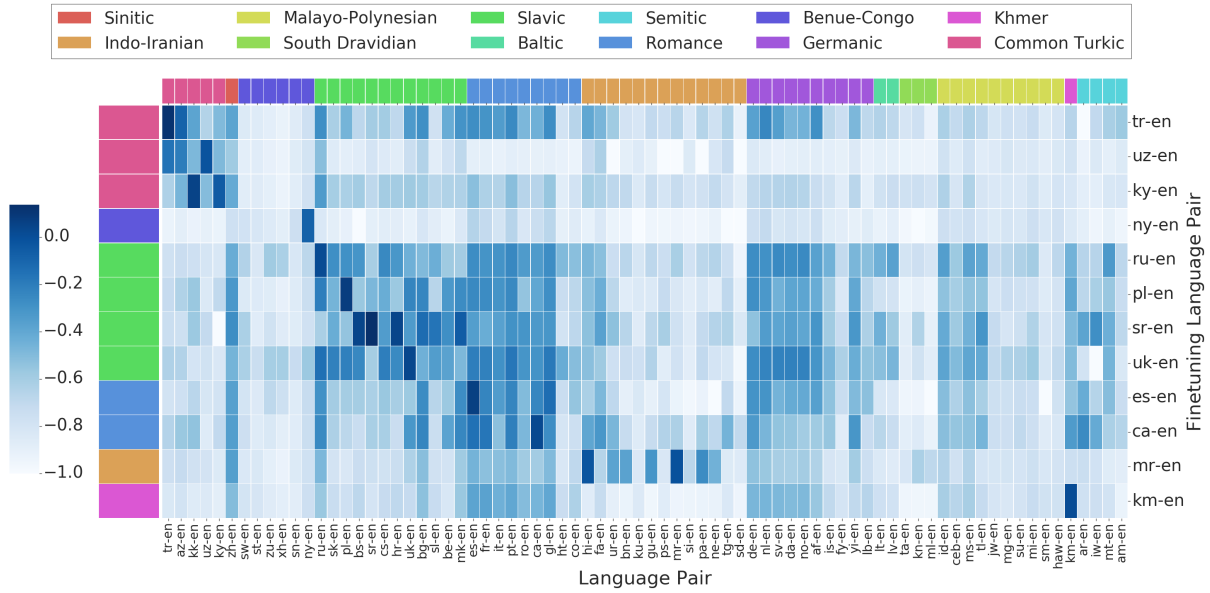
Figure 5: The change in distribution of pairwise SVCCA scores between language pairs across layers of a multilingual NMT model, with SVCCA scores between English-to-Any and Any-to-English language pairs visualized separately. We see that while the encoder in (a) and decoder in (b) have dissimilar representations across languages, the English representations of the decoder in (a) and the encoder in (b) diverge depending on the language X.

sociations become stronger. The inset in Figure 4 shows the seven South-Western Slavic languages at the top of the encoder, where they have clustered closer together. Again, Serbian and Croatian are an excellent example: *by the top of the encoder, they have become superimposed, diminishing the effect of the difference in script*.



We find that the trends discussed above are generally true for other language groupings too. The Appendix shows an example with the Dravidian, Indo-Aryan, and Iranian language families, demonstrating the same phenomena discussed above (Appendix Figure 12). Section A.5 further analyzes how the nearest neighbors of languages in SVCCA space become more linguistically coherent as one moves up the encoder.

3.3 Representational Similarity evolves across Layers



To visualize the how the representational overlap across languages evolves in the model, we plot how the distribution of pairwise SVCCA scores change across layers. For each layer, we first compute the pair-wise similarity between all pairs of languages. These similarity scores are then aggregated into a distribution and represented in Figures 5a and 5b, separately for the Any-to-English (X-En) and English-to-Any (En-X) language pairs.

For the Any-to-English (X-En) language pairs (Figure 5a), we notice that similarity between the source languages (X) increase as we move up the encoder, from embeddings towards higher level encoder layers, suggesting that the encoder attempts to learn a common representation for all source languages. This might also be motivated by training on a shared target language (En). However, representations at the top of the encoder are far from perfectly aligned, possibly indicating that different languages are represented in only partially overlapping sub-spaces. On the other hand, as the decoder incorporates more information from the source language (X), representations of the target (En) diverge. This is also in line with some findings of studies on translationese (Koppel and Ordan, 2011), where the authors show that that the translated text is predictive of the source language. For English-to-Any (En-X) language pairs (Figure 5b) we observe a similar trend. Representations of the source language (En) diverge as we move up the encoder, indicating that the representations of English sentences separate conditioned on the target language.

While it is a natural assumption that the encoder in a seq2seq model encodes the source, and the decoder decodes it into the target (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015), our results indicate that this change from source to target might be more gradual, and the boundary between encoder and decoder, in terms of the localization of the representation is blurry.

(a) SVCCA scores between the representations (top encoder layer) of *xx-en* language pairs before and after finetuning on various X-En language pairs. Darker cell means less change in representation (and higher SVCCA score) of *xx-en* on finetuning with X-En.

(b) Relative change in BLEU scores of *xx-en* language pairs after finetuning with various language pairs of the form X-En. Darker cell means less change in BLEU score of *xx-en* on finetuning with X-En.

Figure 6: Visualization depicting the (a) change in representations (using SVCCA) and (b) relative change in performance (in terms of test BLEU) of *xx-en* language pairs (x-axis), after fine-tuning a large multilingual model on various X-En language pairs (y-axis). Language sub-families on the axes are color-coded. We notice that representations of high resource languages are relatively robust to fine-tuning on any language. Additionally, languages linguistically similar to the one being fine-tuned on observe less distortion from their original representations.

4 Analyzing representation robustness to fine-tuning

In this section, we try to analyze the robustness of encoder representations, when fine-tuning a multilingual model on a single language pair. Note that here we define robustness to mean representational rigidity to fine-tuning, aka robustness to catastrophic forgetting (McCloskey and Cohen, 1989). Understanding the factors that affect robustness during fine-tuning is critical to determining how much cross-lingual transfer can be expected for individual languages in a zero or few-shot setting.

Analysis Setup: We fine-tune a fully trained multilingual model separately on 12 Any-to-English language pairs for 40k steps using the op-

timizer as described in A.1. These selected languages form a mix of high and low resource language pairs, from 6 language sub-families.[9]

We first attempt to quantify the extent of distortion in language representations caused by the fine-tuning process. To this end, we calculate the SVCCA similarity between the encoder representations of a language, before and after fine-tuning. We do this for all languages, in order to understand which factors determine the extent of distortion. We visualize these changes in Figure 6a for the final encoder layer, for all X-En language pairs. To complement our analysis of representational similarity, we visualize the relative change in BLEU score after fine-tuning in Figure 6b.

Observations: The first observation from Figures 6a and 6b is that the variations in SVCCA scores correspond very well with changes in BLEU; degradation in translation quality is strongly correlated with the magnitude of change in representations during fine-tuning.

We find that representations of high resource languages are quite robust to fine-tuning on any language. In Figure 6a, we see that high resource languages such as Chinese, German, Russian and Italian do not change much, irrespective of the language the model is fine-tuned on.

In general, we find that language representations are relatively robust to fine-tuning on a language pair from the same linguistic family. For example, on fine-tuning with tr-en (Turkish) or ky-en (Kyrgyz), the Turkic language group does not experience much shift in representation. We see a similar pattern with models fine-tuned on es-en (Spanish), ca-en (Catalan) and the Romance languages, uk-en (Ukranian), sr-en (Serbian), ru-en (Russian) and the Slavic languages.

An exception to these general trends seems to be fine-tuning on ny-en (Nyanja: Benue-Congo subfamily); all language pairs degrade by roughly the same extent, irrespective of language similarity or resource size. It's worth noting that all of the languages from the Benue-Congo sub-family are low-resource in our corpus.

These observations suggest that high resource languages might be responsible for partitioning the representation space, while low-resource languages become closely intertwined with linguistically similar high-resource languages. Low resource languages unrelated to any high resource languages have representations spread out across multiple partitions.

While these observations are based on representations from the top of the encoder, we further analyze sensitivity of representations to fine-tuning across different layers in the Appendix A.6. One key observation from that analysis is the robustness of embeddings to fine-tuning on any individual language; there is no significant change in the embedding representations (Correlation between representation of any language before and after finetuning $\bar{\rho} > 0.98$).

5 Discussion

Our work uncovers a few observations that might be of interest to practitioners working in multilingual NMT and cross-lingual transfer.

Our analysis reveals that language representations cluster based on language similarity. While language similarity has been exploited for adaptation previously (Neubig and Hu, 2018), our work is the first to concretely highlight which factors affect the overlap in representations across languages. This has potential implications for transfer learning: for example, it is possible to identify and exploit the nearest neighbors of a low resource language to maximize adaptation performance.

We also highlight how representation overlap evolves across layers, which is, again, of interest for cross-lingual transfer. For example, our analysis reveals that embeddings of different languages are less overlapping than the final encoder outputs. This hints that it might not be might not be effective to utilize input embeddings learned in multilingual NMT, since they don't overlap as much as the final encoder outputs. We also notice that encoder representation overlap across languages is not perfect, which explains why explicit language alignment or consistency losses might be needed to enable zero-shot NMT (Arivazhagan et al., 2019a; Al-Shedivat and Parikh, 2019).

We further analyze the robustness of language representations to fine-tuning, and notice that high-resource and linguistically similar languages are more robust to fine-tuning on an arbitrary language. This might help explain why linguistically distant languages typically result in poor zero-shot transfer (Wu and Dredze, 2019). Applying explicit losses, like elastic-weight consolidation (Kirkpatrick et al., 2017), to force language rep-

[9] More details on the relative resource sizes of different language pairs can be found in the Appendix A.6.

resentations of distant languages from getting distorted might help improve transfer performance.

6 Conclusion

To conclude, we analyzed factors that affect the overlap in representations learned by multilingual NMT models. We used SVCCA to show that multilingual neural networks share representations across languages strongly along the lines of linguistic similarity, and encoder representations diverge based on the target language. With this work we hope to inspire future work on understanding multitask and multilingual NLP models.

Hierarchical Modeling of Global Context for Document-Level Neural Machine Translation

Xin Tan, Longyin Zhang, Deyi Xiong, Guodong Zhou*

Abstract

Document-level machine translation (MT) remains challenging due to the difficulty in efficiently using document context for translation. In this paper, we propose a hierarchical model to learn the global context for document-level neural machine translation (NMT). This is done through a sentence encoder to capture intra-sentence dependencies and a document encoder to model document-level inter-sentence consistency and coherence. With this hierarchical architecture, we feedback the extracted global document context to each word in a top-down fashion to distinguish different translations of a word according to its specific surrounding context. In addition, since large-scale in-domain document-level parallel corpora are usually unavailable, we use a two-step training strategy to take advantage of a large-scale corpus with out-of-domain parallel sentence pairs and a small-scale corpus with in-domain parallel document pairs to achieve the domain adaptability. Experimental results on several benchmark corpora show that our proposed model can significantly improve document-level translation performance over several strong NMT baselines.

1 Introduction

Due to its flexibility and much less demand of manual efforts for feature engineering, neural machine translation (NMT) has achieved remarkable progress and become the *de-facto* standard choice in machine translation. During the last few years, a variety of NMT models have been proposed to reduce the quality gap between human translation and machine translation (Sutskever et al., 2014; Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017). Among them, the Transformer model (Vaswani et al., 2017) has achieved the state-of-the-art performance in sentence-level translation and results on news benchmark test sets have shown its "translation quality at human parity when compared to professional human translators" (Hassan et al., 2018). However, when turning to document-level translation, even the Transformer model yields a low performance as it translates each sentence in the document independently and suffers from the problem of ignoring document context.

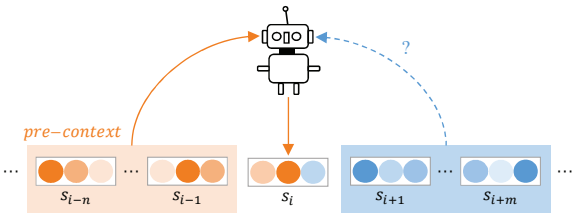

Figure 1: An illustration of document-level translation under the guidance of context.

To address above challenge, various extraction-based methods (Maruf and Haffari, 2018; Wang et al., 2017; Zhang et al., 2018; Miculicich et al., 2018) have been proposed to extract previous context (*pre-context*) to guide the translation of the current sentence s_i, as shown in Figure 1. However, when there exists a huge gap between the *pre-context* and the context after the current sentence s_i, the guidance from *pre-context* is not sufficient for the NMT model to fully disambiguate the sentence s_i. On the one hand, the translation of the current sentence s_i may be inaccurate due to the one-sidedness of partial context. On the other hand, translating the succeeding sentences in the document may much suffer from the semantic bias due to the transmissibility of the improper *pre-context*.

To alleviate the aforementioned issues, we propose to improve document-level translation with the aid of global context, which is hierarchically extracted from the entire document with a sen-

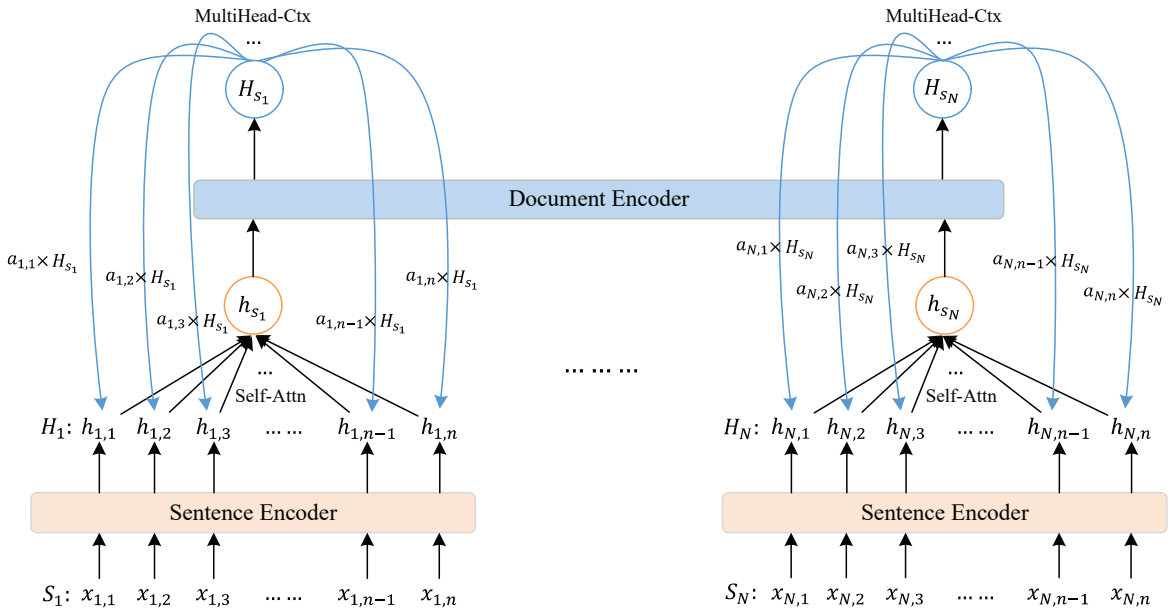

Figure 2: Diagram of the proposed hierarchical modeling of global document context (HM-GDC).

tence encoder modeling intra-sentence dependencies and a document encoder modeling document-level inter-sentence context. To avoid the issue of translation bias propagation caused by improper *pre-context*, we propose to extract global context from all sentences of a document once for all. Additionally, we propose a novel method to feed back the extracted global document context to each word in a top-to-down manner to clarify the translation of words in specific surrounding contexts. In this way, the proposed model can better translate each sentence under the guidance of the global context, thus effectively avoiding the transmissibility of improper *pre-context*. Furthermore, motivated by Zhang *et al.* (2018) and Miculicich *et al.* (2018) who exploit a large amount of sentence-level parallel pairs to improve the performance of document-level translation, we employ a two-step training strategy in taking advantage of a large-scale corpus of out-of-domain sentence-level parallel pairs to pre-train the model and a small-scale corpus of in-domain document-level parallel pairs to fine-tune the pretrained model.

We conduct experiments on both the traditional RNNSearch model and the state-of-the-art Transformer model. Experimental results on Chinese-English and German-English translation show that our proposed model can achieve the state-of-the-art performance due to its ability in well capturing global document context. It is also inferential to notice that our proposed model can explore a large dataset of out-of-domain sentence-level parallel pairs and a small dataset of in-domain document-level parallel pairs to achieve domain adaptability.

2 NMT with Hierarchical Modeling of Global Document Context

In this work, our ultimate goal is to incorporate the global document context into NMT to improve the performance of document-level translation. This is first achieved with the hierarchical modeling of global document context (HM-GDC) based on sentence-level hidden representation and document-level consistency and coherence modeling. Then, we integrate the proposed HM-GDC model into NMT models to help improve the performance of document-level translation.

2.1 Hierarchically Modeling Global Context

To avoid the one-sidedness of partial context and the transmissibility of the improper *pre-context* in previous studies, we take all sentences of the document into account and extract the global context once for all. Inspired by Sordoni *et al.* (2015), we build our HM-GDC model in a hierarchical way which contains two levels of encoder structure, i.e., the bottom sentence encoder layer to capture intra-sentence dependencies and the upper document encoder layer to capture document-level context. In this way, the global document context is captured for NMT. In order to make the translation of each word in specific surrounding context more robust, we propose to equip each word with global

document context. This is done by backpropagating the extracted global context to each word in a top-down fashion, as shown in Figure 2. The following is the detailed description of the proposed HM-GDC model.

Sentence encoder. Given an input document with N sentences $(S_1, S_2, ..., S_N)$, the sentence encoder maps each word $x_{i,k}$ in the sentence S_i into the corresponding hidden state $h_{i,k}$, obtaining:

$$H_i = \text{SentEnc}(S_i) \quad (1)$$

where $S_i = (x_{i,1}, x_{i,2}, \ldots, x_{i,n})$ is the i^{th} sentence in the document, SentEnc is the sentence encoder function (corresponding to Bi-RNNs and multi-head self-attention (Vaswani et al., 2017) for the RNNSearch model and the Transformer model respectively), and $H_i = (h_{i,1}, h_{i,2}, \ldots, h_{i,n}) \in \mathbb{R}^{D \times n}$ is the output hidden state.

Document encoder. Following the Transformer model (Vaswani et al., 2017), we employ the multi-head self-attention mechanism to determine the relative importance of different H_i. The model architecture of the document encoder here is the same as the sentence-level encoding stated before. And the document context is formulated as:

$$h_{S_i} = \text{MultiHead-Self}(H_i, H_i, H_i) \quad (2)$$

$$\tilde{h}_{S_i} = \sum\nolimits_{h \in h_{S_i}} h \quad (3)$$

$$H_S = \text{DocEnc}(\tilde{h}_S) \quad (4)$$

where MultiHead-Self$(\mathbf{Q}, \mathbf{K}, \mathbf{V})$ is the multi-head self-attention mechanism corresponding to Self-Attn in Figure 2, $h_{S_i} \in \mathbb{R}^{D \times n}$, $\tilde{h}_{S_i} \in \mathbb{R}^{D \times 1}$, $\tilde{h}_S = (\tilde{h}_{S_1}, \tilde{h}_{S_2}, \ldots, \tilde{h}_{S_N}) \in \mathbb{R}^{D \times N}$, DocEnc is the document-level encoding function (corresponding to Bi-RNNs and multi-head self-attention for the RNNSearch model and the Transformer model respectively), and $H_S = (H_{S_1}, H_{S_2}, \ldots, H_{S_N}) \in \mathbb{R}^{D \times N}$ is the global document context.

Backpropagation of global context. To equip each word with global document context, we propose to assign the context information to each word in the sentence using another multi-head attention (Vaswani et al., 2017), which we refer to as the multi-head context attention (MultiHead-Ctx in Figure 2). And the context information assigned to the j^{th} word in the sentence S_i is detailed as:

$$\alpha_{i,j} = \text{MultiHead-Ctx}(h_{i,j}, h_{i,j}, H_{S_i}) \quad (5)$$

$$d_ctx_{i,j} = \alpha_{i,j} H_{S_i} \quad (6)$$

where $\alpha_{i,j}$ is the attention weight assigned to the word and $d_ctx_{i,j}$ is the corresponding context information distributed to the word.

2.2 Integrating the HM-GDC model into NMT

Different from previous works, we equip the representation of each word with global document context. The word representations are sequential in format, which makes it easy to integrate our proposed HM-GDC model into sequential models like RNNSearch and Transformer. In this section, we mainly introduce the process of integrating HM-GDC into the state-of-the-art Transformer model.

Integration in the Encoding Phase

Consider that the global document context is first extracted during the encoding phase and then distributed to each word in the document, as stated in Section 2.1. On this basis, we propose to employ the residual connection function (He et al., 2016) to incorporate the extracted global context information into the word representation. And the integrated representation of the j^{th} word in the i^{th} sentence is detailed as:

$$h_ctx_{i,j} = h_{i,j} + \text{ResidualDrop}(d_ctx_{i,j}, P) \quad (7)$$

where ResidualDrop is the residual connection function, $P = 0.1$ is the rate of residual dropout, $h_{i,j}$ is the corresponding hidden state of the word during the sentence encoding phase, $d_ctx_{i,j}$ is the global document context assigned to the word, and $h_ctx_{i,j}$ is the integrated representation of the word.

Integration in the Decoding Phase

With the help of the multi-head attention sub-layer in the decoder, the Transformer model is capable of well employing the information obtained from the encoder. Inspired by this, we introduce an additional sub-layer into the decoder that performs multi-head attention over the output of the document encoder, which we refer to as DocEnc-Decoder attention (shown in Figure 3). Different from (Vaswani et al., 2017), the keys and values of our DocEnc-Decoder attention come from the output of the document encoder. In this way, the global document context is well employed to supervise the decoding process. And Specially,

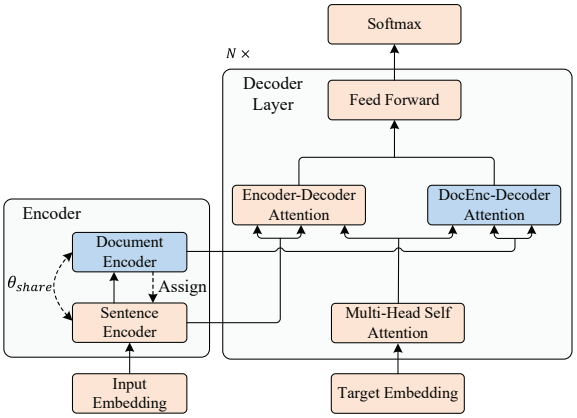

Figure 3: Integration of global document context into the decoder of the Transformer model.

the additional DocEnc-Decoder attention is formulated as:

$$C = [h_ctx_1; h_ctx_2; ...; h_ctx_N] \quad (8)$$

$$G^{(n)} = \text{MultiHead-Attn}(T^{(n)}, C^{(n)}, C^{(n)}) \quad (9)$$

where h_ctx_i denotes the integrated representation of the i^{th} sentence, $C^{(0)} = C$ is the concatenated global document context, $T^{(n)}$ is the output of the multi-head self-attention sub-layer in the decoder. On this basis, we combine the outputs of both the Encoder-Decoder attention sub-layer and the DocEnc-Decoder attention sub-layer into one single output $H^{(n)}$:

$$H^{(n)} = E^{(n)} + G^{(n)} \quad (10)$$

where $E^{(n)}$ is the output of the Encoder-Decoder attention sub-layer, and $G^{(n)}$ is the output of the DocEnc-Decoder attention sub-layer.

2.3 Model Training

In document-level translation, the standard training objective is to maximize the log-likelihood of the document-level parallel corpus. However, due to the size limitation of document-level parallel corpora, previous studies (Zhang et al., 2018; Miculicich et al., 2018; Shen et al., 2016) use two-step training strategies to take advantage of large-scale sentence-level parallel pairs. Following their studies, we also take a two-step training strategy to train our model. Specially, we borrow a large-scale corpus with out-of-domain sentence-level parallel pairs D_s to pre-train our model first, and then use a small-scale corpus with in-domain document-level parallel pairs D_d to fine-tune it.

In this work, we follow Voita *et al.* (2018) to make the sentence and document encoders share the same model parameters. For the RNNSearch model, we share the parameters in the hidden layers of Bi-RNNs in the sentence and document encoders. For the Transformer model, we share the parameters of the multi-head self-attention layers in the sentence and document encoders.

During training, we first optimize the sentence-level parameters θ_s (colored in wheat in Figure 3) with the large-scale sentence-level parallel pairs D_s:

$$\hat{\theta}_s = \arg\max_{\theta_s} \sum_{<x,y>\in D_s} \log P(y|x;\theta_s) \quad (11)$$

Then, we optimize the document-level parameters θ_d (colored in pale blue in Figure 3) with the document-level parallel corpus D_d and fine-tune the pre-trained sentence-level parameters $\hat{\theta}_s$ as follows:

$$\hat{\theta}_d = \arg\max_{\theta_d} \sum_{<x,y>\in D_d} \log P(y|x;\theta_d,\hat{\theta}_s) \quad (12)$$

3 Experimentation

To examine the effect of our proposed HM-GDC model, we conduct experiments on both Chinese-English and German-English translation.

3.1 Experimental Settings

Datasets

For Chinese-English translation, we carry out experiments with sentence- and document-level corpora on two different domains: news and talks. For the sentence-level corpus, we use 2.8M sentence pairs from news corpora LDC2003E14, LDC2004T07, LDC2005T06, LDC2005T10 and LDC2004T08 (Hongkong Hansards/Laws/News). We use the Ted talks corpus from the IWSLT 2017 (Cettolo et al., 2012) evaluation campaigns[1] as the document-level parallel corpus, including 1,906 documents with 226K sentence pairs. We use *dev2010* which contains 8 documents with 879 sentence pairs for development and *tst2012-tst2015* which contain 62 documents with 5566 sentence pairs for testing.

For German-English translation, we use the document-level parallel Ted talks corpus from the IWSLT 2014 (Cettolo et al., 2012) evaluation campaigns, which contain 1,361 documents with 172K

Table 1: Performance (BLEU scores) comparison with the four baseline models on Chinese-English document-level translation. The first three rows are based on RNNSearch and the remaining rows are on top of Transformer. And the *p-value* between Ours and the other models are all less than 0.01.

sentence pairs as training data. We use *dev2012* which contains 7 documents with 1172 sentence pairs for development and *tst2013-tst2014* which contain 31 documents with 2329 sentence pairs for testing.

Model Settings

We integrate our proposed HM-GDC into the original Transformer model implemented by OpenNMT (Klein et al., 2017). Following the Transformer model (Vaswani et al., 2017), the hidden size and filter size are set to 512 and 2048 respectively. The numbers of layers in encoder and decoder are all set to 6. The multi-head attention mechanism of each layer contains 8 individual attention heads. We set both the source and target vocabulary size as 50K and each batch contains 4096 tokens. The beam size and dropout (Srivastava et al., 2014) rate are set to 5 and 0.1 respectively. Other settings with the Adam (Kingma and Ba, 2015) optimization and regularization methods are the same as the default Transformer model.

To comprehensively evaluate the performance of our proposed HM-GDC model, we integrate the HM-GDC into the standard RNNSearch model to serve as a supplementary experiment. For the RNNSearch network, we borrow the implementation from OpenNMT (Klein et al., 2017). The encoder and decoder layers are all set to 2, the size of the hidden layer is set to 500, and the batch size is set to 64. Same as the Transformer model, we use the most frequent 50K words for both source and target vocabularies. We borrow other settings from (Bahdanau et al., 2015). The evaluation metric for both tasks is case-insensitive BLEU (multi-bleu) (Papineni et al., 2002).

3.2 Experimental Results

In this paper, we compare our model with four strong baselines as shown in Table 1. Among them, the RNNSearch (Bahdanau et al., 2015) is a traditional RNN-based encoder-decoder model. Wang *et al.* (2017) propose to use a hierarchical model to extract partial document context based on the RNNSearch model. To compare with these two RNN-based works, we integrate our proposed HM-GDC model into the encoder of the RNNSearch model using the same method in Section 2.2 and keep other settings the same as the basic RNNSearch model. Different from RNN-based works, Vaswani *et al.* (2017) propose the Transformer model, which achieves the state-of-the-art performance in sentence-level translation with only attention mechanism. On this basis, Zhang *et al.* (2018) add an additional multi-head attention to extract partial document context to improve the Transformer model in document-level translation. In particular, Zhang *et al.* (2018) use a two-step training strategy in their work, so we also report the performance comparison with respect to the training strategy. For the RNNSearch and Transformer models, we run them with their default settings. And we reimplement the models of Wang *et al.* (2017) and Zhang *et al.* (2018) to conduct experiments on our datasets.

As shown in Table 1, we divide the results into two main groups, i.e., in the framework of RNNSearch (the first three rows) and Transformer (the remaining rows). The results in the first group reveal that our proposed model can significantly improve the RNNSearch model and can further improve the model of Wang *et al.* (2017) in

document-level translation by 0.76 BLEU points. In addition, the results in the second group is further split into two parts depending on whether the *pre-training* strategy is used. For the first part, we train our model and the two baselines with only the small-scale document-level parallel corpus without *pre-training* (the first three rows in the second group). From the results, the model of Zhang *et al.* (2018) achieves much worse results (-4.21 BLEU points) when compared with the standard Transformer model, which is consistent with what they state in their paper. By contrast, our proposed model can achieve 0.62 BLEU points over the Transformer model, which indicates the robustness of our model. For the second part, to further compare with (Zhang et al., 2018), we use the *pre-training* strategy to take advantage of large-scale sentence-level parallel corpus D_s for these models (the last three rows). From the results, our proposed HM-GDC can significantly improve the performance of the Transformer model by 2.12 BLEU points and can further improve the performance of (Zhang et al., 2018) by 0.54 BLEU points.

From the overall results, it's not difficult to find that using a large-scale corpus with out-of-domain parallel pairs D_s to pre-train the Transformer model results in worse performance due to domain inadaptability (the first and the fourth row in the second group). By contrast, our proposed model can effectively eliminate this domain inadaptability (the third and sixth row in the second group). In general, our proposed HM-GDC model is robust when integrated into frameworks like RNNSearch and Transformer and it can help improve the performance of document-level translation.

4 Analysis and Discussion

To further demonstrate the effectiveness of our proposed HM-GDC model, we illustrate several experimental results in this section and give our analysis on them.

4.1 The Effect of HM-GDC Integration

As the state-of-the-art Transformer model is well-designed in the model structure, an analysis of the integration in Transformer is thus necessary. Therefore, we perform experiments on Chinese-English document-level translation for analyzing. Table 2 illustrates the effectiveness of integrating our proposed HM-GDC model into the encoder, decoder and both sides of the Transformer model with respect to the number of layers in the multi-head self-attention in the document encoder (see Section 2.1).

N	Encoder	Decoder	Both
1	17.34	**17.54**	17.49
2	17.30	17.43	17.56
3	**17.39**	**17.54**	17.45
4	17.27	17.45	17.55
5	17.31	17.49	**17.63**
6	17.25	17.40	17.58

Table 2: The effect of integrating HM-GDC into Transformer with respect to the layer number (N) of the self-attention in the document encoder. The results here refer to the average BLEU scores of test sets.

Model	tst13	tst14	Avg
Baseline	27.89	23.75	25.82
Ours	28.58	24.85	**26.72**

Table 3: Comparison with the Transformer model on German-English document-level translation. And the *p-value* between Ours and Baseline is less than 0.01.

From the results, the overall performance of integrating HM-GDC into both the encoder and decoder is better than integrating it into the encoder or decoder only. However, the layer number of the multi-head self-attention does not make much difference in our experiments. It shows that when the HM-GDC is integrated into both the encoder and decoder and the layer number equals to 5, the Transformer model can achieve a relatively better performance.

4.2 Different Language Pairs

In this paper, we aim to propose a robust document context extraction model. To achieve this goal, we perform experiments on different language pairs to further illustrate the effectiveness of our proposed HM-GDC model. Table 3 shows the performance of our model on German-English document-level translation and the baseline here refers to the Transformer model. For clarity, we only use the German-English document-level parallel corpus to train these two models without *pre-training*. From the results, our proposed HM-GDC model can help improve the Transformer model on German-English document-level translation by 0.90 BLEU points. The experimental re-

sent	*doc*	tst12	tst13	tst14	tst15	Avg
×	×	16.58	17.03	15.22	17.96	16.70
✓	×	16.94	18.31	16.21	19.07	**17.63**
✓	✓	20.08	21.04	19.48	22.46	**20.77**

Table 4: Results of our model with and without *pre-training* on Chinese-English document-level translation. *sent* refers to the sentence-level parallel corpus and *doc* refers to the document-level parallel corpus. ✓means that the corresponding corpus is used for pre-training while × means not.

	Chinese-English					German-English		
Model	tst12	tst13	tst14	tst15	Avg	tst13	tst14	Avg
Baseline	58.06	55.10	51.71	52.48	54.34	86.47	84.78	85.63
Ours	59.29	55.48	52.95	53.22	**55.24**	87.36	85.64	**86.50**

Table 5: Evaluation on pronoun translation of Chinese-English and German-English document-level translation. The baseline model refers to the Transformer.

sults further validate the robustness of our model in different language pairs.

4.3 The Effect of Pre-training

Due to the size limitation of document-level parallel corpora, previous studies (Zhang et al., 2018; Miculicich et al., 2018; Shen et al., 2016) use two-step training strategies to take advantage of a large-scale corpus with sentence-level parallel pairs. Inspired by them, we use a two-step training strategy to train our model, which we refer to as the *pre-training* strategy (see Section 2.3). In this section, we perform the *pre-training* strategy on the HM-GDC integrated Transformer model to further analysis the ability of our model in utilizing resources of different domains. The results of our model with and without the *pre-training* strategy are shown in Table 4. The first row in the table gives the result of our model without *pre-training*, where only the talks-domain document-level parallel corpus D_d are used to train the model. The remaining rows give the results of our model with the *pre-training* strategy, where we first use the large-scale sentence-level parallel pairs D_s to pre-train the model and then the small-scale talks-domain document-level parallel corpus D_d to fine-tune the entire model.

From the results, the performance of our model is significantly improved by 0.93 BLEU points (the first two rows in Table 4) when the large-scale sentence-level parallel corpus is used for the pre-training process. In particular, when we use the mixed data of both sentence- and document-level parallel corpora[2] to first pre-train our model, the performance of our model is significantly improved by 5.26 BLEU points (the last row in Table 4). The overall results prove that our proposed model is robust and promising. It can significantly improve the performance of document-level translation when a two-step training strategy is used.

4.4 Pronoun & Noun Translation

To intuitively illustrate how the translation performance is improved by our proposed HM-GDC model, we conduct a further analysis on pronoun and noun translation.

For the pronoun translation, we evaluate the coreference and anaphora using the reference-based metric: the accuracy of pronoun translation (Miculicich Werlen and Popescu-Belis, 2017) in Chinese-English and German-English translation as shown in Table 5. From the results, our proposed HM-GDC model can well improve the performance of pronoun translation in both corpora due to the well captured global document context assigned to each word. Correspondingly, we display a translation example in Table 6 to further illustrate this. From the example, given the surrounding context, our proposed HM-GDC model can well infer the latent pronoun *it* and thus improve the translation performance of the Transformer model.

For the analysis of noun translation, we display another example in Table 7. From the example,

[2]We shuffle sentences in D_d to get sentence-level parallel pairs.

Source	dan xifang zhengfu ye tongyang dui tamen ziji zheyang zuo **ta**.
Reference	But western governments are doing **it** to themselves as well.
Baseline	But the western governments do the same for themselves.
Ours	But the western governments do **it** the same for themselves.

Table 6: An example of pronoun translation in the Chinese-English document-level translation. The word "ta" in bold in the source sentence is an omitted pronoun.

Pre-context	$\cdots$ renhe yige youxiu de **chengxuyuan** dou hui zuo de $\cdots$
Rear-context	$\cdots$ zai xiaweiyi de **IT** bumen shangban de ren kandao le $\cdots$
Source	ta xie le yige xiangduilaishuo bijiao xiao de **chengxu**
Reference	he wrote a modest little **app**
Baseline	he wrote a relatively small **procedure**
Ours	he wrote a relative smaller **program**

Table 7: An example of noun translation in the Chinese-English document-level translation. The baseline model here refers to the Transformer.

the word *chengxu* is translated into *procedure* and *program* by the Transformer model and the model integrated with HM-GDC respectively. Comparing with the reference translation, the word *program* translated by our model is more appropriate. Although the words *chengxuyuan* and *IT* in the global context provide essential evidence for an accurate translation of *chengxu*, it is hard for the baseline model to obtain the information. Different from previous works which do not use or use only partial document context, we propose to incorporate the HM-GDC into the NMT model to take global context into consideration and thus it can safely disambiguate those multi-sense words like *chengxu*.

5 Related Work

Recent years have witnessed a variety of approaches proposed for document-level machine translation. Most of existing studies aim to improve overall translation quality with the aid of document context. Among them, Maruf and Haffrai (2018), Wang *et al.* (2017), Zhang *et al.* (2018) and Miculicich *et al.* (2018) use extraction-based models to extract partial document context from previous sentences of the current sentence. In addition, Tu *et al.* (2018) and Kuang *et al.* (2018) employ cache-based models to selectively memorize the most relevant information in the document context. Different from above extraction-based models and cache-based models, there are also some works (Bawden et al., 2018; Voita et al., 2018) that pay much attention to discourse phenomena (Mitkov, 1999) related to document-level translation.

Although these approaches have achieved some progress in document-level machine translation, they still suffer from incomplete document context. Further more, most of previous works are based on the RNNSearch model, and only few exceptions (Zhang et al., 2018; Miculicich et al., 2018) are on top of the state-of-the-art Transformer model.

6 Conclusion

We have presented a hierarchical model to capture the global document context for document-level NMT. The proposed model can be integrated into both the RNNSearch and the state-of-the-art Transformer frameworks. Experiments on two benchmark corpora show that our proposed model can significantly improve document-level translation performance over several strong document-level NMT baselines. Additionally, we observe that pronoun and noun translations are significantly improved by our proposed HM-GDC model. In our future work, we plan to enrich our HM-GDC model to solve discourse phenomena such as (zero) anaphora.

Abstract

Though the community has made great progress on Machine Reading Comprehension (MRC) task, most of the previous works are solving English-based MRC problems, and there are few efforts on other languages mainly due to the lack of large-scale training data. In this paper, we propose Cross-Lingual Machine Reading Comprehension (CLMRC) task for the languages other than English. Firstly, we present several back-translation approaches for CLMRC task, which is straightforward to adopt. However, to accurately align the answer into another language is difficult and could introduce additional noise. In this context, we propose a novel model called Dual BERT, which takes advantage of the large-scale training data provided by rich-resource language (such as English) and learn the semantic relations between the passage and question in a bilingual context, and then utilize the learned knowledge to improve reading comprehension performance of low-resource language. We conduct experiments on two Chinese machine reading comprehension datasets CMRC 2018 and DRCD. The results show consistent and significant improvements over various state-of-the-art systems by a large margin, which demonstrate the potentials in CLMRC task. [1]

1 Introduction

Machine Reading Comprehension (MRC) has been a popular task to test the reading ability of the machine, which requires to read text material and answer the questions based on it. Starting from cloze-style reading comprehension, various neural network approaches have been proposed and massive progresses have been made in creating large-scale datasets and neural models (Hermann et al., 2015; Hill et al., 2015; Kadlec et al., 2016; Cui et al., 2017; Rajpurkar et al., 2016; Dhingra et al., 2017). Though various types of contributions had been made, most works are dealing with English reading comprehension. Reading comprehension in other than English has not been well-addressed mainly due to the lack of large-scale training data.

To enrich the training data, there are two traditional approaches. Firstly, we can annotate data by human experts, which is ideal and high-quality, while it is time-consuming and rather expensive. One can also obtain large-scale automatically generated data (Hermann et al., 2015; Hill et al., 2015; Liu et al., 2017), but the quality is far beyond the usable threshold. Another way is to exploit cross-lingual approaches to utilize the data in rich-resource language to implicitly learn the relations between <passage, question, answer>.

In this paper, we propose the Cross-Lingual Machine Reading Comprehension (CLMRC) task that aims to help reading comprehension in low-resource languages. First, we present several back-translation approaches when there is no or partially available resources in the target language. Then we propose a novel model called Dual BERT to further improve the system performance when there is training data available in the target language. We first translate target language training data into English to form pseudo bilingual parallel data. Then we use multilingual BERT (Devlin et al., 2019) to simultaneously model the <passage, question, answer> in both languages, and fuse the representations of both to generate final predictions. Experimental results on two Chinese reading comprehension dataset CMRC 2018 (Cui et al., 2019) and DRCD (Shao et al., 2018) show that by utilizing English resources could substantially improve system performance and the proposed Dual BERT achieves state-of-the-art performances on both datasets, and even surpass human performance on some metrics. Also, we

conduct experiments on the Japanese and French SQuAD (Asai et al., 2018) and achieves substantial improvements. Moreover, detailed ablations and analysis are carried out to demonstrate the effectiveness of exploiting knowledge from rich-resource language. To best of our knowledge, this is the first time that the cross-lingual approaches applied and evaluated on realistic reading comprehension data. The main contributions of our paper can be concluded as follows.

- We present several back-translation based reading comprehension approaches and yield state-of-the-art performances on several reading comprehension datasets, including Chinese, Japanese, and French.
- We propose a model called Dual BERT to simultaneously model the <passage, question> in both source and target language to enrich the text representations.
- Experimental results on two public Chinese reading comprehension datasets show that the proposed cross-lingual approaches yield significant improvements over various baseline systems and set new state-of-the-art performances.

2 Related Works

Machine Reading Comprehension (MRC) has been a trending research topic in recent years. Among various types of MRC tasks, span-extraction reading comprehension has been enormously popular (such as SQuAD (Rajpurkar et al., 2016)), and we have seen a great progress on related neural network approaches (Wang and Jiang, 2016; Seo et al., 2016; Xiong et al., 2016; Cui et al., 2017; Hu et al., 2019), especially those were built on pre-trained language models, such as BERT (Devlin et al., 2019). While massive achievements have been made by the community, reading comprehension in other than English has not been well-studied mainly due to the lack of large-scale training data.

Asai et al. (2018) proposed to use runtime machine translation for multilingual extractive reading comprehension. They first translate the data from the target language to English and then obtain an answer using an English reading comprehension model. Finally, they recover the corresponding answer in the original language using soft-alignment attention scores from the NMT model. However, though an interesting attempt has been made, the zero-shot results are quite low, and alignments between different languages, especially for those have different word orders, are significantly different. Also, they only evaluate on a rather small dataset (hundreds of samples) that was translated from SQuAD (Rajpurkar et al., 2016), which is not that realistic.

To solve the issues above and better exploit large-scale rich-resourced reading comprehension data, in this paper, we propose several zero-shot approaches which yield state-of-the-art performances on Japanese and French SQuAD data. Moreover, we also propose a supervised approach for the condition that there are training samples available for the target language. To evaluate the effectiveness of our approach, we carried out experiments on two realistic public Chinese reading comprehension data: CMRC 2018 (simplified Chinese) (Cui et al., 2019) and DRCD (traditional Chinese) (Shao et al., 2018). Experimental results demonstrate the effectiveness by modeling training samples in a bilingual environment.

3 Back-Translation Approaches

In this section, we illustrate back-translation approaches for cross-lingual machine reading comprehension, which is natural and easy to implement. Before introducing these approaches in detail, we will clarify crucial terminologies in this paper for better understanding.

- **Source Language**: Rich-resourced and has sufficient large-scale training data that we aim to extract knowledge from. We use subscript S for variables in the source language.
- **Target Language**: Low-resourced and has only a few training data that we wish to optimize on. We use subscript T for variables in the target language.

In this paper, we aim to improve the machine reading comprehension performance in Chinese (target language) by introducing English (source language) resources. The general idea of back-translation approaches is to translate <passage, question> pair into the source language and generate an answer using a reading comprehension system in the source language. Finally, the generated answer is back-translated into the target language. In the following subsections, we will introduce several back-translation approaches

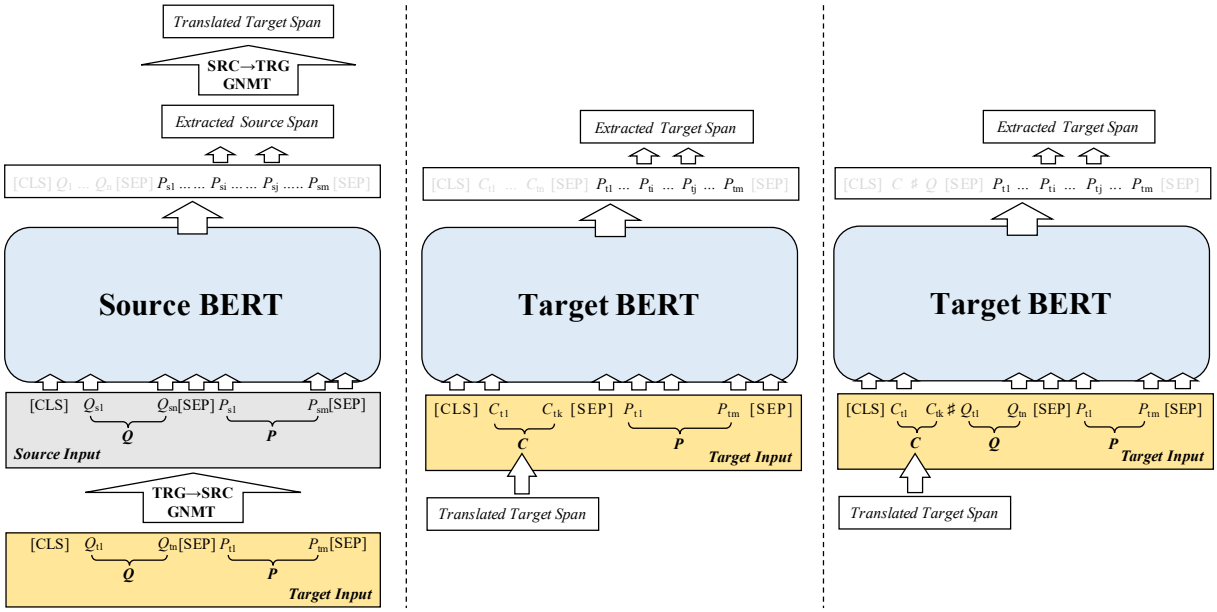

Figure 1: Back-translation approaches for cross-lingual machine reading comprehension (Left: GNMT, Middle: Answer Aligner, Right: Answer Verifier)

for cross-lingual machine reading comprehension task. The architectures of the proposed back-translation approaches are depicted in Figure 1.

3.1 GNMT

To build a simple cross-lingual machine reading comprehension system, it is straightforward to utilize translation system to bridge source and target language (Asai et al., 2018). Briefly, we first translate the target sample to the source language. Then we use a source reading comprehension system, such as BERT (Devlin et al., 2019), to generate an answer in the source language. Finally, we use back-translation to get the answer in the target language. As we do not exploit any training data in the target language, we could regard this approach as a *zero-shot* cross-lingual baseline system.

Specifically, we use Google Neural Machine Translation (GNMT) system for source-to-target and target-to-source translations. One may also use advanced and domain-specific neural machine translation system to achieve better translation performance, while we leave it for individuals, and this is beyond the scope of this paper.

However, for span-extraction reading comprehension task, a major drawback of this approach is that the translated answer may not be the exact span in the target passage. To remedy this, we propose three simple approaches to improve the quality of the translated answer in the target language.

3.2 Simple Match

We propose a simple approach to align the translated answer into extract span in the target passage. We calculate character-level text overlap (for Chinese) between translated answer A_{trans} and arbitrary sliding window in target passage $\mathcal{P}_{T[i:j]}$. The length of sliding window ranges $len(A_{trans}) \pm \delta$, with a relax parameter δ. Typically, the relax parameter $\delta \in [0, 5]$ as the length between ground truth and translated answer does not differ much in length. In this way, we would calculate character-level F1-score of each candidate span $\mathcal{P}_{T[i:j]}$ and translated answer A_{trans}, and we could choose the best matching one accordingly. Using the proposed SimpleMatch could ensure the predicted answer is an exact span in target passage. As SimpleMatch does not use target training data either, it could also be a pipeline component in *zero-shot* settings.

3.3 Answer Aligner

Though we could use unsupervised approaches for aligning answer, such as the proposed SimpleMatch, it stops at token-level and lacks semantic awareness between the translated answer and ground truth answer. In this paper, we also propose two supervised approaches for further improving the answer span when there is training data available in the target language.

The first one is Answer Aligner, where we feed

translated answer $\mathcal{A}_{trans}$ and target passage $\mathcal{P}_T$ into the BERT and outputs the ground truth answer span $\mathcal{A}_T$. The model will learn the semantic relations between them and generate improved span for the target language.

3.4 Answer Verifier

In Answer Aligner, we did not exploit question information in target training data. One can also utilize question information to transform Answer Aligner into Answer Verifier, as we use complete $\langle \mathcal{P}_T, \mathcal{Q}_T, \mathcal{A}_T \rangle$ in the target language and additional translated answer $\mathcal{A}_{trans}$ to verify its correctness and generate improved span.

4 Dual BERT

One disadvantage of the back-translation approaches is that we have to recover the source answer into the target language. To remedy the issue, in this paper, we propose a novel model called Dual BERT to simultaneously model the training data in both source and target language to better exploit the relations among <passage, question, answer>. The model could be used when there is training data available for the target language, and we could better utilize source language data to enhance the target reading comprehension system. The overall neural architecture for Dual BERT is shown in Figure 2.

4.1 Dual Encoder

Bidirectional Encoder Representation from Transformers (BERT) has shown marvelous performance in various NLP tasks, which substantially outperforms non-pretrained models by a large margin (Devlin et al., 2019). In this paper, we use multi-lingual BERT for better encoding the text in both source and target language. Formally, given target passage $\mathcal{P}_T$ and question $\mathcal{Q}_T$, we organize the input X_T for BERT as follows.

$$\texttt{[CLS]}\ \mathcal{Q}_T\ \texttt{[SEP]}\ \mathcal{P}_T\ \texttt{[SEP]}$$

Similarly, we can also obtain source training sample by translating target sample with GNMT, forming input X_S for BERT. Then we use X_T and X_S to obtain deep contextualized representations through a *shared* multi-lingual BERT, forming $B_T \in \mathbb{R}^{L_T * h}, B_S \in \mathbb{R}^{L_S * h}$, where L represents the length of input and h is the hidden size (768 for multi-lingual BERT).

4.2 Bilingual Decoder

Typically, in the reading comprehension task, attention mechanism is used to measure the relations between the passage and question. Moreover, as Transformers are fundamental components of BERT, multi-head self-attention layer (Vaswani et al., 2017) is used to extract useful information within the input sequence.

Specifically, in our model, to enhance the target representation, we use a multi-head self-attention layer to extract useful information in source BERT representation B_S. We aim to generate target span by not only relying on target representation but also on source representation to simultaneously consider the <passage, question> relations in both languages, which can be seen as a bilingual decoding process.

Briefly, we regard target BERT representation B_T as *query* and source BERT representation B_S as *key* and *value* in multi-head attention mechanism. In original multi-head attention, we calculate a raw dot attention as follows. [2] This will result in an attention matrix A_{TS} that indicate raw relations between each source and target token.

$$A_{TS} = B_T \cdot B_S^\top, \quad A_{TS} \in \mathbb{R}^{L_T * L_S} \tag{1}$$

To combine the benefit of both inter-attention and self-attention, instead of using Equation 1, we propose a simple modification on multi-head attention mechanism, which is called **Self-Adaptive Attention (SAA)**. First, we calculate self-attention of B_T and B_S and apply the softmax function, as shown in Equation 2 and 3. This is designed to use self-attention to filter the irrelevant part within each representation firstly, and inform the raw dot attention on paying more attention to the self-attended part, making the attention more precise and accurate.

$$A_T = \mathbf{softmax}(B_T \cdot B_T^\top) \tag{2}$$

$$A_S = \mathbf{softmax}(B_S \cdot B_S^\top) \tag{3}$$

Then we use self-attention A_T and A_S, inter-attention A_{TS} to get self-attentive attention $\tilde{A}_{TS}$. We calculate dot product between A_{ST} and B_S to obtain attended representation $R' \in \mathbb{R}^{L_T * h}$.

$$\tilde{A}_{TS} = A_T \cdot A_{TS} \cdot {A_S}^\top, \tilde{A}_{TS} \in \mathbb{R}^{L_T * L_S} \tag{4}$$

$$R' = \mathbf{softmax}(\tilde{A}_{TS}) \cdot B_S \tag{5}$$

[2] We omit rather extensive formulations of representation transformations and kindly advise the readers refer to the attention implementation in BERT: https://github.com/google-research/bert/blob/master/modeling.py#L558

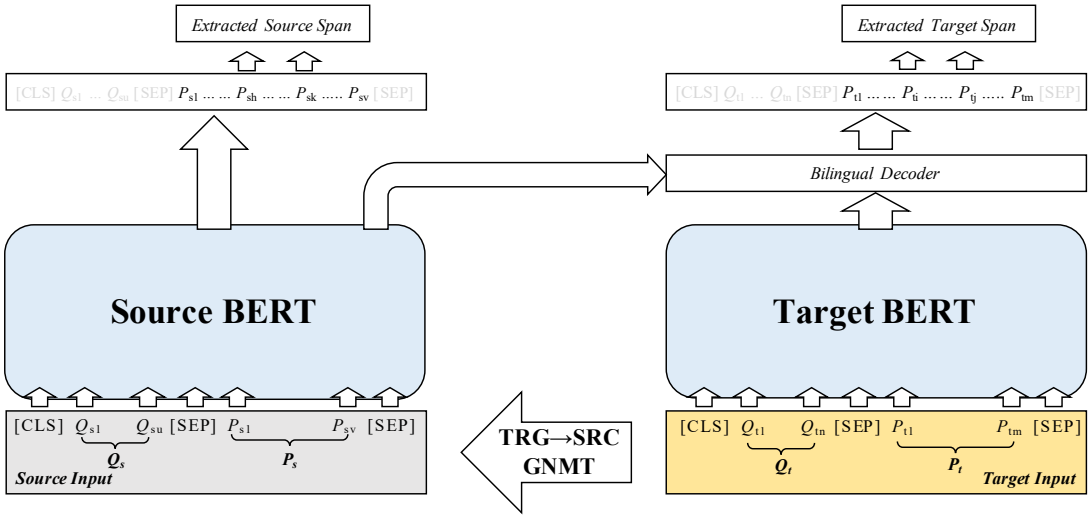

Figure 2: System overview of the Dual BERT model for cross-lingual machine reading comprehension task.

After obtaining attended representation R', we use an additional fully connected layer with residual layer normalization which is similar to BERT implementation.

$$R = W_r R' + b_r, \quad W_r \in \mathbb{R}^{h*h} \tag{6}$$

$$H_T = concat[B_T, \mathbf{LayerNorm}(B_T + R)] \tag{7}$$

Finally, we calculate weighted sum of H_T to get final span prediction P_T^s, P_T^e (superscript s for start, e for end). For example, the start position P_T^s is calculated by the following equation.

$$P_T^s = \mathbf{softmax}(W_T^\top H_T + b), \quad W_T \in \mathbb{R}^{2h} \tag{8}$$

We calculate standard cross entropy loss for the start and end predictions in the target language.

$$\mathcal{L}_T = -\frac{1}{N}\sum_{i=1}^{N}(y_T^s \log(P_T^s) + y_T^e \log(P_T^e)) \tag{9}$$

4.3 Auxiliary Output

In order to evaluate how translated sample behaves in the source language system, we also generate span prediction for source language using BERT representation B_S directly without further calculation, resulting in the start and target prediction P_S^s, P_S^e (similar to Equation 8). Moreover, we also calculate cross-entropy loss $\mathcal{L}_{aux}$ for translated sample (similar to Equation 9), where a λ parameter is applied to this loss.

Instead of setting λ with heuristic value, in this paper, we propose a novel approach to better adjust λ automatically. As the sample was generated by the machine translation system, there would be information loss during the translation process. Wrong or partially translated samples may harm the performance of reading comprehension system. To measure how the translated samples assemble the real target samples, we calculate cosine similarity between the *ground truth* span representation in source and target language (denoted as $\tilde{H}_S$ and $\tilde{H}_T$). When the ground truth span representation in the translated sample is similar to the real target samples, the λ increase; otherwise, we only use target span loss as λ may decrease to zero.

The span representation is the concatenation of three parts: BERT representation of ground truth start $B^s \in \mathbb{R}^h$, ground truth end $B^e \in \mathbb{R}^h$, and self-attended span $B^{att} \in \mathbb{R}^h$, which considers both boundary information (start/end) and mixed representation of the whole ground truth span. We use BERT representation B[3] to get a self-attended span representation B^{att} using a simple dot product with average pooling, to get a 2D-tensor.

$$\tilde{H}_S = concat[B_S^s, B_S^e, B_S^{att}] \tag{10}$$

$$\tilde{H}_T = concat[B_T^s, B_T^e, B_T^{att}] \tag{11}$$

$$\lambda = \max\{0, \cos < \tilde{H}_S, \tilde{H}_T >\} \tag{12}$$

The overall loss for Dual BERT is composed by two parts: target span loss $\mathcal{L}_T$ and auxiliary span loss in source language $\mathcal{L}_{aux}$.

$$\mathcal{L} = \mathcal{L}_T + \lambda \mathcal{L}_{aux} \tag{13}$$

[3]We mask out the values that out of span.

5 Experiments

5.1 Experimental Setups

We evaluate our approaches on two public Chinese span-extraction machine reading comprehension datasets: CMRC 2018 (simplified Chinese) (Cui et al., 2019)[4] and DRCD (traditional Chinese) (Shao et al., 2018)[5]. The statistics of the two datasets are listed in Table 1.

	Train	Dev	Test	Challenge
CMRC 2018				
Question #	10,321	3,219	4,895	504
Answer #	1	3	3	3
DRCD				
Question #	26,936	3,524	3,493	-
Answer #	1	2	2	-

Table 1: Statistics of CMRC 2018 and DRCD.

Note that, since the test and challenge sets are preserved by CMRC 2018 official to ensure the integrity of the evaluation process, we submitted our best-performing systems to the organizers to get these scores. The resource in source language was chosen as SQuAD (Rajpurkar et al., 2016) training data. The settings of the proposed approaches are listed below in detail.

- **Tokenization**: Following the official BERT implementation, we use WordPiece tokenizer (Wu et al., 2016) for English and character-level tokenizer for Chinese.

- **BERT**: We use pre-trained English BERT on SQuAD 1.1 (Rajpurkar et al., 2016) for initialization, denoted as SQ-B_{en} (base) and SQ-L_{en} (large) for back-translation approaches. For other conditions, we use multi-lingual BERT as default, denoted as B_{mul} (and SQ-B_{mul} for those were pre-trained on SQuAD).[6]

- **Translation**: We use Google Neural Machine Translation (GNMT) system for translation.[7] We evaluated GNMT system on NIST MT02/03/04/05/06/08 Chinese-English set and achieved an average BLEU score of 43.24, compared to previous best work (43.20) (Cheng et al., 2018), yielding state-of-the-art performance.

- **Optimization**: Following original BERT implementation, we use ADAM with weight decay optimizer (Kingma and Ba, 2014) using an initial learning rate of 4e-5 and use cosine learning rate decay scheme instead of the original linear decay, which we found it beneficial for stabilizing results. The training batch size is set to 64, and each model is trained for 2 epochs, which roughly takes 1 hour.

- **Implementation**: We modified the TensorFlow (Abadi et al., 2016) version `run_squad.py` provided by BERT. All models are trained on Cloud TPU v2 that has 64GB HBM.

5.2 Overall Results

The overall results are shown in Table 2. As we can see that, without using any alignment approach, the zero-shot results are quite lower regardless of using English BERT-base (#1) or BERT-large (#2). When we apply SimpleMatch (#3), we observe significant improvements demonstrating its effectiveness. The Answer Aligner (#4) could further improve the performance beyond SimpleMatch approach, demonstrating that the machine learning approach could dynamically adjust the span output by learning the semantic relationship between translated answer and target passage. Also, the Answer Verifier (#5) could further boost performance and surpass the multi-lingual BERT baseline (#7) that only use target training data, demonstrating that it is beneficial to adopt rich-resourced language to improve machine reading comprehension in other languages.

When we do not use SQuAD pre-trained weights, the proposed Dual BERT (#8) yields significant improvements (all results are verified by p-test with $p < 0.05$) over both Chinese BERT (#6) and multi-lingual BERT (#7) by a large margin. If we only train the BERT with SQuAD (#9), which is a zero-shot system, we can see that it achieves decent performance on two Chinese reading comprehension data. Moreover, we can also pursue further improvements by continue training (#10) with Chinese data starting from the system #9, or mixing Chinese data with SQuAD and training from initial multi-lingual BERT (#11). Under powerful SQuAD pre-trained baselines, Dual BERT (#12) still gives moderate and consistent improvements over Cascade Training (#10) and Mixed Training (#11) baselines

and set new state-of-the-art performances on both datasets, demonstrating the effectiveness of using machine-translated sample to enhance the Chinese reading comprehension performance.

5.3 Results on Japanese and French SQuAD

In this paper, we propose a simple but effective approach called SimpleMatch to align translated answer to original passage span. While one may argue that using neural machine translation attention to project source answer to original target passage span is ideal as used in Asai et al. (2018). However, to extract attention value in neural machine translation system and apply it to extract the original passage span is bothersome and computationally ineffective. To demonstrate the effectiveness of using SimpleMatch instead of using NMT attention to extract original passage span in zero-shot condition, we applied SimpleMatch to Japanese and French SQuAD (304 samples for each) which is what exactly used in Asai et al. (2018). The results are listed in Table 3.

From the results, we can see that, though our baseline (GNMT+BERT$_{L_{en}}$) is higher than previous work (Back-Translation (Asai et al., 2018)), when using SimpleMatch to extract original passage span could obtain competitive of even larger

	Japanese EM	Japanese F1	French EM	French F1

BERT$_{SQ-B_{mul}}$	61.3	73.4	57.6	77.1

Table 3: Zero-shot cross-lingual machine reading comprehension results on Japanese and French SQuAD data. † are extracted in Asai et al. (2018).

improvements. In Japanese SQuAD, the F1 score improved by 9.6 in Asai et al. (2018) using NMT attention, while we obtain larger improvement with 11.8 points demonstrating the effectiveness of the proposed method. BERT with pre-trained SQuAD weights yields the best performance among these systems, as it does not require the machine translation process and has unified text representations for different languages.

5.4 Ablation Studies

In this section, we ablate important components in our model to explicitly demonstrate its effectiveness. The ablation results are depicted in Table 4.

As we can see that, removing SQuAD pre-

	EM	F1
Dual BERT (w/ SQuAD)	**68.0**	**88.1**
w/o Auxiliary Loss	67.5 (-0.5)	87.7 (-0.4)
w/o Dynamic Lambda	67.3 (-0.7)	87.5 (-0.6)
w/o Self-Adaptive Att.	67.2 (-0.8)	87.5 (-0.6)
w/o Source BERT	66.6 (-1.4)	87.3 (-0.8)
w/o SQuAD Pre-Train	65.8 (-2.2)	86.3 (-1.8)

Table 4: Ablations of Dual BERT on the CMRC 2018 development set.

trained weights (i.e., using randomly initialized BERT) hurts the performance most, suggesting that it is beneficial to use pre-trained weights though the source and the target language is different. Removing source BERT will degenerate to cascade training, and the results show that it also harms overall performance, demonstrating that it is beneficial to utilize translated sample for better characterizing the relations between <passage, question, answer>. The other modifications seem to also consistently decrease the performance to some extent, but not as salient as the data-related components (last two lines), indicating that data-related approaches are important in cross-lingual machine reading comprehension task.

6 Discussion

In our preliminary cross-lingual experiments, we adopt English as our source language data. However, one question remains unclear.

Is it better to pre-train with larger data in a distant language (such as English, as oppose to Simplified Chinese), or with smaller data in closer language (such as Traditional Chinese)?

To investigate the problem, we plot the multi-lingual BERT performance on the CMRC 2018 development data using different language and data size in the pre-training stage. The results are depicted in Figure 3, and we come to several observations.

Firstly, when the size of pre-training data is under 25k (training data size of DRCD), we can see that there is no much difference whether we use Chinese or English data for pre-training, and even the English pre-trained models are better than Chinese pre-trained models in most of the times, which is not expected. We suspect that, by using multi-lingual BERT, the model tend to provide universal representations for the text and learn the language-independent semantic relations among the inputs which is ideal for cross-lingual tasks,

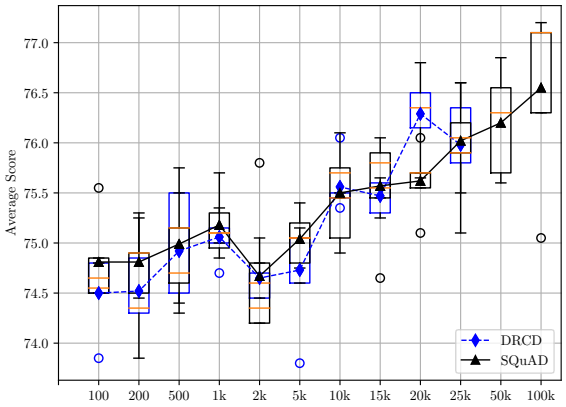

Figure 3: BERT performance (average of EM and F1) with different amount of pre-training SQuAD (English) or DRCD (Traditional Chinese).

thus the model is not that sensitive to the language in the pre-training stage. Also, as training data size of SQuAD is larger than DRCD, we could use more data for pre-training. When we add more SQuAD data (>25k) in the pre-training stage, the performance on the downstream task (CMRC 2018) continues to improve significantly. In this context, we conclude that,

- When the pre-training data is not abundant, there is no special preference on the selection of source (pre-training) language.
- If there are large-scale training data available for several languages, we should select the source language as the one that has the largest training data rather than its linguistic similarity to the target language.

Furthermore, one could also take advantages of data in various languages, but not only in a bilingual environment, to further exploit knowledge from various sources, which is beyond the scope of this paper and we leave this for future work.

7 Conclusion

In this paper, we propose Cross-Lingual Machine Reading Comprehension (CLMRC) task. When there is no training data available for the target language, firstly, we provide several zero-shot approaches that were initially trained on English and transfer to other languages, along with three methods to improve the translated answer span by using unsupervised and supervised approaches. When there is training data available for the target language, we propose a novel model

called Dual BERT to simultaneously model the <passage, question, answer> in source and target languages using multi-lingual BERT. The proposed method takes advantage of the large-scale training data by rich-resource language (such as SQuAD) and learns the semantic relations between the passage and question in both source and target language. Experiments on two Chinese machine reading comprehension datasets indicate that the proposed model could give consistent and significant improvements over various state-of-the-art systems by a large margin and set baselines for future research on CLMRC task.

Future studies on cross-lingual machine reading comprehension will focus on 1) how to utilize various types of English reading comprehension data; 2) cross-lingual machine reading comprehension without the translation process, etc.

A Multi-Type Multi-Span Network for Reading Comprehension that Requires Discrete Reasoning

Minghao Hu, Yuxing Peng, Zhen Huang, Dongsheng Li
National University of Defense Technology, Changsha, China
{huminghao09,pengyuxing,huangzhen,dsli}@nudt.edu.cn

Abstract

Rapid progress has been made in the field of reading comprehension and question answering, where several systems have achieved human parity in some simplified settings. However, the performance of these models degrades significantly when they are applied to more realistic scenarios, where answers are involved with various types, multiple text strings are correct answers, or discrete reasoning abilities are required. In this paper, we introduce the Multi-Type Multi-Span Network (MTMSN), a neural reading comprehension model that combines a multi-type answer predictor designed to support various answer types (e.g., span, count, negation, and arithmetic expression) with a multi-span extraction method for dynamically producing one or multiple text spans. In addition, an arithmetic expression reranking mechanism is proposed to rank expression candidates for further confirming the prediction. Experiments show that our model achieves 79.9 F1 on the DROP hidden test set, creating new state-of-the-art results. Source code[1] is released to facilitate future work.

1 Introduction

This paper considers the reading comprehension task in which some *discrete-reasoning* abilities are needed to correctly answer questions. Specifically, we focus on a new reading comprehension dataset called DROP (Dua et al., 2019), which requires Discrete Reasoning Over the content of Paragraphs to obtain the final answer. Unlike previous benchmarks such as CNN/DM (Hermann et al., 2015) and SQuAD (Rajpurkar et al., 2016) that have been well solved (Chen et al., 2016; Devlin et al., 2019), DROP is substantially more challenging in three ways. First, the answers to the questions involve a wide range of types such as numbers, dates, or text strings. Therefore, various kinds of prediction strategies are required to successfully find the answers. Second, rather than restricting the answer to be a span of text, DROP loosens the constraint so that answers may be a set of multiple text strings. Third, for questions that require discrete reasoning, a system must have a more comprehensive understanding of the context and be able to perform numerical operations such as addition, counting, or sorting.

Existing approaches, when applied to this more realistic scenario, have three problems. First, to produce various answer types, Dua et al. (2019) extend previous one-type answer prediction (Seo et al., 2017) to multi-type prediction that supports span extraction, counting, and addition/subtraction. However, they have not fully considered all potential types. Take the question "*What percent are not non-families?*" and the passage snippet "*39.9% were non-families*" as an example, a *negation* operation is required to infer the answer. Second, previous reading comprehension models (Wang et al., 2017; Yu et al., 2018; Hu et al., 2018) are designed to produce one single span as the answer. But for some questions such as "*Which ancestral groups are smaller than 11%?*", there may exist several spans as correct answers (e.g., "*Italian*", "*English*", and "*Polish*"), which can not be well handled by these works. Third, to support numerical reasoning, prior work (Dua et al., 2019) learns to predict signed numbers for obtaining an arithmetic expression that can be executed by a symbolic system. Nevertheless, the prediction of each signed number is isolated, and the expression's context information has not been considered. As a result, obviously-wrong expressions, such as all predicted signs are either minus or zero, are likely produced.

To address the above issues, we introduce

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1596–1606, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

the Multi-Type Multi-Span Network (MTMSN), a neural reading comprehension model for predicting various types of answers as well as dynamically extracting one or multiple spans. MTMSN utilizes a series of pre-trained Transformer blocks (Devlin et al., 2019) to obtain a deep bidirectional context representation. On top of it, a multi-type answer predictor is proposed to not only support previous prediction strategies such as span, count number, and arithmetic expression, but also add a new type of logical negation. This results in a wider range of coverage of answer types, which turns out to be crucial to performance. Besides, rather than always producing one single span, we present a multi-span extraction method to produce multiple answers. The model first predicts the number of answers, and then extracts non-overlapped spans to the specific amount. In this way, the model can learn to dynamically extract one or multiple spans, thus being beneficial for multi-answer cases. In addition, we propose an arithmetic expression reranking mechanism to rank expression candidates that are decoded by beam search, so that their context information can be considered during reranking to further confirm the prediction.

Our MTMSN model outperforms all existing approaches on the DROP hidden test set by achieving 79.9 F1 score, a 32.9% absolute gain over prior best work at the time of submission. To make a fair comparison, we also construct a baseline that uses the same BERT-based encoder. Again, MTMSN surpasses it by obtaining a 13.2 F1 increase on the development set. We also provide an in-depth ablation study to show the effectiveness of our proposed methods, analyze performance breakdown by different answer types, and give some qualitative examples as well as error analysis.

2 Task Description

In the reading comprehension task that requires discrete reasoning, a passage and a question are given. The goal is to predict an answer to the question by reading and understanding the passage. Unlike previous dataset such as SQuAD (Rajpurkar et al., 2016) where the answer is limited to be a single span of text, DROP loosens the constraint so that the answer involves various types such as number, date, or span of text (Figure 1). Moreover, the answer can be multiple text strings instead of single continuous span ($\mathbf{A}_2$). To successfully find the answer, some discrete reasoning abilities, such as sorting ($\mathbf{A}_1$), subtraction ($\mathbf{A}_3$), and negation ($\mathbf{A}_4$), are required.

Passage: As of the census of 2000, there were 218,590 people, 79,667 households, ... 22.5% were of German people, 13.1% Irish people, 9.8% Italian people, ...
$\mathbf{Q}_1$: Which group from the census is larger: German or Irish?
$\mathbf{A}_1$: German
$\mathbf{Q}_2$: Which ancestral groups are at least 10%?
$\mathbf{A}_2$: German, Irish
$\mathbf{Q}_3$: How many more people are there than households?
$\mathbf{A}_3$: 138,923
$\mathbf{Q}_4$: How many percent were not German?
$\mathbf{A}_4$: 77.5

Figure 1: Question-answer pairs along with a passage from the DROP dataset.

3 Our Approach

Figure 2 gives an overview of our model that aims to combine neural reading comprehension with numerical reasoning. Our model uses BERT (Devlin et al., 2019) as encoder: we map word embeddings into contextualized representations using pre-trained Transformer blocks (Vaswani et al., 2017) (§3.1). Based on the representations, we employ a multi-type answer predictor that is able to produce four answer types: (1) span from the text; (2) arithmetic expression; (3) count number; (4) negation on numbers (§3.2). Following Dua et al. (2019), we first predict the answer type of a given passage-question pair, and then adopt individual prediction strategies. To support multi-span extraction (§3.3), the model explicitly predicts the number of answer spans. It then outputs non-overlapped spans until the specific amount is reached. Moreover, we do not directly use the arithmetic expression that possesses the maximum probability, but instead re-rank several expression candidates that are decoded by beam search to further confirm the prediction (§3.4). Finally, the model is trained under weakly-supervised signals to maximize the marginal likelihood over all possible annotations (§3.5).

3.1 BERT-Based Encoder

To obtain a universal representation for both the question and the passage, we utilize BERT (Devlin et al., 2019), a pre-trained deep bidirectional Transformer model that achieves state-of-the-art performance across various tasks, as the encoder.

Specifically, we first tokenize the question and

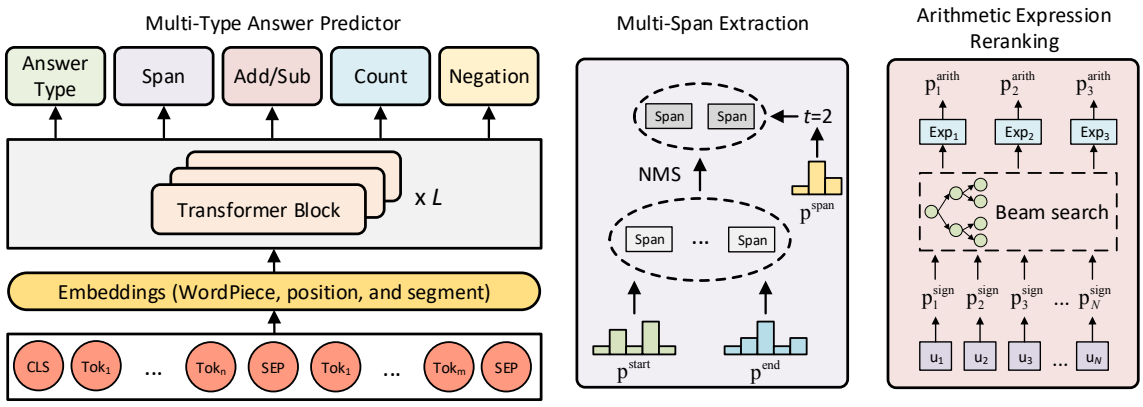

Figure 2: An illustration of MTMSN architecture. The multi-type answer predictor supports four kinds of answer types including span, addition/subtraction, count, and negation. A multi-span extraction method is proposed to dynamically produce one or several spans. The arithmetic expression reranking mechanism aims to rank expression candidates that are decoded by beam search for further validating the prediction.

the passage using the WordPiece vocabulary (Wu et al., 2016), and then generate the input sequence by concatenating a `[CLS]` token, the tokenized question, a `[SEP]` token, the tokenized passage, and a final `[SEP]` token. For each token in the sequence, its input representation is the element-wise addition of WordPiece embeddings, positional embeddings, and segment embeddings (Devlin et al., 2019). As a result, a list of input embeddings $\mathbf{H}_0 \in \mathbb{R}^{T \times D}$ can be obtained, where D is the hidden size and T is the sequence length. A series of L pre-trained Transformer blocks are then used to project the input embeddings into contextualized representations $\mathbf{H}_i$ as:

$$\mathbf{H}_i = \text{TransformerBlock}(\mathbf{H}_{i-1}), \forall i \in [1, L]$$

Here, we omit a detailed introduction of the block architecture and refer readers to Vaswani et al. (2017) for more details.

3.2 Multi-Type Answer Predictor

Rather than restricting the answer to always be a span of text, the discrete-reasoning reading comprehension task involves different answer types (e.g., number, date, span of text). Following Dua et al. (2019), we design a multi-type answer predictor to selectively produce different kinds of answers such as span, count number, and arithmetic expression. To further increase answer coverage, we propose adding a new answer type to support logical negation. Moreover, unlike prior work that separately predicts passage spans and question spans, our approach directly extracts spans from the input sequence.

Answer type prediction Inspired by the Augmented QANet model (Dua et al., 2019), we use the contextualized token representations from the last four blocks ($\mathbf{H}_{L-3}$, ..., $\mathbf{H}_L$) as the inputs to our answer predictor, which are denoted as $\mathbf{M}_0$, $\mathbf{M}_1$, $\mathbf{M}_2$, $\mathbf{M}_3$, respectively. To predict the answer type, we first split the representation $\mathbf{M}_2$ into a question representation $\mathbf{Q}_2$ and a passage representation $\mathbf{P}_2$ according to the index of intermediate `[SEP]` token. Then the model computes two vectors $\mathbf{h}^{\mathbf{Q}_2}$ and $\mathbf{h}^{\mathbf{P}_2}$ that summarize the question and passage information respectively:

$$\boldsymbol{\alpha}^Q = \text{softmax}(\mathbf{W}^Q \mathbf{Q}_2), \quad \mathbf{h}^{\mathbf{Q}_2} = \boldsymbol{\alpha}^Q \mathbf{Q}_2$$

where $\mathbf{h}^{\mathbf{P}_2}$ is computed in a similar way over $\mathbf{P}_2$.

Next, we calculate a probability distribution to represent the choices of different answer types as:

$$\mathbf{p}^{\text{type}} = \text{softmax}(\text{FFN}([\mathbf{h}^{\mathbf{Q}_2}; \mathbf{h}^{\mathbf{P}_2}; \mathbf{h}^{\text{CLS}}]))$$

Here, $\mathbf{h}^{\text{CLS}}$ is the first vector in the final contextualized representation $\mathbf{M}_3$, and FFN denotes a feed-forward network consisting of two linear projections with a GeLU activation (Hendrycks and Gimpel, 2016) followed by a layer normalization (Lei Ba et al., 2016) in between.

Span To extract the answer either from the passage or from the question, we combine the gating mechanism of Wang et al. (2017) with the standard decoding strategy of Seo et al. (2017) to predict the starting and ending positions across the entire sequence. Specifically, we first compute three vectors, namely $\mathbf{g}^{\mathbf{Q}_0}$, $\mathbf{g}^{\mathbf{Q}_1}$, $\mathbf{g}^{\mathbf{Q}_2}$, that summarize

the question information among different levels of question representations:

$$\boldsymbol{\beta}^{Q} = \text{softmax}(\text{FFN}(\mathbf{Q}_2), \quad \mathbf{g}^{\mathbf{Q}_2} = \boldsymbol{\beta}^{Q}\mathbf{Q}_2$$

where $\mathbf{g}^{\mathbf{Q}_0}$ and $\mathbf{g}^{\mathbf{Q}_1}$ are computed over $\mathbf{Q}_0$ and $\mathbf{Q}_1$ respectively, in a similar way as described above.

Then we compute the probabilities of the starting and ending indices of the answer span from the input sequence as:

$$\begin{aligned}
\bar{\mathbf{M}}^{\text{start}} &= [\mathbf{M}_2; \mathbf{M}_0; \mathbf{g}^{\mathbf{Q}_2} \otimes \mathbf{M}_2; \mathbf{g}^{\mathbf{Q}_0} \otimes \mathbf{M}_0], \\
\bar{\mathbf{M}}^{\text{end}} &= [\mathbf{M}_2; \mathbf{M}_1; \mathbf{g}^{\mathbf{Q}_2} \otimes \mathbf{M}_2; \mathbf{g}^{\mathbf{Q}_1} \otimes \mathbf{M}_1], \\
\mathbf{p}^{\text{start}} &= \text{softmax}(\mathbf{W}^{S}\bar{\mathbf{M}}^{\text{start}}), \\
\mathbf{p}^{\text{end}} &= \text{softmax}(\mathbf{W}^{E}\bar{\mathbf{M}}^{\text{end}})
\end{aligned}$$

where $\otimes$ denotes the outer product between the vector $\mathbf{g}$ and each token representation in $\mathbf{M}$.

Arithmetic expression In order to model the process of performing addition or subtraction among multiple numbers mentioned in the passage, we assign a three-way categorical variable (plus, minus, or zero) for each number to indicate its sign, similar to Dua et al. (2019). As a result, an arithmetic expression that has a number as the final answer can be obtained and easily evaluated.

Specifically, for each number mentioned in the passage, we gather its corresponding representation from the concatenation of $\mathbf{M}_2$ and $\mathbf{M}_3$, eventually yielding $\mathbf{U} = (\mathbf{u}_1, ..., \mathbf{u}_N) \in \mathbb{R}^{N \times 2*D}$ where N numbers exist. Then the probabilities of the i-th number being assigned a plus, minus or zero is computed as:

$$\mathbf{p}_i^{\text{sign}} = \text{softmax}(\text{FFN}([\mathbf{u}_i; \mathbf{h}^{\mathbf{Q}_2}; \mathbf{h}^{\mathbf{P}_2}; \mathbf{h}^{\text{CLS}}]))$$

Count We consider the ability of counting entities and model it as a multi-class classification problem. To achieve this, the model first produces a vector $\mathbf{h}^{\mathbf{U}}$ that summarizes the important information among all mentioned numbers, and then computes a counting probability distribution as:

$$\begin{aligned}
\boldsymbol{\alpha}^{U} &= \text{softmax}(\mathbf{W}^{U}\mathbf{U}), \quad \mathbf{h}^{\mathbf{U}} = \boldsymbol{\alpha}^{U}\mathbf{U}, \\
\mathbf{p}^{\text{count}} &= \text{softmax}(\text{FFN}([\mathbf{h}^{\mathbf{U}}; \mathbf{h}^{\mathbf{Q}_2}; \mathbf{h}^{\mathbf{P}_2}; \mathbf{h}^{\text{CLS}}]))
\end{aligned}$$

Negation One obvious but important linguistic phenomenon that prior work fails to capture is *negation*. We find there are many cases in DROP that require to perform logical negation on numbers. The question ($\mathbf{Q}_4$) in Figure 1 gives a qualitative example of this phenomenon. To model this phenomenon, we assign a two-way categorical variable for each number to indicate whether a negation operation should be performed. Then we compute the probabilities of logical negation on the i-th number as:

$$\mathbf{p}_i^{\text{negation}} = \text{softmax}(\text{FFN}([\mathbf{u}_i; \mathbf{h}^{\mathbf{Q}_2}; \mathbf{h}^{\mathbf{P}_2}; \mathbf{h}^{\text{CLS}}]))$$

3.3 Multi-Span Extraction

Although existing reading comprehension tasks focus exclusively on finding one span of text as the final answer, DROP loosens the restriction so that the answer to the question may be several text spans. Therefore, specific adaption should be made to extend previous single-span extraction to multi-span scenario.

To do this, we propose directly predicting the number of spans and model it as a classification problem. This is achieved by computing a probability distribution on span amount as

$$\mathbf{p}^{\text{span}} = \text{softmax}(\text{FFN}([\mathbf{h}^{\mathbf{Q}_2}; \mathbf{h}^{\mathbf{P}_2}; \mathbf{h}^{\text{CLS}}]))$$

To extract non-overlapped spans to the specific amount, we adopt the non-maximum suppression (NMS) algorithm (Rosenfeld and Thurston, 1971) that is widely used in computer vision for pruning redundant bounding boxes, as shown in Algorithm 1. Concretely, the model first proposes a set of top-K spans $\mathbf{S}$ according to the descending order of the span score, which is computed as $\mathbf{p}_k^{\text{start}}\mathbf{p}_l^{\text{end}}$ for the span (k, l). It also predicts the amount of extracted spans t from $\mathbf{p}^{\text{span}}$, and initializes a new set $\tilde{\mathbf{S}}$. Next, we add the span $\mathbf{s}_i$ that possesses the maximum span score to the set $\tilde{\mathbf{S}}$, and remove it from $\mathbf{S}$. We also delete any remaining span $\mathbf{s}_j$ that overlaps with $\mathbf{s}_i$, where the degree of overlap is measured using the text-level F1 function. This process is repeated for remaining spans in $\mathbf{S}$, until $\mathbf{S}$ is empty or the size of $\tilde{\mathbf{S}}$ reaches t.

3.4 Arithmetic Expression Reranking

As discussed in §3.2, we model the phenomenon of discrete reasoning on numbers by learning to predict a plus, minus, or zero for each number in the passage. In this way, an arithmetic expression composed of signed numbers can be obtained, where the final answer can be deduced by performing simple arithmetic computation. However, since the sign of each number is only determined by the number representation and some coarse-grained global representations, the context information of the expression itself has not been considered. As a result, the model may predict some

Algorithm 1 Multi-span extraction

Generate the set $\mathbf{S}$ by extracting top-K spans
Sort $\mathbf{S}$ in descending order of span scores
$t = \arg\max \mathbf{p}^{\text{span}} + 1$
Initialize $\tilde{\mathbf{S}} = \{\}$
while $\mathbf{S} \neq \{\}$ and $|\tilde{\mathbf{S}}| < t$ **do**
    for $\mathbf{s}_i$ in $\mathbf{S}$ **do**
        Add span $\mathbf{s}_i$ to $\tilde{\mathbf{S}}$
        Remove span $\mathbf{s}_i$ from $\mathbf{S}$
        for $\mathbf{s}_j$ in $\mathbf{S}$ **do**
            if $\text{f1}(\mathbf{s}_i, \mathbf{s}_j) > 0$ **then**
                Remove span $\mathbf{s}_j$ from $\mathbf{S}$
return $\tilde{\mathbf{S}}$

obviously wrong expressions (e.g., the signs that have maximum probabilities are either minus or zero, resulting in a large negative value). Therefore, in order to further validate the prediction, it is necessary to rank several highly confident expression candidates using the representation summarized from the expression's context.

Specifically, we use beam search to produce top-ranked arithmetic expressions, which are sent back to the network for reranking. Since each expression consists of several signed numbers, we construct an expression representation by taking both the numbers and the signs into account. For each number in the expression, we gather its corresponding vector from the representation $\mathbf{U}$. As for the signs, we initialize an embedding matrix $\mathbf{E} \in \mathbb{R}^{3\times 2*D}$, and find the sign embeddings for each signed number. In this way, given the i-th expression that contains M signed numbers at most, we can obtain number vectors $\mathbf{V}_i \in \mathbb{R}^{M\times 2*D}$ as well as sign embeddings $\mathbf{C}_i \in \mathbb{R}^{M\times 2*D}$. Then the expression representation along with the reranking probability can be calculated as:

$$\boldsymbol{\alpha}_i^V = \text{softmax}(\mathbf{W}^V(\mathbf{V}_i + \mathbf{C}_i)),$$
$$\mathbf{h}_i^{\mathbf{V}} = \boldsymbol{\alpha}_i^V(\mathbf{V}_i + \mathbf{C}_i),$$
$$\mathbf{p}_i^{\text{arith}} = \text{softmax}(\text{FFN}([\mathbf{h}_i^{\mathbf{V}}; \mathbf{h}^{\mathbf{Q}_2}; \mathbf{h}^{\mathbf{P}_2}; \mathbf{h}^{\text{CLS}}]))$$

3.5 Training and Inference

Since DROP does not indicate the answer type but only provides the answer string, we therefore adopt the weakly supervised annotation scheme, as suggested in Berant et al. (2013); Dua et al. (2019). We find all possible annotations that point to the gold answer, including matching spans, arithmetic expressions, correct count numbers, negation operations, and the number of spans. We use simple rules to search over all mentioned numbers to find potential negations. That is, if 100 minus a number is equal to the answer, then a negation occurs on this number. Besides, we only search the addition/subtraction of three numbers at most due to the exponential search space.

To train our model, we propose using a two-step training method composed of an inference step and a training step. In the first step, we use the model to predict the probabilities of sign assignments for numbers. If there exists any annotation of arithmetic expressions, we run beam search to produce expression candidates and label them as either correct or wrong, which are later used for supervising the reranking component. In the second step, we adopt the marginal likelihood objective function (Clark and Gardner, 2018), which sums over the probabilities of all possible annotations including the above labeled expressions. Notice that there are two objective functions for the multi-span component: one is a distantly-supervised loss that maximizes the probabilities of all matching spans, and the other is a classification loss that maximizes the probability on span amount.

At test time, the model first chooses the answer type and then performs specific prediction strategies. For the span type, we use Algorithm 1 for decoding. If the type is addition/subtraction, arithmetic expression candidates will be proposed and further reranked. The expression with the maximum product of cumulative sign probability and reranking probability is chosen. As for the counting type, we choose the number that has the maximum counting probability. Finally, if the type is negation, we find the number that possesses the largest negation probability, and then output the answer as 100 minus this number.

4 Experiments

4.1 Implementation Details

Dataset We consider the reading comprehension benchmark that requires Discrete Reasoning Over Paragraphs (DROP) (Dua et al., 2019) to train and evaluate our model. DROP contains crowdsourced, adversarially-created, 96.6K question-answer pairs, with 77.4K for training, 9.5K for validation, and another 9.6K hidden examples for testing. Passages are extracted from Wikipedia articles and the answer to each question involves various types such as number, date, or text string. Some answers may even be a set of multiple spans of text in the passage. To find the answers, a com-

prehensive understanding of the context as well as the ability of numerical reasoning are required.

Model settings We build our model upon two publicly available uncased versions of BERT: $\text{BERT}_{\text{BASE}}$ and $\text{BERT}_{\text{LARGE}}$[2], and refer readers to Devlin et al. (2019) for details on model sizes. We use Adam optimizer with a learning rate of 3e-5 and warmup over the first 5% steps to train. The maximum number of epochs is set to 10 for base models and 5 for large models, while the batch size is 12 or 24 respectively. A dropout probability of 0.1 is used unless stated otherwise. The number of counting class is set to 10, and the maximum number of spans is 8. The beam size is 3 by default, while the maximum amount of signed numbers M is set to 4. All texts are tokenized using WordPiece vocabulary (Wu et al., 2016), and truncated to sequences no longer than 512 tokens.

Baselines Following the implementation of Augmented QANet (NAQANet) (Dua et al., 2019), we introduce a similar baseline called Augmented BERT (NABERT). The main difference is that we replace the encoder of QANet (Yu et al., 2018) with the pre-trained Transformer blocks (Devlin et al., 2019). Moreover, it also supports the prediction of various answer types such as span, arithmetic expression, and count number.

4.2 Main Results

Two metrics, namely Exact Match (EM) and F1 score, are utilized to evaluate models. We use the official script to compute these scores. Since the test set is hidden, we only submit the best single model to obtain test results.

Table 1 shows the performance of our model and other competitive approaches on the develop-

Table 5: Performance breakdown of $\text{NABERT}_{\text{LARGE}}$ and $\text{MTMSN}_{\text{LARGE}}$ by predicted answer types.

ment and test sets. MTMSN outperforms all existing approaches by a large margin, and creates new state-of-the-art results by achieving an EM score of 75.85 and a F1 score of 79.88 on the test set. Since our best model utilizes $\text{BERT}_{\text{LARGE}}$ as encoder, we therefore compare $\text{MTMSN}_{\text{LARGE}}$ with the $\text{NABERT}_{\text{LARGE}}$ baseline. As we can see, our model obtains 12.07/13.19 absolute gain of EM/F1 over the baseline, demonstrating the effectiveness of our approach. However, as the human achieves 95.98 F1 on the test set, our results suggest that there is still room for improvement.

4.3 Ablation Study

Component ablation To analyze the effect of the proposed components, we conduct ablation studies on the development set. As illustrated in Table 2, the use of addition and subtraction is extremely crucial: the EM/F1 performance of both the base and large models drop drastically by more than 20 points if it is removed. Predicting count numbers is also an important component that contributes nearly 5% gain on both metrics. Moreover, enhancing the model with the negation type significantly increases the F1 by roughly 9 percent on both models. In brief, the above results show that multi-type answer prediction is vitally important for handling different forms of answers, especially in cases where discrete reasoning abilities are required.

We also report the performance after removing the multi-span extraction method. The results reveal that it has a more negative impact on the F1 score. We interpret this phenomenon as follows: producing multiple spans that are partially matched with ground-truth answers is much easier than generating an exactly-matched set of multiple answers. Hence for multi-span scenarios, the gain of our method on F1 is relatively easier to obtain than the one on EM. Finally, to ablate arithmetic expression reranking, we simply use the arithmetic expression that has the maximum cumulative sign probability instead. We find that our reranking mechanism gives 1.8% gain on both metrics for the large model. This confirms that validating expression candidates with their context information is beneficial for filtering out highly-confident but wrong predictions.

Architecture ablation We further conduct a detailed ablation in Table 3 to evaluate our architecture designs. First, we investigate the effects of some "global vectors" used in our model. Specifically, we find that removing the question and passage vectors from all involved computation leads to 1.3 % drop on F1. Ablating the representation of `[CLS]` token leads to even worse results. We also try to use the last hidden representation (denoted as $\mathbf{M}_3$) to calculate question and passage vectors, but find that does not work. Next, we remove the gating mechanism used during span prediction, and observe a nearly 0.8% decline on both metrics. Finally, we share parameters between the arithmetic expression component and the negation component, and find the performance drops by 1.1% on F1.

4.4 Analysis and Discussion

Performance breakdown We now provide a quantitative analysis by showing performance breakdown on the development set. Table 4 shows that our gains mainly come from the most frequent number type, which requires various types of symbolic, discrete reasoning operations. Moreover, significant improvements are also obtained in the multi-span category, where the F1 score increases by more than 40 points. This result further proves the validity of our multi-span extraction method.

We also give the performance statistics that are categorized according to the predicted answer types in Table 5. As shown in the Table, the main improvements are due to the addition/subtraction and negation types. We conjecture that there are two reasons for these improvements. First, our

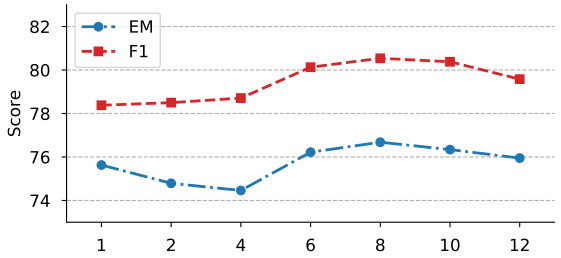

Figure 3: EM/F1 scores of $\text{MTMSN}_{\text{LARGE}}$ with different maximum numbers of spans.

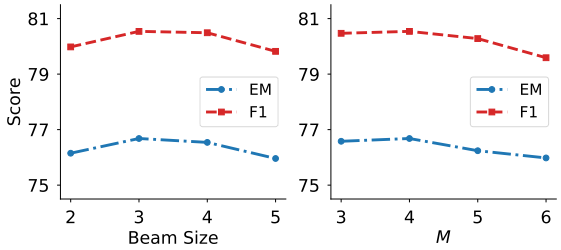

Figure 4: EM/F1 scores of $\text{MTMSN}_{\text{LARGE}}$ with different beam sizes and amounts of signed numbers (M).

proposed expression reranking mechanism helps validate candidate expressions. Second, a new inductive bias that enables the model to perform logical negation has been introduced. The impressive performance on the negation type confirms our judgement, and suggests that the model is able to find most of negation operations. In addition, we also observe promising gains brought by the span and count types. We think the gains are mainly due to the multi-span extraction method as well as architecture designs.

Effect of maximum number of spans To investigate the effect of maximum number of spans on multi-span extraction, we conduct an experiment on the dev set and show the curves in Figure 3. We vary the value from 2 to 12, increased by 2, and also include the extreme value 1. According to the Figure, the best results are obtained at 8. A higher value could potentially increase the answer recall but damage the precision by making more predictions, and a smaller value may force the model to produce limited number of answers, resulting in high precision but low recall. Therefore, a value of 8 turns out to be a good trade-off between recall and precision. Moreover, when the value decreases to 1, the multi-span extraction degrades to previous single-span scenario, and the performance drops significantly.

Configuration	Skipped	Kept	Ratio (%)	F1
Span	33752	43657	56.4	38.9
+ ♣	6384	71025	91.7	59.2
+ ♣ + ♠	4282	73127	94.4	63.6
+ ♣ + ♠ + ♡	1595	75814	97.9	72.8

Table 6: Annotation statistics under different combinations of answer types in the DROP train set. "Kept" and "Skipped" mean the number of examples with or without annotation, respectively. ♣ refers to Add/Sub, ♠ denotes Count, and ♡ indicates Negation. F1 scores are benchmarked using $\text{MTMSN}_{\text{BASE}}$ on the dev set.

Effect of beam size and M We further investigate the effect of beam size and maximum amount of signed numbers in Figure 4. As we can see, a beam size of 3 leads to the best performance, likely because a larger beam size might confuse the model as too many candidates are ranked, on the other hand, a small size could be not sufficient to cover the correct expression. In addition, we find that the performance constantly decreases as the maximum threshold M increases, suggesting that most of expressions only contain two or three signed numbers, and setting a larger threshold could bring in additional distractions.

Annotation statistics We list the annotation statistics on the DROP train set in Table 6. As we can see, only annotating matching spans results in a labeled ratio of 56.4%, indicating that DROP includes various answer types beyond text spans. By further considering the arithmetic expression, the ratio increase sharply to 91.7%, suggesting more than 35% answers need to be inferred with numeral reasoning. Continuing adding counting leads to a percentage of 94.4%, and a final 97.9% coverage is achieved by additionally taking negation into account. More importantly, the F1 score constantly increases as more answer types are considered. This result is consistent with our observations in ablation study.

Error analysis Finally, to better understand the remaining challenges, we randomly sample 100 incorrectly predicted examples based on EM and categorize them into 7 classes. 38% of errors are incorrect arithmetic computations, 18% require sorting over multiple entities, 13% are due to mistakes on multi-span extraction, 10% are single-span extraction problems, 8% involve miscounting, another 8% are wrong predictions on span number, the rest (5%) are due to various reasons

such as incorrect preprocessing, negation error, and so on. See Appendix for some examples of the above error cases.

5 Related Work

Reading comprehension benchmarks Promising advancements have been made for reading comprehension due to the creation of many large datasets. While early research used cloze-style tests (Hermann et al., 2015; Hill et al., 2016), most of recent works (Rajpurkar et al., 2016; Joshi et al., 2017) are designed to extract answers from the passage. Despite their success, these datasets only require shallow pattern matching and simple logical reasoning, thus being well solved (Chen et al., 2016; Devlin et al., 2019). Recently, Dua et al. (2019) released a new benchmark named DROP that demands discrete reasoning as well as deeper paragraph understanding to find the answers. Saxton et al. (2019) introduced a dataset consisting of different types of mathematics problems to focuses on mathematical computation. We choose to work on DROP to test both the numerical reasoning and linguistic comprehension abilities.

Neural reading models Previous neural reading models, such as BiDAF (Seo et al., 2017), R-Net (Wang et al., 2017), QANet (Yu et al., 2018), Reinforced Mreader (Hu et al., 2018), are usually designed to extract a continuous span of text as the answer. Dua et al. (2019) enhanced prior single-type prediction to support various answer types such as span, count number, and addition/subtraction. Different from these approaches, our model additionally supports a new negation type to increase answer coverage, and learns to dynamically extract one or multiple spans. Morevoer, answer reranking has been well studied in several prior works (Cui et al., 2016; Wang et al., 2018a,b,c; Hu et al., 2019). We follow this line of work, but propose ranking arithmetic expressions instead of candidate answers.

End-to-end symbolic reasoning Combining neural methods with symbolic reasoning was considered by Graves et al. (2014); Sukhbaatar et al. (2015), where neural networks augmented with external memory are trained to execute simple programs. Later works on program induction (Reed and De Freitas, 2016; Neelakantan et al., 2016; Liang et al., 2017) extended this idea by using several built-in logic operations along with a key-value memory to learn different types of compositional programs such as addition or sorting. In contrast to these works, MTMSN does not model various types of reasoning with a universal memory mechanism but instead deals each type with individual predicting strategies.

Visual question answering In computer vision community, the most similar work to our approach is Neural Module Networks (Andreas et al., 2016b), where a dependency parser is used to lay out a neural network composed of several pre-defined modules. Later, Andreas et al. (2016a) proposed dynamically choosing an optimal layout structure from a list of layout candidates that are produced by off-the-shelf parsers. Hu et al. (2017) introduced an end-to-end module network that learns to predict instance-specific network layouts without the aid of a parser. Compared to these approaches, MTMSN has a static network layout that can not be changed during training and evaluation, where pre-defined "modules" are used to handle different types of answers.

6 Conclusion

We introduce MTMSN, a multi-type multi-span network for reading comprehension that requires discrete reasoning over the content of paragraphs. We enhance a multi-type answer predictor to support logical negation, propose a multi-span extraction method for producing multiple answers, and design an arithmetic expression reranking mechanism to further confirm the prediction. Our model achieves 79.9 F1 on the DROP hidden test set, creating new state-of-the-art results. As future work, we would like to consider handling additional types such as sorting or multiplication/division. We also plan to explore more advanced methods for performing complex numerical reasoning.

Abstract

Supervised training of neural models to duplicate question detection in community Question Answering (cQA) requires large amounts of labeled question pairs, which are costly to obtain. To minimize this cost, recent works thus often used alternative methods, e.g., adversarial domain adaptation. In this work, we propose two novel methods: (1) the automatic generation of duplicate questions, and (2) weak supervision using the title and body of a question. We show that both can achieve improved performances even though they do not require any labeled data. We provide comprehensive comparisons of popular training strategies, which provides important insights on how to 'best' train models in different scenarios. We show that our proposed approaches are more effective in many cases because they can utilize larger amounts of unlabeled data from cQA forums. Finally, we also show that our proposed approach for weak supervision with question title and body information is also an effective method to train cQA answer selection models without direct answer supervision.

1 Introduction

The automatic detection of question duplicates in community Question Answering (cQA) forums is an important task that can help users to more effectively find existing questions and answers (Nakov et al., 2017; Cao et al., 2012; Xue et al., 2008; Jeon et al., 2005), and to avoid posting similar questions multiple times. Neural approaches to duplicate detection typically require large quantities of labeled question pairs for supervised training—i.e., labeled pairs of duplicate questions that can be answered with the same information.[1]

In practice, it is often difficult to obtain such data because of the immense manual effort that is required for annotation. A large number of cQA forums thus do not contain enough labeled data for supervised training of neural models.[2] Therefore, recent works have used alternative training methods. This includes weak supervision with question-answer pairs (Qiu and Huang, 2015), semi-supervised training (Uva et al., 2018), and adversarial domain transfer (Shah et al., 2018). An important limitation of these methods is that they still rely on substantial amounts of labeled data—either thousands of duplicate questions (e.g., from a similar source domain in the case of domain transfer) or large numbers of question-answer pairs. Furthermore, unsupervised methods rely on encoder-decoder architectures that impose limitations on the model architectures and they often fall short of the performances that are achieved with supervised training (Lei et al., 2016), or they need to be combined with complex features to achieve state-of-the-art results (Zhang and Wu, 2018). To train effective duplicate question detection models for the large number of cQA forums without labeled duplicates we thus need other methods that do not require any annotations while performing on-par with supervised in-domain training.

In this work, we propose two novel methods for scenarios where we only have access to unlabeled questions (title-body), including (1) automatic duplicate question generation (*DQG*); and (2) weak supervision with the title-body pairs (*WS-TB*). Because a question body typically provides additional important information that is not included in the title (Wu et al., 2018), we hypothesize that titles and bodies have similar properties as duplicate ques-

[1] For example, "Nautilus shortcut for new blank files?" and "How do you create a new document keyboard shortcut?" are titles of labeled duplicate questions from AskUbuntu.com.

[2] Shah et al. (2018) argue that even larger StackExchange sites do not offer enough duplicates for supervised training. Further, there exist many platforms that do not contain any labeled duplicates (e.g., https://gutefrage.net).

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tions. For instance, they are only partially redundant but fundamentally describe the same question (see Figure 1 for an example). As a consequence, we can use the information from titles and bodies together with their relations to train our models.

In DQG, we use question generation models to generate a new question title from the body and then consider the generated title as a duplicate to the question's original title. In WS-TB, we take this one step further and directly train models on title-body pairs—i.e., learning to predict whether both texts belong to the same question. The advantage of our proposed methods, compared to previous work, is that they can make use of the large number of unlabeled questions (titles and bodies) in cQA forums, which is typically an order of magnitude more data than is available for supervised training.[3]

In our experiments, we evaluate common question retrieval and duplicate detection models such as RCNN (Lei et al., 2016) and BiLSTM and compare a wide range of training methods: DQG, WS-TB, supervised training, adversarial domain transfer, weak supervision with question-answer pairs, and unsupervised training. We perform extensive experiments on multiple datasets and compare the different training methods in different scenarios, which provides important insights on how to 'best' train models with varying amounts training data. We show that:

1. Training models with title-body information is very effective. With larger amounts of unlabeled questions, WS-TB and DQG outperform adversarial domain transfer from similar source domains by more than 5.8pp on average. Because the amounts of labeled question duplicates is often limited, WS-TB and DQG can in some cases achieve better performances than supervised training.

2. DQG transfers well across domains, i.e., question generation models can be applied to novel target domains to obtain generated duplicates that are suitable for model training.

3. Our training methods are effective when being used to fine-tune more recent models such as BERT (Devlin et al., 2018a).

[3] Question titles and bodies are common in all StackExchange sites, popular platforms in other languages (e.g., GuteFrage.net), and forums such as Reddit. A counterexample is Quora, which only contains question titles. However, there exists a large annotated corpus of question pairs for this forum.

TITLE

How to customize each Firefox window icon individually?

BODY (1st PARAGRAPH)

I'm a tab hoarder and I admit it. But at least I've sorted them into contextual windows now, and I'd love to have different icons for each window in the Windows task bar (not the tab bar, which is governed by the favicons). How can this be achieved?

ANSWER

This can be done using the free AutoHotkey. Create a .ahk text file and enter these contents: (. . .)

Figure 1: An example question, the first paragraph of its body, and the first answer (from SuperUser[4]).

4. WS-TB can also be used to train cQA answer selection models without direct answer supervision. This shows that our methods can have broader impact on related tasks and beyond duplicate question detection.

2 Related Work

Duplicate question detection is closely related to question-question similarity and question retrieval. Early approaches use translation models (Jeon et al., 2005; Xue et al., 2008; Zhou et al., 2011) that were further enhanced with question category information (Cao et al., 2012) and topic models (Ji et al., 2012; Zhang et al., 2014).

More recent works in the context of the SemEval cQA challenges (Nakov et al., 2017) improve upon this and use tree kernels (TK) (Da San Martino et al., 2016), TK with neural networks (Romeo et al., 2016), neural networks with multi-task learning (Bonadiman et al., 2017), and encoder-decoder architectures together with shallow lexical matching and mismatching (Zhang and Wu, 2018). Common neural models such as CNNs achieved superior performance compared to TK when they were trained on sufficiently large numbers of labeled question pairs (Uva et al., 2018).

Similarly, neural representation learning methods have proved to be most effective in technical cQA domains. Santos et al. (2015), for example, learn representations of questions with CNNs and compare them with cosine similarity for scoring. Lei et al. (2016) propose RCNN, which extends CNN with a recurrent mechanism (adaptive gated

Method	Duplicates	Answers	Bodies
Supervised	×	-	(×)
WS-QA	-	×	(×)
Domain Transfer	×*	-	(×)
DQG	-	-	×
WS-TB	-	-	×

Table 1: The different training methods and the data they use. Models typically also use text from the bodies during training and evaluation, which we indicate with (×). ×* = domain transfer requires duplicates from a sufficiently similar source domain.

decay). This approach was further extended with question-type information (Gupta et al., 2018).

If in-domain training data is scarce—i.e., if the cQA platform does not offer enough labeled duplicates—alternative training strategies are required. If there exist some labeled question pairs (thousands), one can first train a less data-hungry non-neural model and use it for supervised training of neural models (Uva et al., 2018). Further, if there exist large numbers of labeled question-answer pairs, we can use them for weakly-supervised training (Wang et al., 2017; Qiu and Huang, 2015).

More related to our work are methods that do not rely on any labeled data in the target domain. Existing methods use unsupervised training with encoder-decoder architectures (Lei et al., 2016; Zhang and Wu, 2018), and adversarial domain transfer where the model is trained on a source domain and adversarially adapted to a target domain (Shah et al., 2018). However, such approaches typically fall short of the performances that are being achieved with in-domain supervised training.

In contrast, we propose two novel methods, DQG and WS-TB, that do not require any annotations for model training and in some cases perform better than in-domain supervised training with duplicate questions. While WS-TB is related to the approaches mentioned before, DQG is is also related to question generation (QG). Most of the previous work in QG is in the context of reading comprehension (e.g., Du et al., 2017; Subramanian et al., 2018; Zhao et al., 2018; Du and Cardie, 2018) or QG for question answering (Duan et al., 2017). They substantially differ from our approach because they generate questions based on specific answer spans, while DQG generates a new title from a question's body that can be used as a question duplicate.

3 Training Methods

Given a pair of questions, our goal is to determine whether they are duplicates or not. In practice, the model predictions are often used to rank a list of potentially similar questions in regard to a new user question, e.g., to retrieve the most likely duplicate for automatic question answering.

To train models, we obtain a set of examples $\{(x_1, y_1), \ldots, (x_N, y_N)\}$ in which each $x_n \in \mathcal{X}$ is an instance, i.e., a tuple containing texts such as two questions, and $y_n \in \{-1, +1\}$ is its corresponding binary label, e.g., duplicate/no-duplicate. Obtaining instances with positive labels $\mathcal{X}^+ = \{x_n^+ \in \mathcal{X} | y_n = 1\}$ is generally more difficult than obtaining $\mathcal{X}^-$ because instances with negative labels can be automatically generated (e.g., by randomly sampling unrelated questions).

In the following, we outline three existing training methods that use different kinds of instances, and in §3.2 we present our two novel methods: duplicate question generation, and weak supervision with title-body pairs. Both do not require any annotations in $\mathcal{X}^+$, and can therefore use larger amounts of data from the cQA forums. Table 1 gives an overview of the different training methods.

3.1 Existing Methods

Supervised (in-domain) training is the most common method, which requires labeled question duplicates, i.e., $x_n^+ = (q_n, \tilde{q}_n)$. Unrelated questions can be randomly sampled. With this data, we can train representation learning models (e.g., Lei et al., 2016) or pairwise classifiers (e.g., Uva et al., 2018). Most models combine the titles and bodies of the questions during training and evaluation (e.g., by concatenation), which can improve performances (Lei et al., 2016; Wu et al., 2018).

Weak supervision with question-answer pairs (WS-QA) is an alternative to supervised training for larger platforms without duplicate annotations (Qiu and Huang, 2015). WS-QA trains models with questions q_n and accepted answers a_n, and therefore $x_n^+ = (q_n, a_n)$. Instances in X^- can be obtained by randomly sampling unrelated answers for a question. An advantage of this method is that there typically exist more labeled answers than duplicate questions. For instance, Yahoo! answers has accepted answers but it does not contain labeled duplicate questions.

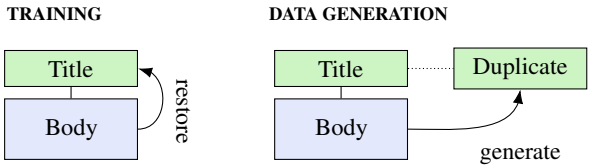

Figure 2: During training we restore the original question title from its body. During data generation we consider the generated title as a new duplicate question.

Domain transfer performs supervised training in a source domain and applies the trained model to a different target domain in which no labeled duplicate questions exist. Shah et al. (2018) use this method with adversarial training to learn domain-invariant question representations prior to transfer. They show that adversarial training can considerably improve upon direct transfer, but their method requires sufficiently similar source and target domains. For instance, they could not successfully transfer models between technical and other non-technical domains.

3.2 Proposed Methods with Unlabeled Data

The disadvantage of the existing methods is that they require labeled question duplicates, accepted answers, or similar source and target domains for transfer. We could alternatively use unsupervised training within an encoder-decoder framework, but this imposes important limitations on the network architecture, e.g., a question can only be encoded independently (no inter-attention).

Our proposed methods do not suffer from these drawbacks, i.e., they do not require labeled data and they do not impose architectural limitations.

Duplicate question generation (DQG) generates new question titles from question bodies, which we then consider as duplicates to the original titles. Our overall approach is depicted in Figure 2. First, we train a question generation model QG to maximize $P(\text{title}(q_n)|\text{body}(q_n))$. This is similar to news headline generation or abstractive summarization (Rush et al., 2015; Chopra et al., 2016) because QG needs to identify the most relevant aspects in the body that best characterize the question. However, restoring the exact title is usually not possible because titles and bodies often contain complementary information (see, e.g., Figure 1). We therefore consider $\text{QG}(\text{body}(q_n))$ as a duplicate of $\text{title}(q_n)$ and obtain positive labeled instances $x_n^+ = (\text{title}(q_n), \text{QG}(\text{body}(q_n)))$.

Dataset	Train / Dev / Test	|Q|	|A|
AskUbuntu-Lei	12,584 / 200 / 200	288k	84k
AskUbuntu	9106 / 1000 / 1000	288k	84k
SuperUser	9106 / 1000 / 1000	377k	142k
Apple	- / 1000 / 1000	89k	29k
Android	- / 1000 / 1000	47k	14k

Table 2: The dataset statistics. Numbers for Train/Dev/Test refer to the number of questions with duplicates. |Q| refers to the number of unlabeled questions, and |A| refers to the number of accepted answers.

Because DQG requires no annotated data, we can use this method to train duplicate detection models for all cQA forums that offer a reasonable number of unlabeled title-body pairs to obtain a suitable QG model (the smallest number of questions we tried for training of question generation models is 23k, see §5). An important advantage is that we can make use of *all questions* (after some basic filtering), which is often an order of magnitude more training data than annotated duplicates.

We can use any sequence to sequence model for QG, and we performed experiments with a Transformer (Vaswani et al., 2017) and MQAN (McCann et al., 2018).

Weak supervision with title-body pairs (WS-TB) takes the assumption of DQG one step further. If question titles and question bodies have similar attributes as duplicates, we could also just train duplicate detection models directly on this data without prior question generation.

In WS-TB, we thus train models to predict whether a given title and body are related, i.e., whether they belong to the same question. Therefore, $x^+ = (\text{title}(q_n), \text{body}(q_n))$.

This method considerably simplifies the sourcing of training data because it requires no separate question generation model. However, it also means that the duplicate detection model must be able to handle texts of considerably different lengths during training (for instance, bodies in SuperUser.com have an average length of 125 words). This might not be suitable for some text matching models, e.g., ones that were designed to compare two sentences.

4 Experiments

4.1 Experimental Setup

We use models and data from previous literature to obtain comparable results for evaluation, and we rely on their official implementations, default

hyperparameters, and evaluation measures. An overview of the datasets is given in Table 2, which also shows that they considerably differ in the amounts of data that is available for the different training methods.

The evaluation setup is the same for all datasets: given a user question q and a list of potentially related questions, the goal is to re-rank this list to retrieve duplicates of q (one or more potential related questions are labeled as duplicates). Even though some training methods do not use bodies during training, e.g., WS-DQG, during evaluation they use the same data (annotated pairs of questions with titles and bodies).[5]

AskUbuntu-Lei. First, we replicate the setup of Lei et al. (2016), which uses RCNN to learn dense vector representations of questions and then compares them with cosine similarity for scoring. Besides supervised training, this also includes unsupervised training with the encoder-decoder architecture. We report precision at 5 (P@5), i.e., how many of the top-5 ranked questions are actual duplicates. The dataset is based on the AskUbuntu data of Santos et al. (2015) with additional manual annotations for dev/test splits (user questions have an average of 5.7 duplicates).

Android, Apple, AskUbuntu, and Superuser. Second, we replicate the setup of Shah et al. (2018), which uses BiLSTM to learn question representations. This setup also includes adversarial domain transfer. The data is from the AskUbuntu, Superuser, Android, and Apple sites of StackExchange, and different to AskUbuntu-Lei, each question has only one duplicate. We measure AUC(0.05), which is the area under curve with a threshold for false positives—Shah et al. (2018) argue that this is more stable when there are many unrelated questions.

Questions and answers. To train the models with WS-TB and WS-QA, we use questions and answers from publicly available data dumps[6] of the StackExchange platforms. We obtain our new training sets as specified in §3.2. For instance, for WS-TB we replace every annotated duplicate $(q_n, \tilde{q}_n)$ from the original training split with $(\text{title}(q_n), \text{body}(q_n))$, and we randomly sample unrelated bodies to obtain training instances with negative labels.

It is important to note that the number of questions and answers is much larger than the number of annotated duplicate questions. Therefore, we can add more instances to the training splits with these methods. However, if not otherwise noted, we use the same number of training instances as in the original training splits with duplicates.

DQG setup. To train question generation models, we use the same StackExchange data. We filter the questions to ensure that the bodies contain multiple sentences. Further, if a body contains multiple paragraphs, we only keep the one with the highest similarity to the title. Details of the filtering approach are included in the Appendix. Less than 10% of the questions are discarded on average.

We train a MQAN (Multi-task Question Answering Network) model, which was proposed as a very general network architecture to solve a wide variety of tasks as part of the Natural Language Decathlon (McCann et al., 2018). The model first encodes the input with LSTMs and applies different attention mechanisms, including multi-headed self-attention. MQAN also includes pointer-generator networks (See et al., 2017), which allow it to copy tokens from the input text depending on the attention distribution of an earlier layer.

We performed the same experiments with a Transformer sequence to sequence model (Vaswani et al., 2017), but on average MQAN performed better because of its ability to copy words and phrases from the body. We include the Transformer results and a comparison with MQAN in the Appendix.

We use all available questions from a cQA forum to train the question generation model. We perform early stopping using BLEU scores to avoid overfitting. To generate duplicate questions, we then apply the trained model on all questions from the same cQA forum. We do not use a separate heldout set because this would considerably limit both the question generation training data and the number of generated duplicates. We did not observe negative effects from using this procedure.

4.2 Experimental Results

The results are given in Table 3. For domain transfer, we report the best scores from Shah et al. (2018), which reflects an optimal transfer setup from a similar source domain.

[5] It has been shown that including bodies in the experimental setup can lead to improved performances (Lei et al., 2016). In initial experiments, we found that the performances are mostly impacted by having access to bodies during evaluation.

Table 3: Results of the models with different training strategies. Android and Apple datasets do not contain labeled duplicates for supervised in-domain training.

Supervised training. As we expect, supervised in-domain training with labeled duplicates achieves better scores compared to other training methods when we consider the same number of training instances. An exception is on AskUbuntu-Lei where DQG, WS-TB, and WS-QA can achieve results that are on the same level on test or marginally worse on dev.

One reason for the better performances with labeled duplicates is that they contain more information, i.e., a pair of questions consist of two titles and two bodies compared to just one title and body for each training instance in WS-TB. However, the results show that all weakly supervised techniques as well as DQG are effective training methods.

DQG, WS-TB, and WS-QA. All methods outperform direct transfer from a similar source domain as well as the encoder-decoder approach on AskUbuntu-Lei. On average, WS-TB is the most effective method, and it consistently outperforms adversarial domain transfer (0.9pp on average).

We otherwise do not observe large differences between the three methods DQG, WS-TB, and WS-QA, which shows that (1) the models we use can learn from different text lengths (title-body, question-answer); and (2) the information that we extract in DQG is suitable for training (examples are given in §6). The good results of WS-TB might suggest that question generation as separate step is not required, however we argue that it can be important in a number of scenarios, e.g., when we need to train sentence matching models that would otherwise not be able to handle long texts.

Using all available data. One of the biggest advantages of our proposed methods is that they can use larger amounts of training data. This greatly improves the model performances for BiLSTM, where we observe average improvements of up to 4.7pp (for WS-TB). In many cases our methods now perform better than supervised training. We observe smaller improvements for WS-QA (2.8pp on avg) because it has access to fewer training instances. The performances for RCNN on AskUbuntu-Lei are mostly unchanged with minor improvements on dev. The reason is that the performances were already close to supervised training with the same data sizes.

In Figure 3 we plot the performance scores of BiLSTM averaged over the four StackExchange datasets in relation to the available training data with WS-TB. We see that the model performance consistently improves when we increase the training data (we observe similar trends for DQG and WS-QA). Thus, it is crucial to make use of all available data from the cQA forums.

We also explored a combination of our two proposed approaches where we merge their respective training sets. We find that this helps mostly for smaller cQA platforms with fewer questions (where larger training sets would be most necessary), e.g., the performances on Android and Apple improve by 0.6–1.1pp compared to WS-TB. Even though the combination does not introduce new information because both use the same question data, complementing WS-TB with DQG can provide additional variation with the generative component.

In summary, our results show that even when we

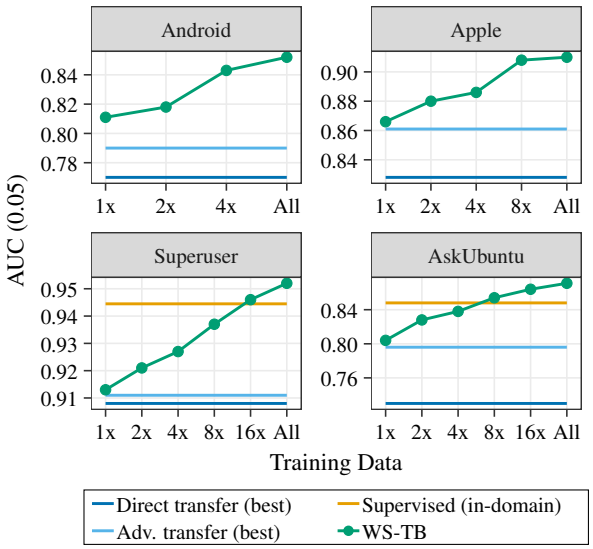

Figure 3: Performances of BiLSTM as a function of the available training data. '2x' means that there are twice as many (unlabeled) questions available to WS-TB than there are annotated duplicate questions in the original dataset (1x = 9106).

have access to sufficient numbers of labeled duplicates, the 'best' method is not always supervised training. When we use larger numbers of title-body pairs, DQG and WS-TB can achieve better performances.

5 Further Application Scenarios

To test if our methods are applicable to other scenarios with high practical relevance, we explore (1) whether DQG can be used in cQA forums with fewer unlabeled title-body pairs, (2) if we can use WS-TB to train answer selection models without labeled question-answer pair, and (3) how well large pre-trained language models perform when being fine-tuned with our methods.

5.1 DQG for Small-Scale cQA Forums

In our previous experiments, we assumed that there exist enough unlabeled questions to train the question generation model (at least 47k questions, see Table 2). To simulate a more challenging scenario with fewer in-domain questions, we explore the effects of cross-domain question generation. This is highly relevant for DQG because in such scenarios the generated duplicates could be combined with WS-TB to obtain more training data.

We replicate the transfer setup of Shah et al. (2018) where they originally transfer the duplicate question detection model from a source to a target domain. For DQG we instead train the question generation model on the source domain and generate duplicates for the target domain, with which we then train the duplicate detection model. To provide a fair comparison against adversarial domain transfer, we always use the same number of 9106 duplicates to train the duplicate detection models.

Source	Target	Adv. DT	DQG	Δ
AskUbuntu	Android	0.790	**0.797**	+0.004
	Apple	0.855	**0.861**	−0.009
	SuperUser	0.911	**0.916**	−0.005
SuperUser	Android	0.790	**0.794**	+0.001
	Apple	**0.861**	**0.861**	−0.009
	AskUbuntu	0.796	**0.809**	+0.008
Academia	Android	-	0.776	−0.017
	Apple	-	0.854	−0.016
	SuperUser	-	0.912	−0.009
	AskUbuntu	-	0.760	−0.039

Table 4: The domain transfer performances. Δ denotes the difference to the setup with in-domain DQG.

Results for the transfer from SuperUser and AskUbuntu to other domains are given in Table 4. They show that the question generation model for DQG can be successfully transferred across similar domains with only minor effects on the performances. Importantly, DQG still performs better than adversarial domain transfer with the same number of training instances.

To test an even more extreme case, we also transfer from StackExchange Academia (only 23k title-body pairs to train question generation) to the technical target domains. This could, e.g., be realistic for other languages with fewer cQA forums. Most notably, the performance of DQG decreases only mildly, which demonstrates its practical applicability in even more challenging scenarios. This is mostly due to the copy mechanism of MQAN, which is stable across domains (see §6).

5.2 Answer Selection

In answer selection we predict whether a candidate answer is relevant in regard to a question (Tay et al., 2017; Nakov et al., 2017; Tan et al., 2016; Rücklé and Gurevych, 2017), which is similar to duplicate question detection.

To test whether our strategy to train models with title-body pairs is also suitable for answer selection, we use the data and code of Rücklé et al. (2019a) and train two different types of models with WS-TB on their five datasets that are based on StackExchange Apple, Aviation, Academia, Cooking, and Travel. We train (1) a siamese BiLSTM, which

Model	Supervised	WS-TB	WS-TB (all)
BiLSTM	35.3	37.5	42.5
COALA	44.7	45.2	44.5

Table 5: Answer selection performances (averaged over five datasets) when trained with question-answer pairs vs. WS-TB.

learns question and answer representations; and (2) their neural relevance matching model COALA. Both are evaluated by how well they re-rank a list of candidate answers in regard to a question.

The results are given in Table 5 where we report the accuracy (P@1), averaged over the five datasets. Interestingly, we do not observe large differences between supervised training and WS-TB for both models when they use the same number of positive training instances (ranging from 2.8k to 5.8k). Thus, using title-body information instead of question-answer pairs to train models without direct answer supervision is feasible and effective. Further, when we use all available title-body pairs, the BiLSTM model substantially improves by 5pp, which is only slightly worse than COALA (which was designed for smaller training sets). We hypothesize that one reason is that BiLSTM can learn improved representations with the additional data. Further, title-body pairs have a higher overlap than question-answer pairs (see §6) which provides a stronger training signal to the siamese network.

These results demonstrate that our work can have broader impact to cQA, e.g., to train models on other tasks beyond duplicate question detection.

5.3 BERT Fine-Tuning

Large pre-trained language models such as BERT (Devlin et al., 2018b) and RoBERTa (Liu et al., 2019) have recently led to considerable improvements across a wide range of NLP tasks. To test whether our training strategies can also be used to fine-tune such models, we integrate BERT in the setups of our previous experiments.[7] We fine-tune a pre-trained BERT-base (uncased) model with supervised training, WS-TB (1x), and WS-TB (8x).

The results are given in Table 6. We observe similar trends as before but with overall better results. When increasing the number of training examples, the model performances consistently improve. We note that we have also conducted preliminary experiments with larger BERT models where we observed further improvements.

[7]We add the AskUbuntu-Lei dataset to the framework of Rücklé et al. (2019a) for our BERT experiments. Details are given in the Appendix.

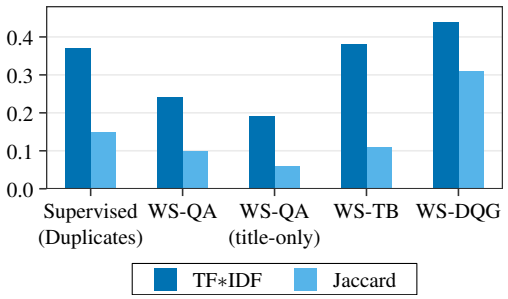

Figure 4: Average overlap of texts from positive training instances (words were stemmed and lowercased).

6 Analysis

6.1 Overlap

To analyze the differences in the training methods we calculate the overlap between the texts of positive training instances (e.g., question-question, title-body, question-answer etc.). For questions, we concatenate titles and bodies.

Figure 4 shows the Jaccard coefficient and the TF∗IDF score averaged over all instances in the four StackExchange datasets of §4.2. We observe that the overlap in WS-TB is similar to the overlap of actual duplicate questions in supervised training. The WS-DQG overlap is higher, because generated titles only contain relevant content (e.g., no conversational phrases). We also found that the BLEU scores of the MQAN model for QG are not very high (between 13.3–18.9 BLEU depending on the dataset), which shows that the texts are still sufficiently different. The overlap shows that both our methods use suitable training data with sufficiently similar, but not fully redundant texts.

Interestingly, the overlap scores of question-answer pairs are lower, especially when considering title-answer pairs as it is the case in the answer selection experiments (§5.2). This could explain one factor that may contribute to the better scores that we achieve with WS-TB for BiLSTM in this scenario. Because the overlap of title-body pairs is higher, the siamese network can receive a stronger training signal for positive instances, which could lead to better representations for similarity scoring.

6.2 Qualitative Analysis

To better understand the results for DQG and WS-QA, we manually checked a random sample of 200 generated questions and title-body pairs from multi-

	AskUbuntu-Lei	Android	Apple	AskUbuntu	Superuser	Answer Selection
	Measuring P@5. Results for dev / test	Measuring AUC(0.05)				Measuring Accuracy
Supervised (in-domain)	**54.0 / 52.3**	-	-	0.862	0.954	56.8
WS-TB (1x)	47.8 / 47.2	0.857	0.908	0.841	0.932	55.5
WS-TB (8x)	50.4 / 49.6	**0.896**	**0.933**	**0.897**	**0.971**	**59.7**

Title: Grub2 not updating

DQG: How to fix Grub2 error

Figure 5: Random samples of titles and DQG output.

ple platforms. Three titles and generated duplicates from AskUbuntu are shown in Figure 5.

For DQG we found that most of the generated duplicates are sensible, and most of the error cases fall into one of the following two categories:

(1) Some generated questions are somewhat off-topic because they contain information that was generated from a body that has minimal overlap with the title (see example 4 in the Appendix).

(2) A number of questions include wrong version numbers or wrong names (see example 5 in the Appendix, or the second example in Figure 5).

Generally, however, we find that many of the generated titles introduce novel information, as can be seen in Figure 5 (e.g., 'ALSA', 'boot loader' etc). The same drawbacks and benefits also apply to title-body information in WS-TB, with the exception that they are less noisy (i.e., not generated) but contain conversational phrases and many details.

We also checked the training data of the difficult DQG domain transfer case to explore reasons for the small performance decreases when transferring the question generation model. Most importantly, we find that the model often falls back to copying important phrases from the body and sometimes generates additional words from the source domain. We note that this is not the case for models without copy mechanisms, e.g., Transformer often generates unrelated text (examples are in the Appendix).

7 Conclusion

In this work, we have trained duplicate question detection models without labeled training data. This can be beneficial for a large number of cQA forums that do not contain enough annotated duplicate questions or question-answer pairs to use existing training methods. Our two novel methods, duplicate question generation and weak supervision with title-body pairs, only use title-body information of unlabeled questions and can thus utilize more data during training. While both are already highly effective when using the same number of training instances as other methods (e.g., outperforming adversarial domain transfer), our experiments have shown that we can outperform even supervised training when using larger amounts of unlabeled questions.

Further, we have demonstrated that weak supervision with title-body pairs is well-suited to train answer selection models without direct answer supervision. This shows that our work can potentially benefit a much wider range of related tasks beyond duplicate question detection. For instance, future work could extend upon this by using our methods to obtain more training data in cross-lingual cQA setups (Joty et al., 2017; Rücklé et al., 2019b), or by combining them with other training strategies, e.g., using our methods for pre-training.

The source code and the data of our experiments are publicly available: `http://github.com/UKPLab/emnlp2019-duplicate_question_detection`.

Abstract

The ability to ask clarification questions is essential for knowledge-based question answering (KBQA) systems, especially for handling ambiguous phenomena. Despite its importance, clarification has not been well explored in current KBQA systems. Further progress requires supervised resources for training and evaluation, and powerful models for clarification-related text understanding and generation. In this paper, we construct a new clarification dataset, CLAQUA, with nearly 40K open-domain examples. The dataset supports three serial tasks: given a question, identify whether clarification is needed; if yes, generate a clarification question; then predict answers base on external user feedback. We provide representative baselines for these tasks and further introduce a coarse-to-fine model for clarification question generation. Experiments show that the proposed model achieves better performance than strong baselines. The further analysis demonstrates that our dataset brings new challenges and there still remain several unsolved problems, like reasonable automatic evaluation metrics for clarification question generation and powerful models for handling entity sparsity.[1]

1 Introduction

Clarification is an essential ability for knowledge-based question answering, especially when handling ambiguous questions (Demetras et al., 1986). In real-world scenarios, ambiguity is a common phenomenon as many questions are not clearly articulated, e.g. *"What are the languages used to create the source code of Midori?"* in Figure 1. There are two "*Midori*" using different programming languages, which confuses the system.

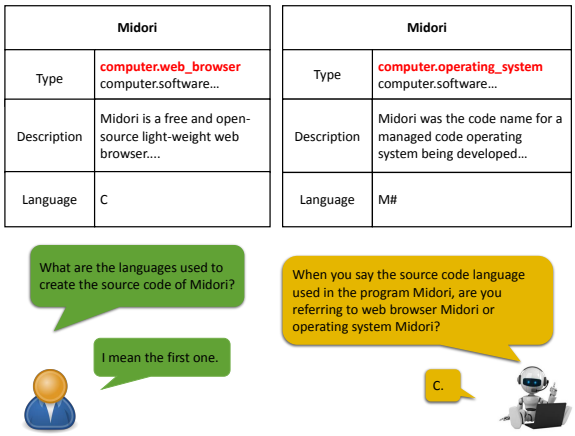

Figure 1: An example of a clarification question in KBQA. There are two entities named "Midori" using different programming languages, which confuses the system.

For these ambiguous or confusing questions, it is hard to directly give satisfactory responses unless systems can ask clarification questions to confirm the participant's intention. Therefore, this work explores how to use clarification to improve current KBQA systems.

We introduce an open-domain clarification corpus, CLAQUA, for KBQA. Unlike previous clarification-related datasets with limited annotated examples (De Boni and Manandhar, 2003; Stoyanchev et al., 2014) or in specific domains (Li et al., 2017; Rao and III, 2018), our dataset covers various domains and supports three tasks. The comparison of our dataset with relevant datasets is shown in Table 1. Our dataset considers two kinds of ambiguity for single-turn and multi-turn questions. In the single-turn case, an entity name refers to multiple possible entities in a knowledge base while the current utterance lacks necessary identifying information. In the multi-turn case, ambiguity mainly comes from the omission where a pronoun refers to multiple possible entities from the previous conversation turn. Unlike CSQA

* The work was done while Jingjing Xu and Yuechen Wang were interns in Microsoft Research, Asia.

Dataset	Domain	Size	Task
De Boni and Manandhar (2003)	Open domain	253	Clarification question generation.
Stoyanchev et al. (2014)	Open domain	794	Clarification question generation.
Li et al. (2017)	Movie	180K	Learning to generate responses based on previous clarification questions and user feedback in dialogue.
Guo et al. (2017)	Synthetic	100K	Learning to ask clarification questions in reading comprehension.
Rao and III (2018)	Operating system	77K	Ranking clarification questions in an online QA forum, StackExchange[2].
CLAQUA (Our dataset)	Open domain	40K	Clarification in KBQA, supporting clarification identification, clarification question generation, and clarification-based question answering.

Table 1: The comparison of our dataset with relevant datasets. The first and second datasets focus on generating clarification questions while the small size limits their applications. The middle three tasks are either not designed for KBQA or limited in specific domains. Unlike them, we present an open-domain dataset for KBQA.

dataset (Saha et al., 2018) that constructs clarification questions base on predicate-independent templates, our clarification questions are predicate-aware and more diverse. Based on the clarification raising pipeline, we formulate three tasks in our dataset, including clarification identification, clarification question generation, and clarification-based question answering. These tasks can naturally be integrated into existing KBQA systems. Since asking too many clarification questions significantly lowers the conversation quality, we first design the task of identifying whether clarification is needed. If no clarification is needed, systems can directly respond. Otherwise, systems need to generate a clarification question to request more information from the participant. Then, external user feedback is used to predict answers.

Our main contribution is constructing a new clarification dataset for KBQA. To build high-quality resources, we elaborately design a data annotation pipeline, which can be divided into three steps: sub-graph extraction, ambiguous question annotation, and clarification question annotation. We design different annotation interfaces for single-turn and multi-turn cases. We first extract "ambiguous sub-graphs" from a knowledge base as raw materials. To enable systems to perform robustly across domains, the sub-graphs are extracted from an open-domain KB, covering domains like music, tv, book, film, etc. Based on the sub-graphs, annotators are required to write ambiguous questions and clarification questions.

We also contribute by implementing representative neural networks for the three tasks and further developing a new coarse-to-fine model for clarification question generation. Take multi-turn as an example. In the task of clarification identification, the best performing system obtains an accuracy of 86.6%. For clarification question generation, our proposed coarse-to-fine model achieves a BLEU score of 45.02, better than strong baseline models. For clarification-based question answering, the best accuracy is 74.7%. We also conduct a detailed analysis for three tasks and find that our dataset brings new challenges that need to be further explored, like reasonable automatic evaluation metrics and powerful models for handling the sparsity of entities.

2 Data Collection

The construction process consists of three steps, sub-graph extraction, ambiguous question annotation, and clarification question annotation. We design different annotation interfaces for single-turn and multi-turn cases.

2.1 Single-Turn Annotation

Sub-graph Extraction. As shown in Figure 2, we extract ambiguous sub-graphs from an open-domain knowledge base[3], like FreeBase. For simplification, we set the maximum number of ambiguous entities to 2. In single-turn cases, we focus on shared-name ambiguity where two entities have the same name and there is a lack of necessary distinguishing information. To construct such cases, we extract two entities sharing the same entity name and the same predicate. Predicate represents the relation between two entities. The sub-graphs provide reference for human annotators to write diverse ambiguous questions based on the shared predicates.

[2]An online QA community.

[3]To persevere anonymity, the name of the used KB is hidden for now. We will release our dataset and codes.

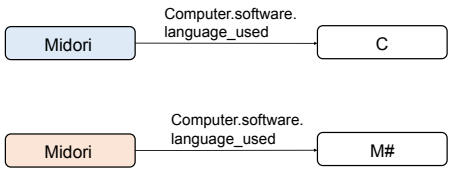

Figure 2: An extracted ambiguous sub-graph in the single-turn case. Two entities share the same name "Midori" and the same predicate "Computer.software,language_used".

Shared Name	Midori
Predicate # 1	computer.software.language_used
Predicate Description	A property relating an instance of computer.software to a programming language that was used to create the source code for the software.
Q_a: What are the languages used to create the source code of Midori?	

Table 2: An ambiguous question annotation example in the single-turn case.

E_1 Name	**Midori**
E_1 Type	computer.software **computer.web_browser** media_common.creative_work ... ...
E_1 Description	Midori is a free and open-source light-weight **web browser**. It uses the WebKit rendering engine and the GTK+ 2 or GTK+ 3 ... ...
E_2 Name	**Midori**
E_2 Type	**computer.operating_system** computer.software
E_2 Description	Midori was the code name for a managed code **operating system** being developed by Microsoft with joint effort of Microsoft Research... ...
Q_a	What are the languages used to create the source code of Midori?
Q_c: When you say the source code language used in the program Midori, are you referring to **[web browser Midori]** or **[operating system Midori]**?	

Table 3: A clarification question annotation example in the single-turn case.

Ambiguous Question Annotation. In this step, the input is a table listing the shared entity name, predicate name, and predicate description. Based on this table, annotators need to write ambiguous questions, e.g., *"What are the languages used to create the source code of Midori?"*. An annotation example is shown in Table 2. For diversity, annotators are encouraged to paraphrase the intention words in the predicate description.

Clarification Question Annotation. Based on entities and the annotated ambiguous question, annotators are required to summarize distinguishing information and write a multi-choice clarification question with a special marker for separating entity information and pattern information, e.g., *"When you say the source code language used in the program Midori, are you referring to [web browser Midori] or [operating system Midori]?"*. Annotators are asked to write predicate-aware clarification questions instead of general questions, like *"Which one do you mean, A or B?"* or *"do you mean A?"* as adopted in (Saha et al., 2018). An example is shown in Table 3.

We use multi-choice as our basic type of clarification. There are three possible clarification question types, including zero-choice type (e.g., *I don't understand, can you provide more details?*), single-choice type (e.g., *Do you mean A?*), and multi-choice type (e.g., *Which one do you mean, A or B?*). The zero-choice type means that the system does not understand the question and expects more details from the participant. Though simple, it costs more user efforts as it pushes the participant to figure out what confuses the system. In comparison, the advantage of single-choice type lies in the control of conversation direction. However, if the system cannot provide user-expected choices, conversation may be longer. As for the multi-choice type, its advantage is less conversation turns to ask for more valuable information while it requires more annotation work.

2.2 Multi-Turn Annotation

Sub-graph Extraction. In multi-turn cases, ambiguity comes from the omission of the target entity name from the previous conversation turn. We first extract two connected entities. If they also share another predicate, we extract all related information as an ambiguous sub-graph, as shown in Figure 3. By asking the shared predicate, we get an ambiguous question.

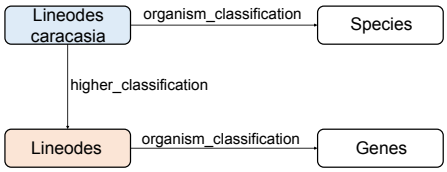

Figure 3: An extracted ambiguous sub-graph in the multi-turn case. "Lineodes caracasia" and "Lineodes" are linked and share the same relation "organism_classification".

E_1 Name	**Lineodes caracasia**
E_2 Name	**Lineodes**
Predicate #1	biology.higher_classification
Predicate Description	Property relating an biology.organism_classification to its higher or parent biology.organism_classification.
Predicate #2	biology.organism_classification
Predicate Description	Relating an biology.organism to its biology.organism_classification, the formal or informal taxonomy grouping for the organism.
Q_h: What is the higher classification for **Lineodes caracasia?** R_h: **Lineodes.** Q_a: What is the biological classification?	

Table 4: An ambiguous question annotation example in the multi-turn case.

E_1 Name	**Lineodes caracasia**
E_1 Type	media_common.cataloged_instance biology.organism_classification ... ...
E_1 Description	Lineodes caracasia is a moth in the family Crambidae... ...
E_2 Name	**Lineodes**
E_2 Type	media_common.cataloged_instance biology.organism_classification
E_2 Description	Lineodes is a genus of moths of the Crambidae family. ... ...
Q_h R_h Q_a	What is the higher classification for Lineodes caracasia? Lineodes. What is the biological classification?
Q_c: Are you referring to **[Lineodes caracasia]** or **[Lineodes]**, when you ask the biological classification?	

Table 5: A clarification question annotation example in the multi-turn case.

Ambiguous Question Annotation. An annotation example is shown in Table 4. Based on two entities in the extracted sub-graph, annotators construct a conversation turn and then write an ambiguous question where the entity name is omitted, e.g, *"What is the biological classification?"*.

Clarification Question Annotation. The annotation guideline of this step is the same as in single-turn annotation. The input includes two candidate entities and the annotated ambiguous question. The output is a clarification question. An annotation example is shown in Table 5.

3 Tasks

Our dataset aims to enable systems to ask clarification questions in open-domain question answering. Three tasks are designed in this work, including clarification identification, clarification question generation, and clarification-based question answering. Figure 4 shows the distribution of the top-10 domains in our dataset.

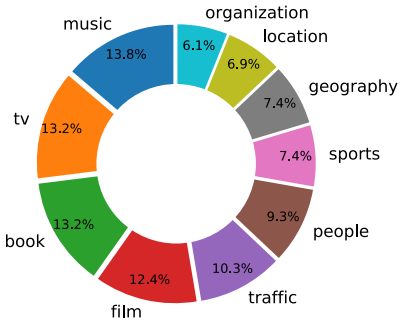

Figure 4: The distribution of top-10 domains.

3.1 Clarification Identification

Clarification identification can be regarded as a classification problem. It takes conversation context and candidate entity information as input. The output is a label identifying whether clarification is needed. Specifically, the input is $\{Q_a, E_1, E_2\}$ for single-turn cases or $\{Q_p, R_p, Q_a, E_1, E_2\}$ for multi-turn cases. Q_a represents the current question. E_1 and E_2 represent the candidate entities. Q_p and R_p are question and response from the previous conversation turn. The output is a binary label from set $Y = \{0, 1\}$ where 1 indicates that the input question is ambiguous and 0 indicates the opposite.

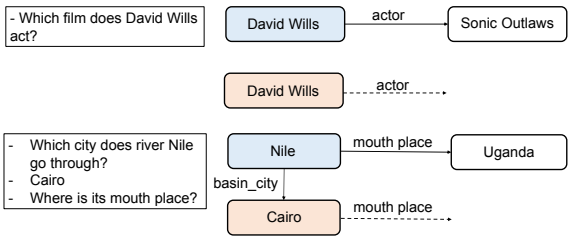

Figure 5: Negative examples of unambiguous sub-graphs and annotated conversations. The dotted line means the non-existent relation. The upper figure is in the single-turn case and the lower one is in the multi-turn case.

As Figure 5 shows, negative examples are annotated in the same way as the positive (ambiguous) examples do, but without the clarification related steps. In their sub-graphs, one of the entities has its unique predicate. The unique predicates are included in the user questions like "Where is its mouth place?". As only river "Nile" has mouth places, this question is unambiguous.

	Single-Turn		Multi-Turn	
	Positive	Negative	Positive	Negative
Train	8,139	6,841	12,173	8,289
Dev	487	422	372	601
Test	637	673	384	444

Table 6: Statistics of the dataset. It is important to note that three tasks share the same split. Since clarification question generation and clarification-based question answering are built upon ambiguous situations, they only use the positive data in their training, development, and test sets.

The statistics of our dataset are shown in Table 6. It is important to note that three tasks share the same split. Since clarification question generation and clarification-based question answering are built upon ambiguous situations, they only use the positive (ambiguous) data in their training, development, and test sets. For generalization, we add some examples with unseen entities and predicates into the development and test sets.

3.2 Clarification Question Generation

This text generation task takes ambiguous context and entity information as input, and then outputs a clarification question. For single-turn cases, the input is $\{Q_a, E_1, E_2\}$. For multi-turn cases, the input is $\{Q_p, R_p, Q_a, E_1, E_2\}$. In both cases, the output is a clarification question Q_c. We use BLEU as the automatic evaluation metric.

3.3 Clarification-Based Question Answering

As our dataset focuses on simple questions, this task can be simplified as the combination of entity identification and predicate identification. Entity identification is to extract entity e from candidate entities based on current context. Predicate identification is to choose predicate p that describes the ambiguous question. The extracted entity e and predicate p are combined to query the knowledge triple (e, p, o). The model is correct when both tasks are successfully completed.

Additional user responses toward clarification questions are also necessary for this task. Due to the strong pattern in responses, we use a template-based method to generate the feedback. We first design four templates, "I mean the first one", "I mean the second one", "I mean [entity name]", "I mean [entity type] [entity name]". Then for each clarification example, we randomly select a candidate entity and fill its information into the template as the user response, e.g., "I mean web browser Midori." for the clarification question in Table 3. For entity identification, we use the selected entity as the gold label. For predicate prediction, we use the predicate in the current ambiguous question as the gold label. In muli-turn cases, the predicate label is *Predicate #1* as shown in Table 2. In single-turn cases, the predicate label is *Predicate #2* as shown in Table 4.

Entity identification and predicate identification are both classification tasks. They take the same information as input, including ambiguous context, clarification question, and user response. For single-turn cases, the input is $\{Q_a, E_1, E_2, Q_c, R_c\}$ where R_c is the feedback of the participant toward clarification question Q_c. For multi-turn cases, the input is $\{Q_p, R_p, Q_a, E_1, E_2, Q_c, R_c\}$. For entity identification, the output is a label from set $Y_E = \{E_1, E_2\}$. For predicate identification, we randomly choose 1 negative predicates from the training set and combine them with the gold predicate together as the candidate set Y_P. The output of predicate identification is the index of the gold predicate in Y_P.

4 Approach

For three tasks, we implement several representative neural networks as baselines. Here we introduce these models in detail.

4.1 Classification Identification Models

The input of classification models is the ambiguous context and entity information. For simplification, we use a special symbol, `[S]`, to concatenate all the entity information together. These two parts can be regarded as different source information. Based on whether the inter-relation between different source information is explicitly explored, the classification models can be classified into two categories, unstructured models and structured models.

Unstructured models concatenate different source inputs into a long sequence with a special separation symbol `[SEL]`. We implement several widely-used sequence classification models, including Convolutional Neural Network (CNN) (Kim, 2014), Long-Short Term Memory Network (LSTM) (Schuster and Paliwal, 1997), and Recurrent Convolutional Neural Network (RCNN) (Lai et al., 2015), Transformer. The details of the models are shown in Supplementary Materials.

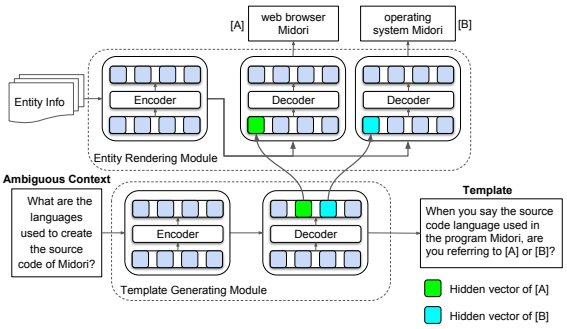

Figure 6: An illustration of the proposed coarse-to-fine model. The proposed model consists of a template generating module and an entity rendering module. The former is used to generate a clarification template based on ambiguous question, e.g., "When you say the source code language used in the program Midori, are you referring to [A] or [B]?". The latter is used to fill up the generated template with detailed entity information.

Structured models use separate structures to encode different source information and adopt an additional structure to model the inter-relation of the source information. Specifically, we use two representative neural networks, Hierarchical Attention Network (HAN) (Yang et al., 2016) and Dynamic Memory Network (DMN) (Kumar et al., 2016), as our structured baselines. The details of the models are shown in Supplementary Materials.

4.2 Clarification Question Generation Models

The input of the generation model is the ambiguous context and entity information. In single-turn cases, the ambiguous context is current question Q_a. In multi-cases, the input is current question and the previous conversation turn $\{Q_p, R_p, Q_a\}$. We use `[S]` to concatenate all entity information together, and use `[SEL]` to concatenate entity information and context information into a long sequence. We adopt Seq2Seq (Bahdanau et al., 2015) and Transformer (Vaswani et al., 2017) as our baselines and further develop a new generation model. The details of baselines can be found in Supplementary Materials.

Coarse-to-fine Model. Generally speaking, a clarification question contains two parts, entity phrases (e.g., "*web browser Midori*") and pattern phrases (e.g. *"When you say the source code language used in the program Midori, are you referring to [A] or [B]?*"). The entity phrase is summarized from the given entity information for distinguishing between two entities. The pattern phrase is used to locate the position of ambiguity, which is closely related with the context. In summary, two kinds of phrases refer to different source information. Based on this feature, we propose a new coarse-to-fine model, as shown in Figure 6. Similar ideas have been successfully applied to semantic parsing (Dong and Lapata, 2018).

The proposed model consists of a template generating module T_θ and an entity rendering module R_ϕ. T_θ first generates a template containing pattern phrases and the symbolic representation of the entity phrases. Then, the symbolized entities contained in the generated template are further properly rendered by the entity rendering module R_ϕ to reconstruct complete entity information. Since the annotated clarification questions explicitly separate entity phrases and pattern phrases, we can easily build training data for these two modules. For clarity, the template is constructed by replacing entity phrases in a clarification question with special symbols, `[A]` and `[B]`, which represent the positions of two entities.

The template generating module T_θ uses Transformer (Vaswani et al., 2017) as implementation. The input is the ambiguous context and the output is a clarification template.

Similar to T_θ, the entity rendering module R_ϕ is also implemented with a Transformer structure. More specifically, for each symbolized entity in the template, we add the hidden state of the decoder of T_θ corresponding to this symbolized entity into the decoder input.

4.3 Clarification-Based Question Answering Models

This task contains two sub-tasks, entity identification and predicate identification. They share the same input. In single-turn cases, the input is $\{Q_a, Q_c, R_c, E_1, E_2\}$. In multi-cases, the input is $\{Q_p, R_p, Q_a, Q_c, R_c, E_1, E_2\}$. Considering these two sub-tasks both belong to classification tasks, we use the same models as used in the task of clarification identification for implementation.

5 Experiments

We report the experiment results on three formulated tasks and give a detailed analysis. More details of hyper-parameters are in Supplementary Materials.

Model	Single-Turn	Multi-Turn
CNN	83.3	80.0
RNN	83.8	72.7
Transformer	84.0	72.8
HAN	83.1	73.0
DMN	**86.6**	**80.5**

Table 7: Results of clarification identification models.

5.1 Experiment Results

Clarification Identification. As shown in Table 7, the structured models have the best performance, with a 86.6% accuracy on single-turn cases and a 80.5% accuracy on multi-turn cases. Compared to the best-performing unstructured model, the structured architecture brings obvious performance improvements, with 2.6% and 6.7% accuracy increases. It indicates that the structured architectures have learned the inter-relation between the context and entity details, which is a vital part for reasoning whether a question is ambiguous. We also find that the models all achieve better results on multi-turn cases. Multi-turn cases contain additionally previous conversation turn, which can help the models capture more key phrases from the entity information.

Clarification Question Generation. Table 8 shows that Seq2Seq achieves low BLEU scores, which indicates its tendency to generate irrelevant text. Transformer achieves higher performance than Seq2Seq. Our proposed coarse-to-fine model demonstrates a new state of the art, improving the current highest baseline result by 3.35 and 0.60 BLEU scores, respectively.

We also find that multi-turn cases generally obtain higher BLEU scores than single-turn cases. In single-turn cases, the same-name characteristic makes it hard to summarize key distinguishing information. As a comparison, in multi-turn cases, two candidate entities usually have different names and it is easier to generate clarification questions. It is due to the flexible structure of ambiguous questions, which makes it hard to define universal rules to identify the asked objects. Table 9 shows a an example generated by the proposed model.

Clarification-Based Question Answering. As Table 10 shows, the unstructured models perform better than the structured models, indicating that this task tends to be over-fitting and small models have better the generalization ability.

Model	Single-Turn	Multi-Turn
Seq2Seq	18.84	31.62
Transformer	20.69	44.42
The proposed Model	**24.04**	**45.02**

Table 8: Results of clarification question generation models.

E_1 Name	Lineodes interrupta
E_1 Type	biology.organism_classification
E_1 Description	Lineodes interrupta is a moth in the Crambidae family. It was described by Zeller in 1873. It is found in Mexico and the United States, where it has been recorded from Florida, Louisiana, Oklahoma and Texas.
E_2 Name	Lineodes
E_2 Type	biology.organism_classification
E_2 Description	Lineodes is a genus of moths of the Crambidae family.
Q_p	What is higher classification of Lineodes interrupta?
R_p	Lineodes.
Q_a	Biologically speaking, what is the classification?
Output: Are you referring to Lineodes interrupta or Lineodes, when you ask the biological classification?	

Table 9: An example of the generated clarification questions.

5.2 Discussion

Automatic Evaluation. In the task of clarification question generation, we use BLEU, a widely used evaluation metric on language generation tasks, as the automatic evaluation metric. BLEU evaluates the generated text by computing its similarity with the gold text. However, we find this metric not suitable for our task. A good answer can ask different aspects as long as it can distinguish the entities. The given answer in our dataset is one of possible answers but not the only correct answer. A good answer may get a low BLEU score. Therefore, a more reasonable evaluation metric needs to be explored in the future, like paraphrase-based BLEU.

Error Analysis. In clarification question generation, although our proposed model has achieved the best performance, it still generates some low-quality questions. We conduct a human evaluation on 100 generated clarification questions and summarize two error categories. The first one is the entity error where the generated clarification question has a correct multi-choice structure but with irrelevant entity information. Here we present one example in Table 11. In this example, our model generates entity phrases irrelevant to the input am-

Model	Single-Turn	Multi-Turn
CNN	**60.8**	74.7
RNN	56.4	**76.0**
Transformer	52.1	58.9
DMN	50.9	54.5
HAN	51.7	54.7

Table 10: Results of clarification-based question answering models.

E_1 Name	**Come Back, Little Sheba**
E_1 Type	award.winning_work award.nominated_work ... ...
E_1 Description	Come Back, Little Sheba is a 1950 theater production of the play by William Inge... ...
E_2 Name	**Come Back, Little Sheba**
E_2 Type	theater.production award.nominated_work
E_2 Description	Come Back, Little Sheba is a 2008 theater production of the play by William Inge.... ...
Q_h: Who directed Come Back, Little Sheba? **Output**: Which one do you mean, winning work visual artist Claudia Coleman or winning work Elmer Gantry, when you ask the directors?	

Table 11: A bad generated case.

biguous question. This failure is mainly due to the unseen entity name "Come Back, Little Sheba", which leads the model to wrong generation decisions. Since there are lots of entities with different names and descriptions, how to handle the sparse information is a non-trivial problem. The second one is the grammar error where models sometimes generate low-quality phrases after generating a low-frequency entity word. These errors both can be attributed to the sparsity of entities to some extent. How to deal with the sparsity of entity information still needs further exploration.

6 Related Work

Our work is related to clarification question and question generation.

6.1 Clarification Question in Other Tasks

There are several studies on asking clarification questions. Stoyanchev et al. (2014) randomly drop one phrase from a question and require annotators to ask a clarification question toward the dropped information, e.g.*"Do you know the birth data of XXX"*. However, the small dataset size makes it hard to help downstream tasks. Following this work, Guo et al. (2017) provide a larger synthetic dataset QRAQ by replacing some of entities with variables. Li et al. (2017) use misspelled words to replace entities in questions to build ambiguous questions. Although these studies are good pioneering studies, the synthetic constructing way makes them unnatural and far from real world questions.

Different from these studies, Braslavski et al. (2017) investigate a community question answering (CQA) dataset and study how to predict the specific subject of a clarification question. Similarly, Rao and III (2018) focus on learning to rank human-written clarification questions in an online QA forum, StackExchange. Our work differs from these two studies in that we have a knowledge graph at the backend, and the clarification-related components are able to facilitate KBQA.

6.2 Question Generation

For different purposes, there are various question generation tasks. Hu et al. (2018) aim to ask questions to play the 20 question game. Dhingra et al. (2017) teach models to ask questions to limit the number of answer candidates in task-oriented dialogues. Ke et al. (2018) train models to ask questions in open-domain conversational systems to better interact with people. Guo et al. (2018) develop a sequence-to-sequence model to generate natural language questions.

7 Conclusion and Future Work

In this work, we construct a clarification question dataset for KBQA. The dataset supports three tasks, clarification identification, clarification question generation, and clarification-based question answering. We implement representative neural networks as baselines for three tasks and propose a new generation model. The detailed analysis shows that our dataset brings new challenges. More powerful models and reasonable evaluation metrics need further explored.

In the future, we plan to improve our dataset by including more complex ambiguous situations for both single-turn and multi-turn questions, such as multi-hop questions, aggregation questions, etc. We also plan to integrate the clarification-based models into existing KBQA system, and study how to iteratively improve the model based on human feedback.

Acknowledgments

Table 12: Settings of classification models.

Table 12 shows the detailed hyper-parameter settings of these classification models. Here we introduce the classification models used in our experiments.

CNN. It first feeds the input embedding sequence into a convolutional layer. The convolutionial layer contains K filters $f \in R^{s,d}$ where s is the size of filters and d is the dimension of word embeddings. We use different sizes of filters to get rich features. Then, a max pooling layer takes K vectors as input and generates a distributed input representation $\boldsymbol{h}$. Finally, the vector $\boldsymbol{h}$ is projected to the probability of labels.

RNN. It is built on a traditional bi-directional gated recurrent unit (GRU) structure, which is used to capture global and local dependencies inside the input sequence. The last output of GRU is then fed into the output layer to generate the probability of labels.

Transformer. A model similar with RNNs. It removes the recurrent unit in RNNs and replaces it with a special attention mechanism. called multi-head attention. The model is composed of a stack of 2 identical layers. Each identical layer has two sub-layers. The first sub-layer is a multi-head self-attention layer, and the second is a position-wise fully connected feed-forward layer. Since input nodes are not sequentially in order, the positional embedding layer is removed from the model. The decoder is also composed of a stack of 2 identical layers.

Table 13: Settings of generation models.

HAN. It is built upon two self-attention layers. The first layer is responsible for encoding context information and entity information. Then, the second layer uses a self-attention mechanism to learn the inter-relations between them. Finally, the output of the second layer is fed into the output layer for predicting labels.

DMN. This model regards context information as query and entity information as input to learn their inter-relations. It consists of four modules, an input module, a question module, an episodic memory module, and an answer module. The input module and thed question module encode query and input into distributed vector representations. The episodic memory module decodes which parts of the entity information to focus on through the attention mechanism. Finally, the answer module generates an answer based on the final memory vector of the memory module.

A.2 Clarification Question Generation Models

Here is the detailed introduction about the generation baselines.

Seq2Seq (Bahdanau et al., 2015). This model is based on a traditional encoder-decoder framework which encodes the input sequence into a dense vector and then decodes the target sequence word by word. Attention is used to capture global dependencies between input and output.

Transformer (Vaswani et al., 2017). It is based solely on attention mechanism to capture global dependencies. Similar to Seq2Seq, it uses an encoder-decoder framework but with different implementation.

Table 13 shows the detailed hyper-parameter settings of generation models.

Multi-View Domain Adapted Sentence Embeddings for Low-Resource Unsupervised Duplicate Question Detection

Abstract

We address the problem of Duplicate Question Detection (DQD) in low-resource domain-specific Community Question Answering forums. Our multi-view framework MV-DASE combines an ensemble of sentence encoders via Generalized Canonical Correlation Analysis, using unlabeled data only. In our experiments, the ensemble includes generic and domain-specific averaged word embeddings, domain-finetuned BERT and the Universal Sentence Encoder. We evaluate MV-DASE on the CQADupStack corpus and on additional low-resource Stack Exchange forums. Combining the strengths of different encoders, we significantly outperform BM25, all single-view systems as well as a recent supervised domain-adversarial DQD method.

1 Introduction

Duplicate Question Detection is the task of finding questions in a database that are equivalent to an incoming query. Many Community Question Answering (CQA) forums leave this task to the collective memory of their users. This results in unnecessary manual work for community members as well as delayed access to answers (Hoogeveen et al., 2015).

Automatic DQD is often approached as a supervised problem with community-generated training labels. However, smaller CQA forums may suffer from label sparsity: On Stack Exchange, 50% of forums have fewer than 160 user-labeled duplicates, and 25% have fewer than 50 (see Figure 1).[1]

To overcome this problem, two avenues have been explored: The first is supervised domain-adversarial training on a label-rich source forum (Shah et al., 2018), which works best when source and target domains are related. The second is unsupervised DQD via representation learning (Charlet and Damnati, 2017; Lau and Baldwin, 2016), which requires only unlabeled questions. In this paper, we take the unsupervised avenue.

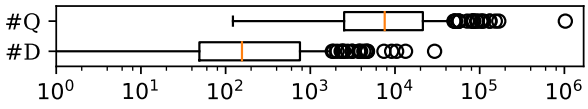

Figure 1: Distribution (log-scale box plot) of number of questions (#Q) and number of labeled duplicates (#D) on Stack Exchange. $N = 165$ forums.

A major challenge in the context of domain-specific CQA forums is that language usage may differ from the "generic" domains of existing representations. To illustrate this point, compare the following Nearest Neighbor lists of the word "tree", based either on generic GloVe embeddings (Pennington et al., 2014) or on FastText embeddings (Bojanowski et al., 2017) that were trained on specific CQA forums:

generic (GloVe): trees, branches, leaf
chess: searches, prune, modify
outdoors: trees, trunk, trunks
gis: strtree, rtree, btree
wordpress: trees, hierachy, hierarchial
gaming: trees, treehouse, skills

Charlet and Damnati (2017) and Lau and Baldwin (2016) report that representations trained on in-domain data perform better on unsupervised DQD than generic representations. But in a low-resource setting, the amount of unlabeled in-domain data is limited. This can result in low coverage or quality, as illustrated by the in-domain embedding neighbors of "tree" in the smallest forum from our dataset:

windowsphone: dreamspark, l535ds, generally

	generic	domain-specific
contextualized	f_G: GloVe	f_D: FastText (in-domain)
noncontextualized	f_U: USE	f_B: BERT (domain-finetuned)

Table 1: Ensemble used in our experiments.

It is therefore desirable to combine the overall quality and coverage of generic representations with the domain-specificity of in-domain representations via multi-view learning. There is a large body of work on multi-view word embeddings (see Section 2.3), including domain adapted word embeddings (Sarma et al., 2018).

Recent representation learning techniques go beyond the word level and embed larger contexts (e.g., sentences) jointly (Peters et al., 2018; Devlin et al., 2019; Cer et al., 2018). To reflect this paradigm shift, we take multi-view representation learning from the word to the sentence level and propose MV-DASE (Multi-View Domain Adapted Sentence Embeddings), a framework that combines an ensemble of sentence encoders via Generalized Canonical Correlation Analysis (see Section 3.1).

MV-DASE uses **unlabeled in-domain data only**, making it applicable to the problem of unsupervised DQD. As a framework, it is **agnostic** to the internal specifics of its ensemble. In Section 3.2, we describe an ensemble of different sentence encoders: domain-specific and generic, contextualized and noncontextualized (see Table 1). In Sections 4 and 5, we demonstrate that MV-DASE is effective at **duplicate retrieval** on the CQADupStack corpus (Hoogeveen et al., 2015) and on additional low-resource Stack Exchange forums. **Significance tests** show significant gains over BM25, all single-view systems and domain-adversarial supervised training as proposed by Shah et al. (2018). In Sections 6 and 7, we successfully evaluate MV-DASE on **two additional benchmarks**: the SemEval-2017 DQD shared task (Nakov et al., 2017) as well as the unsupervised STS Benchmark (Cer et al., 2017).

2 Related Work

2.1 Duplicate Question Detection

Most prior work on DQD (e.g., Bogdanova et al. (2015); Dos Santos et al. (2015); Baldwin et al. (2016); Zhang et al. (2017); Rodrigues et al. (2017); Hoogeveen et al. (2018)) focuses on supervised architectures. As discussed, these approaches are not applicable to forums with few or no labeled duplicates.

Shah et al. (2018) tackle label sparsity by domain-adversarial training (ADA). More specifically, they train a bidirectional Long-Short Term Memory Network (LSTM) (Hochreiter and Schmidhuber, 1997) on a label-rich source forum, while minimizing the distance between source and target domain representations. Their approach beats BM25 and a simple transfer baseline in cases where source and target domain are closely related (e.g., *AskUbuntu→SuperUser*), but not on more distant pairings. This is not ideal, as the existence of a big related source forum is not guaranteed.

An alternative is unsupervised DQD via representation learning, which does not require any labels. Charlet and Damnati (2017) use a word embedding-based soft cosine distance for duplicate ranking. In a recent DQD shared task (SemEval-2017 task 3B, Nakov et al. (2017)), their best unsupervised system trails the best supervised system by only 2% Mean Average Precision (MAP). This seems reasonable, given that the implicit objective of many representation learning methods (similar representations for similar objects) is closely related to the notion of a duplicate.

Charlet and Damnati (2017) report overall better results when embeddings are trained on domain-specific data rather than Wikipedia. However, they make no attempts to combine the two domains. Lau and Baldwin (2016) evaluate two representation learning techniques (doc2vec (Le and Mikolov, 2014) and word2vec (Mikolov et al., 2013a)) on CQADupStack. They also report better results when representations are learned on domain-specific rather than generic data.

2.2 Sentence embeddings and STS

Unsupervised DQD is related to the task of unsupervised Semantic Textual Similarity (STS), i.e., sentence similarity scoring (Cer et al., 2017). Arora et al. (2017) show that a weighted average over pre-trained word embeddings, followed by principal component removal, is a strong baseline for STS. We use their weighting scheme, Smooth Inverse Frequency (SIF), in Section 3.2.

Averaged word embeddings are insensitive to word order. This stands in contrast to contextualized encoders, such as LSTMs or Transform-

ers (Vaswani et al., 2017). Contextualized encoders are typically trained as unsupervised language models (Peters et al., 2018; Devlin et al., 2019) or on supervised transfer tasks (Conneau et al., 2017; Cer et al., 2018). At the time of writing, weighted averaged word embeddings achieve better results than contextualized encoders on unsupervised STS.[2]

2.3 Multi-view word embeddings

Multi-view representation learning is an umbrella term for methods that transform different representations of the same entities into a common space. In NLP, it has typically been applied to word embeddings. A famous example is the cross-lingual projection of word embeddings (Mikolov et al., 2013b; Faruqui and Dyer, 2014). Monolingually, Rastogi et al. (2015) use Generalized Canonical Correlation Analysis (GCCA) to project different word representations into a common space. Yin and Schütze (2016) combine word embeddings by concatenation, truncated Singular Value Decomposition and linear projections; Bollegala and Bao (2018) use autoencoders. Sarma et al. (2018) correlate generic and domain-specific word embeddings by Canonical Correlation Analysis (CCA).

All of these methods are post-training, i.e., they are applied to fully trained word embeddings. MV-DASE falls into the same category, albeit at the sentence level (see Section 3.1). Other methods, which we will call in-training, encourage the alignment of embeddings during training (e.g., Bollegala et al. (2015); Yang et al. (2017)).

2.4 Multi-view sentence embeddings

Multi-view sentence embeddings are less frequently explored than multi-view word embeddings. One exception is Tang and de Sa (2019), who train a recurrent neural network and an average word embedding encoder jointly on an unlabeled corpus. This method is in-training, i.e., it cannot be used to combine pre-existing encoders.

Kiela et al. (2018) dynamically integrate an ensemble of word embeddings into a task-specific LSTM. They require labeled data and the resulting embeddings are task-specific.

Sarma et al. (2018) marry domain-adapted word embeddings (see Section 2.3) with InferSent (Conneau et al., 2017), a bidirectional LSTM sentence encoder trained on Stanford Natural Language Inference (SNLI) (Bowman et al., 2015). They initialize InferSent with the adapted embeddings and then retrain it on SNLI. Note that this approach is not feasible when the training regime of an encoder cannot be reproduced, e.g., when the original training data is not publicly available.

3 Method

We now describe MV-DASE as a general framework. For details on the ensemble used in this paper, see Section 3.2.

3.1 Framework

GCCA basics. Given zero-mean random vectors $\mathbf{x}_1 \in \mathbb{R}^{d_1}, \mathbf{x}_2 \in \mathbb{R}^{d_2}$, Canonical Correlation Analysis (CCA) finds linear transformations $\boldsymbol{\theta}_1 \in \mathbb{R}^{d_1}, \boldsymbol{\theta}_2 \in \mathbb{R}^{d_2}$ such that $\boldsymbol{\theta}_1^T \mathbf{x}_1$ and $\boldsymbol{\theta}_2^T \mathbf{x}_2$ are maximally correlated. Bach and Jordan (2002) show that CCA reduces to a generalized eigenvalue problem. A generalized eigenvalue problem finds scalar-vector pairs $(\rho, \boldsymbol{\theta})$ that satisfy $\mathbf{A}\boldsymbol{\theta} = \rho\mathbf{B}\boldsymbol{\theta}$ for matrices $\mathbf{A}, \mathbf{B}$. Here, $\mathbf{A}, \mathbf{B}$ are the following block matrices:

$$\begin{bmatrix} \mathbf{0} & \boldsymbol{\Sigma}_{1,2} \\ \boldsymbol{\Sigma}_{2,1} & \mathbf{0} \end{bmatrix} \boldsymbol{\theta} = \rho \begin{bmatrix} \boldsymbol{\Sigma}_{1,1} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Sigma}_{2,2} \end{bmatrix} \boldsymbol{\theta} \quad (1)$$

where $\boldsymbol{\Sigma}_{1,1}, \boldsymbol{\Sigma}_{2,2}$ are the covariance matrices of $\mathbf{x}_1, \mathbf{x}_2$ and $\boldsymbol{\Sigma}_{1,2}, \boldsymbol{\Sigma}_{2,1}$ are their cross-covariance matrices. We stack all d eigenvectors into an operator $\boldsymbol{\Theta} \in \mathbb{R}^{d \times d_1 + d_2}$. Using this operator, multi-view representations are projected as:

$$\mathbf{x}_{\text{mv}} = \boldsymbol{\Theta} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \end{bmatrix} \quad (2)$$

Generalized CCA (GCCA) generalizes CCA to three or more random vectors $\mathbf{x}_1 \ldots \mathbf{x}_J$. There are several variants of GCCA (Kettenring, 1971); we follow Bach and Jordan (2002) and solve a multi-view version of Equation 1:

$$\begin{aligned} &\begin{bmatrix} \mathbf{0} & \boldsymbol{\Sigma}_{\ldots} & \boldsymbol{\Sigma}_{1,J} \\ \boldsymbol{\Sigma}_{\ldots} & \mathbf{0} & \boldsymbol{\Sigma}_{\ldots} \\ \boldsymbol{\Sigma}_{J,1} & \boldsymbol{\Sigma}_{\ldots} & \mathbf{0} \end{bmatrix} \boldsymbol{\theta} \\ &= \rho \begin{bmatrix} \boldsymbol{\Sigma}_{1,1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Sigma}_{\ldots} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \boldsymbol{\Sigma}_{J,J} \end{bmatrix} \boldsymbol{\theta} \end{aligned} \quad (3)$$

For stability, we add $\tau\sigma_j \mathbf{I}_j$ to every covariance matrix $\boldsymbol{\Sigma}_{j,j}$, where τ is a hyperparameter (here: $\tau = 0.1$), $\mathbf{I}_j$ is the identity matrix and σ_j is the

average variance of $\mathbf{x}_j$. Like in the two-view case, we stack all d eigenvectors into an operator: $\mathbf{\Theta} \in \mathbb{R}^{d \times \sum_j d_j}$.

GCCA application. Assume that we have an ensemble of J sentence encoders. The j'th encoder is denoted $f_j : \mathbb{S} \rightarrow \mathbb{R}^{d_j}$, where $\mathbb{S}$ is the set of all possible in-domain strings (here: in-domain questions) and d_j is determined by f_j. Assume also that we have a sample from $\mathbb{S}$, i.e., a corpus of unlabeled in-domain strings, denoted $S = \{s_1, \ldots, s_N\}$. From this corpus, we create one training matrix $\mathbf{X}_j$ per encoder:

$$\mathbf{X}_j \in \mathbb{R}^{N \times d_j} = \begin{bmatrix} — & f_j(s_1) & — \\ & \vdots & \\ — & f_j(s_N) & — \end{bmatrix} \quad (4)$$

From $\mathbf{X}_j$ we estimate mean vector $\bar{\mathbf{x}}_j \in \mathbb{R}^{d_j}$, covariance matrix $\mathbf{\Sigma}_{j,j} \in \mathbb{R}^{d_j \times d_j}$ and cross-covariance matrices $\mathbf{\Sigma}_{j,j'} \in \mathbb{R}^{d_j \times d_{j'}}$. We then apply GCCA as described before, yielding $\mathbf{\Theta} \in \mathbb{R}^{d \times \sum_j d_j}$. The multi-view embedding of a new input q (e.g., a test query) is:

$$f_{\text{mv}}(q) = \mathbf{\Theta} \begin{bmatrix} f_1(q) - \bar{\mathbf{x}}_1 \\ \vdots \\ f_J(q) - \bar{\mathbf{x}}_J \end{bmatrix} \quad (5)$$

3.2 Ensemble

We use MV-DASE on the following ensemble:

- weighted averaged generic GloVe vectors (Pennington et al., 2014)
- weighted averaged domain-specific FastText vectors (Bojanowski et al., 2017)
- Universal Sentence Encoder (USE) (Cer et al., 2018)
- domain-finetuned BERT (Devlin et al., 2019)

In this section, we describe the encoders in detail. Note that the choice of encoders is orthogonal to the framework and other resources could be used. Where possible, we base our selection on the literature: We choose USE over InferSent due to better performance on STS (Perone et al., 2018), and BERT over ELMo (Peters et al., 2018) due to better performance on linguistic probing tasks (Liu et al., 2019a). The choice of GloVe for generic word embeddings is based on Sarma et al. (2018).

Weighted averaged word embeddings. We denote generic and domain-specific word embeddings of some word type i as $\mathbf{w}_{G,i} \in \mathbb{R}^{d_G}$ and $\mathbf{w}_{D,i} \in \mathbb{R}^{d_D}$. For $\mathbf{w}_{G,i}$, we use pre-trained 300-d GloVe vectors.[3] $\mathbf{w}_{D,i}$ are trained using skipgram FastText[4] (100-d, default parameters) on the in-domain corpus S. We SIF-weight all word embeddings by $a \cdot (a + p(i))^{-1}$, where $p(i)$ is the unigram probability of the word type and the smoothing factor (here: $a = 10^{-3}$) is taken from Arora et al. (2017). We find that probabilities estimated on S produce better results than the Wikipedia-based probabilities provided by Arora et al. (2017) (see Table 2, top), hence this is what we use below. After weighting, we perform top-3 principal component removal on the embedding matrices, which is beneficial for word-level similarity tasks (Mu et al., 2018). We denote the new embeddings of word type i as $\hat{\mathbf{w}}_{G,i}, \hat{\mathbf{w}}_{D,i}$. The embedding of a tokenized string $s = (s_1, \ldots, s_T)$ is computed by averaging:

$$f_G(s) = \frac{1}{T} \sum_{t=1}^{T} \hat{\mathbf{w}}_{G,s_t} \quad f_D(s) = \frac{1}{T} \sum_{t=1}^{T} \hat{\mathbf{w}}_{D,s_t}$$

Contextualized encoders. USE and BERT are downloaded as pre-trained models.[5] [6] USE is a Transformer trained on SkipThought (Kiros et al., 2015), conversation response prediction (Henderson et al., 2017) and SNLI. It outputs a single 512-d sentence embedding, which we use as-is. Below, USE is denoted f_U.

	f_G (GloVe)	f_D (FastText)	f_B (BERT)
no SIF	.089	.083	.134
wiki SIF	.128	.100	.159
in-domain SIF	.147	.104	.176

	f_B (BERT)	ELMo
generic	.138	.103
domain-finetuned	.176	.155

Table 2: Mean Average Precision (MAP) averaged over heldout forums. Top: MAP as a function of whether and where SIF weights are estimated. Bottom: MAP of generic vs. domain-finetuned BERT and ELMo. Evaluation setup is as described in Section 4, using four heldout forums. Gray: best in column.

[6] tfhub.dev/google/bert_uncased_L-12_H-768_A-12/1

BERT is a Transformer that was pre-trained as a masked language model with next sentence prediction. We find that domain-finetuning BERT on S results in improvements over generic BERT (see Table 2, bottom). Note that domain-finetuning refers to unsupervised training as a masked language model, i.e., we only require unlabeled data (Howard and Ruder, 2018). We use default parameters[7] except for a reduced batch size of 8.

At test time, we take the following approach: BERT segments a token sequence $s = (s_1, \ldots, s_T)$ into a subword sequence $s' = ([\text{CLS}], s'_1, \ldots, s'_{T'}, [\text{SEP}])$, where [CLS] and [SEP] are special tokens that were used during pre-training, and $T' \geq T$. BERT produces one 768-d vector $\mathbf{v}_{l,t}$ per subword s'_t and layer $l \in [1, \ldots, L]$, where L is the total number of layers (here: 12). We SIF-weight all vectors according to the probability of their subword (estimated on S) and average over layers and subwords, excluding the special tokens:

$$f_B(s) = \frac{1}{T' \cdot L} \sum_{t=1}^{T'} \sum_{l=1}^{L} \frac{a}{a + p(s'_t)} \mathbf{v}_{l,t}$$

4 Evaluation on Stack Exchange

4.1 Data

Corpora. We evaluate MV-DASE on the CQADupStack corpus (Hoogeveen et al., 2015), which is based on a 2014 Stack Exchange dump. CQADupStack contains 12 forums that have enough duplicates for supervised training; as a consequence, it may not be representative of low-resource domains. We therefore supplement it with 12 low-resource forums from the 2018-12-20 Stack Exchange dump.[8] For our purposes, low-resource means a forum with 100–200 duplicates, which we consider sufficient for evaluation but insufficient for supervised training. All duplicates in the datasets were labeled by unpaid community members. As a result, false negatives (i.e., unflagged duplicates) are common in the gold standard (Hoogeveen et al., 2016). While we do not explicitly filter for language, the vast majority of the data is in English.

Table 3: Forum statistics. #Q: total number of questions, #D: number of labeled duplicates, #T: number of tokens in training set S. Gray: heldout forums.

Data split. We split every forum into a test and training set, such that the test set contains all duplicates and the training set contains the remaining unlabeled questions.[9] The unlabeled training set is used for FastText training, BERT domain-finetuning, SIF weight estimation and GCCA. Test queries are never seen during training, not even in an unsupervised way. For hyperparameter choices, we hold out two high-resource and two low-resource forums (highlighted in Table 3). They are not used for the final evaluation and significance tests.

Preprocessing. Every question object consists of a title (average length 9 words), a body (average length 125 words), any number of answers or comments, and metadata (e.g., upvotes, view counts). We preprocess the data with the CQADupStack package.[10] To calculate question representations, we use the concatenation of question title and body. We always ignore answers, comments and metadata, as this information is not usually available at the time a question is posted.

[9] We do not use the official CQADupStack train / test split, as it is meant for supervised training and has comparatively few duplicates per test set. Since MV-DASE is unsupervised, we can afford a more robust evaluation on all labeled duplicates.

Table 4: Main results. Left: MAP on individual forums (heldout and test forums). Rightmost five columns: all metrics averaged over test forums (excluding heldout forums). Gray: best in column.

4.2 Evaluation and Metrics

Given a test query q, we rank all candidates $c \neq q$ from the same forum by $\cos(f(q), f(c))$, where f is an encoder (e.g., MV-DASE). Our metrics are MAP, AUC(.05), Normalized Discounted Cumulative Gain (NDCG), Recall@3 (R@3) and Precision@3 (P@3). AUC(.05), the area under the ROC curve up to a false positive rate of .05, is used by Shah et al. (2018). Note that upper bounds on P@3 and R@3 are not 1, since most duplicates have only one original and a few have more than three.

4.3 Baselines

Unsupervised. Our IR baseline is BM25 (Robertson et al., 1995) as implemented in Elasticsearch 6.5.4 (Gormley and Tong, 2015) with default parameters. We test against all single-view encoders from our ensemble. The remaining unsupervised baselines are:

- ELMo (Peters et al., 2018).[11] We treat ELMo like BERT (Section 3.2), i.e., we finetune[12] the language model on the in-domain corpus (3 epochs, batch size 8), SIF-weight all vectors according to in-domain word probability and then average over layers and tokens.
- Doc2vec (Le and Mikolov, 2014) trained on the in-domain corpus, using the best DQD hyperparameters reported in Lau and Baldwin (2016).
- InferSent V.1.[13] (Conneau et al., 2017)
- Our re-implementation of domain-adapted CCA word embeddings (Sarma et al. (2018), see Section 2.3). We use the same word embeddings, SIF weights and component removal described in Section 3.2. Denoted "word-level CCA" below.

Table 6: Ablation study. Deltas relative to MV-DASE. Metrics were averaged over test forums before calculating deltas. concat/avg are naive view concatenation and averaging. Gray: better than MV-DASE.

ADA. We evaluate the supervised domain-adversarial method of Shah et al. (2018) (ADA) on the low-resource forums. Recall that ADA requires a related labeled source domain. To achieve this, we pair every low-resource forum (target) with the CQADupStack forum (source) with which it has the highest word trigram overlap. See supplementary material for more details and a table of all source-target mappings.[14]

4.4 Ablation studies

We perform a set of experiments where we omit views from the ensemble. We also replace GCCA with naive view concatenation or view averaging. When averaging, we pad lower-dimensional vectors (Coates and Bollegala, 2018).

4.5 Significance tests

We perform paired t-tests, using the 20 test set forums as data points.[15] We then find groups of equivalent methods by transitive closure of $a \sim b \equiv p \geq .05$. Group A being ranked higher than group B means that every method in A performs significantly better than every method in B. Two methods in the same group may differ significantly, but there exists a chain between them of methods with insignificant differences.

5 Discussion

5.1 Comparison with baselines

BM25. BM25 is a tough baseline for DQD: In terms of MAP, it is better than or comparable to every single view (see Table 5). MV-DASE on the other hand, which is built from the same views, outperforms BM25 significantly and almost consistently (19 out of 20 test forums), regardless of the metric. This underlines the usefulness of our multi-view approach.

Single views. MV-DASE outperforms the views that make up its ensemble significantly and almost consistently. There are two exceptions (out of 20 test forums): On *law* and *outdoors*, f_U (USE) performs slightly better on its own (Table 4, row 15). Since these forums are less "technical" than most, we hypothesize that they may be less in need of domain adaptation.

Word-level CCA. The word-level CCA baseline by Sarma et al. (2018) outperforms f_G and f_D on their own (see Table 4, rows 10, 21), which validates the approach. The method is directly comparable to MV-DASE$\neg(f_U, f_B)$, i.e., MV-DASE on generic and domain-specific averaged word embeddings (see Table 6). The main differences between them are (a) the order in which CCA and averaging are performed and (b) whether the CCA "vocabulary" is composed of word types or sentences. Note that in contrast to MV-DASE, word-level CCA is incompatible with contextualized embeddings, since it requires a context-independent one-to-one mapping between word types and vectors.

[14] We also experiment with Multinomial Adversarial Networks (MAN) (Chen and Cardie, 2018), a multi-source multi-target framework that can be trained on all 24 forums jointly. Initial results were not competitive with ADA, so we do not include them here. See supplementary material for details.

[15] Ten forums for t-tests involving ADA.

ADA. Supervised domain-adversarial ADA performs significantly worse than unsupervised MV-DASE (see Table 5). It is comparable to BM25 in terms of AUC(.05) (the metric used by Shah et al. (2018)), but not in terms of MAP.

Recall that we restricted the choice of source domains to the 12 CQADupStack forums. As a consequence, some target forums were paired with non-ideal source forums (e.g., *english→buddhism*). It is possible that the baseline would have performed better with a wider choice of source domains. Nonetheless, this observation highlights a key advantage of our approach: It does not depend on the availability of a label-rich related source domain (or indeed, any labels at all).

Other baselines. InferSent performs poorly on the DQD task, which is surprising given its similarity to USE. Recall that InferSent and USE are pre-trained on sentence-level SNLI, but that the training regime of USE also contains conversation response prediction. So USE is expected to be better equipped to handle (a) multi-sentence documents and (b) forum-style language.

Doc2vec is trained on the same data as f_D, but performs significantly worse. The difference between them may be due to the ability of FastText to exploit orthography. Domain-finetuned ELMo performs comparably to domain-finetuned BERT on some forums but not consistently.

5.2 Ablation study

View ablation. On the low-resource forums, omitting f_D has a beneficial effect (Table 6, row 10). This suggests that the in-domain FastText embeddings have insufficient quality when learned on the smallest forums and / or that domain-finetuned BERT subsumes any positive effect. On the high-resource CQADupStack forums, domain-specific embeddings contribute positively, while generic GloVe does not (rows 1,2). Table 5 shows that omitting either f_G or f_D from the ensemble does not lead to a significant drop in MAP, but omitting both does.

USE has the biggest positive effect on MV-DASE (Table 6, rows 3,11), also evidenced by the fact that omitting it is significantly more harmful than omitting any other single view (Table 5). Recall from Section 3.2 that USE is trained on supervised transfer tasks, while the remaining encoders are fully unsupervised.

GCCA ablation. The naive concatenation or averaging of views is significantly less effective than view correlation by GCCA (Table 6, rows 7,8,15,16, and Table 5). This underlines that multi-view learning is not just about *which* views are combined, but also about *how*. Intuitively, GCCA discovers which features from the different encoders "mean the same thing" in the domain. By contrast, concatenation treats views as orthogonal, while averaging mixes them in an unstructured way.

6 Evaluation on SemEval-2017 3B

In this section, we evaluate MV-DASE on SemEval-2017 3B, a DQD shared task based on the QatarLiving CQA forum. The benchmark provides manually labeled question pairs for training as well as additional unlabeled in-domain data. Since MV-DASE is unsupervised, we discard all training labels and concatenate training and unlabeled data into a text corpus ($\approx$ 1.5M tokens). This corpus is used for FastText training, BERT domain-finetuning, SIF weight estimation and GCCA, as described in Section 3.

The test set contains 88 queries q with ten candidates $c_1 \dots c_{10}$ each. We preprocess all data with the CQADupStack package and concatenate question subjects and bodies, before encoding them. We rank candidates by $\cos(f(q), f(c))$ and evaluate the result with the official shared task scorer.[16] In keeping with the original leaderboard, we report MAP and MRR (Mean Reciprocal Rank). We compare against previous literature as well as all individual views, view concatenation and averaging. See Table 7 for results. Like we observed on the Stack Exchange data, MV-DASE outperforms its individual views, their concatenation and average. It beats the previous State of the Art (a supervised system) by a margin of 2.5% MAP.

7 Evaluation on unsupervised STS

While this paper focuses on Duplicate Question Detection, MV-DASE is also applicable to other unsupervised sentence-pair tasks. As proof of concept, we test it on the unsupervised STS Benchmark (Cer et al., 2017). Here, the task is to predict similarity scores $y \in \mathbb{R}$ for sentence pairs (s_1, s_2).

Table 7: MAP and MRR (percentages) on SemEval-2017 3B test set. *Shared task top teams (best run out of three) and baselines as reported in Nakov et al. (2017), Table 6. Gray: best in column.

We treat the benchmark training set as an unlabeled corpus, i.e., we discard all labels and destroy the original sentence pairings by shuffling. The resulting corpus is used for BERT domain-finetuning, SIF weight estimation and GCCA. At test time, we measure Pearson's r between $\cos(f(s_1), f(s_2))$ and y, where f is an encoder (e.g., MV-DASE) and y is the ground truth similarity of test set pair (s_1, s_2).

In this experiment, the ensemble contains USE (f_U), domain-finetuned BERT (f_B) and f_G. For f_G, we either use SIF-weighted averaged GloVe vectors (Section 3.2), or unweighted averaged ParaNMT[17] word and trigram vectors (Wieting and Gimpel, 2018), which are the current State of the Art on the unsupervised STS Benchmark test set (Ethayarajh, 2018). The unlabeled training set is very small (64K tokens); hence, we do not include f_D in the ensemble, and we finetune the BERT language model for 10K rather than 100K steps to avoid overfitting. Like on the DQD tasks, MV-DASE beats its individual views as well as naive view concatenation and averaging (see Table 8). After adding ParaNMT to the ensemble, we achieve competitive results.

8 Future Work

Non-Linear GCCA. In Section 3.1, we assumed that relationships between representations are linear. This is probably reasonable for word embeddings (most cross-lingual word embeddings are linear projections, e.g. Artetxe et al. (2018)), but it is unclear whether it holds for sentence embeddings. Potential avenues for non-linear GCCA include Kernel GCCA (Tenenhaus et al., 2015) and Deep GCCA (Benton et al., 2017).

[17] github.com/jwieting/para-nmt-50m

		f_G = GloVe	f_G = ParaNMT
1	f_G	.731 / .647	.817 / .799
2	f_U (USE)	.793 / .762	.793 / .762

6	avg	.790 / .729	.823 / .771

Table 8: Pearson's r (dev / test) on the unsupervised STS Benchmark, using different embeddings for f_G. Gray: best in column. Underlined: current unsupervised SoTA on test set (Wieting and Gimpel, 2018).

More views. A major advantage of MV-DASE is that it is agnostic to the number and specifics of its views. We plan to investigate whether additional or different views (e.g., encoders learned on related domains) can increase performance.

9 Conclusion

We have presented a multi-view approach to unsupervised Duplicate Question Detection in low-resource, domain-specific Community Question Answering forums. MV-DASE is a multi-view sentence embedding framework based on Generalized Canonical Correlation Analysis. It combines domain-specific and generic weighted averaged word embeddings with domain-finetuned BERT and the Universal Sentence Encoder, using unlabeled in-domain data only.

Experiments on the CQADupStack corpus and additional low-resource forums show significant improvements over BM25 and all single-view baselines. MV-DASE sets a new State of the Art on a recent DQD shared task (SemEval-2017 3B), with a 2.5% MAP improvement over the best supervised system. Finally, an experiment on the STS Benchmark suggests that MV-DASE has potential on other unsupervised sentence-pair tasks.

Abstract

Sexism, an injustice that subjects women and girls to enormous suffering, manifests in blatant as well as subtle ways. In the wake of growing documentation of experiences of sexism on the web, the automatic categorization of accounts of sexism has the potential to assist social scientists and policy makers in utilizing such data to study and counter sexism better. The existing work on sexism classification, which is different from sexism detection, has certain limitations in terms of the categories of sexism used and/or whether they can co-occur. To the best of our knowledge, this is the first work on the multi-label classification of sexism of any kind(s), and we contribute the largest dataset for sexism categorization. We develop a neural solution for this multi-label classification that can combine sentence representations obtained using models such as BERT with distributional and linguistic word embeddings using a flexible, hierarchical architecture involving recurrent components and optional convolutional ones. Further, we leverage unlabeled accounts of sexism to infuse domain-specific elements into our framework. The best proposed method outperforms several deep learning as well as traditional machine learning baselines by an appreciable margin.

1 Introduction

Sexism, discrimination on the basis of one's sex, prevails in our society in numerous forms, causing immense suffering to women and girls. Online forums have enabled victims of sexism to share their experiences freely and widely by facilitating anonymity and connecting far-away people. A meaningful categorization of these accounts of sexism can play a part in analyzing sexism with a view to developing sensitization programs, systemic safeguards, and other mechanisms against this injustice. Given the rising volume of such information on digital media, automated sexism categorization can aid social scientists and policy makers in combating sexism by conducting such analyses efficiently.

While sexism is detected as a category of hate in some of the hate speech classification work (Badjatiya et al., 2017; Waseem and Hovy, 2016), it does not perform sexism classification. Except the work on categorizing sexual harassment by Karlekar and Bansal (2018), the prior work on classifying sexism assumes the categories to be mutually exclusive (Anzovino et al., 2018; Jha and Mamidi, 2017). Moreover, the existing category sets number between 2 to 5. In this paper, we focus on the new problem of the multi-label categorization of an account of sexism reporting any type(s) of sexism. We create a dataset comprising 13023 accounts of sexism, including first-person accounts from survivors, each tagged with at least one of 23 categories of sexism. The categories were defined keeping in mind the discourse and campaigns on gender-related issues along with potential policy implications, under the guidance of a social scientist. Ten annotators, most of whom have formally studied topics related to gender and/or sexuality, were recruited to label textual accounts of sexism. The accounts are drawn from the Everyday Sexism Project website[1], where voluntary contributors from all over the world document experiences of sexism suffered or witnessed by them. For classification experiments, the categories found in less than 400 accounts in our dataset are appropriately merged with others, resulting in 14 categories.

The rationale for formulating this classification as multi-label is that many experiences inherently involve multiple types of sexism. For instance, *"I*

*The author is also an applied researcher at Microsoft.

overheard a co-worker saying that I should be in more team events and photos because I am pleasing to the eye! Disgusting." is an experience of sexism wherein the victim was subjected to three types of sexism, namely hyper-sexualization, sexual harassment, and hostile work environment.

We develop a novel neural architecture for the multi-label classification of accounts of sexism that enables flexibly combining sentence representations created using models such as BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2018) with distributional word embeddings like ELMo (Embeddings from Language Models) (Peters et al., 2018) and Global Vectors (GloVe) (Pennington et al., 2014) and a linguistic feature representation through hierarchical convolutional and/or recurrent operations. Leveraging general-purpose models such as BERT for encoding sentences likely makes our model better equipped to capture semantic aspects effectively, since they are trained on substantially larger textual data than the domain-specific labeled data that we have. Moreover, we adapt a BERT model for the domain of instances of sexism using unlabeled data. Embeddings from sentence encoders are complemented by sentence representations built from word embeddings as a function of trainable neural network parameters. We explore multiple ways to deal with the multi-label aspect. The adopted method produces label-wise probabilities directly and simultaneously using shared weights and a joint loss function. Our experimentation finds multiple instances of the proposed framework outperforming several diverse baselines on established multi-label classification metrics.

Our key contributions are summarized below.

- We propose a neural framework for the multi-label classification of accounts of sexism that can combine sentence representations built from word embeddings of different kinds through learnable model parameters with those created using pre-trained models. It yields results superior to many deep learning and traditional machine learning baselines.
- To the best of our knowledge, this is the first work on classifying an account recounting any type(s) of sexism without the assumption of the mutual exclusivity of classes.
- We provide a dataset consisting of 13023 accounts of sexism by survivors and observers annotated with one or more of 23 carefully formulated categories of sexism.

2 Related Work

Substantial work has been directed to hate speech detection in recent years. Since some of it involves the detection of sexism (Badjatiya et al., 2017; Waseem and Hovy, 2016), we review it along with the work on sexism classification.

2.1 Hate Speech Detection

Warner and Hirschberg (2012) identify anti-semitic hate speech using SVM. Gao et al. (2017) perform hate speech detection in a weakly supervised fashion. Nobata et al. (2016) distinguish abusive comments from clean ones through various NLP and embedding-derived features. Burnap and Williams (2016) classify cyber hate with respect to race, disability, and sexual orientation using text parsing to extract typed dependencies. Waseem and Hovy (2016) explore the role of extra-linguistic features along with character n-grams in classifying tweets as racist, sexist or neither. Badjatiya et al. (2017) experiment with various deep learning approaches for the same three-way classification. Zhang and Luo (2018) explore skipped CNN and a combination of CNN and GRU for hate speech detection. Unlike these papers, we seek to categorize accounts of sexism, a specific form of discrimination or hate.

2.2 Sexism Categorization

Anzovino et al. (2018) use features such as (Part of Speech) n-grams and text embeddings for the 5-class categorization of misogynistic language. Jafarpour et al. (2018) classify sexist tweets into one of four categories, which deal with harassment and threats. Jha and Mamidi (2017) experiment with SVM, biLSTM with attention, and fastText to categorize tweets as benevolent, hostile, or non-sexist. Their way of categorizing sexism relates to the manner in which sexism is stated. While it is applicable to all sexist remarks, narrated accounts of sexism may not always capture how the perpetrators stated sexism. Karlekar and Bansal (2018) focus on accounts of sexual harassment, exploring CNN and/or RNN for their 3-class classification. As far as we know, our paper presents the first attempt to categorize accounts involving any type(s) of sexism in a multi-label way. Moreover, we pro-

vide a larger dataset and significantly more extensive or finer-grained categorization scheme than these papers.

3 Dataset Construction

Creating our multi-label sexism account categorization dataset entailed two parts: textual data collection and data annotation. To collect data, we crawled the Everyday Sexism Project website, which receives numerous accounts of sexism from survivors themselves as well as observers. After removing entries with less than 7 words, around 20000 entries were shortlisted for annotation; we prioritized shorter ones and tried to approximate the tag distribution on the website. Though shorter entries were preferred keeping in mind the potential future work of transfer learning to Twitter content, our neural framework is devised in a size-agnostic way.

Under the direction of a social scientist, 23 categories of sexism were formulated taking into account gender-related discourse and campaigns (Dutta and Sircar, 2013; Eccles et al., 1990; Mead, 1963; Menon, 2012) as well as possible impact on public policy. Table 1 provides succinct descriptions for the categories.

We followed a three-phase annotation process to ensure that the categorization of each account of sexism in the final dataset involved the labeling of it by at least two of our 10 annotators, most of whom have studied topics related to gender and/or sexuality formally. The annotators were given detailed guidelines, which evolved during the course of their work. Each annotator was given training, which included a pilot round involving evaluation and feedback. Phase 1 involved identifying one or more textual portions capturing distinct accounts of sexism from an entry obtained from Everyday Sexism Project and subsequently tagging each portion with at least one of the 23 categories of sexism, producing over 23000 labeled accounts. In phases 2 and 3, we sought redundancy of annotations for improved quality, as permitted by the availability of annotators adequately knowledgeable about sexism. Over 21000 accounts were categorized again in phase 2 such that the annotators for phases 1 and 2 were different. The inter-annotator agreement across phases 1 and 2, measured by the average of the Cohen's Kappa (Cohen, 1960; Artstein and Poesio, 2008) scores for the per-category pairs of binary label vectors, is 0.584. Each account for which the label sets annotated across phases 1 and 2 were identical was included in the dataset along with the associated label set. In phase 3, some of the accounts for which there was a mismatch between the phase 1 and phase 2 annotations were selected. For each account, the annotators were presented with only the mismatched categories and asked to select or reject each. Duplicates and records for which the Everyday Sexism Project entry numbers match but the accounts do not fully match were removed at multiple stages. In order to improve the annotation reliability further, some records for which the annotations differed across phases 1 and 2 were discarded based on the annotators involved and sensitivities of the categories, resulting in a multi-label sexism categorization dataset of 13023 accounts. For our automated sexism classification experiments, we merge the categories found in less than 400 records with others as follows, resulting in 14 categories. 'Menstruation-related discrimination' and 'Motherhood-related discrimination' are merged into 'Motherhood and menstruation related discrimination'; 'Mansplaining', 'Gaslighting', 'Religion-based sexism', 'Physical violence (excluding sexual violence)', and 'Other' are merged into 'Other'; 'Pay gap' and 'Hostile work environment (excluding pay gap)' are merged into 'Hostile work environment'; 'Tone policing', 'Moral policing (excluding tone policing)', and 'Victim blaming' are merged into 'Moral policing and victim blaming'; 'Rape' and 'Sexual assault (excluding rape)' are merged into 'Sexual assault'. Our dataset, however, retains all 23 categories. Fig. 1 shows the frequency distribution of the number of labels per account in the dataset, demonstrating the multi-label nature of instances of sexism.

Caution: 1) The category frequencies in our dataset (used for merging categories) do not represent real-world instances of sexism, as they are affected by several factors including the bias of our sampling scheme toward smaller posts and the small size of our dataset relative to the immense degree of prevalence of sexism in the world. 2) Labeling categories of sexism can be complex in many cases. Hence, despite our best efforts, our labeled data may contain inaccuracies or discrepancies. We also recognize that our categorization scheme could be improved.

Table 1: Descriptions of the categories of sexism used in our dataset

Category	Description
Role stereotyping	Socially constructed false generalizations about certain roles being more appropriate for women; also applies to such misconceptions about men
Attribute stereotyping	Mistaken linkage of women with some physical, psychological, or behavioral qualities or likes/dislikes; also applies to such false notions about men
Body shaming	Objectionable comments or behaviour concerning appearance including the promotion of certain body types or standards
Hyper-sexualization (excluding body shaming)	Unwarranted focus on physical aspects or sexual acts
Internalized sexism	The perpetration of sexism by women via comments or other actions
Pay gap	Unequal salaries for men and women for the same work profile
Hostile work environment (excluding pay gap)	Sexism encountered by an employee at the workplace; also applies when a sexist misdeed committed outside the workplace by a co-worker makes working uncomfortable for the victim
Denial or trivialization of sexist misconduct	Denial or downplaying of sexist wrongdoings
Threats	All threats including wishing for violence or joking about it, stalking, threatening gestures, or rape threats
Rape	FBI's expanded definition of rape
Sexual assault (excluding rape)	Any sexual contact without consent; unwanted touching
Sexual harassment (excluding assault)	Any sexually objectionable behaviour
Tone policing	Comments or actions that cause or aggravate restrictions on how women communicate
Moral policing (excluding tone policing)	The promotion of discriminatory codes of conduct for women in the guise of morality; also applies to statements that feed into such codes and narratives
Victim blaming	The act of holding the victim responsible (fully or partially) for sexual harassment, violence, or other sexism perpetrated against her
Slut shaming	Inappropriate comments made about women 1) deviating from conservative expectations relating to sex or 2) dressing in a certain way when it gets linked to sexual availability
Motherhood-related discrimination	Shaming, prejudices, or other discrimination or misconduct related to the notion of motherhood; also applies to the violation of reproductive rights
Menstruation-related discrimination	Shaming, prejudices, or other discrimination or wrongdoings related to periods
Religion-based sexism	Sexist discrimination or prejudices stemming from religious scriptures or constructs
Physical violence (excluding sexual violence)	Domestic abuse, murder, kidnapping, confinement, or other physical acts of violence linked to sexism
Mansplaining	A woman being condescendingly talked down to by a man; also applies when a man gives an unsolicited advice or explanation to a woman related to something she knows well that she disapproves of
Gaslighting	Sexist manipulation of the victim through psychological means into doubting her own sanity
Other	Any type of sexism not covered by the above categories

3.1 Ethical Data Use and Release

We are committed to following ethical practices, which includes protecting the privacy and anonymity of the victims. We only use accounts of sexism and tags from entries on the Everyday Sexism Project website (ESP). The entry titles, which could contain sensitive information related to the names or locations of the victims (or contributors), are not saved or used at all.

Our dataset can be requested for academic purposes only by providing some prerequisites as recommended by an ethics committee and agreeing to certain terms through our website[2]. The requesters who fulfill these conditions will be emailed 1) the data comprising only numerical placeholders and labels, 2) a script that fetches only accounts of sexism from ESP to obtain the account for each placeholder, and 3) the annotation guidelines used. We have devised this method to ensure that if an entry gets removed from ESP by a victim (or contributor), any and all parts of it in our dataset will also be removed.

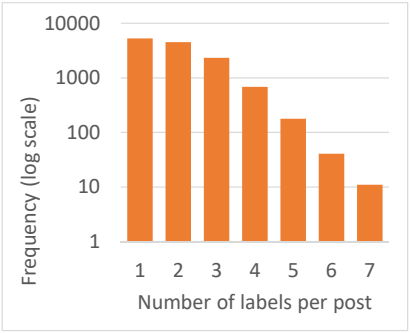

Figure 1: Frequency distribution of #labels per post

4 Sexism Categorization Approach

Given an account of sexism (post), our objective is to predict a list of up to 14 applicable categories of sexism, making this a multi-label multi-class classification task. In this section, we detail our proposed framework, which enables combining sentence representations derived from word embeddings using trainable model parameters with those obtained using general-purpose models. Our architecture is depicted in Fig. 2. We also discuss how we tap unlabeled data and loss functions.

4.1 Sexism Categorization Architecture

Let each post contain a maximum of $|S|$ sentences with a maximum of $|W|$ words per sentence. Ev-

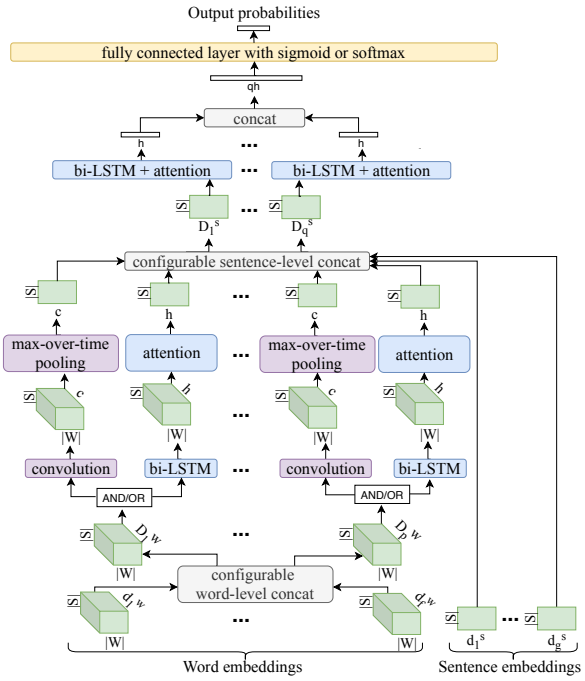

Figure 2: Proposed sexism categorization architecture

ery word (or sentence) can be represented using multiple word (or sentence) embedding methods. Let f (or g) be the number of word (or sentence) embedding methods chosen. Let d_i^w (or d_j^s) be the embedding dimension for the i^{th} (or j^{th}) word (or sentence) embedding scheme. Each post is represented using two kinds of tensors: (a) f tensors $\in \mathcal{R}^{|S|\times|W|\times d_i^w}$ created using different word embeddings, and (b) g tensors $\in \mathcal{R}^{|S|\times d_j^s}$ constructed using different sentence encoders.

First, subsets of the f tensors based on word embeddings are concatenated in a configurable manner (*configurable word-level concat* in Fig. 2), producing p tensors $\in \mathcal{R}^{|S|\times|W|\times D_i^w}$, where D_i^w is the dimension resulting from the i^{th} concatenation. Next, we construct vector representations for the sentences word-embedded in each of the p tensors using CNN-based and/or LSTM-based operations as configured. The CNN-based operations begin with convolutional filters being applied along the word dimension (Kim, 2014) to generate many bigram, trigram and 4-gram based features. This is followed by max-over-time pooling, which picks the largest value for each filter and produces a sentence representing tensor $\in \mathcal{R}^{|S|\times c}$, where c is the total number of convolutional filters used. The LSTM-based components include biLSTM followed by an attention mechanism (Yang et al., 2016) through which the LSTM outputs across time steps are aggregated into a vector representation for each sentence, resulting in a tensor $\in \mathcal{R}^{|S|\times h}$, where h is the bi-LSTM output length. At this stage, we have three types of sentence representing tensors if both CNN-based and RNN-based operations are chosen to be applied on all word embedding tensors: (a) p tensors $\in \mathcal{R}^{|S|\times c}$ from the CNN-based processing, (b) p tensors $\in \mathcal{R}^{|S|\times h}$ from the LSTM-based processing, and (c) g tensors $\in \mathcal{R}^{|S|\times d_j^s}$ obtained using general-purpose sentence encoders.

From these sentence representing tensors, subsets are concatenated to produce q tensors $\in \mathcal{R}^{|S|\times D_j^s}$ (*configurable sentence-level concat* in Fig. 2), where D_j^s is the dimension stemming from the j^{th} concatenation. The sequence of sentence vectors in each of these q tensors is then passed through bi-LSTM followed by attention-based aggregation, producing q representations for a post collectively. These vectors are then concatenated to produce the overall post representation. The final step involves a fully connected layer with a sigmoid or softmax non-linearity depending on the loss function used, generating the output probabilities.

4.2 Word and Sentence Representations

We model a post using both word embeddings and sentence embeddings. We experiment with three distributional word vectors, namely ELMo (Peters et al., 2018), GloVe (Pennington et al., 2014), and fastText (Bojanowski et al., 2017), and a linguistic feature vector. Our linguistic feature representation comprises a variety of features, namely features from the biased language detection work (assertive verb, implicative verb, hedges, factive verb, report verb, entailment, strong subjective, weak subjective, positive word, and negative word) (Recasens et al., 2013), PERMA (Positive Emotion, Engagement, Relationships, Meaning, and Accomplishments) features for both polarities (Schwartz et al., 2016), associations with eight basic emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) and two sentiments (negative and positive) from the NRC emotion lexicon (Mohammad and Turney, 2013), and affect (valence, arousal, and dominance) scores (Mohammad, 2018). Missing values are filled with zero for binary features and with the mean for non-binary ones.

We explore the following for creating sentence embeddings: BERT (Devlin et al., 2018), Universal Sentence Encoder (USE) (Cer et al., 2018), and

InferSent (Conneau et al., 2017). Our choice of utilizing these models is warranted by the fact that the corpora that they are trained on are considerably bigger than the textual data that we have for supervised learning and hence likely contain greater semantic diversity.

4.3 Utilizing Unlabeled Data

Models such as BERT are not trained to generate representations tuned to a specific domain. We use over 90000 entries crawled from Everyday Sexism Project's website to tailor a pre-trained BERT model for obtaining more effective representations for our model. After removing the unlabeled entries corresponding to the posts in the test and validation data, we use the rest to tune the BERT parameters using its masked language modeling and next sentence prediction tasks. We henceforth refer to this refined model as tBERT (tuned BERT).

4.4 Loss Function Choice

Since the popular cross-entropy loss is inapt for our multi-label classification task in its standard form, we explore two alternatives. Binary (multi-hot) target vectors are used for both.

4.4.1 Extended Binary Cross Entropy Loss

We adopt an Extended version of the Binary Cross Entropy loss ($EBCE$), formulated as a weighted mean of label-wise binary cross entropy values in order to neutralize class imbalance.

$$L_{EBCE} = -\frac{1}{n}\sum_{i=1}^{n}\frac{1}{L}\sum_{j=1}^{L} w_{jy_{ij}}\left\{y_{ij}\log(\hat{p}_{ij}^{\sigma}) + (1-y_{ij})\log(1-\hat{p}_{ij}^{\sigma})\right\} \quad (1)$$

Here, n and L denote the number of samples (posts) and the number of classes respectively. y_{ij} is 1 if label l_j applies to post x_i and 0 otherwise. $\hat{p}_{ij}^{\sigma}$ is the estimated probability of label l_j being applicable to post x_i computed using a sigmoid activation atop the fully connected layer with L output units. The weights for correcting class imbalance w_{jv} are computed as follows.

$$w_{jv} = \frac{n}{2|\{x_i \mid y_{ij} = v, 1 \leq i \leq n\}|} \quad (2)$$

4.4.2 Normalized Cross Entropy Loss

We also experiment with a Normalized variant of the Cross Entropy loss tailored for a multi-label problem configuration also mitigating class imbalance (referred to as NCE).

$$L_{NCE} = -\frac{1}{n}\sum_{i=1}^{n}\frac{1}{|\mathbf{y_i^+}|}\sum_{j=1}^{L} w_j^c\{y_{ij}\log(\hat{p}_{ij})\} \quad (3)$$

Here, $\mathbf{y_i^+}$ is the set of labels applicable to post x_i. $\hat{p}_{ij}$ denotes the estimated probability of label l_j being applicable to post x_i computed through a softmax function. The class imbalance negating weights w_j^c are generated as follows.

$$w_j^c = \frac{n}{\sum_{i=1}^{n}\frac{y_{ij}}{|\mathbf{y_i^+}|}} \quad (4)$$

Unlike in single-label multi-class classification, wherein $\arg\max$ can be applied to the probability vector generated by softmax to make the prediction, we could apply a threshold on probability vector $\hat{\mathbf{p}}_\mathbf{i}$ to find the (potentially) multiple applicable classes for post x_i. Instead of using a fixed, manually tuned threshold-related parameter, we devise an automated method for estimating a per-sample cut-off position. For each sample, we descendingly sort the probability scores, compute the differences between successive (sorted) score pairs, find the index m corresponding to the maximum value in the list of differences, and select the classes corresponding to indices $[1..m]$. Note that when sigmoid (along with $EBCE$ loss) is used instead of softmax, the prediction is made by rounding the probability vector, since it comprises the class-wise binary prediction probabilities.

4.4.3 Discussion on Single-label Transformations

Traditional approaches to multi-label classification include transforming the problem to one or more single-label classification problems. The Label Powerset (LP) method (Boutell et al., 2004) treats each distinct combination of classes existing in the training set as a separate class. The standard cross-entropy loss can then be used along with softmax. This transformative method may impose a greater computational cost than the direct approach using the $EBCE$ loss since the cardinality of the transformed label set may be relatively high. Moreover, LP does not generalize to label combinations not covered in the training set. Another approach based on problem transformation is binary relevance (BR) (Boutell et al., 2004). An independent binary classifier is trained to predict the applicability of each label in this method. This entails training a total of L classifiers, making BR computationally very expensive. Additionally, its performance is affected by the fact that it disregards correlations existing between labels.

5 Experiments

We evaluate the proposed framework against several baselines and provide qualitative and quantitative analyses. Our code is available on GitHub[3]. Our implementation utilizes parts of the code from (Agrawal and Awekar, 2018; Pattisapu et al., 2017; Liao, 2017) and libraries Keras and Scikit-learn (Pedregosa et al., 2011). We reserve 15% of the data for testing and validation each.

5.1 Evaluation Metrics

Owing to the multi-label nature of this classification, standard metrics used in single-label multi-class classification are unsuitable. We adopt established example (instance) based metrics, namely F1 (F_I) and accuracy (Acc_I), and label-based metrics, namely F1 macro (F_{macro}) and F1 micro (F_{micro}) used in multi-label classification (Zhang and Zhou, 2014).

5.2 Baselines

Random

Labels are selected randomly as per their normalized frequencies in the training data for each test sample.

Traditional Machine Learning (ML)

We experiment with Support Vector Machine (SVM), Random Forests (RF), and Logistic Regression (LR). The features explored include TF-IDF on character n-grams (1-5 characters), TF-IDF on word unigrams and bigrams, the mean of the ELMo vectors for the words in a post, and the composite set of features similar to (Anzovino et al., 2018) comprising n-gram based, POS-based, and doc2vec (Le and Mikolov, 2014) features, the post length, and the adjective count.

LSTM-based Architectures

biLSTM: The word embeddings for all words in a post are fed to bidirectional LSTM.

biLSTM-Attention: Same as biLSTM but with the attention mechanism by Yang et al. (2016).

Hierarchical-biLSTM-Attention: For the words in each sentence, the word embeddings are passed through biLSTM with attention to create a sentence embedding. These sentence embeddings are in turn fed to another instance of biLSTM with attention. This broadly follows the architecture proposed for document classification by Yang et al. (2016) with GRUs replaced with LSTMs.

[3] https://github.com/pulkitparikh/sexism_classification

Sentence embeddings with biLSTM-Attention: Sentence representations generated using a generic encoder (BERT using bert-as-service (Xiao, 2018), USE, and InferSent) are passed through biLSTM with attention.

CNN and CNN-LSTM based Architectures

CNN-Kim: Similar to (Kim, 2014), this involves applying convolutional filters followed by max-over-time pooling to the word vectors for a post.

C-biLSTM: In this variant of the C-LSTM architecture (Zhou et al., 2015) somewhat related to an approach used by Karlekar and Bansal (2018) for multi-label sexual harassment classification, after applying convolution on the word vectors for a post, the feature maps are stacked along the filter dimension to create a sequence of window vectors, which are then fed to biLSTM.

CNN-biLSTM-Attention: For each sentence, convolutional and max-over-time pooling layers are applied on the embeddings of its words. The resultant sentence representations are put through bi-LSTM with the attention mechanism. This approach is similar to (Wang et al., 2016) with the attention scheme from (Yang et al., 2016) added.

The architectures of the deep learning baselines have a fully connected layer with the sigmoid or softmax non-linearity (depending on the loss function used) at the end.

5.3 Results

Table 2 shows results produced using traditional ML methods (SVM, RF, and LR) across four different feature sets (word n-grams, character n-grams, averaged ELMo vectors, and composite features). We use Label Powerset for these methods, since the direct (non-transformative) formulation cannot be used with them. Among these combinations, logistic regression with averaged ELMo embeddings as features performs the best.

Table 3 contains results for the random and deep learning baselines and different variants of the proposed framework. For each method, the average over three runs is reported for each metric. We find ELMo to be better than GloVe and fastText for word embeddings across multiple baselines and hence show only ELMO-based results for the baselines. We report all results with the EBCE loss; the NCE loss produced inferior results across multiple methods. For our framework, s() denotes sentence-level concatenation; wl() de-

Table 2: Results with traditional machine learning (Label Powerset)

Features⟶	Word n-grams				Character n-grams				Averaged ELMo vectors				Composite features			
Classifier↓	F_I	F_{macro}	Acc_I	F_{micro}	F_I	F_{macro}	Acc_I	F_{micro}	F_I	F_{macro}	Acc_I	F_{micro}	F_I	F_{macro}	Acc_I	F_{micro}
SVM	0.448	0.373	0.324	0.410	0.449	0.374	0.331	0.416	0.546	0.430	0.431	0.500	0.178	0.094	0.116	0.174
LR	0.357	0.315	0.236	0.349	0.357	0.311	0.230	0.352	**0.595**	**0.479**	**0.478**	**0.549**	0.438	0.370	0.311	0.421
RF	0.531	0.398	0.438	0.476	0.395	0.205	0.325	0.349	0.375	0.164	0.305	0.331	0.460	0.311	0.380	0.415

notes word level concatenation and LSTM-based processing; wc() denotes word level concatenation and CNN-based processing. We note that the results are reported for only some of the many instances that can arise from our configurable architecture. Our framework provides the ability to explore different configurations such as those with multiple s() operations, depending on the problem at hand.

We observe the following: (1) The random baseline performs poorly, confirming the complexity of the problem. (2) biLSTM-Attention and Hierarchical-biLSTM-Attention are the two best baselines. (3) Several variants of the proposed framework outperform all baselines. Based on F_I and F_{macro}, our best method is s(wl(ELMo), wl(GloVe), tBERT), though adding linguistic features (Ling) to it slightly improves some metrics. (4) BERT tuned on unlabeled instances of sexism (tBERT) works better than the vanilla BERT counterpart and other sentence encoders. (5) Combining tBERT sentence representations with those generated from ELMo word vectors using biLSTM with attention works better than using either individually. (6) Along with tBERT, concatenating ELMo and GloVe at the sentence level (s(wl(ELMo), wl(GloVe), tBERT)) is better than concatenating them at the word level (s(wl(ELMo, GloVe), tBERT)) while processing word vectors using biLSTM with attention. (7) The LSTM based processing of word embeddings produces better results than the CNN based counterpart.

Table 3: Results for the proposed methods and deep learning baselines (using ELMo embeddings) with the EBCE loss and Random

	s(wc(ELMo), wl(ELMo), wc(GloVe), wl(GloVe), tBERT)	0.741	0.664	0.625	0.705

The pre-processing steps that we perform for all deep learning methods include removing certain non-alpha-numeric characters and extra spaces, lower-casing, and zero-padding input tensors as appropriate. While breaking a post into sentences, each sentence containing more than 35 words is split into multiple sentences, ensuring the maximum sentence length of 35 words.

Using experiments on a validation set, which was merged into the training set during the test runs, for each method, we choose the values of three hyper-parameters: the LSTM dimension, the attention dimension, and the number CNN filters for kernel sizes 2, 3, and 4 each. The values used for instances of our framework and the deep learning baselines are provided in Table 5.

We employ 0.25 dropouts after each input and before the final, fully connected layer. The learning rate was set to 0.001 and the number of epochs to 10. We use a batch size of 64. These fixed parameters were kept unchanged across methods.

The hyper-parameter values for the traditional ML methods are as follows. For SVM, soft margin (C) is set to 1.0. For RF (Random Forest), the number of estimators is 100. For extracting character and word n-grams, the maximum number of features used, word n-gram range, and character n-gram range are 10000, (1,2), and (1,5) respectively. For SVM and LR (Logistic Regression), we apply class imbalance correction.

For tapping unlabeled data, we pre-train the 'BERT-Base, Uncased' model[4] for 100000 steps with a batch size of 25. For vannila BERT, we use the bigger 'BERT-Large, Uncased' model, which we could not use for pre-training because of computational constraints. For generating GloVe word embeddings, we use the 840B-token, cased model.

Table 4 lists accounts of sexism from the test set for which our best method made the right predictions but the best baseline did not, along with the labels. It also highlights the top two words per sentence based on the word-level attention weights for wl(ELMo) and wl(GloVe) combined through element-wise max operations. For the first ac-

Table 6: Performance variation across #labels per post

#Labels per post	F_I	F_{macro}	Acc_I	F_{micro}
1	0.729	0.527	0.632	0.637
2	0.754	0.675	0.631	0.722
3	0.781	0.721	0.652	0.764
4	0.743	0.722	0.604	0.735
5	0.739	0.592	0.592	0.735

count of sexism, our model produces words like "intern", "assistant" and "boss", associated with role stereotyping, among the top two words across sentences. Likewise, "honey" related to sexual harassment and "boss", "coworker", and "services" related to hostile work environments also surface. Moreover, the top two sentences based on the sentence-level attention weights of our model are the last two, which evidence all category labels. For other posts too, the model produces category-relevant top two words per sentence; "womens" and "work" relate to role stereotyping and moral policing; "tight" and "trowsers" relate to hyper-sexualization and moral policing; "makeup" relates to attribute stereotyping; "hair" from "short hair" relates to body shaming; "cat" from "cat calls" relates to sexual harassment; "compliments" from "take cat calls as compliments" relates to denial or trivialization of sexist misconduct.

Table 6 shows results for one run of our best method across different numbers of labels per post (1 to 5). Entries for values 6 and 7, which have less than 10 associated test samples, are omitted. The best results are observed for values 2 to 4, suggesting that our approach performs better on multi-label samples.

6 Conclusion

We explored classifying an account reporting any kind(s) of sexism such that the categories can co-occur. We developed a neural framework that outperforms many deep learning and traditional ML baselines for this multi-label sexism classification. Moreover, we provided the largest dataset for sexism classification, linked with 23 categories. Directions for future work include devising approaches that perform sexism classification more accurately, enhancing the categorization scheme, and developing other ways to help counter sexism. We hope that this paper will give rise to further work aimed at fighting sexism.

7 Acknowledgments

We are really grateful to Everyday Sexism Project. We also thank Bhavapriya Thottakad, Himakshi Baishya, Aanchal Gupta, Subhashini R, Shalini Pathi, Hadia Ahsan, and Reshma Kalpana, without whose efforts in analyzing accounts of sexism this paper would not have materialized. We are grateful to Ponnurangam Kumaraguru, too, for his time and inputs.

Abstract

The sequence of documents produced by any given author varies in style and content, but some documents are more typical or representative of the source than others. We quantify the extent to which a given short text is characteristic of a specific person, using a dataset of tweets from fifteen celebrities. Such analysis is useful for generating excerpts of high-volume Twitter profiles, and understanding how representativeness relates to tweet popularity. We first consider the related task of binary author detection (is x the author of text T?), and report a test accuracy of 90.37% for the best of five approaches to this problem. We then use these models to compute characterization scores among all of an author's texts. A user study shows human evaluators agree with our characterization model for all 15 celebrities in our dataset, each with p-value < 0.05. We use these classifiers to show surprisingly strong correlations between characterization scores and the popularity of the associated texts. Indeed, we demonstrate a statistically significant correlation between this score and tweet popularity (likes/replies/retweets) for 13 of the 15 celebrities in our study.

1 Introduction

Social media platforms, particularly microblogging services such as Twitter, have become increasingly popular (Statista, 2019) as a means to express thoughts and opinions. Twitter users emit tweets about a wide variety of topics, which vary in the extent to which they reflect a user's personality, brand and interests. This observation motivates the question we consider here, of how to quantify the degree to which tweets are characteristic of their author?

People who are familiar with a given author appear to be able to make such judgments confidently. For example, consider the following pair of tweets written by US President Donald Trump, at the extreme sides of our characterization scores (0.9996 vs. 0.0013) for him:

> **Tweet 1:** Thank you for joining us at the Lincoln Memorial tonight- a very special evening! Together, we are going to MAKE AMERICA GREAT AGAIN!

> **Tweet 2:** "The bend in the road is not the end of the road unless you refuse to take the turn." - Anonymous

Although both these tweets are from the same account, we assert that Tweet 1 sounds more characteristic of Donald Trump than Tweet 2. We might also guess that the first is more popular than second. Indeed, Tweet 1 received 155,000 likes as opposed to only 234 for Tweet 2.

Such an author characterization score has many possible applications. With the ability to identify the most/least characteristic tweets from a person, we can generate reduced excerpts for high-volume Twitter profiles. Similarly, identifying the least characteristic tweets can highlight unusual content or suspicious activity. A run of sufficiently unrepresentative tweets might be indicative that a hacker has taken control of a user's account.

But more fundamentally, our work provides the necessary tool to study the question of how "characteristic-ness" or novelty are related to tweet popularity. Do tweets that are more characteristic of the user get more likes, replies and retweets? Is such a relationship universal, or does it depend upon the personality or domain of the author? Twitter users with a large follower base can employ our methods to understand how characteristic a new potential tweet sounds, and obtain an estimate of how popular it is likely to become.

To answer these questions, we formally define the problem of author representativeness testing, and model the task as a binary classification prob-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1653–1663,

lem. Our primary contributions in this paper include:

- **Five approaches to authorship verification:** As a proxy for the question of representativeness testing (which has no convincing source of ground truth without extensive human annotation), we consider the task of distinguishing tweets written by a given author from others they did not write. We compare five distinct computational approaches to such binary tweet classification (user vs. non-user). Our best model achieves a test accuracy of 90.37% over a dataset of 15 Twitter celebrities. We use the best performing model to compute a score (the probability of authorship), which quantifies how characteristic of the user a given tweet is.

- **Human evaluation study:** To verify that our results are in agreement with human judgment of how 'characteristic' a tweet is, we ask human evaluators which of a pair of tweets sounds more characteristic of the given celebrity. The human evaluators are in agreement with our model 70.40% of the time, significant above the 0.05 level for each of our 15 celebrities.

- **Correlation analysis for popularity:** Our characterization score exhibits strikingly high absolute correlation with popularity (likes, replies and retweets), despite the fact that tweet text is the only feature used to train the classifier which yields these scores.

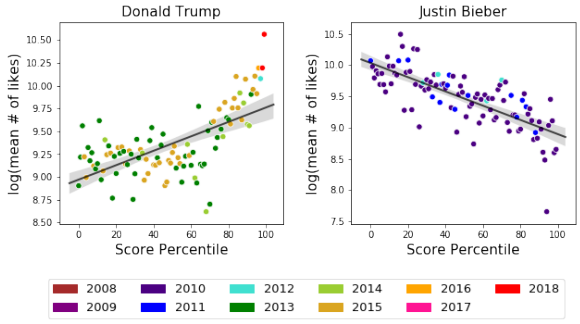

Figure 1: Plot of log mean number of likes against tweet score percentile for Donald Trump and Justin Bieber. Node color denotes the year for which the maximum number of tweets are present in each percentile bucket, demonstrating that this is not merely a temporal correlation.

For 13 of the 15 celebrities in our dataset, we observe a statistically significant correlation between characterization score and popularity. Figure 1 shows the relation between tweet score and tweet popularity for Donald Trump and Justin Bieber respectively. The figure shows that the sign of this association differs for various celebrities, reflecting whether their audience seeks novelty or reinforcement.

- **Iterative sampling for class imbalance:** Our task requires distinguishing a user's tweets (perhaps 1,000 positive training examples) from the sea of all other user's tweets (implying billions of possible negative training examples). We present an iterative sampling technique to exploit this class imbalance, which improves the test accuracy for negative examples by 2.62%.

2 Problem Formulation

We formally define the author representativeness problem as follows:

Input: A Twitter author U and the collection of their tweets, and a new tweet T.
Problem: Compute score(T, U), the probability that T was written by U. This score quantifies how characteristic of writer U, tweet T is.

2.1 Methodology

In order to obtain this representativeness score, we model our task as a classification problem, where we seek to distinguish tweets from U against tweets from all other users.

By modeling this as a binary classification problem, it becomes possible to quantify how characteristic of a writer a tweet is, as a probability implied by its distance from the decision boundary. Thus, we obtain a characterization score between 0 and 1 for each tweet.

Challenges: In training a classifier to distinguish between user and non-user tweets, we should ideally have an equal amount of examples of both classes. User tweets are simply all the tweets from that user's Twitter account, and measure perhaps in the thousands. Indeed, the number of tweets per user per day is limited to 2400 per day by current Twitter policy (https://help.twitter.com/en/rules-and-policies/twitter-limits). The negative examples consist of all tweets written by other Twitter users, a total of approximately 500 million per day

(https://business.twitter.com). Thus there is an extreme class imbalance between user and non-user tweets. Moreover, the nature of language used on Twitter does not conform to formal syntactic or semantic rules. The sentences tend to be highly unstructured, and the vocabulary is not restricted to a particular dictionary.

2.2 Data

For the binary classification task described in Section 2.1, we term tweets from U as positive examples, and tweets from other users as negative examples.

- **Positive examples:** We take tweets written by 15 celebrities from various domains, from 01-Jan-2008 to 01-Dec-2018, as positive examples. Properties of these Twitter celebrities are provided in Table 1.

- **Negative examples:** We have collected 1% of tweets from Twitter's daily feed using the Twitter API (https://developer.twitter.com/en/docs.html) to use as negative examples.

User	Tweet count (Before)	Tweet count (After)	Domain	Foll.
Amitabh Bachchan	49437	10342	Acting	37.0
Ariana Grande	37738	13657	Music	62.3
Barack Obama	11350	6772	Politics	106.0
Bill Gates	2699	1754	Business	47.1
Donald Trump	35549	18295	Politics	59.9

LeBron James	5145	2102	Sports	42.6
Narendra Modi	17613	6672	Politics	47.0
Oprah Winfrey	11685	4588	TV	42.2

Table 1: Twitter celebrities in our dataset, with tweet counts before and after filtering (Foll. denotes followers in millions)

Preprocessing and Filtering: We have preprocessed and filtered the data to remove tweets that are unrepresentative or too short for analysis. All text has been converted to lowercase, and stripped of punctuation marks and URLs. This is because our approaches are centered around word usage. However, in future models, punctuation may prove effective as a feature. Further, we restrict analysis to English language tweets containing no attached images. We select only tweets which are more than 10 words long, and contain at least 5 legitimate (dictionary) English words. We define an unedited transfer of an original tweet as a retweet, and remove these from our dataset. Since comments on retweets are written by the user themselves, we retain these in our dataset.

We note that celebrity Twitter accounts can be handled by PR agencies, in addition to the owner themselves. Because our aim is to characterize Twitter profiles as entities, we have not attempted to distinguish between user-written and agency-written tweets. However, this is an interesting direction for future research.

We use a train-test split of 70-30% on the positive examples, and generate negative training and test sets of the same sizes for each user, by randomly sampling from the large set of negative examples.

3 Related work

3.1 Author identification and verification

The challenge of author identification has a long history in NLP. PAN 2013 (Juola and Stamatatos, 2013) introduced the question: "Given a set of documents by the same author, is an additional (out-of-set) document also by that author?" The corpus is comprised of text pieces from textbooks, newspaper articles, and fiction. Submissions to PAN 2014 (Stamatatos et al., 2014) also model authorship verification as binary classification, by using non-author documents as negative examples. The best submission (Seidman, 2013) in PAN 2013 uses the General Impostors (GI) method, which is a modification of the Impostors Method (Koppel et al., 2012). The best submission (Khonji and Iraqi, 2014) in PAN 2014 presents a modification of the GI method. These methods are based on the impostors framework (Koppel and Winter, 2014).

Veenman and Li (2013) used compression distance as a document representation, for authorship verification in PAN 2013. HB et al. (2015) present a global feature extraction approach and achieve state-of-the-art accuracy for the PAN 2014 corpus. The best submission (Bagnall, 2015) in PAN 2015 (Stamatatos et al., 2015) uses a character-level RNN model for author identification, in which each author is represented as a sub-model, and the

recurrent layer is shared by all sub-models. This is useful if the number of authors is fixed, and the problem is modeled as multi-class classification. Mohsen et al. (2016) also approach multi-class author identification, using deep learning for feature extraction, and Nirkhi et al. (2016) using hierarchical clustering.

Potha and Stamatatos (2018) propose an intrinsic profile-based verification method that uses latent semantic indexing (LSI), which is effective for longer texts. Koppel and Schler (2004) and Luyckx and Daelemans (2008) explore methods for authorship verification for larger documents such as essays and novels. Nizamani and Memon (2013) and Brocardo et al. (2013) explore author identification for emails, and Chen and Sun (2017) for scientific papers. Azarbonyad et al. (2015) make use of temporal changes in word usage to identify authors of tweets and emails. Fissette (2010), Green and Sheppard (2013), and Zhang et al. (2014) evaluate the utility of various features for this task. Stamatatos (2008) proposes text sampling to address the lack of text samples of undisputed authorship, to produce a desirable distribution over classes.

Koppel et al. (2009) compare methods for variants of the authorship attribution problem. Bhargava et al. (2013) apply stylometric analysis to tweets to determine the author. López-Monroy et al. (2015) propose a document representation capturing discriminative and subprofile-specific information of terms. Rocha et al. (2016) review methods for authorship attribution for social media forensics. Peng et al. (2016a) use bit-level n-grams for determining authorship for online news. Peng et al. (2016b) apply this method to detect astroturfing on social media. Theóphilo et al. (2019) employ deep learning specifically for authorship attribution of short messages.

3.2 Predicting tweet popularity

Suh et al. (2010) leverages features such as URL, number of hashtags, number of followers and followees etc. in a generalized linear model, to predict the number of retweets. Naveed et al. (2011) extend this approach to perform content-based retweet prediction using several features including sentiments, emoticons, punctuations etc. Bandari et al. (2012) apply the same approach for regression as well as classification, to predict the number of retweets specifically for news articles. Zaman et al. (2014) present a Bayesian model for retweet prediction using early retweet times, retweets of other tweets, and the user's follower graph. Tan et al. (2014) analyze whether different wording of a tweet by the same author affects its popularity. SEISMIC (Zhao et al., 2015) and PSEISMIC (Chen and Li, 2017) are statistical methods to predict the final number of retweets. Zhang et al. (2018) approach retweet prediction as a multi-class classification problem, and present a feature-weighted model, where weights are computed using information gain.

3.3 Training with imbalanced datasets

Various methods to handle imbalanced datasets have been described by Kotsiantis et al. (2006). These include undersampling (Kotsiantis and Pintelas, 2003), oversampling, and feature selection (Zheng et al., 2004) at the data level. However, due to random undersampling, potentially useful samples can be discarded, while random oversampling poses the risk of overfitting. This problem can be handled at the algorithmic level as well: the threshold method (Weiss, 2004) produces several classifiers by varying the threshold of the classifier score. One-class classification can be performed using a divide-and-conquer approach, to iteratively build rules to cover new training instances (Cohen, 1995). Cost-sensitive learning (Domingos, 1999) uses unequal misclassification costs to address the class imbalance problem.

4 Approaches to authorship verification

As described in Section 2.1, we build classification models to distinguish between user and non-user tweets. We have explored five distinct approaches to build such models.

4.1 Approach 1: Compression

This approach is inspired from Kolmogorov complexity (Li and Vitányi, 2013), which argues that the compressibility of a text reflects the quality of the underlying model. We use the Lempel-Ziv-Welch (LZW) compression algorithm (Welch, 1984) to approximate Kolmogorov complexity by dynamically building a dictionary to encode word patterns from the training corpus. The longest occurring pattern match present in the dictionary is used to encode the text.

We hypothesize that the length of a tweet T from user U, compressed using a dictionary built

from positive examples, will be less than the length of the same tweet compressed using a dictionary built from negative examples.

We use the following setup to classify test tweets for each Twitter user in our dataset:

1. Build an encoding dictionary using positive examples ($\text{train}_{\text{pos}}$), and an encoding dictionary using negative examples ($\text{train}_{\text{neg}}$).

2. Encode the new tweet T using both these dictionaries, to obtain $T_{\text{pos}} = \text{encode}_{\text{pos}}(T)$ and $T_{\text{neg}} = \text{encode}_{\text{neg}}(T)$ respectively.

3. If the length of T_{pos} is less than that of T_{neg}, classify T as positive; else, classify it as negative.

This gives us the class label for each new tweet T. In addition, we compute the characterization score of tweet T with respect to user U, as described in Equation 1.

$$\text{score}(T, U) = 1 - \frac{\text{len}(T_{\text{pos}})}{\text{len}(T)} \quad (1)$$

Thus the shorter the length of the encoded tweet, the more characteristic of the user T is.

4.2 Approach 2: Topic modeling

We hypothesize that each user writes about topics with a particular probability distribution, and that each tweet reflects the probability distribution over these topics. We train a topic model using Latent Dirichlet Allocation (LDA) (Blei et al., 2003) on a large corpus of tweets, and use this topic model to compute topic distributions for individual tweets. We then use these values as features. We experiment with two types of classifiers: Logistic Regression (LR), and Multi Linear Perceptron (MLP) of size $(5, 5, 5)$. We represent each tweet as a distribution over $n = 500$ topics.

The characterization score of a tweet T is given by the classifier's confidence that T belongs to the positive class.

4.3 Approach 3: n-gram probability

We hypothesize that a Twitter user can be characterized by usage of words and their frequencies in tweets, and model this using n-gram frequencies.

We use the following setup to classify test tweets for each Twitter user in our dataset:

1. Build a frequency dictionary of all n-grams in positive examples ($\text{train}_{\text{pos}}$), and a frequency dictionary of all n-grams in negative examples ($\text{train}_{\text{neg}}$).

2. Compute the average probability of all n-gram sequences in the new tweet T using both these dictionaries, to obtain $\text{prob}_{\text{pos}}(T)$ and $\text{prob}_{\text{neg}}(T)$ respectively. Here, we use add-one smoothing and conditional backoff to compute these probability values.

3. If $\text{prob}_{\text{pos}}(T)$ is greater than $\text{prob}_{\text{neg}}(T)$, classify T as positive; else, classify it as negative.

The characterization score of tweet T is given by the average n-gram probability computed using the frequency dictionary of $\text{train}_{\text{pos}}$. We experiment with $n = 1$ (unigrams) and $n = 2$ (bigrams).

4.4 Approach 4: Document embeddings

We hypothesize that if we obtain latent representations of tweets as documents, tweets from the same author will cluster together, and will be differentiable from tweets from others. To that end, we use the following setup:

1. We obtain representations of tweets as document embeddings. We experiment with two types of document embeddings: FastText (Facebook-Research, 2016) (embedding size = 100) and BERT-Base, uncased (Devlin et al., 2018) (embedding size = 768).

2. We then use these embeddings as features to train a classification model. We experiment with two types of classifiers: Logistic Regression (LR) and Multi Linear Perceptron (MLP) of size $(5, 5, 5)$.

The characterization score of tweet T is given by the classifier's confidence that T belongs to the positive class.

Iterative sampling: As described in Section 2.1, there exists an extreme class imbalance for this binary classification task, in that the number of negative examples is far more than the number of positive examples. Here, we explore an iterative sampling technique to address this problem. We train our classifier for multiple iterations, coupling the same $\text{train}_{\text{pos}}$ with a new randomly sampled $\text{train}_{\text{neg}}$ set in each iteration.

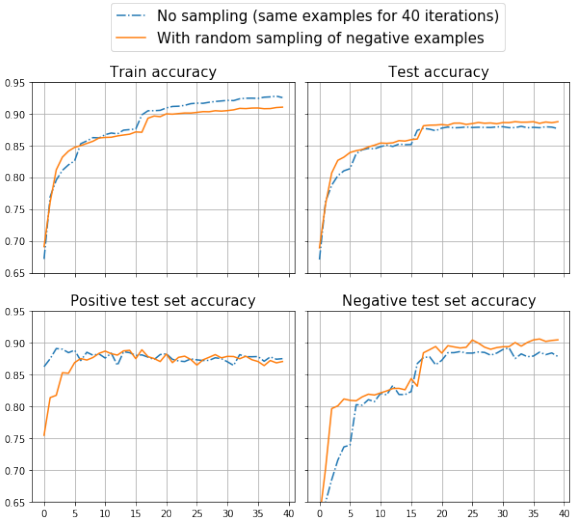

Figure 2: Mean accuracy of the BERT + MLP classifier for all users over 40 iterations

We conduct this experiment for all users with the best performing model for this approach, i.e. we use BERT embeddings as features, and MLP for classification. We train this classifier for 40 iterations, and compare the model's performance when we use the same set of negative examples vs. when we randomly sample new negative examples in each iteration.

Figure 2 shows the mean train and test accuracy for all users over 40 iterations. As expected, the training accuracy is higher if we do not sample, as the model gets trained on the same data repeatedly in each iteration. However, if we perform random sampling, the model is exposed to a larger number of negative examples, which results in a higher test accuracy (+ 1.08%), specifically for negative test examples (+ 2.62%).

4.5 Approach 5: Token embeddings and sequential modeling

In this approach, we tokenize each tweet, and obtain embeddings for each token. We then sequentially give these embeddings as input to a classifier.

We use a pretrained model (BERT-Base, Uncased: 12-layer, 768-hidden, 12-heads, 110M parameters) to generate token embeddings of size 768, and pass these to a Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) classifier. We use an LSTM layer with 768 units with dropout and recurrent dropout ratio 0.2, followed by a dense layer with sigmoid activation.

User	(1) Compression	(2) LDA + LR	(2) LDA + MLP	(3) Bigram	(3) Unigram	(4) FT + LR	(4) FT + MLP	(4) BERT + LR	(4) BERT + MLP	(5) BERT + LSTM

Table 2: Test accuracy (%) of five approaches to classify user vs. non-user tweets (The best performing approach is shown in **bold** for each user) [Note that for each user, the test set contains an equal number of positive and negative examples.]

We train this model using the Adam optimizer (Kingma and Ba, 2014) and binary cross-entropy loss, with accuracy as the training metric.

4.6 Results and Comparison

Table 2 presents the user-wise test accuracy of the five approaches under the specified configurations. Note that the test set contains an equal number of positive and negative examples for each author.

Other baselines that we attempted to compare against include the best submissions to the PAN 2013 and 2014 author verification challenge: Seidman (2013) and Khonji and Iraqi (2014), which are variants of the Impostors Method. This challenge employed significantly longer documents (with an average of 1039, 845, and 4393 words per document for articles, essays and novels respectively, as opposed to an average of 19 words per tweet) and significantly fewer documents per author (an average of 3.2, 2.6 and 1 document/s per author, as opposed to an average of 6738 tweets per user). Our experiments with the authorship verification classifier (Eder et al., 2016) showed that the Impostors Method is prohibitively expensive on larger corpora, and also performed too inaccurately on short texts to provide a meaningful baseline.

For 13 of the 15 users in our dataset, Approach 4.5 (token embeddings followed by sequential modeling) has the highest accuracy. This model correctly identifies the author of 90.37% of all tweets in our study, and will be used to define the characterization score for our subsequent studies.

5 User study

To verify whether human evaluators are in agreement with our characterization model, we conducted a user study using MTurk (Amazon, 2005).

5.1 Setup

For each user in our dataset, we build a set of 20 tweet pairs, with one tweet each from the 50 top-scoring and bottom-scoring tweets written by the user. We ask the human evaluator to choose which tweet sounds more characteristic of the user. To validate that the MTurk worker knows enough about the Twitter user to pick a characteristic tweet, we use a qualification test containing a basic set of questions about the Twitter user. We were unable to find equal numbers of Turkers familiar with each subject, so our number of evaluators n differs according to author.

5.2 Results

Table 3 describes the results obtained in the user study: the mean and standard deviation of percentage of answers in agreement with our model, the p-value, and the number of MTurk workers who completed each task. We find that the average agreement of human evaluators with our model is 70.40% over all 15 users in our dataset.

User	Mean(%)	σ(%)	p-value	n
Amitabh Bachchan	67.08	16.44	**1.30e-07**	12
Ariana Grande	67.19	24.01	**7.60e-10**	16
Barack Obama	55.75	17.04	2.43e-02	20
Bill Gates	70.26	14.19	**1.72e-15**	19
Donald Trump	83.85	8.87	**2.52e-58**	26
Ellen DeGeneres	73.75	14.22	**5.44e-22**	20
J K Rowling	65.79	10.04	**7.51e-10**	19
Jimmy Fallon	80.00	21.93	**5.76e-25**	14
Justin Bieber	71.94	22.57	**3.97e-17**	18
Kevin Durant	64.38	15.04	**3.04e-07**	16
Kim Kardashian	71.25	14.95	**9.27e-18**	20
Lady Gaga	85.00	10.31	**1.45e-22**	9
LeBron James	63.50	12.15	**7.38e-08**	20
Narendra Modi	60.45	13.68	2.34e-03	11
Oprah Winfrey	75.79	18.12	**1.25e-24**	19

Table 3: MTurk user study results: For each of these 15 celebrities, human evaluators support our representativeness scores with a significance level above 0.05. (p-values $< 10^{-5}$ are shown in **bold**.)

For each of the 15 celebrities, the human evaluators agree with our model above a significance level of 0.05, and in 13 of 15 cases above a level of 10^{-5}. This makes clear our scores are measuring what we intend to be measuring.

6 Mapping with popularity

6.1 Correlation

We now explore the relationship between characterization score and tweet popularity for each of the users in our dataset. To analyze this relationship, we perform the following procedure for each author U:

1. Sort all tweets written by U in ascending order of characterization score.
2. Bucket the sorted tweets by percentile score (1 to 100).
3. For each bucket, calculate the mean number of likes, replies, and retweets.

4. Compute the correlation of this mean and the percentile score.

User	Likes	Replies	Retweets
Donald Trump	**0.64**	**0.63**	**0.55**
Amitabh Bachchan	**0.58**	**0.81**	**0.69**
Narendra Modi	**0.46**	0.01	0.22
Jimmy Fallon	**0.29**	**0.54**	**0.41**
J K Rowling	0.21	**0.32**	0.14
Lady Gaga	0.05	0.12	-0.01
Bill Gates	-0.05	-0.11	-0.21
LeBron James	-0.22	**-0.27**	-0.24
Oprah Winfrey	**-0.30**	**-0.41**	-0.17
Ellen DeGeneres	**-0.34**	**-0.29**	**-0.40**
Barack Obama	**-0.45**	**-0.46**	**-0.45**
Kevin Durant	**-0.57**	**-0.67**	**-0.53**
Kim Kardashian	**-0.71**	**-0.72**	**-0.70**
Justin Bieber	**-0.73**	**-0.50**	**-0.71**
Ariana Grande	**-0.74**	**-0.77**	**-0.75**

Table 4: Pearson correlation coefficients between mean popularity measure and percentile, for each user (Coefficients with p-value < 0.01 are shown in **bold** color). Green values exhibit significant positive correlation, and red values significant negative correlation.

The Pearson correlation coefficients (r-values) are listed in Table 4. The users at the top (Trump, Bachchan, Modi) all display very strong positive correlation. We name this group UPC (Users with Positive Correlation), and the group of users at the bottom (Grande, Bieber, Kardashian) as UNC (Users with Negative Correlation).

6.2 Interpretation

For users with positive correlation, the higher the tweet's characterization score, the more popular it becomes, i.e. the more likes, replies, and retweets it receives. In contrast, for users with negative correlation, the higher the tweet score, the less popular it becomes.

Figure 3 shows the plot of log mean number of likes per bucket vs. tweet score percentile, for users with the highest positive correlation. Similarly, Figure 4 shows the plot of log mean number of likes per bucket vs. tweet score percentile, for users with the highest negative correlation.

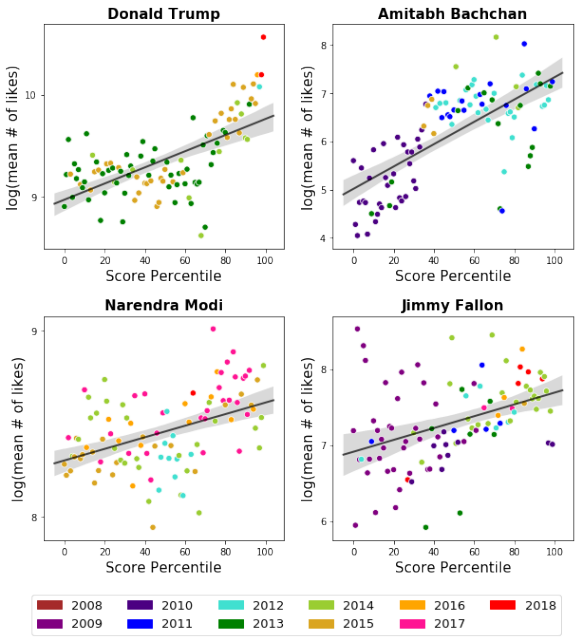

Figure 3: Log mean likes vs. percentile for users of positive correlation (The color denotes the year for which maximum tweets are present in the percentile bucket).

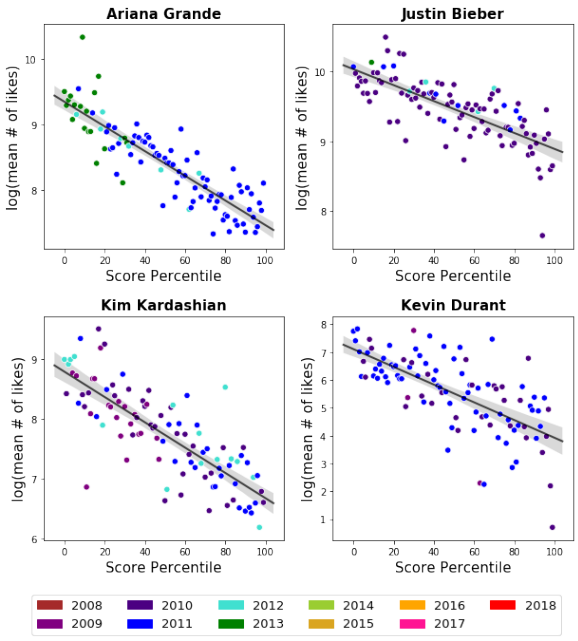

Figure 4: Log mean likes vs. percentile for users of negative correlation (The color denotes the year for which maximum tweets are present in the percentile bucket).

One may question whether these results are due to temporal effects: user's popularity vary with time, and perhaps the model's more characteristic tweets simply reflect periods of authorship. Figures 3 and 4 disprove this hypothesis.

Here the color of each point denotes the year for which most tweets are present in the corresponding bucket. Since the distribution of colors over time is not clustered, we infer that the observed result is not an artifact of temporal effects. In both cases, there is a strong trend in tweet popularity based on tweet score. We note that the plots are presented on the log scale, meaning the trends here are exponential.

6.3 Qualitative Analysis

We present examples of the most and least characteristic tweets for celebrities from three categories, along with their corresponding characterization scores computed using Approach 4.5.

6.3.1 Users with Positive Correlation (UPC)

Donald Trump

Tweet	Score
Prior to the election it was well known that I have interests in properties all over the world. Only the crooked media makes this a big deal!	0.9998
Today is the first day of the rest of your life - make the most of it!	0.0001

Amitabh Bachchan

Tweet	Score
T 2843 - The work is demanding .. the crew binding .. the city exciting .. and the dialogues expanding .. 'BADLA' is grinding .. !!	0.9996
hahaha .. now i dont have a HD .. but ya a car ride is on ..	0.0002

The characterization score appears to have correctly captured aspects of the user's personality from their corpus of tweets. For these celebrities, high scoring tweets generally prove more popular (In this example - Donald Trump: 70.5K vs. 693 likes; Amitabh Bachchan: 7.1K vs. 9 likes), as reflected in their positive correlation coefficients.

6.3.2 Users with Negative Correlation (UNC)

Ariana Grande

Tweet	Score
Finalizing the set list for Fresno! Getting so excited.. Can't believe the show is already almost sold out, you guys are amazing. Xoxo!	0.9997
The first thing I do when I get to a new city is look up how close the nearest Whole Foods is.	0.0002

Justin Bieber

Tweet	Score
grateful to everyone who came out and to my band, dancers, and whole crew. The energy last night was incredible and cant wait to tour	0.9999
Less cantaloupe, more berries. I'm talking to you, pre-packaged fruit salads. Don't play me like that.	0.00002

Again, high scoring tweets appear more characteristic of their respective users. But here, low scoring tweets are generally more popular (In this example - Ariana Grande: 622 vs. 2.4K likes; Justin Bieber: 454 vs. 13.8K likes), as reflected in their negative correlation coefficients.

6.3.3 Users with no significant correlation

Bill Gates

Tweet	Score
I recently visited a lab doing super-cool energy work-a good reminder of why governments should sponsor R&D	0.9986
There's a lot of green on this map-which is good-but still not enough.	0.0027

Here, tweets from extreme ends of the spectrum have similar content, so little variation can be expected in their popularity. For this celebrity, there is no significant correlation between characterization score and popularity.

7 Conclusions

We have presented and evaluated measures of binary author classification, to obtain a user-specific characterization score for each tweet. We demonstrate that sequential modeling on word embeddings yields the best result of 90.37% mean test accuracy, and that human evaluators are in agreement with our model 70.40% of the time. Our work demonstrates that representativeness scores correlate with popularity, and opens new research directions concerning virality on social media.

Finding Microaggressions in the Wild: A Case for Locating Elusive Phenomena in Social Media Posts

Luke M. Breitfeller[♠] **Emily Ahn**[♠] **David Jurgens**[♢] **Yulia Tsvetkov**[♠]

Abstract

Microaggressions are subtle, often veiled, manifestations of human biases. These uncivil interactions can have a powerful negative impact on people by marginalizing minorities and disadvantaged groups. The linguistic subtlety of microaggressions in communication has made it difficult for researchers to analyze their exact nature, and to quantify and extract microaggressions automatically. Specifically, the lack of a corpus of real-world microaggressions and well-defined criteria for annotating them have prevented researchers from addressing these problems at scale. In this paper, we devise a general but nuanced, computationally operationalizable typology of microaggressions based on a small subset of microaggression data that we have. We then create two datasets: one with examples of diverse types of microaggressions recollected by their targets, and another with gender-based microaggressions in public conversations on social media. We introduce a new, more objective criterion for annotation and an active-learning based procedure that increases the likelihood of surfacing posts containing microaggressions. Finally, we analyze the trends that emerge from these new datasets.

1 Introduction

Toxicity and offensiveness are not always expressed with toxic language. While a substantial community effort has rightfully focused on identifying, preventing, and mitigating overtly toxic, profane, and hateful language (Schmidt and Wiegand, 2017), offensiveness spans a far larger spectrum that includes comments with more implicit and subtle signals that are no less offensive (Jurgens et al., 2019). One significant class of subtle-but-offensive comments includes *microaggressions* (Sue et al., 2007, MAs), defined in Merriam-Webster as "a comment or action that subtly or often unconsciously expresses a prejudiced attitude toward a member of a marginalized group such as a racial minority." Though subtle, MAs have been shown to have lasting harmful impacts on their targets. Qualitative interviews suggest that the subtlety of MAs may cause even greater levels of situational stress than overt aggression (Sue, 2010; Nadal et al., 2014).

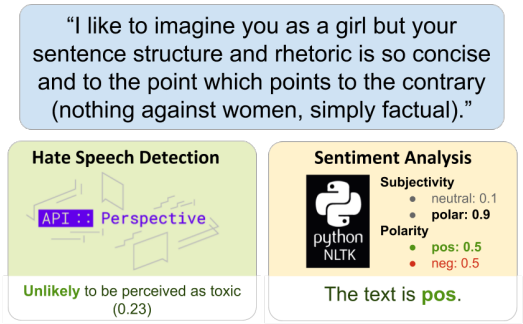

Figure 1: Existing state-of-the-art tools for hate speech detection and sentiment analysis cannot identify the veiled offensiveness of microaggressions (MAs) like the one in this real comment, because in many cases, the framing of a MA includes stylistic markers of positive language. This motivates the need for a corpus and new tools for detecting MAs.

Despite a public effort to recognize and reduce—if not eliminate—their occurrence (Kim, 2013; Neff, 2015), there has been no computational work to detect and *analyze* MAs *at scale*. Instead, much of the recent work has focused on explicitly toxic language (e.g., Waseem et al., 2017), with surveys of the area also overlooking this important and challenging task of recognizing this subtle toxicity (van Aken et al., 2018; Salminen et al., 2018; Fortuna and Nunes, 2018). Indeed, as Figure 1 suggests, current popular tools for toxic language detection do not recognize the toxicity of MAs and further, sentiment tools can label these comments as being positive. As a result, applications using such techniques to promote inoffensive content may potentially *promote* MAs. Such biased online content is then used

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1664–1674, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

as training data in NLP tools—dialogue systems, question answering, and others—thereby perpetuating and amplifying biases (Zhao et al., 2017).

Computational modeling of MAs is challenging for many reasons. MAs are subjective, context-sensitive, and expressed subtly in language (as shown in Figure 1); there are no well-defined annotation guidelines, no corpus of MAs for training and evaluating a model, and prior computational approaches to detecting overtly offensive speech are likely not suitable for classifying MAs. Moreover, they are diluted in the ocean of social media content, and it would be infeasible to create a corpus of diverse types of MAs just by crowdsourcing annotations of randomly sampled social media posts. This paper makes a first step towards closing this gap, providing (i) a typology of MAs, (ii) a corpus, and (iii) a first computational model to surfacing MAs.

Here, we introduce the first computational analysis of MAs with three main contributions. First, we create a seed corpus through collecting self-reported accounts of MAs online; we analyze this data using prior research in social science on MAs in order to derive an operationalizable classification scheme (§2.2), which we show can be used as training data to classify types of MAs (§2.4). Second, we develop a new active-learning based crowdsourcing technique to identify candidate microaggression messages for annotation (§3). In a large-scale study of gender-based MAs on Reddit, we show that our method is effective at surfacing MAs. Our novel approach surfaces MAs not found through simply looking for offensive posts (§3.3). Finally, we compare the types of MAs from self-reported accounts and those observed in social media comments, and we draw new conclusions about how MAs behave and may be identified in online settings (§4). [1]

2 A Corpus of Microaggression Classes

Previous examinations of MAs have typically focused on small scale studies with interviews, surveys, or discussions with clinicians (e.g., Shelton and Delgado-Romero, 2013; Campbell and Manning, 2014; Forrest-Bank and Jenson, 2015), aiming at understanding the causes and effects of MAs on their targets (Wong et al., 2014). A crucial gap in existing MAs research is the lack of systematic analysis of reports (Lilienfeld, 2017), which has contributed to the difficulty of understanding what constitutes a microagression. Here, we aim to address this gap by introducing a new dataset of MAs and then use this data and prior qualitative research to construct a new typology of MAs. This new typology enables us to ground the notion of what is a microagression, which also addresses criticism that the concept is too slippery. The typology is critical for downstream analyses of determining who is affected and how they are being targeted. Further, we use the typology as a practical heuristic for identifying which types of MAs are the highest impact for computational approaches. As a test, we develop a classifier using the typology and show that different types of MAs are readily distinguished.

2.1 SELFMA: microaggressions.com Dataset

The Tumblr website www.microaggressions.com curates a collection of self-reported accounts of MAs. They were collected by asking people to fill out an online form with three questions: the story of the microaggression, the context, and how the microaggression made them feel. As such, the microaggression accounts in this corpus come from individuals who self-report the incident, and who, presumably, are at least familiar with the term "microaggressions."

From this website, we collected 2,934 accounts of MAs (henceforth, *posts*). Most posts are manifestations of bias, targeting social groups frequently discriminated against, including gender (1,314 posts), race (1,278 posts), sexuality (461 posts), and religion (88 posts), among others. Some are formatted to show the conversation structure of the recollection of the incidents, while some others are shown as plain narratives. We refer to this dataset as SELFMA.

2.2 A New Typology of Microaggressions

As originally specified in Sue et al. (2007), MAs were categorized into 13 themes across specific axes of discrimination such as racism and sexism. These themes were developed qualitatively from transcripts with therapists. However, while they were comprehensive in the clinical domain, here, we aim to create a more general framework for classifying MAs in online interactions. Specifically, our new typology builds upon the work of Sue et al. (2007) with three goals in mind: the ty-

[1] All data and code produced through this work is available at https://bit.ly/2lVv3BG. This study was approved by the Institutional Review Board (IRB).

pology should be (1) generalizable across different axes of discrimination, (2) sufficiently represented in our corpus, and (3) comprehensive over all distinct microaggression types in the corpus.

Four key themes were identified in our analysis of the MAS data: Attributive, Institutionalized, Teaming, and Othering (see Table 1). We discuss each of these next.[2]

The **Attributive** theme covers instances where a microaggression attributes a stereotype to an individual based on their identity. These stereotypes may have inherently negative connotations ("lazy"), but may also be neutral ("liking pink") or positive ("strong"), which complements recent work on benevolent sexism (Jha and Mamidi, 2017). The **Institutionalized** theme reflects larger institutionalized biases, such as in employment or law enforcement. The **Teaming** theme is derived from the term *forced teaming*, coined by de Becker (1997) to describe a strategy of abuse where the abusers frames themselves as being on the same team as the victim. The **Othering** theme covers MAS which revolve around framing the target in relation to some "othered" group. This theme often co-exists with "Attribution of Stereotype," but is distinct in that its focus is on redefining the target's sense of identity.

2.3 Annotation Results

Three annotators familiar with the theoretical background and prior research on microagressions performed an open coding procedure after examining the SELFMA data to codify the typology and determine annotation guidelines. All three labeled 200 instances of the dataset to estimate agreement.

Despite the difficulty of the task, annotators had moderate agreement, as shown in Table 2. While lower than what is considered high agreement (Artstein and Poesio, 2008), given the potentially-subjective nature of MAS and criticism for lack of objectivity (Lilienfeld, 2017), we view this result as a strongly positive sign that reliable annotation is possible despite the challenge. This moderate agreement is on-par with other difficult annotation tasks, such as those for connotation frames (Rashkin et al., 2016), which had 0.52 percentage agreement for rating the polarity of the sentence towards a target, dimensions of social relationships (Rashid and Blanco, 2017), which had κ values as low as 0.59, and Word Sense Disambiguation (Passonneau et al., 2012), which reported α values for some words below 0.30 at determining meaning.

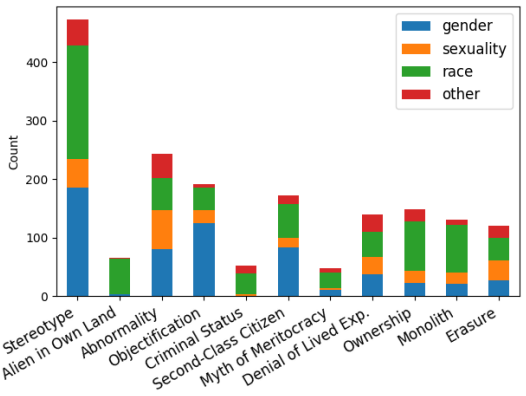

Figure 2: The distribution of four axes of discrimination (gender, race, sexuality, and other) in each subtheme.

The final dataset was determined by first retaining all posts where at least two annotators agreed (183 posts). And where there were no agreement (17 posts), the annotators determine the labels through a follow-up adjudication process.[3] After this process, another 1,100 posts were singly annotated, distributed across the three annotators, for a total of 1,300 posts. Relative percentages of each theme and examples comments are shown in Table 3. We also show the distribution of different axes of discrimination among the subthemes in Figure 2.

2.4 Classifying Types of Microaggressions

As a further examination of the typology, we perform a study where a model is trained to classify a comment into one of the four themes. Linear SVM classifiers were trained in a one-versus-rest setup using (i) word unigrams and bigrams on the tokenized version of the posts,[4] (ii) categories in the 2015 LIWC lexicon (Pennebaker et al., 2015), (iii) sentiment lexicons, and (iv) the topic distribution for a 40-topic LDA model (Blei et al., 2003). They were trained on 1,000 posts and evaluated using a held-out test set of 300 posts.

Classifier performance, measured as F1, was on

[2]The full description of themes, sub-themes, and examples can be found in Supplementary Material §2.

[3]There were 26 posts deemed to be exclusively overt aggressions (which could be detected using existing hate speech classifiers), and these occurred only in the training set. We removed them from our corpus.

[4]We used NLTK `wordpunct_tokenize` on the concatenated texts from the structured and unstructured format of the posts, normalizing two or more repeated characters into two. We only take those unigram and bigram features which appear in at least two posts as our feature set. This gives us 8,853 distinct features in the training data.

	Sub-theme	Definition and Example
Attributive	Attribution of Stereotype	Link some attributes to an individual based on their identity. "Girls just aren't good at math."
	Alien in Own Land	Marginalized individuals are foreign. "But where are you from, originally?"
	Abnormality	Marginalized individuals are abnormal. "Why do we need the word cisgender? That's just normal people."
Institutionalized	Objectification	Diminish the humanity of marginalized individuals. "If you don't want to get hit on, wear a longer skirt."
	Criminal Status	Link a persons identity to criminality, danger, or illness. "You look like a terrorist with that beard."
	Second-Class Citizen	Marginalized individuals belong to low-status positions in society. "Oh, you work at an office? I bet you're a secretary."
Forced Teaming	Myth of Meritocracy	Differences in treatment are due to ones merit. "They just cast actors who are best for it. Why does it matter if they're all white?"
	Denial of Lived Experience	Minimize the experiences of a marginalized individuals. "It was just a joke! You're too sensitive."
	Ownership	Anyone can have some claim to a marginalized groups experiences. "Why is it offensive for a white person to wear a bindi? It's just jewelry."
Othering	Monolith	All members of a marginalized group are identical. "My gay friend doesn't have a problem with this show. I don't get why you're mad."
	Erasure	Anyone can claim that an individual does not belong to that group. "Your mom is white, so it's not like you're really black, though."

Table 1: Sub-themes that we developed based on the data from www.microaggressions.com, and short excerpts that show the main claim or assumption of each sub-theme. Examples demonstrate that MAs can harm and invalidate in a subtle way, typically targeting disadvantaged populations. The phenomenon is complex, different from overt profanity or negative sentiment.

Theme	Fleiss' κ
Attributive	0.4156
Institutionalized	0.5058
Teaming	0.5048
Othering	0.4300
Overall	0.4641

Table 2: Inter-annotator agreement across three annotators on the four themes of microaggressions.

par with annotator agreement at 44.25. However, individual themes varied substantially in their performance, indicating not all were easily recognizable. Attributive and Institutionalized had the highest performance at 58.33 and 44.76, respectively; in contrast, Teaming and Othering had far lower F1 scores at 32.69 and 15.87, respectively. Both Teaming and Othering were the least frequent themes in the corpus, increasing the difficulty of recognizing them from limited data.

3 Locating Microaggressions in the Wild

The vast majority of microaggression data comes from self-reported recollections, including the MAs corpus that we collected. Self-reported data is crucial for studying the phenomenon and its effects, but is arguably not suitable for training classifiers, due to two critical limitations: (i) biases in how the offending comment was originally made versus how it was recalled, and (ii) biases in which kinds of microaggression comments are recalled. These make future computational attempts at detecting MAs more difficult by skewing a model away from linguistic signals used in real-world—rather than recalled—behavior.

A natural solution is to collect and annotate examples of MAs, scaling this process by using crowdsourcing. There are, however, two critical obstacles to using the straightforward approach of asking crowdworkers to identify random social media posts as MAs: (1) untrained crowdworkers are unlikely to reliably identify these posts due to the potential *subjectivity* of MAs, and (2) a naive random sampling of social media posts is unlikely to uncover MAs due to their *sparsity*, and since MAs are veiled manifestations of biases, it is also not clear how to use lexicons as a sieve for a stratified selection of posts to annotate.

In this second part of the paper, we devise a novel methodology to address the two challenges to curate microaggression corpora from social media posts with a two-pronged approach: operationalizing and surfacing MAs.

Operationalizing Microaggressions As the first study to crowdsource MAs, we focus on finding examples of gender-based MAs. By focusing

Category	%	Examples	Toxicity
Attributive	50	For a female, you've got backbone.	.12
		There's fighting, for you boys, and romance, for you ladies	.10
Institutionalized	28	So you make the coffee and he does the work?	.07
		Summer's coming! Gotta fit into that tight swimsuit.	.23
Teaming	23	Most workplace harassment is an example of women being oversensitive to advances of men	.27
		So were you good enough to get in or did you get in through a women's quota?	.19
Othering	17	I don't want another woman boss. Already have one and she has me running around all the time	.17

Table 3: The final microaggression typology after analyzing 1,300 self-reported microaggressions in SELFMA dataset. As shown by the percentages of instances covered each category, this typology effectively summarizes the broad themes (note that one instance may be labeled with multiple categories). For each category, the overall toxicity score (measured in [0,1] using the Google Perspective API) is low, indicating that currently none are reliably recognized as being offensive.

on gender-based MAs, the dominant group (male annotators) and the marginalized groups (women and non-binary annotators)[5] are easily elicited from the annotators through self-reporting. Since training crowdworkers to directly identify MAs is infeasible, we look for a more objective proxy that can identify, or at least help surface, posts containing MAs. A key property of MAs is that they often result from different lived experience between the individuals in the dominant group and those in the marginalized groups. Thus, our hypothesis is: *there will be a discrepancy of perceived offensiveness between the dominant group and the marginalized groups for* MAs. If true, we can then ask annotators to annotate the perceived offensiveness of a statement, and use this as a proxy to surface MAs from social media posts. Based on Figure 2, we pick gender as the discrimination axis for this work, since it covers a large number of our posts.

Surfacing Microaggressions To alleviate the sparsity issue, we treat the annotation process as an active learning procedure, where batches of posts to be annotated are provided by a classifier that is trained to predict the discrepancy of perceived offensiveness of a post, which we have claimed above to be a proxy to MAs. This classifier can then be iteratively updated using the results of all previous batches. Assuming the classifier is good enough in predicting the proxy, the classifier will help surface the most likely candidates of posts that contain MAs. In what follows, we describe the annotation process in detail and the resulting crowdsourced dataset.

3.1 Crowdsourcing Microaggressions

The full data collection process is set-up using a *multi-round annotation scheme*, summarized as follows. We first select a random sample of Reddit posts from relevant subreddits. These posts are then given to crowdworkers to be annotated for perceived offensiveness. This first round of annotations is then used to train a classifier for a MA-relavent task. The classifier's ratings are used to pick the next batch of Reddit posts to be annotated, in order to surface more instances than random sampling.

Task Crowdworkers are shown comments in the context of an internet forum discussion. Crowdworkers are asked to imagine they have written the displayed post, and then after a button click, we reveal how someone (a replier) has commented to that post. They are then asked rate if they found the response offensive and if so, to what degree was it offensive on a seven-point Likert scale. This scale of offensiveness allows us to capture cases where a microaggression is perceived as offensive by both annotator groups (genders), but to different degrees. To test our hypothesis and quantify how certain posts could be perceived differently by annotators of different genders, each annotation task includes a demographic question.[6]

Data To focus the data on interactions where gender may be a salient variable, Reddit data was drawn from RtGender (Voigt et al., 2018), which has a post-and-reply interactions where the gender of each author has been inferred with high confidence. After preliminary analyses, the initial data was randomly selected from 28 subreddits based on their focus around gender issues (e.g,. Relationships, AskWomen).[7]

For the **first round of annotation**, we used these four subsets of posts to be annotated for of-

[5]Even this interpretation of gender is limited, as women and nonbinary individuals experience gendered discrimination in different ways, and transgender men also have a marginalized gender identity.

[6]Following best practices in gender elicitation (Jaroszewski et al., 2018), we include a third option of "nonbinary, genderqueer, or otherwise", which has a free-form text box. We opted not to ask about cis or trans status in the demographic survey.

[7]See Supplementary Material §1 for the complete list.

fensiveness by the crowdworkers:

1. (SELFMA) Posts from our MAS corpus (§2) that contain gender-based MAS ($n = 59$);
2. (NON-OFFENSIVE) Posts manually picked from the Reddit dataset that should quite clearly be perceived as not offensive by everyone ($n = 36$);
3. (OFFENSIVE) Posts manually picked from the Reddit dataset, filtering by profane lexicons targeting women, and a corpus of Twitter hate speech (Davidson et al., 2017) that should quite clearly be perceived as offensive ($n = 21$);
4. (RANDOM) Posts randomly selected from the 28 subreddits ($n = 1007$).

The first three sets of posts serve as controls both to verify the soundness of our hypothesis (SELFMA) and to filter out untrusted crowdworkers (NON-OFFENSIVE and OFFENSIVE).

Adaptive Data Selection As described previously, after the first round of annotations, we use a classifier trained to predict discrepancy in perceived offensiveness to pick the next batch of posts for the **second round of annotation**. The classifier was given, as positive examples, posts with ≥ 0.25 discrepancy[8] between the averaged perceived offensiveness of the dominant group and the marginalized groups. Other posts are considered negative examples. The feature sets that we used are motivated by prior work on gender bias and power dynamics. The following seven feature categories are used: (1) unigram and bigram features to capture lexical patterns, (2) two categories of formal and informal words derived from the formality corpus of Pavlick and Tetreault (2016), (3) the gendered occupations lexicon of Bolukbasi et al. (2016), grouped across definitional and stereotypical gender (male, female, neutral), (4) the gender stereotype lexicon of Fast et al. (2016), (5) the gender lexicon for social media from (Sap et al., 2014), (6) a manually-compiled corpus of gendered words, extended from seed list from https://www.hrc.org/resources/glossary-of-terms and (7) a manually-compiled sentiment lexicon, inspired by LIWC. To facilitate reproducibility, all lexicons will be available in the software release.

[8]The threshold was chosen empirically to ensure enough number of positive examples.

3.2 Experimental Setup

We designed the annotation task with two purposes in mind: (1) We want to test our hypothesis that there is discrepancy in how annotators of different genders perceive MAS. By comparing the distribution of discrepancy of perceived offensiveness in SELFMA, which consists solely of MAS, and of that in OFFENSIVE, which consists solely of offensive posts, we can see whether the discrepancy test actually is an **operationalizable criteria** to distinguish MAS from offensive posts in general. (2) We want to test our hypothesis that the discrepancy can be used **to surface MAS**, better than the alternatives. For the purpose of this experiment, we also trained a classifier to predict the offensiveness level of a post, and use that to provide a batch of posts to be annotated as well. By comparing the actual number of MAS by these two classifiers, we can test whether discrepancy can be used to surface more MAS compared to offensiveness in general.

Platform Setup Data was crowdsourced using Figure Eight with only Level 3 workers, a small "group of most experienced, highest accuracy contributors". Workers were shown 10 posts and replies per page, one of which was a test question. Workers whose ratings were substantially outside of the rating range of our ground truth annotations in more than 60% of cases were removed. Workers were paid $0.40 per page. To control for language and cultural norms, workers were restricted to being from the US, UK, Canada, and Australia.

Much like Mechanical Turk (Hara et al., 2019), Figure Eight has substantial representation of female-identifying individuals (Posch et al., 2018), with slightly more than 60% of users in the US identifying as female on both platforms (a higher rate than other countries). Studying gender-based MAS on these platforms means we are more likely to get a gender-balanced sample than compared with other social categories subject to microaggressions such as religion, age, or sexual orientation, which would likely require targeted recruiting of respondents or a massive collection of responses in order to achieve a balanced sample.

3.3 Results

For the first experiment, Figure 3 shows the distribution of perceived offensiveness discrepancy between the dominant group (men) and the marginalized group (women and non-binary) an-

Figure 3: Difference in perceived offensiveness between annotator genders show that MAs in the SELFMA were perceived as substantially more offensive by annotators identifying as women (shown through a positive rating discrepancy on y-axis) than offensive comments in OFFENSIVE. Difference is significant under t-test ($p < 0.001$).

notators, which supports our hypothesis that MAs in SELFMA are perceived as substantially more offensive by annotators identifying as women and non-binary.

For the second experiment, we asked crowdworkers to annotate 2,000 posts with the highest scores as predicted by the classifier, and then we took the top 6% of Reddit posts with the highest discrepancies scores and manually annotated them for MAs. We predicted that these posts contain a higher percentage of MA posts than those selected randomly, and this hypothesis is supported: Out of these aggregate 120 posts, 13 are MAs (10.8%),[9] compared to a manually annotated 200 random posts from the RANDOM batch, where only 6 of them (3%) were MAs. Examples are given in Table 4.

A potential next hypothesis suggested by our original hypothesis is that the classifiers trained on annotator discrepancy (with a higher level of offense for female and non-binary annotators) would be more successful in locating MAs than the classifiers trained on pure offensiveness. However, we did find equal performance or slight gains in microaggression location when using the offensiveness classifier. Based on analysis of the SELFMA data, we believe the cause may be that gender-based MAs were not always annotated as being more offensive to female annotators–many had strong discrepancies with male annotators being more offended. As our annotator discrepancy classifier was trained on samples more offensive to women, these types of MAs would be filtered out and decrease the model's overall effectiveness at surfacing MAs.

[9]The 2,000 posts were selected by taking the top 500 posts from the discrepancy and offensiveness classifiers on two different subsets of the Reddit data. Out of the 13 MAs, 6 come from the discrepancy classifiers, and 7 come from the offensiveness classifier.

4 Reported vs Observed Themes

How do self-reported and passively-observed MAs differ in thematic frequencies? Here, we use our thematic classifier (§2.4) to label all the microaggression data in Reddit. Analyzing the thematic differences reveals substantial differences between the two datasets. The Stereotype theme was by far the most common in our SELFMA data (53%), but it rarely occurs in our Reddit (3%). Instead, Objectification is the most common, as shown through the Institutionalized category (79%). Analyzing *where* the MAs occurred in Reddit, we observed that of the 19 instances of MAs identified by our annotators, many came from strongly male-focused subreddits (e.g., MensRights, Tinder, seduction, justneckbeardthings), where it would be expected that one male poster is talking to another. These online settings mirror offline highly-gendered settings where casually sexist language is known to happen, e.g., "locker room talk" (Katz, 1995). This is embodied in our Institutionalized category (specifically the subcategory "Objectification") having a much stronger presence in the Reddit MAs than the SELFMA ones in Table 5. While such language may not be perceived as offensive in the original dialog context, other readers who encounter it would likely feel offended and potentially marginalized.

Our work further points to two potential limitation of self-reported statements. First, the baseline rates of MAs may not be reliably estimated since the offensive comments are made elsewhere (outside of direct experience) and would only be discovered to through observational analysis. Second, the difference in baseline rates suggests that the relative differences in perceived offensiveness by theme may result in different reported quantities of microagressions; as not all comments and themes are equally offensive, people are more likely to recall the extremes of events (Tversky and Kahneman, 1973), potentially contributing to the difference in thematic rates in our two datasets.

5 Discussion and Limitations

As a first computational study of MAs, our work comes with some notable limitations that each provide clear avenues for future work. First, the current dataset contains just over 6.5K instances. While useful, this corpus does is likely not fully

Classifier	Category	Subreddit : Examples
Discrepancy	Institutionalized	r/skateboarding: "this isn't a real competitor though. She's just a gross bimbo looking for attention [...]"
Discrepancy	Teaming	r/changemyview: "[...] Don't you think you ignored the real points I was making? Puting him in a "pro"-molester group, when he maybe just be pro tolerance?"
Offensive	Institutionalized	r/Tinder: "I'd f*** a stupid girl, but I definitely won't date or marry her. Other intelligent men are the same."
Offensive	Teaming	r/MensRights: "[...] I myself don't want to get the police involved over some girl saying she'll dump a guy or have an affair if he doesn't meet her sexual standards."

Table 4: Examples of MAs surfaced by the discrepancy/offensiveness classifiers, with corresponding manually-annotated labels of their typology category.

	Percentage	
Category	SELFMA (§2.1)	Reddit
Attributive	53	3
Institutionalized	59	79
Teaming	10	21
Othering	7	10

Table 5: Gender-based MAs crawled in SELFMA ($n = 59$) and found in Reddit ($n = 19$) after the second round of annotation, according to their category from our proposed typology (§2.2).

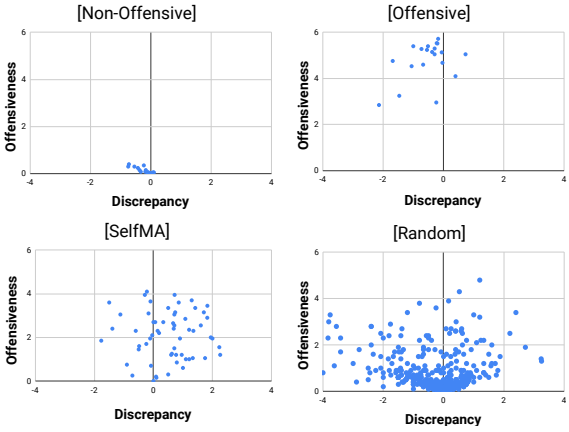

Figure 4: Offensiveness (y-axis) vs Discrepancy (x-axis) of perceived offensiveness between annotator gender. for the four sets of posts (§3.1). Note that compared to clearly offensive data [OFFENSIVE] and clearly non-offensive data [NON-OFFENSIVE], the SELFMA data (§2.1) identified as gendered MAs are annotated as somewhat offensive (indicated by the distribution around the middle of the y-axis), and having more discrepancy in perceived offensiveness between annotator genders (indicated by the higher degree of spread on the +x-axis). RANDOM data collected from Reddit sit all along the two axes of offensiveness and discrepancy.

representative of all types of MAs. However, our crowdsourcing approach does provide an effective way to surface MAs and our dual objective approach, which uses both annotator discrepancy and offensiveness, provides complementary views into what statements could be perceived as MAs. Additional iterations of this procedure are likely to improve microaggression recognition and substantially increase the seize of the corpus. We note that one option is to have workers *generate* examples, rather than rate (e.g., Xu et al., 2013; Su et al., 2016; Jiang et al., 2018); however, such a process raises ethical concerns of having crowdworkers generate toxic statements towards others.

Second, our current focus is on gender-based MAs. This choice was motivated by the observation that gender-based MAs are the largest category in the SELFMA data and, given that prior studies have shown substantial gender disparity online, with women receiving more negative behaviors (Duggan, 2017), this choice has the potential for highest impact. Our work builds upon a growing body of literature focused on identifying and mitigating gender disparity through computational means (e.g., Magno and Weber, 2014; Garimella and Mihalcea, 2016; Li et al., 2018; Field et al., 2019; Field and Tsvetkov, 2019). Further, our focus on gender also allows us to reliably recruit crowdworkers across the gender spectrum, whereas other social categories such as race or religion are more difficult to recruit in a balanced proportion through traditional mechanisms. However, despite this current focus, both the typology and annotation approach are designed for and readily amenable to other societal dimensions of MAs.

Third, performance could still be improved even for the targeted case of gender-based MAs. For example, Figure 4 plots the distribution of posts according to the averaged perceived offensiveness (y-axis) and the discrepancy between the dominant group and the marginalized groups (x-axis). This shows that offensiveness and discrepancy in conjunction are better features than using just discrepancy in separating MAs from simply offensive and non-offensive posts. A possible future direction could be to train a multi-task classifier to predict both features in order to choose posts to annotate.

A final concern is that our approach may not truly be an "objective" replacement to current MAIdentification, as annotator bias is still present in this process. By choosing perceived offensiveness and discrepancies in perception as proxy measures for MAs, we hope to shift studies of

MAs from a judgment call on an individual's intent to a description of how it affects its targets, which can be described as an objective measure of human behavior that can be validated through study. However, it is true that without that validation, it is difficult to prove the behavior of our crowdsourced annotators represents inherent, objective truths about how groups react to MAs.

6 Conclusion

Offensive language can take many forms: seemingly positive comments can in reality be dismissive of the experiences and validity of other persons. MAs, everyday comments that marginalize others on the basis of their identity, are a common form of this linguistically subtle offensive language. While prior work in NLP has largely focused on overtly offensive language, efforts to recognize this more insidious and equally impactful language has been stymied by the lack of data and methods for effectively annotating large corpora. In this work, we posit that covert toxicity can be detected through contextualized analysis of subtle linguistic cues: pronoun uses, adjectives, mentions of social groups, stylistic cues, etc. We thus view the task of detection of MAs as a yet unexplored, socially-relevant NLP task, somewhat similar to (but possibly harder than) sentiment analysis and detection of hate speech.

This work makes three key contributions. First, we introduce a new thematic classification of MAs and show that annotations can reach moderate agreement on a highly difficult task–countering claims that microaggressions are too subjective to be reliable–and also showing that computational methods can distinguish these themes. Second, we introduce a new active-learning crowdsourcing approach for surfacing potential MAs from social media using not only predictions of offensiveness but also predictions of rating discrepancy by gender within the annotators themselves. We show that both classifiers are effective at increasing rates of finding microaggression *and* that each finds different types. Finally, we show that self-reported and observed microaggression differ substantially in their types, suggesting computational mechanisms are needed to precisely estimate their true pervasiveness. Our work and corresponding data and models fill a key missing gap for expanding the range of offensive language detection to linguistically subtle comments.

Acknowledgments

The authors would like to thank the three reviewers for their very helpful and insightful feedback, Figure Eight for providing funding as a part of their AI for Everyone project, and the Washington Post data science team for data used during initial pilot studies of this project. Abstract

To automatically assess the helpfulness of a customer review online, conventional approaches generally acquire various linguistic and neural embedding features solely from the textual content of the review itself as the evidence. We, however, find out that a helpful review is largely concerned with the metadata (such as the name, the brand, the category, etc.) of its target product. It leaves us with a challenge of how to choose the correct *key-value* product metadata to help appraise the helpfulness of *free-text* reviews more precisely. To address this problem, we propose a novel framework composed of two mutual-benefit modules. Given a product, a selector (agent) learns from both the *keys* in the product metadata and one of its reviews to take an action that selects the correct *value*, and a successive predictor (network) makes the *free-text* review attend to this *value* to obtain better neural representations for helpfulness assessment. The predictor is directly optimized by SGD with the loss of helpfulness prediction, and the selector could be updated via policy gradient rewarded with the performance of the predictor. We use two real-world datasets from Amazon.com and Yelp.com, respectively, to compare the performance of our framework with other mainstream methods under two application scenarios: helpfulness identification and regression of customer reviews. Extensive results demonstrate that our framework can achieve state-of-the-art performance with substantial improvements.

1 Introduction

The massive number of reviews left by many experienced consumers on online products are our priceless treasure in e-commerce. We believe that online customer reviews can provide more subjective and informative opinions from various perspectives on the products besides the objective descriptions given by their merchants. Hence, we prefer browsing the reviews online for the sake of finding our desirable products. However, it is quite time-consuming for potential buyers to sift through millions of online reviews with uneven qualities to make purchase decisions.

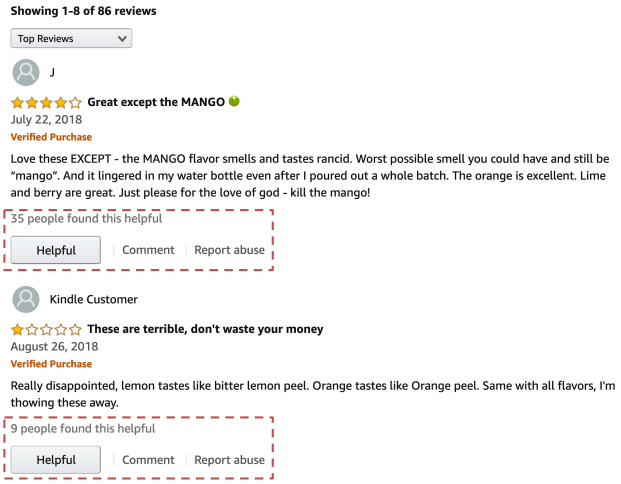

Figure 1: A screenshot of the top review on a product sold in Amazon.com: *SodaStream Fruit Drops Variety Pack, 1.67 Pound*. Online users can vote for the helpfulness of each customer review by clicking the "Helpful" button underneath.

To discover and surface helpful reviews for customers, some well-known websites (e.g., Amazon.com) have launched a module illustrated by Figure 1 which asks for feedback on the helpfulness of online reviews. And a recent study[1] reported that this featured module can increase the revenue of Amazon with an estimated 27 billion U.S. dollars annually. Although this crowdsourcing module is quite useful to find a fraction of helpful reviews, statistics (Fan et al., 2018) indicate that roughly **60%** online reviews still do not receive any vote of helpfulness or unhelpful-

ness. This phenomenon on unknown helpfulness is even more prominent in low-traffic items including those less popular and new arrival products.

We believe it is a promising study that establishes an automatic helpfulness assessment system for online reviews, which can be as useful as a product recommendation engine (Park et al., 2012) in e-commerce. Moreover, review helpfulness assessment (Diaz and Ng, 2018) and sentiment analysis (Liu and Zhang, 2012) are two different but related lines of work to study on the user-generated content (UGC). Sentiment analysis mainly focuses on identifying the opinion orientation of the reviewer himself/herself on the target product. A reviewer can express several emotional words in his/her comment. However, this comment may contain less information on the target product and may not be helpful to other potential consumers. Therefore, review helpfulness assessment concerns more about whether a comment is useful/helpful to other potential consumers.

So far as we know, a series of work on review helpfulness prediction has been proposed from two perspectives: 1) some work leveraged domain-specific knowledge to extract a wide range of hand-crafted features (including structural (Mudambi and Schuff, 2010; Xiong and Litman, 2014), lexical (Kim et al., 2006; Xiong and Litman, 2011), syntactic (Kim et al., 2006), emotional (Martin and Pu, 2014), semantic (Yang et al., 2015) and even argument features (Liu et al., 2017)) from the raw text of reviews as the evidence fed to off-the-shelf learning tools for helpfulness prediction; and 2) recent studies (Chen et al., 2018a,b; Fan et al., 2018) took advantages of deep neural nets by modifying the convolutional neural network (Kim, 2014) to acquire the low-dimensional representations of helpful reviews without the aid of feature engineering. Overall, these mainstream methods extract various linguistic and neural features solely from the raw text of a review as the evidence for helpfulness assessment.

We, on the other hand, consider that identifying the helpfulness of a review should be fully aware of the metadata (such as the name, the brand, the place of origin, the category, the description, etc.) of the target product besides the textual content of the review itself. To illustrate our idea, Figure 2 shows an example of two customer reviews in Amazon.com with diverse helpfulness scores on

PRODUCT METADATA

Title:	Sodastream Sodamix Variety Pack (6 diet and 6 trial portion packs)
Brand:	SodaStream
Description:	SodaStream Soda mixes let you add new flavors to your repertoire for parties, dinners and other gatherings. This variety pack includes 12 single-use samples to try some of SodaStream's most popular flavors...
Categories:	[Grocery, Gourmet Food]

==========

CUSTOMER REVIEWS

I did not need this but I read a review about it that highly recommended getting it. Waste of my money. (**Helpfulness: [0, 17]**)

I recently bought a Sodastream Genesis for the purpose of creating my own club soda. It a great machine. As an additional experiment, I've tried a few of the flavors from this sampler pack ... (**Helpfulness: [104, 114]**)

Figure 2: Two customer reviews with diverse helpfulness scores on the same product in Amazon.com.

the same product online. We can easily figure out that the helpful review (104 of 114 people found it helpful) may concern the key of "description" in the metadata of the product, while the unhelpful review (0 of 17 people found it helpful) talks nothing about the product but expresses deep remorse. Without direct supervision from human beings, it is difficult for machines to infer the correct key/aspect in the product metadata that helpful reviews really concern.

It leaves us with a problem of how to teach machines learning to choose the correct *key-value* product metadata to help assess the helpfulness of *free-text* reviews more precisely. To address the issue, this paper introduces a novel framework composed of two mutual-benefit modules: a product metadata selector (agent) and a review helpfulness predictor (network). This work is proposed to be deployed in a real-world system. Therefore, we suggest to decouple the two modules (i.e., the selector and the predictor). Leveraging the attention mechanism is an alternative approach on an end-to-end framework. However, the decoupled modules are preferred in an industrial system.

Given a product, the selector **explores** the connection between the *keys* in the product metadata and one of its reviews to take an action that selects the correct *value*, and the successive predictor **exploits** this *value* attended by the *free-text* review to acquire better neural representations for helpfulness prediction. The predictor is directly

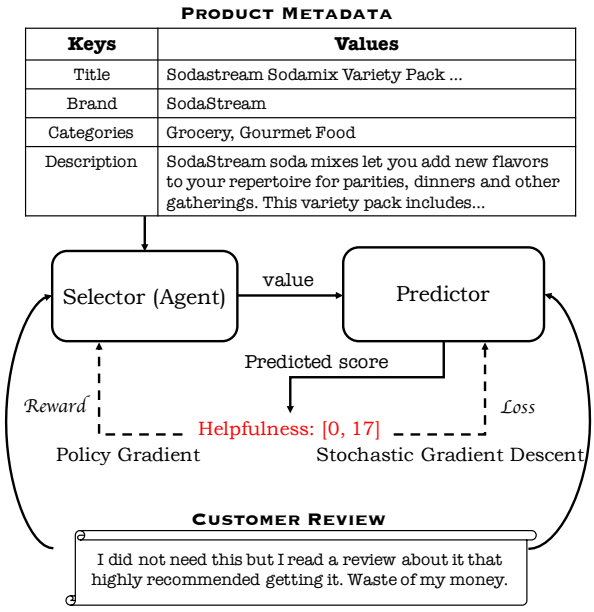

Figure 3: Our reinforced framework for review helpfulness prediction: R^{2}HP.

optimized by the stochastic gradient descent algorithm (Ruder, 2016) with the loss of prediction, and the selector can be updated via the policy gradient method (Sutton et al., 2000) rewarded with the performance of the predictor.

We use two real-world datasets from Amazon.com and Yelp.com, to compare the performance with other mainstream approaches on two application tasks: helpfulness identification and regression of customer reviews. The experimental results reveal that our framework can reach state-of-the-art performance on both tasks with substantial improvements. In addition, our framework can help acquire the embeddings of the keys in product metadata, and visualization results illustrate that they can capture various aspects on customer reviews.

2 Framework

The intuition of our framework (named *reinforced review helpfulness prediction*, abbr. as R^{2}HP) is to predict the helpfulness of a customer review which is fully aware of the correct product metadata selected by a reinforced selector (agent). This work is proposed to be deployed in a real-world system which is responsible for recommending helpful reviews to millions of customers. Therefore, we suggest decoupling the two modules (selector and predictor). Leveraging the attention mechanism (Vaswani et al., 2017) is an alternative approach to establishing an end-to-end framework. However, the decoupled modules are preferred by the industry.

As shown by Figure 3, the selector (agent) learns from both the *keys* in the product metadata and one of its reviews to take an action that selects the correct *value*, and a successive predictor (network) makes the *free-text* review attend to this *value* to obtain better neural representations for helpfulness prediction. The predictor is directly optimized by SGD with the loss of prediction, and the selector could be updated via policy gradient rewarded with the performance of the predictor.

2.1 Reinforced Product Metadata Selection

Given a customer review and the key-value formed product metadata, our reinforced neural selector π takes them as input, to output a policy $\mathbf{p}$ which is the probability distribution over the keys. Suppose that the product metadata contains k keys each of which is represented by an l-dimensional vector. Then we can achieve the embeddings of the keys: $\mathbf{K} \in \mathbb{R}^{l \times k}$.

Assume that there are n words/tokens in the customer review c. We align each word/token with the embedding dictionary acquired by the word embedding approaches such as Word2Vec (Mikolov et al., 2013), Glove (Pennington et al., 2014) or Elmo (Peters et al., 2018) to initialize the distributed representations of the customer review $\mathbf{C} \in \mathbb{R}^{l \times n}$. To achieve the local contextual embeddings of the customer review c, we use a Bi-LSTM network (Schuster and Paliwal, 1997) which takes the word embeddings of the customer review $\mathbf{C}$ as input:

$$\mathbf{H}_c = \text{Bi-LSTM}(\mathbf{C}). \quad (1)$$

$\mathbf{H}_c \in \mathbb{R}^{2l \times n}$ stands for the contextual embeddings where each word can obtain two hidden units with the length of $2l$ encoding both the backward and the forward contextual information of the customer review locally.

We use $\mathbf{B} \in \mathbb{R}^{k \times n}$ to obtain the bilinear relationship between the embeddings of the keys $\mathbf{K}$ and the local contextual embeddings of the customer review $\mathbf{H}_c$:

$$\mathbf{B} = \text{ReLU}(\mathbf{K}^{\mathrm{T}}\mathbf{W}\mathbf{H}_c), \quad (2)$$

where $\mathbf{W} \in \mathbb{R}^{l \times 2l}$ is the weight matrix for the Rectifier Linear Unit (ReLU). The i-th row of $\mathbf{B}$ contains the aspect/topic feature aligned by the local contextual embeddings of the customer review.

We apply the *reduce_max* strategy to each row of $\mathbf{B}$ to keep the most significant feature for each metadata key, and use the *softmax* function to gain the policy $\mathbf{p} \in \mathbb{R}^k$:

$$\mathbf{p} = \text{Softmax}(\text{Reduce_max}(\mathbf{B}, axis = 1)). \quad (3)$$

Then our reinforced selector (agent) can select a metadata value $v \sim \pi(v|\mathbf{K}, \mathbf{C})$ in terms of $\mathbf{p}$.

2.2 Product-aware Review Helpfulness Prediction

In this part, we elaborate our neural predictor for review helpfulness prediction. It is devised based on the motivation that the helpfulness of an online review should be fully aware of the selected metadata of its target product besides the textual content of the customer review itself. The predictor is composed of two components: 1) the local contextual embeddings of a review and 2) the product-aware distributed representations of the review. We have explained how to obtain the local contextual embeddings of a review $\mathbf{H}_c \in \mathbb{R}^{2l \times n}$ in the previous subsection. Here we will describe how to achieve the product-aware distributed representations of the review, denoted by $\overline{\mathbf{H}}_c$.

We use m to stand for the number of tokens/words in the selected metadata value v provided by our reinforced selector. Similarly, we can refine the word embeddings of the value $\mathbf{V}$ of the product metadata via another Bi-LSTM network:

$$\mathbf{H}_v = \text{Bi-LSTM}(\mathbf{V}), \quad (4)$$

and achieve the contextual embeddings of the selected product metadata $\mathbf{H}_v \in \mathbb{R}^{2l \times m}$. To make the contextual embeddings of the customer review fully aware of the product metadata, we design a word-level matching mechanism as follows,

$$\mathbf{Q} = \text{ReLU}(\mathbf{W}'\mathbf{H}_v + \mathbf{b}' \otimes \mathbf{e})^{\mathrm{T}}\mathbf{H}_c, \quad (5)$$

where $\mathbf{W}' \in \mathbb{R}^{2l \times 2l}$ is the weight matrix and $\mathbf{b}' \in \mathbb{R}^{2l}$ is the bias vector. The outer product $\otimes$ copys the bias vector $\mathbf{b}'$ for m times (i.e., $\mathbf{e} \in \mathbb{R}^m$) to generate a $2l \times m$ matrix. Then $\mathbf{Q} \in \mathbb{R}^{m \times n}$ is the sparse matrix that holds the word-level matching information between the value v of the product metadata and the customer review c.

If we further apply the *softmax* function to each column of $\mathbf{Q}$, we will obtain $\mathbf{G} \in \mathbb{R}^{m \times n}$, the i-th column of which represents the normalized attention weights over all the words in the metadata value v for the i-th word in the customer review c:

$$\mathbf{G} = \text{Softmax}(\mathbf{Q}). \quad (6)$$

Then we can use the attention matrix $\mathbf{G} \in \mathbb{R}^{m \times n}$ and the contextual embeddings of the product metadata $\mathbf{H}_v \in \mathbb{R}^{2l \times m}$ to re-form the product-aware review representation $\overline{\mathbf{H}}_c \in \mathbb{R}^{2l \times n}$:

$$\overline{\mathbf{H}}_c = \mathbf{H}_v\mathbf{G}. \quad (7)$$

Driven by original motivation, we need to join the local contextual embeddings of the review ($\mathbf{H}_c$) and the product-aware distributed representations of the review ($\overline{\mathbf{H}}_c$) together for predicting its helpfulness with the feature matrix $\mathbf{H} \in \mathbb{R}^{2l \times n}$:

$$\mathbf{H} = \mathbf{H}_c + \overline{\mathbf{H}}_c. \quad (8)$$

$\mathbf{H}$ can also benefit from the idea of ResNet (He et al., 2016) that efficiently acquires the residual between $\mathbf{H}_c$ and $\overline{\mathbf{H}}_c$, and provides a highway to update $\mathbf{H}_c$ if the residual is tiny.

Generally speaking, we define a loss function[2] $L(s_g|\mathbf{H}_c)$ which takes $\mathbf{H}_c$ as the feature to predict a helpfulness score s_p judged by the ground-truth score s_g. Given the value v is selected by π, our objective is to minimize the expectation:

$$J(\Theta) = \mathbb{E}_{v \sim \pi(v|\mathbf{K},\mathbf{C})}[L(s^g|v, \mathbf{H}^c)], \quad (9)$$

where Θ are parameters to be learned. The gradient of $J(\Theta)$ with respect to Θ is:

$$\begin{aligned} &\nabla_\Theta J(\Theta) \quad (10)\\ &= \nabla_\Theta \sum_v \pi(v|\mathbf{K}, \mathbf{C})[L(s^g|v, \mathbf{H}^c)] \\ &= \sum_v (L(s^g|v, \mathbf{H}^c)\nabla_\Theta \pi(v|\mathbf{K}, \mathbf{C}) + \pi(v|\mathbf{K}, \mathbf{C})\nabla_\Theta L(s^g|v, \mathbf{H}^c)) \\ &= \mathbb{E}_{v \sim \pi(v|\mathbf{K},\mathbf{C})}[L(s^g|v, \mathbf{H}^c)\nabla_\Theta \log \pi(v|\mathbf{K}, \mathbf{C}) + \nabla_\Theta L(s^g|v, \mathbf{H}^c)], \end{aligned}$$

where $\nabla_\Theta L(s^g|v, \mathbf{H}^c)$ refers to training the predictor by SGD and we use the REINFORCE algorithm (Williams, 1992) to update the selector with the gradient of $\log \pi(v|\mathbf{K}, \mathbf{C})$ and the reward $L(s^g|v, \mathbf{H}^c) \in (0.0, 1.0]$.

3 Experiments

3.1 Real-world Datasets

We look up two well-formatted JSON resources online which contain plenty of product metadata (including titles, brands, categories, and descriptions) and numerous customer reviews. One is the data collection[3] of Amazon.com crawled by

[2] We usually use the mean square error (MSE) as the loss function for helpfulness score regression and the cross-entropy as the loss function for helpfulness identification.

[3] The data collection is publicly available at http://jmcauley.ucsd.edu/data/amazon/links.html

(He and McAuley, 2016) up to July 2014. The other one is the dump file[4] directly provided by Yelp.com for academic purposes. We use the product ids (i.e., "asin" in Amazon and "business_id" in Yelp) as the foreign keys to align the metadata of products with customer reviews. 80% products with online reviews are randomly picked as the training set, leaving the rest as the test set. In this way, two real-world datasets, i.e., *Amazon* and *Yelp*, are built, and the statistics of them are shown by Table 1 and Table 2, respectively.

In this study, we regard the reviews which receive at least 1 vote for helpfulness/unhelpfulness, i.e., the column # (R.) $\geq$ 1v. in Table 1 and Table 2, as the experimental samples. In *Amazon*, the crowd-sourcing module for voting helpful reviews provides an "X of Y" helpfulness score, where "Y" stands for the total number of users who participate in voting, and "X" denotes the number of users who think the review is helpful. *Yelp* offers more options: *useful*: X, *cool*: Y, and *funny*: Z, to the users who are willing to give feedback. Regardless of the difference, we generally consider the reviews which receive at least 0.75 ratio of helpfulness/usefulness (helpfulness/usefulness score ≥ 0.75) as positive samples, leaving the others as the negative samples for classification.

3.2 Comparison Methods

We compare our framework (R^{2}HP) with a wide range of prior arts. Specifically, we re-implement the methods of learning from deep neural networks and with hand-crafted features. The up-to-date neural approaches involve the embedding-gated CNN (EG-CNN) (Chen et al., 2018a,b) and the multi-task neural learning (MTNL) architecture (Fan et al., 2018) for review helpfulness prediction. The hand-crafted features include the structural features (STR) (Mudambi and Schuff, 2010; Xiong and Litman, 2014), the lexical features (LEX) (Xiong and Litman, 2011), the emotional features (GALC) (Martin and Pu, 2014) and the semantic features (INQUIRER) (Yang et al., 2015). We also add two more experiments on integrating all the hand-crafted features via the Support Vector Machines (SVM) and the Random

[4]The dump file can be downloaded from https://www.yelp.com/dataset

Forest (R.F.) model for review helpfulness assessment.

3.3 Application Scenarios

Previous studies mostly reported their performance on either the application scenario of review helpfulness identification or regression. Therefore, we conduct extensive experiments comparing the performance of our framework with all the other approaches under both scenarios.

Identification of helpful reviews: As both the training and test sets are imbalanced, we adopt the Area under Receiver Operating Characteristic (AUROC) as the metric to evaluate the performance of all the approaches on helpful review identification. In line with Table 3 and Table 4, MTNL (Fan et al., 2018) achieves the best performance up-to-date on this classification task among the baseline approaches as it achieves the best performance on 12 of 14 categories in *Amazon* and *Yelp* datasets. R^{2}HP surpasses MTNL on both datasets and obtains state-of-the-art (micro-averaged) results of 67.5% AUROC (*Amazon*) and 75.1% AUROC (*Yelp*) with absolute improvements of **4.9%** AUROC and **4.7%** AUROC, respectively.

Regression of helpfulness score: In this task, all the approaches are required to predict the fraction of helpful votes that each review receives. We use the data in the column # (R. $\geq$ 1v.) in Table 1 and Table 2 as the training and test sets. The Squared Correlation Coefficient (R^2-score) is adopted as the metric to evaluate the performance of all the approaches on helpfulness score regression. Table 5 and Table 6 show that MTNL (Fan et al., 2018) achieves state-of-the-art performance on this regression task among the baseline approaches. Our framework outperforms MTNL on both datasets and obtains state-of-the-art (micro-averaged) results of 62.3% R^2-score (*Amazon*) and 74.0% R^2-score (*Yelp*) with absolute improvements of **5.4%** R^2-score and **5.8%** R^2-score, respectively.

4 Discussions

4.1 Ablation Study on Metadata Selector

In this part, we conduct the ablation study on different metadata selectors: i.e., random selector, heuristic selector, and our reinforced selector. The random selector requires no prior knowledge but randomly picks one pair of (key, value) from the product metadata with uniform distribution. The heuristic selector keeps choosing the pair of (key, value) in which the value contains the longest text[5]. Our reinforced selector learns from the reward given by the helpfulness predictor and makes a wise decision on the metadata selection. The values of product metadata selected by the three selectors are fed into the same predictor.

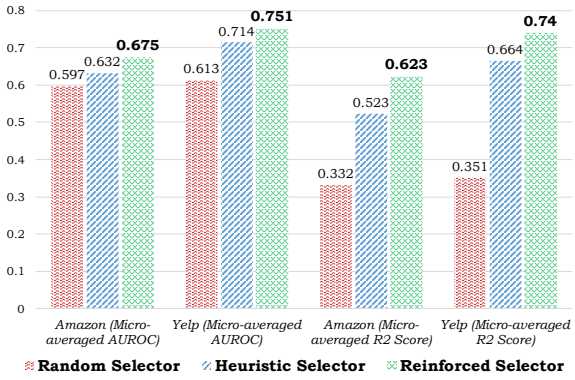

Figure 4: Performances of review helpfulness identification and regression supported by the random, the heuristic, and our reinforced selector on the *Amazon* and *Yelp* datasets.

Figure 4 shows the performance of both identification and regression of review helpfulness supported by the three different selectors, and the results demonstrate that our reinforced selector surpasses the other policies (the random selector and the heuristic selector) for metadata selection.

4.2 Case Study on Key Embeddings

Our framework also helps to acquire the distributed representations of the keys in product metadata. We believe these key embeddings can capture various aspects/topics on customer reviews and lead to the correct value for review helpfulness prediction. With the help of t-SNE (Maaten and Hinton, 2008), we can map the embeddings of the metadata keys from the *Amazon* and *Yelp* datasets into 2D vectors and illustrate them in Figure 5.

It shows that the key embeddings in *Amazon* locate at the bottom-right and the key embeddings in *Yelp* are generally at upper-left. The keys which express similar meanings within the same dataset are close to each other, such as the keys "city", "state" and "address" in *Yelp*, and the keys "title", "description" and "brand" in *Amazon*. Even across

[5]In most cases, the "name" or the "description" of a product is selected by the heuristic selector.

different datasets, the key embeddings draw near to each other if they are close in meaning, e.g., "title" (*Amazon*) and "name" (*Yelp*), or "asin" (*Amazon*) and "business_id" (*Yelp*).

5 Conclusion and Future Work

Driven by the intuition that the helpfulness of an online review should be fully aware of the metadata of its target product besides the textual content of the review itself, we take on the challenge of selecting the correct *key-value* product metadata to help predict the helpfulness of *free-text* reviews more precisely. To address the problem, we propose a novel framework in this paper, which is composed of two interdependent modules. Given a product, an agent (selector) learns from both the *keys* in the product metadata and one of its reviews to take an action that selects the correct *value*, and a successive network (predictor) makes the *free-text* review attend to this *value* to produce better neural representations for helpfulness prediction. We use two real-world datasets from Amazon and Yelp, respectively, to compare the performance of our framework with other mainstream methods on two tasks: helpfulness identification and regression of online reviews. Extensive results show that our framework can achieve state-of-the-art performance with substantial improvements. Further discussions demonstrate that it can not only provide better policies on selecting the correct *value* of product metadata but also acquire the embeddings of the *keys* in the product metadata.

We also believe the study on review helpfulness assessment could be as important as the topic of product recommendation, and several open problems are deserved to be explored in the future:

User-specific and explainable recommendation of helpful reviews: As different users may concern about various aspects of the products online, helpful review recommendation needs to be more user-specific and self-explainable.

Enhancing the prediction of helpful reviews with unlabeled data: As a small proportion of reviews could be heuristically regarded as helpful or unhelpful, it thus becomes a promising study to automatically predict the helpfulness of online reviews based on the small amount of labeled data and a vast amount of unlabeled data.

Cross-domain helpfulness prediction of online reviews (Chen et al., 2018b): Given that it costs a lot on manually annotating a sufficient number of helpful reviews in a new domain, we should explore effective approaches on transferring useful knowledge from limited labeled samples in another domain.

Learning Invariant Representations of Social Media Users

Nicholas Andrews and Marcus Bishop
Human Language Technology Center of Excellence

Abstract

The evolution of social media users' behavior over time complicates user-level comparison tasks such as verification, classification, clustering, and ranking. As a result, naïve approaches may fail to generalize to new users or even to future observations of previously known users. In this paper, we propose a novel procedure to learn a mapping from short episodes of user activity on social media to a vector space in which the distance between points captures the similarity of the corresponding users' invariant features. We fit the model by optimizing a surrogate metric learning objective over a large corpus of unlabeled social media content. Once learned, the mapping may be applied to users not seen at training time and enables efficient comparisons of users in the resulting vector space. We present a comprehensive evaluation to validate the benefits of the proposed approach using data from Reddit, Twitter, and Wikipedia.

1 Introduction

Social media presents a number of challenges for characterizing user behavior, chief among them that the topics of discussion and their participants evolve over time. This makes it difficult to understand and combat harmful behavior, such as election interference or radicalization (Thompson, 2011; Mihaylov and Nakov, 2016; Ferrara et al., 2016; Keller et al., 2017).

This work focuses on the fundamental problem of learning to compare social media users. We propose a procedure to learn embeddings of small samples of users' online activity, which we call *episodes*. This procedure involves learning the embedding using a metric learning objective that causes episodes by the same author to map to nearby points. Through this embedding users may be efficiently compared using cosine similarity. This representation immediately enables several tasks:

Verification. Determining if two episodes have the same author.

Classification. Labeling authors via their k-nearest neighbors.

Clustering. Grouping users via off-the-shelf methods like k-means or agglomerative clustering.

Ranking and retrieval. Sorting episodes according to their distances to a given episode.

The problem considered in this paper is most closely related to author attribution on social media. However, prior work in this area has primarily focused on classifying an author as a member of a closed and typically small set of authors (Stamatatos, 2009; Schwartz et al., 2013; Shrestha et al., 2017). In this paper, we are concerned with an *open-world* setting where we wish to characterize an *unbounded* number of users, some observed at training time, some appearing only at test time. A further challenge is that the episodes being compared may be drawn from different time periods. With these challenges in mind, the primary contributions described in this paper are as follows:

§**3** A training strategy in which a user's history is dynamically sampled at training time to yield multiple short episodes drawn from different time periods as a means of learning invariant features of the user's identity;

§**4** A user embedding that can be trained end-to-end and which incorporates text, timing, and context features from a sequence of posts;

§**5** Reddit and Twitter benchmark corpora for open-world author comparison tasks, which are substantially larger than previously considered;

§**6** Large-scale author ranking and clustering experiments, as well as an application to Wikipedia sockpuppet verification.

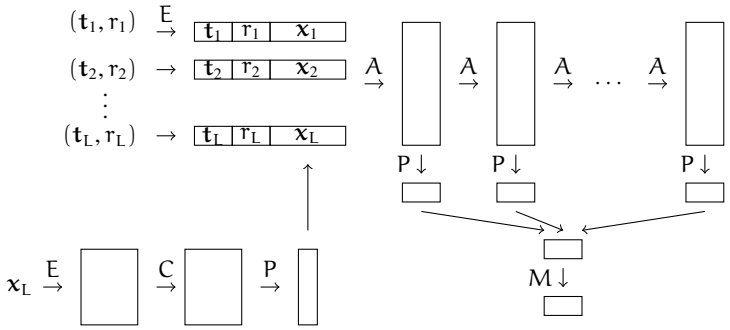

Figure 1: The map f_θ takes an episode as input and outputs a vector. Here A denotes a multi-head self-attention layer, C a stack of 1D convolutions, E an embedding lookup, M an MLP, and P a pooling layer.

2 Preliminaries

Broadly speaking, a corpus of social media data consists of the *actions* of a number of users. Each action consists of all available information from a given platform detailing what exactly the user did, which for purposes of this work we take to include: (1) a timestamp recording when the action occurred, from which we extract a tuple $\mathbf{t}$ of temporal features, (2) unstructured text content $\mathbf{x}$ of the action, and (3) a categorical feature r specifying the context of the action. Thus an action is a tuple of the form $(\mathbf{t}, \mathbf{x}, r)$. This formulation admits all three platforms considered in this work and therefore serves as a good starting point. However, incorporating features specific to particular platforms, such as image, network, and moderation features, might also provide useful signal.

In our experiments we use a data-driven subword representation (Kudo, 2018) of $\mathbf{x}$, which admits multilingual and non-linguistic content, as well as misspellings and abbreviations, all of which useful in characterizing authors. We use a simple discrete time feature for $\mathbf{t}$, namely the hour of the day, although others might be helpful, such as durations between successive actions. In our Reddit experiments we take r to be the subreddit to which a comment was posted. On Twitter we take r to be a flag indicating whether the post was a tweet or a retweet.

3 Learning Invariant Representations

We organize the actions of each user into short sequences of chronologically ordered and ideally contiguous actions, which we call *episodes*. This paper is concerned with devising a notion of distance between episodes for which episodes by the same author are closer to one another than episodes by different authors. Such a distance function must necessarily be constructed on the basis of *past* social media data. But in the future, authors' behavior will evolve and new authors will emerge.

We would like episodes by the same author to be nearby, irrespective of when those episodes took place, possibly *future* to the creation of the distance function. A given user will discuss different topics, cycle through various moods, develop new interests, and so on, but distinctive features like uncommon word usage, misspellings, or patterns of activity will persist for longer and therefore provide useful signal for the distance function.

We would also like the distance to be meaningful when applied to episodes by users who didn't exist when the distance function was created. To this end, the features it considers must necessarily generalize to new users. For example, common stylometric features will be shared by many users, including new users, but their particular combination is distinctive of particular users (Orebaugh and Allnutt, 2009; Layton et al., 2010).

Rather than heuristically defining such a distance function, for example, based on word overlap between the textual content of the episodes, we instead introduce a parameterized embedding f_θ shown in Figure 1 that provides a vector representation of an episode. Then the desired distance between episodes can be taken to be the distance between the corresponding vectors. We fit the embedding f_θ using *metric learning* to simultaneously decrease the distance between episodes by the same user and increase the distance between

episodes by different users (Bromley et al., 1994; Wang et al., 2014).

But doing so requires knowledge of the true author of an episode, something which is not generally available. Therefore we take account names to be an approximation of latent authorship. Of course, account names are not always a reliable indicator of authorship on social media, as the same individual may use multiple accounts, and multiple individuals may use the same account. As such, we expect a small amount of label noise in our data, to which neural networks have proven robust in several domains (Krause et al., 2016; Rolnick et al., 2017).

We fit f_θ to a corpus of social media data using stochastic gradient descent on batches of examples, where each example consists of an episode of a given length drawn uniformly at random from the *full history* of each user's actions.[1] By construction, a metric learning objective with this batching scheme will encourage the embedding of episodes drawn from the same user's history to be close. In order to accomplish this, the model will need to distinguish between ephemeral and invariant features of a user. The invariant features are those that enable the model to consistently distinguish a given users' episodes from those of *all other users*.

4 The Model

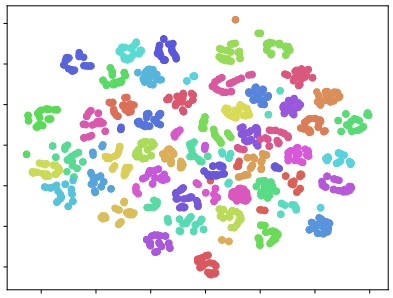
We now describe a mapping f_θ parameterized by a vector θ from the space of user episodes to $\mathbb{R}^D$. The model is illustrated in Figure 1. This embedding induces a notion of distance between episodes that depends on which of the two proposed loss functions from §4.2 is used to train f_θ. We illustrate the embeddings resulting from both losses in Figure 2.

4.1 The encoder

One approach to define f_θ might be to manually define features of interest, such as stylometric or surface features (Solorio et al., 2014; Sari et al., 2018). However, when large amounts of data are available, it is preferable to use a data-driven approach to representation learning. Therefore we define f_θ using a neural network as follows. The network is illustrated in Figure 1.

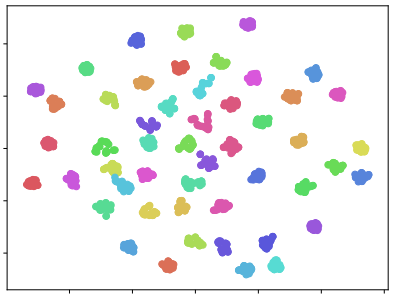
[1]Different metric learning methods will sample users in different ways, for example to ensure a given ratio of examples of the same class. In this work we simply sample users uniformly at random.

Encoding actions. First, we embed each action (t, x, r) of an episode. We encode the time features t and the context r, both assumed to be discrete, using a learned embedding lookup. We next embed every symbol of x, again using a learned embedding lookup, and apply one-dimensional convolutions of increasing widths over this list of vectors, similar to Kim (2014); Shrestha et al. (2017). We then apply the relu activation and take the componentwise maximum of the list of vectors to reduce the text content to a single, fixed-dimensional vector. We optionally apply dropout at this stage if training. Finally, we concatenate the time, text, and context vectors to yield a single vector representing the action.



Embedding episodes. Next we combine the vector representations of the actions of an episode. For this purpose, one option is a recurrent neural network (RNN). However, recurrent models are biased due to processing inputs sequentially, and suffer from vanishing and exploding gradients. Therefore we propose the use of self-attention layers, which avoid the sequential biases of RNNs and admit efficient implementations.

In our particular formulation, we use several layers of multi-head self-attention, each taking the output of the previous layer as input; architectural details of the encoder layers follow those of the Transformer architecture proposed by Vaswani et al. (2017). We apply mean pooling after every layer to yield layer-specific embeddings, which we concatenate. We project to the result to the desired embedding dimension D using an MLP, both its input and output batch normalized (Ioffe and Szegedy, 2015).



4.2 The loss function

For the purpose of training the embedding f_θ we compose it with a discriminative classifier $g_\phi : \mathbb{R}^D \to \mathbb{R}^Y$ with parameters ϕ predicting the author of an episode, where Y is the number of authors in the training set. We estimate θ and ϕ jointly using a standard cross-entropy loss on a corpus of examples with their known authors. Once the model is trained, the auxiliary projection g_ϕ is discarded. Two possibilities for g_ϕ are proposed below.

Softmax (SM). We introduce a weight matrix $W \in \mathbb{R}^{Y \times D}$ and define the map $g_\phi(z) = \mathrm{softmax}(Wz)$ with parameters $\phi = W$. When using this loss function, one compares embed-

(a) Embeddings obtained using **SM** loss.

(b) Embeddings obtained using **AM** loss.

Figure 2: Projections of embeddings of user episodes. Each point is the result of mapping an episode to a single point in $\mathbb{R}^{512}$ and projected to $\mathbb{R}^2$ using t-SNE. The colors of the points correspond with the 50 different authors of the underlying episodes. We emphasize that the episodes shown here were not seen by the model at training time.

dings using Euclidean distance.

Angular margin (AM). Following Deng et al. (2019) we again introduce a weight matrix $\boldsymbol{W} \in \mathbb{R}^{Y \times D}$ whose rows now serve as *class centers* for the training authors. Given the embedding $\boldsymbol{z} \in \mathbb{R}^D$ of an episode, let $\boldsymbol{z}' = \frac{\boldsymbol{z}}{\|\boldsymbol{z}\|}$ be the normalization of $\boldsymbol{z}$ and let $\boldsymbol{W}'$ be obtained from $\boldsymbol{W}$ by normalizing its rows. Then the entries of $\boldsymbol{w} = \boldsymbol{W}'\boldsymbol{z}'$ give the cosines of the angles between $\boldsymbol{z}$ and the class centers. Let $\boldsymbol{w}'$ be obtained from $\boldsymbol{w}$ by modifying the entry corresponding with the correct author by adding a fixed margin $m > 0$ to the corresponding angle.[2] Finally, define $g_\Phi(\boldsymbol{z}) = \text{softmax}(s\boldsymbol{w}')$ where $s > 0$ is a fixed *scale constant*. When using this loss function, one compares embeddings using cosine similarity.

5 Corpora for Large-Scale Author Identification

5.1 Reddit benchmark

Reddit is a large, anonymous social media platform with a permissive public API. Using Reddit consists of reading and posting *comments*, which consist of informal text, primarily in English, each appearing within a particular *subreddit*, which we treat as a categorical feature providing useful contextual signal in characterizing users.

We introduce a new benchmark author identification corpus derived from the API (Gaffney and Matias, 2018) containing Reddit comments by 120,601 active users for training and 111,396 held-out users for evaluation. The training split contains posts published in `2016-08` while the evaluation split contains posts published in `2016-09`. In both cases, we restrict to users publishing at least 100 comments but not more than 500. The lower bound ensures that we have sufficient evidence for any given user for training, while the upper bound is intended to mitigate the impact of bots and atypical users. The evaluation split is disjoint from the training split and contains comments by 42,121 novel authors not contributing to the training split.

Validation. For model selection, we use the first 75% of each user's chronologically ordered posts from the training set, with the final 25% reserved for validation. For example, in our ranking experiments described in §6.3 we use these held-out comments as candidate targets, using ranking performance to inform hyper-parameter choice.

5.2 Twitter benchmark

The microblog domain is sufficiently distinct from Reddit that it is suitable as an additional case study. For this purpose, we sample 169,663 active Twitter users from three months of 2016 as separate training, development, and test sets (`2016-08` through `2016-10`). We use three months because we rely on a sub-sampled collection of Twitter, as little as 1% of all posts published, resulting in significantly fewer posts by each user than on Reddit. Another consequence of this sub-sampling is that the collection violates our assumptions regarding *contiguous* user actions.

[2] One way to calculate $\cos(\theta + m)$ from $\cos\theta$ is $\cos\theta\cos m - \sin\theta\sin m$ where $\sin\theta$ is calculated as $\sqrt{1 - \cos^2\theta}$. Note that this calculation discards the sign of θ.

6 Experiments

In the experiments described below, we refer to our method as IUR for Invariant User Representations.

6.1 Baseline methods

In order to validate the merit of each of our modeling contributions, we compare against three baseline models described below. To the best of our knowledge, we are the first to consider using metric learning to learn embeddings from episodes of user activity. We are also the first to consider doing so in open-world and large-scale settings. As such, the neural baseline described below uses the training scheme proposed in this paper, and was further improved to be more competitive with the proposed model.

Neural author identification. We use the architecture proposed by Shrestha et al. (2017) for closed-set author attribution in place of our $\mathtt{f}_\theta$. At the level of individual posts this architecture is broadly similar to ours in that it applies 1D convolutions to the text content. To extend it to episodes of comments, we simply concatenate the text content into a single sequence with a distinguished end-of-sequence marker. Note that the timing and context features may also be viewed as sequences, and in experiments with these features we run a separate set of one-dimensional filters over them. All max-over-time pooled features are concatenated depthwise. By itself, this model failed to produce useful representations; we found it necessary to apply the batch-normalized MLP described in §4.1 to the output layer before the loss. To train the model, we follow the procedure described in §4.2 to compose the embedding with the **SM** loss function, optimize the composition using cross-entropy loss, and discard the **SM** factor after training.

Document vectors. By concatenating all the textual content of an episode we can view the episode as a single document. This makes it straightforward to apply classical document indexing methods to the resulting pseudo-document. As a representative approach, we use TFIDF with cosine distance (Robertson, 2004). We note that TFIDF is also well-defined with respect to arbitrary bags-of-items, and we make use of this fact to represent a user according to the sequence of subreddits to which they post as a further baseline in §6.3.

Author verification models. We use the SCAP $\mathfrak{n}$-gram profile method of Frantzeskou et al. (2007). Two episodes are compared by calculating the size of the intersection of their $\mathfrak{n}$-gram profiles. We use profiles of fixed length 64 in our experiments.

6.2 Model hyperparameters and training

Below we list our hyperparameter choices for the IUR model, which we define in §4.

For both Twitter and Reddit, we estimate the sub-word vocabulary on training data using an inventory of 65,536 word pieces, including a distinguished end-of-sequence symbol. We truncate comments to 32 word pieces, padding if necessary.[3] We restrict to the 2048 most popular subreddits, mapping all others to a distinguished `unk` symbol. We encode word pieces and subreddits as 256-long vectors. The architecture for the text content uses four convolutions of widths 2, 3, 4, 5 with 256 filters per convolution. We use two layers of self-attention with 4 attention heads per layer, and hidden layers of size 512. Other details such as use of layer normalization match the recommendations of Vaswani et al. (2017).

We train all variations of the IUR for a fixed budget of 200,000 iterations of stochastic gradient descent with momentum 0.9 and a piecewise linear learning rate schedule that starts at 0.1 and is decreased by a factor of 10 at 100,000 and 150,000 iterations. The final MLP has one hidden layer of dimension 512 with output also of dimension $\mathrm{D} = 512$. For the angular margin loss we take $\mathfrak{m} = 0.5$ and $\mathrm{s} = 64$ as suggested in Deng et al. (2019).

6.3 Reddit ranking experiment

Given a query episode by a known user, our author ranking experiment consists of returning a list of target episodes ranked according to their similarity to the query. The problem arises in the moderation of social media content, when say, a user attempts to circumvent an account ban by using another account.

Experimental setup. Recall that we train all Reddit models on the `2016-08` split. In this experiment we draw episodes from the first half of `2016-09` as *queries* and the second half of `2016-09` as *targets*. Specifically, for

[3] In experiments not reported here, we have found that increasing the number of subwords per action increases performance but at the cost of slower training.

Input Features	Method	MRR (⇑)	MR (⇓)	R@1 (⇑)	R@2	R@4	R@8

	IUR	**0.52**	**2**	**0.44**	**0.52**	**0.59**	**0.65**

Table 1: Reddit author ranking results with 111,396 possible targets. The best results for each feature group are in printed in **bold**. The proposed Invariant User Representations are denoted IUR, with variations of the full model noted in parenthesis. MRR stands for the mean reciprocal rank, MR for median rank, and R@k stands for recall at the top k ranked episodes. Larger numbers are better (⇑) except for MR where lower rank is better (⇓). Metrics are computed over 25,000 queries.

each of 25,000 randomly selected users from the `2016-09` split we randomly draw a query episode of length 16 from among those posts published by that user before `2016-09-15`. Then for each of the 111,396 users in the `2016-09` split we randomly draw a target episode of length 16 from among those posts published by that user on or after `2016-09-15`. For each query, the goal of the experiment is to rank the targets according to their likelihoods of being the *unique* target composed by the author of the query.

We compare models using mean reciprocal rank (MRR), median rank (MR), and recall-at-k (R@k) for various k. The MRR is the mean over all 25,000 queries of the reciprocal of the position of the correct target in the ranked list. The MR is the median over the queries of the position of the correct target. The R@k is the proportion of the queries for which the correct target appears among the first k ranked targets.

Results. The results of this experiment are shown in Table 1. For each combination of features considered, the rankings based on the proposed IUR embeddings consistently outperform all methods considered, both neural and classical. We also report results on several variations of our model, noted in parenthesis. First, using the proposed architecture for f_θ but the softmax loss results in ranking performance comparable to the baseline system. Second, using a recurrent architecture rather than self-attention to aggregate information across an episode results in significantly worse performance.[4] Finally, omitting time features results in worse performance.

Performance on novel users. As described above, the experiments presented in Table 1 involved ranking episodes by test authors, some of whom had been seen during training, and some new to the model. To better understand the ability of the proposed embedding to generalize to new users, we performed a further evaluation in which authors were restricted to those *not* seen at training time. For the IUR incorporating all features, this yielded a MRR of 0.50, while our extension of Shrestha et al. (2017) obtains 0.38 for the same queries. Both methods produce salient embeddings of novel users, but IUR retains an edge over the baseline.

Varying episode length. As described above, the experiments presented in Table 1 involved episodes of length exactly 16. In Figure 3, we report results of a further ranking experiment in which we vary the episode length, both at training time and at ranking time. For both the proposed IUR and our extension of Shrestha et al. (2017), performance increases as episode length increases. Furthermore, even for the shortest episodes considered, the proposed approach performs better. This illustrates that the choice of episode length should be decided on an application-specific basis. For example, for social media moderation, it

[4]We choose RNN hyper-parameters such that the numbers of parameters of both models are on the same order of magnitude.

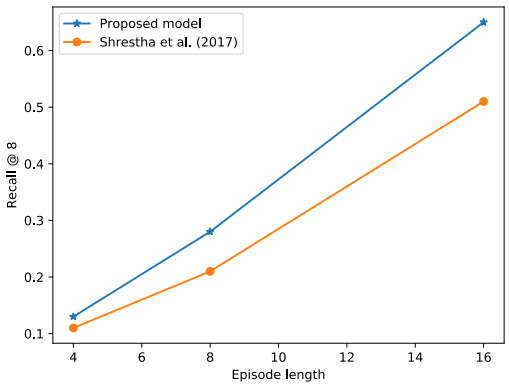

Figure 3: We report Recall@8 for different episode lengths using all features.

may be desirable to quickly identify problematic users on the basis of as few posts as possible.

6.4 Twitter ranking experiment

We repeat the experiment described in §6.3 using data from Twitter in place of Reddit, and with the further difference that the queries were drawn from `2016-08` and the targets from `2016-10` as a mitigation of Twitter's 1% censorship. Unlike the Reddit dataset, all three data splits contain posts by exactly the same authors. The results are shown in Table 2.

6.5 Wikipedia sockpuppet verification

In this section we describe an experiment for the task of sockpuppet verification on Wikipedia using the dataset collected by Solorio et al. (2014). Wikipedia allows editors to open cases against other editors for using suspected *sockpuppet* accounts to promote their contributions. We have reorganized the dataset into pairs of episodes by different accounts. Half of our examples contain a pair deemed by the community to have the same author, while half have been deemed to have different authors. The task is to predict whether a pair of episodes was composed by the same author.

We are interested in whether the text-only version of our IUR model, trained on Reddit data, is able to transfer effectively to this task. This domain is challenging because in many cases sockpuppet accounts are trying to hide their identity, and furthermore, Wikipedia talk pages contain domain-specific markup which is difficult to reliably strip or normalize. Naturally we expect that the identities of Wikipedia editors do not overlap with Reddit authors seen at training time, since the data is drawn from different time periods and from different platforms.

As a baseline, we compare to BERT, a generic text representation model trained primarily on Wikipedia article text (Devlin et al., 2018). While BERT is not specifically trained for author recognition tasks, BERT has obtained state-of-the-art results in many pairwise text classification tasks including natural language inference, question pair equivalence, question answering, and paraphrase recognition. The BERT model used here has 110 million parameters compared to 20 million for our embedding.

Setup. Because many comments are short, we preprocess the data to ensure that each comment has at least 5 whitespace-separated tokens. We restrict to users contributing at least 8 such comments. This left us with 180 cases which we split into 72 for training, and 54 each for validation and testing. We fine-tune both the cased and uncased pretrained English BERT models for our sockpuppet detection task using public models and software.[5] In order to combine the comments comprising an episode for BERT, we explored different strategies, including encoding each comment separately. We found that simply combining comments together and using a long sequence length of 512 gave the best validation performance. For our model, we fine-tune by fitting an MLP on top of our embeddings using binary cross entropy and keeping other parameters fixed. Both methods are tuned on validation data, and the best hyperparameter configuration is then evaluated on held-out test data.

Results. Results are reported in Table 3. The best validation performance is obtained by the cased BERT model. However, both BERT models appear to overfit the training data as test performance is significantly lower. Regarding the proposed IUR model, we see that its performance on validation data is comparable to BERT while generalizing better to held-out test data. For reference, Solorio et al. (2013) report accuracy of 68.83 using the same data using a SVM with hand-crafted features; however, neither their experimental splits nor their model are available for purposes of a direct comparison.

Table 4: Clustering performance on Reddit episodes using embeddings obtained with different methods.

6.6 Clustering users

For certain tasks it is useful to identify groups of accounts shared by the same author or to identify groups of accounts behaving in a similar fashion (Solorio et al., 2013; Tsikerdekis and Zeadally, 2014). To this end, we experiment with how well a clustering algorithm can partition authors on the basis of the cosine similarity of their IUR episode embeddings.

Procedure. Using the pre-trained Reddit IUR model, we embed five episodes of length 16 by 5000 users selected uniformly at random, all drawn from the held-out `2016-09` split. The embeddings are clustered using affinity propagation, hiding both the identities of the users as well as the true number of users from the algorithm (Frey and Dueck, 2007). Ideally the algorithm will arrive at 5000 clusters, each containing exactly five episodes by same author. Clustering performance is evaluated using mutual information (NMI), homogeneity (H), and completeness (C) (Rosenberg and Hirschberg, 2007). NMI involves a ratio of the mutual information of the clustering and ground truth. Homogeneity is a measure of cluster purity. Completeness measures the extent to which data points by the same author are elements of the same cluster. All three measures lie in interval $[0, 1]$ where 1 is best. The results are shown in Table 4.

7 Related Work

This work considers the problem of learning to compare users on social media. A related task which has received considerably more attention is predicting user attributes (Han et al., 2014; Sap et al., 2014; Dredze et al., 2013; Culotta et al., 2015; Volkova et al., 2015; Goldin et al., 2018). The inferred user attributes have proven useful for social science and public health research (Mislove et al., 2011; Morgan-Lopez et al., 2017). While author attributes like gender or political leaning may be useful for population-level studies, they are inadequate for identifying particular users.[6]

More generally, learning representations for downstream tasks using unsupervised training has recently emerged as an effective way to mitigate the lack of task-specific training data (Peters et al., 2018; Devlin et al., 2018). In the context of social media data, unsupervised methods have also been explored to obtain vector representations of individual posts on Twitter (Dhingra et al., 2016; Vosoughi et al., 2016). Our approach is distinguished from this prior work in several respects. First, we embed episodes consisting of multiple documents, which involves aggregating features. Second, for each document, we encode both textual features as well as associated meta-data. Finally, our training procedure is discriminative, embedding episodes into a vector space with an im-

[6]We leave as future work the question of whether the episode embeddings proposed in this paper are useful for attribute prediction.

mediately meaningful distance.

When social network structure is available, for example on Twitter via *followers*, it may be used to learn user embeddings (Tang et al., 2015; Grover and Leskovec, 2016; Kipf and Welling, 2016). Graph representations have successfully been combined with content-based features; for example, Benton et al. (2016) propose matrix decomposition methods that exploit complementary features of Twitter authors. Graph-based embeddings have proven useful in downstream applications such as entity linking (Yang et al., 2016). However, such methods are not applicable when network structure is unavailable or unreliable, such as with new users or on social media platforms like Reddit. In this work, we are motivated in part by adversarial settings such as moderation, where it is desirable to quickly identify the authorship of novel users on the basis of sparse evidence.[7]

The most closely related work is author identification on social media. However, previous work in this area has largely focused on distinguishing among small, closed sets of authors rather than the open-world setting of this paper (Mikros and Perifanos, 2013; Ge et al., 2016). For example, Schwartz et al. (2013) consider the problem of assigning single tweets to one of a closed set of 1000 authors. Overdorf and Greenstadt (2016) consider the problem of cross-domain authorship attribution and consider 100 users active on multiple platforms. In a different direction, Sari et al. (2018) seek to identify stylistic features contributing to successful author identification and consider a closed set of 62 authors. In contrast, the present work is concerned with problems involving several orders of magnitude more authors. This scale precludes methods where similarity between examples is expensive to compute, such as the method of Koppel and Winter (2014).

Prior work on detecting harmful behavior like hate speech has focused on individual documents such as blog posts or comments (Spertus, 1997; Magu et al., 2017; Pavlopoulos et al., 2017; Davidson et al., 2017; de la Vega and Ng, 2018; Basile et al., 2019; Zampieri et al., 2019). Recently, there have been some efforts to incorporate user-level information. For example, for the supervised task of abuse detection, Mishra et al. (2018) find consistent improvements from incorporating user-level features.

8 Conclusion

Learning meaningful embeddings of social media users on the basis of short episodes of activity poses a number of challenges. This paper describes a novel approach to learning such embeddings using metric learning coupled with a novel training regime designed to learn invariant user representations. Our experiments show that the proposed embeddings are robust with respect to both novel users and data drawn from future time periods. To our knowledge, we are the first to tackle open-world author ranking tasks by learning a vector space with a meaningful distance.

There are several natural extensions of this work. An immediate extension is to further scale up the experiments to Web-scale datasets consisting of millions of users, as has been successfully done for face recognition (Kemelmacher-Shlizerman et al., 2016). Sorting episodes according to their distances to a query can be made efficient using a number of approximate nearest neighbor techniques (Indyk and Motwani, 1998; Andoni and Indyk, 2006).

We are also considering further applications of the proposed approach beyond those in this paper. For example, by restricting the features considered in the encoder to text-alone or text and temporal features, it would be interesting to explore cross-domain author attribution (Stamatatos et al., 2018). It would also be interesting to explore community composition on the basis of the proposed embeddings (Newell et al., 2016; Waller and Anderson, 2019).

Finally, it bears mentioning that the proposed model presents a double-edged sword: methods designed to identify users engaging in harmful behavior could also be used to identify authors with legitimate reasons to remain anonymous, such as political dissidents, activists, or oppressed minorities. On the other hand, methods similar to the proposed model could be developed for such purposes and not shared with the broader community. Therefore, as part of our effort to encourage positive applications, we release source code to reproduce our key results.[8]

[7] Incorporating social network information in our model as additional features is in principle straightforward, requiring only minor architectural changes to the model; the metric learning procedure would otherwise remain the same.

(Male, Bachelor) and (Female, Ph.D) have different connotations: Parallelly Annotated Stylistic Language Dataset with Multiple Personas

Dongyeop Kang **Varun Gangal** **Eduard Hovy**
Carnegie Mellon University, Pittsburgh, PA, USA
{dongyeok,vgangal,hovy}@cs.cmu.edu

Abstract

Stylistic variation in text needs to be studied with different aspects including the writer's personal traits, interpersonal relations, rhetoric, and more. Despite recent attempts on computational modeling of the variation, the lack of parallel corpora of style language makes it difficult to systematically control the stylistic change as well as evaluate such models. We release PASTEL, the parallel and annotated stylistic language dataset, that contains $\approx$ 41K parallel sentences (8.3K parallel stories) annotated across different personas. Each persona has different styles in conjunction: gender, age, country, political view, education, ethnic, and time-of-writing. The dataset is collected from human annotators with solid control of input denotation: not only preserving original meaning between text, but promoting stylistic diversity to annotators. We test the dataset on two interesting applications of style language, where PASTEL helps design appropriate experiment and evaluation. First, in predicting a target style (e.g., male or female in gender) given a text, multiple styles of PASTEL make other external style variables controlled (or fixed), which is a more accurate experimental design. Second, a simple supervised model with our parallel text outperforms the unsupervised models using non-parallel text in style transfer. Our dataset is publicly available[1].

1 Introduction

Hovy (1987) claims that appropriately varying the style of text often conveys more information than is contained in the literal meaning of the words. He defines the roles of styles in text variation by pragmatics aspects (e.g., relationship between them) and rhetorical goals (e.g., formality), and provides example texts of how they are tightly coupled in practice. Similarly, Biber (1991) categorizes components of conversational situation by participants' characteristics such as their roles, personal characteristics, and group characteristics (e.g., social class). Despite the broad definition of style, this work mainly focuses on one specific aspect of style, *pragmatics aspects in group characteristics of speakers*, which is also called *persona*. Particularly, we look at multiple types of group characteristics in conjunction, such as gender, age, education level, and more.

Stylistic variation in text primarily manifest themselves at the different levels of textual features: lexical features (e.g., word choice), syntactic features (e.g., preference for the passive voice) and even pragmatics, while preserving the original meaning of given text (DiMarco and Hirst, 1990). Connecting such textual features to someone's persona is an important study to understand stylistic variation of language. For example, do highly educated people write longer sentences (Bloomfield, 1927)? Are Hispanic and East Asian people more likely to drop pronouns (White, 1985)? Are elder people likely to use lesser anaphora (Ulatowska et al., 1986)?

To computationally model a meaning-preserved variance of text across styles, many recent works have developed systems that transfer styles (Reddy and Knight, 2016; Hu et al., 2017; Prabhumoye et al., 2018) or profiles authorships from text (Verhoeven and Daelemans, 2014; Koppel et al., 2009; Stamatatos et al., 2018) without parallel corpus of stylistic text. However, the absence of such a parallel dataset makes it difficult both to systematically learn the textual variation of multiple styles as well as properly evaluate the models.

In this paper, we propose a *large scale, human-annotated, parallel stylistic dataset* called PASTEL, with focus on *multiple types of personas in conjunction*. Ideally, annotations for a parallel

[1] https://github.com/dykang/PASTEL

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1696–1706, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

style dataset should preserve the original meaning (i.e., *denotation*) between reference text and stylistically transformed text, while promoting diversity for annotators to allow their own styles of persona (i.e., *connotation*). However, if annotators are asked to write their own text given a reference sentence, they may simply produce arbitrarily paraphrased output which does not exhibit a stylistic diversity. To find such a proper input setting for data collection, we conduct a denotation experiment in §3. PASTEL is then collected by crowd workers based on the most effective input setting that balances both meaning preservation and diversity metrics (§4).

PASTEL includes stylistic variation of text at two levels of parallelism: ≈8.3K annotated, parallel stories and ≈41K annotated, parallel sentences, where each story has five sentences and has 2.63 annotators on average. Each sentence or story has the seven types of persona styles in conjunction: gender, age, ethnics, countries to live, education level, political view, and time of the day.

In §5, we introduce two interesting applications of style language using PASTEL: controlled style classification and supervised style transfer. The former application predicts a category (e.g., male or female) of target style (i.e., gender) given a text. Multiplicity of persona styles in PASTEL makes other style variables controlled (or fixed) except the target, which is a more accurate experimental design. In the latter, contrast to the unsupervised style transfer using non-parallel corpus, simple supervised models with our parallel text in PASTEL achieve better performance, being evaluated with the parallel, annotated text.

We hope PASTEL sheds light on the study of stylistic language variation in developing a solid model as well as evaluating the system properly.

2 Related Work

Transferring styles between text has been studied with and without parallel corpus:

Style transfer without parallel corpus: Prior works transfer style between text on single type of style aspect such as sentiment (Fu et al., 2018; Shen et al., 2017; Hu et al., 2017), gender (Reddy and Knight, 2016), political orientation (Prabhumoye et al., 2018), and two conflicting corpora (e.g, paper and news (Han et al., 2017), or real and synthetic reviews (Lipton et al., 2015)). They use different types of generative models in the same way as style transfer in images, where meaning preservation is not controlled systematically. Prabhumoye et al. (2018) proposes back-translation to get a style-agnostic sentence representation. However, they lack parallel ground truth for evaluation and present limited evaluation for meaning preservation.

Style transfer with parallel corpus: Few recent works use parallel text for style transfer between modern and Shakespearean text (Jhamtani et al., 2017), sarcastic and literal tweets (Peled and Reichart, 2017), and formal and informal text (Heylighen and Dewaele, 1999; Rao and Tetreault, 2018). Compared to these, we aim to understand and demonstrate style variation owing to multiple demographic attributes.

Besides the style transfer, other applications using stylistic features have been studied such as poetry generation (Ghazvininejad et al., 2017), stylometry with demographic information (Verhoeven and Daelemans, 2014), modeling style bias (Vogel and Jurafsky, 2012) and modeling biographic attributes (Garera and Yarowsky, 2009). A series of works by (Koppel et al., 2011, 2009; Argamon et al., 2009; Koppel and Winter, 2014) and their shared tasks (Stamatatos et al., 2018) show huge progress on author profiling and attribute classification tasks. However, none of the prior works have collected a stylistic language dataset to have multiple styles in conjunction, parallely annotated by a human. The multiple styles in conjunction in PASTEL enable an appropriate experiment setting for controlled style classification task in Section 5.1.

3 Denotation Experiment

We first provide a preliminary study to find the best input setting (or denotation) for data collection to balance between two trade-off metrics: meaning preservation and style diversity.

3.1 Preliminary Study

Table 1 shows output texts produced by annotators given different input denotation settings. The basic task is to provide an input denotation (e.g., a sentence only, a sequence of images) and then ask them to reproduce text maintaining the meaning of the input but with their own persona.

For instance, if we provide a *single reference sentence*, annotators mostly repeat the input text with a little changes of the lexical terms. This

Denotation:	**Produced sentences**:
single ref. sentence	the old door with wood was the only direction to the courtyard
story(imgs)	The old wooden door in the stonewall looks like a portal to a fairy tale.
story(imgs.+keyw words)	Equally so, he is intrigued by the heavy wooden door in the courtyard.
Reference sentence: the old wooden door was only one way into the courtyard.	

Table 1: Textual variation across different denotation settings. Each sentence is produced by a same annotator. Note that providing reference sentence increases fidelity to the reference while decreases diversity.

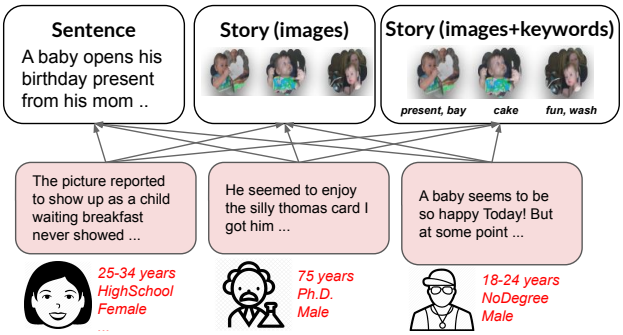

Figure 1: Denotation experiment finds the best input setting for data collection, that preserves meaning but diversifies styles among annotators with different personas.

setup mostly preserves the meaning by simply paraphrasing the sentence, but annotators' personal style does not reflect the variation. With a *single image*, on the other hand, the outputs produced by annotators tend to be diverse. However, the image can be explained with a variety of contents, so the output meaning can drift away from the reference sentence.

If a series of consistent images (i.e., a story) is given, we expect a stylistic diversity can be more narrowed down, by grounding it to a specific event or a story. In addition to that, some keywords added to each image of a story help deliver more concrete meaning of content as well as the style diversity.

3.2 Experimental Setup

In order to find the best input setting that preserves meaning as well as promotes a stylistic diversity, we conduct a denotation experiment as described in Figure 1. The experiment is a subset of our original dataset, which have only 100 samples of annotations.

A basic idea behind this setup is to provide (1) a perceptually common denotation via sentences or images so people share the same context (i.e., denotation) given, (2) a series of them as a "story" to limit them into a specific event context, and (3) two modalities (i.e., text and image) for better disambiguation of the context by grounding them to each other.

We test five different input settings[2]: *Single reference sentence*, ***Story*** *(images)*, ***Story*** *(images)* + *global keywords*, ***Story*** *(images + local keywords)*, and ***Story*** *(images + local keywords + ref. sentence)*.

For the keyword selection, we use RAKE algorithm (Rose et al., 2010) to extract keywords and rank them for each sentence by the output score. Top five uni/bigram keywords are chosen at each story, which are called *global keywords*. On the other hand, another top three uni/bigram keywords are chosen at each image/sentence in a story, which are called *local keywords*. Local keywords for each image/sentence help annotators not deviate too much. For example, *local keywords* look like *(restaurant, hearing, friends)* $\rightarrow$ *(pictures, menu, difficult)* $\rightarrow$ *(salad, corn, chose)* for three sentences/images, while *global keywords* look like *(wait, salad, restaurant)* for a story of the three sentences/images.

We use Visual Story Telling (ViST) (Huang et al., 2016) dataset as our input source. The dataset contains stories, and each story has five pairs of images and sentences. We filter out stories that are not temporally ordered using the timestamps of images. The final number of stories after filtering the non-temporally-ordered stories is 28,130. For the denotation experiment, we only use randomly chosen 100 stories. The detailed pre-processing steps are described in Appendix.

3.3 Measuring Meaning Preservation & Style Diversity across Different Denotations

For each denotation setting, we conduct a quantitative experiment to measure the two metrics: meaning preservation and style diversity. The two metrics pose a trade-off to each other. The best input setting then is one that can capture both in appropriate amounts. For example, we want meaning of the input preserved, while lexical or syn-

[2]Other settings like *Single reference image* are tested as well, but they didn't preserve the meaning well.

	denotation settings	**Style Diversity**	**Meaning Preservation**	
		E(GM)	METEOR	VectorExtrema
sentence-level	*single ref. sentence*	<u>2.98</u>	**0.37**	**0.70**
	***story**(images)*	2.86	0.07	0.38
	***story**(images) + global keywords*	2.85	0.07	0.39
	***story**(images + local keywords)*	**3.07**	0.17	<u>0.53</u>
	***story**(images + local keywords + ref. sentence)*	2.91	<u>0.21</u>	0.43
story-level	***story**(images)*	4.43	0.1	0.4
	***story**(images) + global keywords*	4.43	0.1	0.42
	***story**(images + local keywords)*	**4.58**	<u>0.19</u>	**0.55**
	***story**(images + local keywords + ref. sentence)*	<u>4.48</u>	**0.22**	<u>0.44</u>

Table 2: Denotation experiment to find the best input setting (i.e., meaning preserved but stylistically diverse). **story-level** measures the metrics for five sentences as a story, and **sentence-level** per individual sentence. Note that *single reference sentence* setting only has sentence level. For every metrics in both meaning preservation and style diversity, the higher the better. The **bold** number is the highest, and the <u>underlined</u> is the second highest.

Figure 2: Final denotation setting for data collection: an event that consists of a series of five images with a handful number of keywords. We ask annotators to produce text about the event for each image.

tactic features (e.g., POS tags) can vary depending on annotator's persona. We use the following automatic measures for the two metrics:

Style Diversity measures how much produced sentences (or stories) differ amongst themselves. Higher the diversity, better the stylistic variation in language it contains. We use an entropy measure to capture the variance of n-gram features between annotated sentences: Entropy (Gaussian-Mixture) that combines the N-Gram entropies (Shannon, 1951) using Gaussian mixture model (N=3).

Meaning Preservation measures semantic similarity of the produced sentence (or story) with the reference sentence (or story). Higher the similarity, better the meaning preserved. We use a hard-measure, METEOR (Banerjee and Lavie, 2005), that calculates F-score of word overlaps between the output and reference sentences[3]. Since the hard measures do not take into account all semantic similarities [4], we also use a soft measure, VectorExtrema (VecExt) (Liu et al., 2016). It computes cosine similarity of averaged word embeddings (i.e., GloVe (Pennington et al., 2014)) between the output and reference sentences.

Table 2 shows results of the two metrics across different input settings we define. For the sentence level, as expected, *single reference sentence* has the highest meaning preservation across all the metrics because it is basically paraphrasing the reference sentence. In general, ***Story*** (*images + local keywords*) shows a great performance with the highest diversity regardless of the levels, as well as the highest preservation at the soft measure on the story-level. Thus, we use ***Story***(*images+local keywords*) as the input setting for our final data collection, which has the most balanced performance on both metrics. Figure 2 shows an example of our input setting for crowd workers.

4 PASTEL: A Parallelly Annotated Dataset for Stylistic Language Dataset

We describe how we collect the dataset with human annotations and provide some analysis on it.

[3]Other measures (e.g., BLEU (Papineni et al., 2002), ROUGE (Lin and Hovy, 2003)) show relatively similar performance.

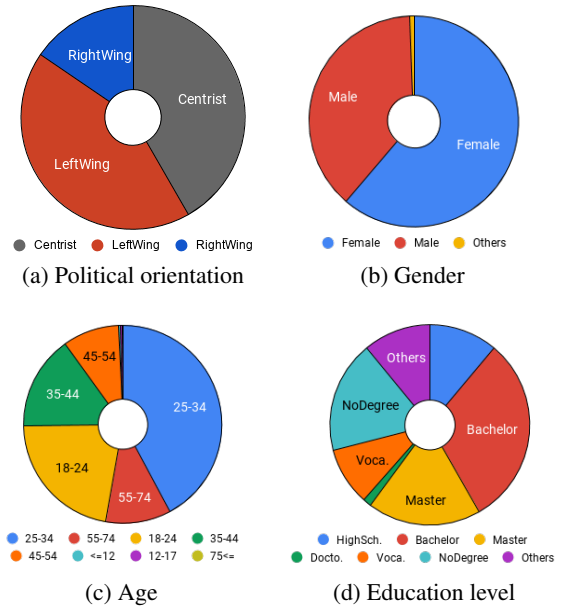
[4]METEOR does consider synonymy and paraphrasing but is limited by its predefined model/dictionaries/resources for the respective language, such as Wordnet

4.1 Annotation Schemes

Our crowd workers are recruited from the Amazon Mechanical Turk (AMT) platform. Our annotation scheme consists of two steps: (1) ask annotator's demographic information (e.g., gender, age) and (2) given an input denotation like Figure 2, ask them to produce text about the denotation with their own style of persona (i.e., connotation).

In the first step, we use seven different types of persona styles; *gender*, *age*, *ethnic*, *country*, *education level*, and *political orientation*, and one additional context style *time-of-day* (tod). For each type of persona, we provide several categories for annotators to choose. For example, *political orientation* has three categories: Centrist, Left Wing, and Right Wing. Categories in other styles are described in the next sub-section.

In the second step, we ask annotators to produce text that describes the given input of denotation. We again use the pre-processed ViST (Huang et al., 2016) data in §3 for our input denotations. To reflect annotators' persona, we explicitly ask annotators to reflect their own persona in the stylistic writing, instead of pretending others' persona. We attach detailed annotation schemes at Figure 5 in Appendix.



To amortize both costs and annotators' effort at answering questions, each HIT requires the participants to annotate three stories after answering demographic questions. One annotator was paid $0.11 per HIT. For English proficiency, the annotators were restricted to be from USA or UK. A total 501 unique annotators participated in the study. The average number of HIT per annotator was 9.97.

	Number of Sentences	Number of Stories
Train	33,240	6,648
Valid	4,155	831
Test	4,155	831
total	41,550	8,310

Table 3: Data statistics of the PASTEL.

Once we complete our annotations, we filter out noisy responses such as stories with missing images and overtly short sentences (i.e., minimum sentence length is 5). The dataset is then randomly split into train, valid, and test set by 0.8, 0.1, and 0.1 ratios, respectively. Table 3 shows the final number of stories and sentences in our dataset.

4.2 Analysis and Examples

(a) Political orientation (b) Gender

(c) Age (d) Education level

Figure 3: Distribution of annotators for each personal style in PASTEL. Best viewed in color.

Figure 3 shows demographic distributions of the annotators. Education-level of annotators is well-balanced, while gender and political view are somewhat biased (e.g., 68% of annotators are Female, only 18.6% represent themselves as right-wing). Table 8 in Appendix includes the categories in other styles and their distributions.

Table 4 shows few examples randomly chosen from our dataset: two at sentence level (top, middle) and one at story level (bottom). Due to paucity of space, we only show a few types of persona styles. For example, we observe that Education level (e.g., NoDegree vs. Graduate) actually reflects a certain degree of formality in their writing at both sentence and story levels. In §5.1, we conduct an in-depth analysis of textual variation with respect to the persona styles in PASTEL.

5 Applications with PASTEL

PASTEL can be used in many style related applications including style classification, stylometry (Verhoeven and Daelemans, 2014), style transfer (Fu et al., 2018), visually-grounded style transfer, and more. Particularly, we chose two applications, where PASTEL helps design appropriate experiment and evaluation: controlled style classification (§5.1) and supervised style transfer (§5.2).

Reference Sentence: went to an art museum with a group of friends.	
edu:HighSchoolOrNoDiploma	My friends and I went to a art museum yesterday .
edu:Bachelor	I went to the museum with a bunch of friends.

Reference Sentence: the living room of our new home is nice and bright with natural light.	
edu:NoDegree, *gender*:Male	The natural lightning made the apartment look quite nice for the upcoming tour .
edu:Graduate, *gender*:Female	The house tour began in the living room which had a sufficient amount of natural lighting.

Reference Story: Went to an art museum with a group of friends . We were looking for some artwork to purchase, as sometimes artist allow the sales of their items . There were pictures of all sorts , but in front of them were sculptures or arrangements of some sort . Some were far out there or just far fetched . then there were others that were more down to earth and stylish. this set was by far my favorite.very beautiful to me .

edu:HighSchool, *ethnic*:Caucasian, *gender*:Female	My friends and I went to a art museum yesterday . There were lots of puchases and sales of items going on all day . I loved the way the glass sort of brightened the art so much that I got all sorts of excited . After a few we fetched some grub . My favorite set was all the art that was made out of stylish trash .
edu:Bachelor, *ethnic*:Caucasian, *gender*:Female	I went to the museum with a bunch of friends . There was some cool art for sale . We spent a lot of time looking at the sculptures . This was one of my favorite pieces that I saw . We looked at some very stylish pieces of artwork .

Table 4: Two sentence-level (top, middle) and one story-level (bottom) annotations in PASTEL. Each text produced by an annotator has their own persona values (underline) for different types of styles (italic). Note that the reference sentence (or story) is given for comparison with the annotated text. Note that misspellings of the text are made by annotators.

5.1 Controlled Style Classification

A common mistake in style classification datasets is not controlling external style variables when predicting the category of the target style. For example, when predicting a gender type given a text $P(\textit{gender}=\underline{Male}|\texttt{text})$, the training data is only labeled by the target style *gender*. However, the `text` is actually produced by a person with not only *gender*=$\underline{Male}$ but also other persona styles such as *age*=55-74 or *education*=HighSchool. Without controlling the other external styles, the classifier is easily biased against the training data.

We define a task called *controlled style classification* where all other style variables are fixed[5], except one to classify. Here we evaluate (1) which style variables are relatively difficult or easy to predict from the text given, and (2) what types of textual features are salient for each type of style classification.

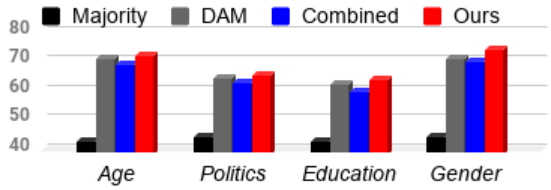
Features. Stylistic language has a variety of features at different levels such as lexical choices, syntactic structure and more. Thus, we use following features:

- **lexical** features: ngram's frequency (n=3), number of named entities, number of stop-words
- **syntax** features: sentence length, number of each Part-of-Speech (POS) tag, number of out-of-vocabulary, number of named entities
- **deep** features: pre-trained sentence encoder using BERT (Devlin et al., 2019)
- **semantic** feature: sentiment score

where named entities, POS tags, and sentiment scores are obtained using the off-the-shelf tools such as Spacy[6] library. We use $70K$ n-gram lexical features, 300 dimensional embeddings, and 14 hand-written features.

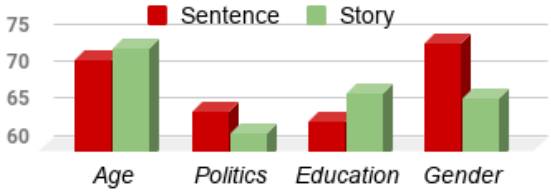
[5]The distribution of number of training instances per variable is given in Appendix

[6]https://spacy.io/



Models. We train a binary classifier for each personal style with different models: logistic regression, SVM with linear/RBF kernels, Random Forest, Nearest Neighbors, Multi-layer Perceptron, AdaBoost, and Naive Bayes. For each style, we choose the best classifiers on the validation. Their F-scores are reported in Figure 4. We use sklearn's implementation of all models (Pedregosa et al., 2011).[7] We consider various regularization parameters for SVM and logistic regression (e.g., c=[0.01, 0.1, 0.25, 0.5, 0.75, 1.0].

We use neural network based baseline models: deep averaging networks (DAN, Iyyer et al., 2015) of GloVe word embeddings (Pennington et al., 2014)[8]. We also compare with the non-controlled model (Combined) which uses a combined set of samples across all other variables except for one to classify using the same features we used.



Setup. We tune hyperparameters using 5-fold cross validation. If a style has more than two categories, we choose the most conflicting two: *gender*:{Male, Female}, *age*: {18-24, 35-44}, *education*: {Bachelor, No Degree}, and *politics*: {LeftWing, RightWing}. To classify one style, all possible combinations of other styles ($2 * 2 * 2$=8) are separately trained by different models. We use the macro-averaged F-scores among the separately trained models on the same test set for every models.

Results. Figure 4 shows F-scores (a) among different styles and (b) between sentences and stories. In most cases, multilayer perceptron (MLP) outperforms the majority classifier and other models by large margins. Compared to the neural baselines and the combined classifier, our models show better performance. In comparison between controlled and combined settings, controlled setting achieves higher improvements, indicating that fixing external variables helps control irrelevant features that come from other variables. Among different styles, gender is easier to predict from the text than ages or education levels. Interestingly, a longer context (i.e., story) is helpful in predicting age or education, whereas not for political view and gender.

In our ablation test among the feature types, the combination of different features (e.g., lexical, syntax, deep, semantic) is very complementary and effective. Lexical and deep features are two most significant features across all style classifiers, while syntactic features are not.

(a) different style types

(b) sentences vs stories

Figure 4: Controlled style classification: F-scores on (a) different types of styles on sentences and on (b) our best models between sentences and stories. Best viewed in color.

Gender:Male	*Gender*:Female
PROPN, ADJ, #_ENTITY, went, party, SENT_LEN	happy, day, end, group, just, snow, NOUN
Politics:LeftWing	*Politics*:RightWing
female, time, NOUN, ADP, VERB, porch, day, loved	SENT_LENGTH, PROPN, #_ENTITY, n't, ADJ, NUM
Education:Bachelor	*Education*:NoDegree
food, went, #_STOPWORDS, race, ADP	!, just, came, love, lots, male, fun, n't, friends, happy
Age:18-24	*Age*:35-44
ADP, come, PROPN, day, ride, playing, sunset	ADV, did, town, went, NOUN, #_STOPWORDS

Table 5: Most salient lexical (lower cased) and syntactic (upper cased) features on story-level classification. Each feature is chosen by the highest coefficients in the logistic regression classifier.

Table 5 shows the most salient features for classification of each style. Since we can't interpret deep features, we only show lexical and syntactic features. The salience of features are ranked by coefficients of a logistic regression classifier. Interestingly, female annotators likely write more nouns and lexicons like 'happy', while male annotators likely use pronouns, adjectives, and named

[7] http://scikit-learn.org/stable/

[8] Other architectures such as convolutional neural networks (CNN, Zhang et al., 2015) and recurrent neural networks (LSTM, Hochreiter and Schmidhuber, 1997) show comparable performance as DAN.

entities. Annotators on left wing prefer to use 'female', nouns and adposition, while annotators on right wing prefer shorter sentences and negative verbs like 'n't'. Not many syntactic features are observed from annotators without degrees compared to with bachelor degree.

5.2 Supervised Style Transfer

The style transfer is defined as $(S, \alpha) \rightarrow \hat{S}$: We attempt to alter a given source sentence S to a given target style α. The model generates a candidate target sentence $\hat{S}$ which preserves the meaning of S but is more faithful to the target style α so being similar to the target annotated sentence $\bar{S}_\alpha$. We evaluate the model by comparing the predicted sentence $\hat{S}$ and target annotated sentence $\bar{S}_\alpha$. The sources are from the original reference sentences, while the targets are from our annotations.

Models. We compare five different models:

- AsItIs: copies over the source sentence to the target, without any alterations.
- WordDistRetrieve: retrieves a training source-target pair that has the same target style as the test pair and is closest to the test source in terms of word edit distance (Navarro, 2001). It then returns the target of that pair.
- EmbDistRetrieve: Similar to WordDistRetrieve, except that a continuous bag-of-words (CBOW) is used to retrieve closest source sentence instead of edit distance.
- Unsupervised: use unsupervised style transfer models using Variational Autoencoder (Shen et al., 2017) and using additional objectives such as cross-domain and adversarial losses (Lample et al., 2017)[9]. Since unsupervised models can't train multiple styles at the same time, we train separate models for each style and macro-average their scores at the end. In order not to use the parallel text in PASTEL, we shuffle the training text of each style.
- Supervised: uses a simple attentional sequence-to-sequence (S2S) model (Bahdanau et al., 2014) extracting the parallel text from PASTEL. The model jointly trains different styles in conjunction by concatenating them to the source sentence at the beginning.

We avoid more complex architectural choices for Supervised models like adding a pointer component or an adversarial loss, since we seek to establish a minimum level of performance on this dataset.

[9]We can't directly compare with Hu et al. (2017); Prabhumoye et al. (2018) since their performance highly depends on the pre-trained classifier that often shows poor performance.

Setup. We experiment with both Softmax and Sigmoid non-linearities to normalize attention scores in the sequence-to-sequence attention. Adam (Kingma and Ba, 2014) is used as the optimizer. Word-level cross entropy of the target is used as the loss. The batch size is set to 32. We pick the model with lowest validation loss after 15 training epochs. All models are implemented in PyTorch (Paszke et al., 2017).

For an evaluation, in addition to the same hard and soft metrics used for measuring the meaning preservation in §3, we also use BLEU_2 (Papineni et al., 2002) for unigrams and bigrams, and ROUGE (Lin and Hovy, 2003) for hard metric and Embedding Averaging (EA) similarity (Liu et al., 2016) for soft metric.

	Hard $(\hat{S},\bar{S}_\alpha)$			Soft $(\hat{S},\bar{S}_\alpha)$

· S2S+GloVe+PreTr.	31.21	10.29	**29.52**	**0.804**	**0.529**

Table 6: Supervised style transfer. GloVe initializes with pre-trained word embeddings. PreTr. denotes pre-training on YAFC. Hard measures are $\mathbf{BLEU_2}$, **M**ETEOR, and **R**OUGE, and soft measures are **E**mbeding**A**veraging and **V**ector**E**xtrema.

Results. Table 6 shows our results on style tranfer. We observe that initializing both en/decoder's word embeddings with GloVe (Pennington et al., 2014) improves model performance on most metrics. Pretraining (PreTr.) on the formality style transfer data YAFC (Rao and Tetreault, 2018) further helps performance. All supervised S2S approaches outperform both retrieval-based baselines on all measures. This illustrates that the performance scores achieved are not simply a result of memorizing the training set. S2S methods surpass AsItIs on both soft measures and ROUGE. The significant gap that remains on BLEU remains

Source (S): I'd never seen so many beautiful flowers.
Style (α): (Morning, HighSchool) $S + \alpha \rightarrow \hat{S}$: the beautiful flowers were beautiful. $\bar{S}_\alpha$: the flowers were in full bloom. **Style** (α): (Afternoon, NoDegree) $S + \alpha \rightarrow \hat{S}$: The flowers were very beautiful. $\bar{S}_\alpha$: Tulips are one of the magnificent varieties of flowers.
Source (S): she changed dresses for the reception and shared food with her new husband.
Style (α): (Master, Centrist) $S + \alpha \rightarrow \hat{S}$: The woman had a great time with her husband $\bar{S}_\alpha$: Her husband shared a cake with her during reception
Style (α): (Vocational, Right) $S + \alpha \rightarrow \hat{S}$: The food is ready for the reception $\bar{S}_\alpha$: The new husband shared the cake at the reception

Table 7: Examples of style transferred text by our supervised model (S2S+GLOVE+PRETR.) on PASTEL. Given source text (S) and style (α), the model predicts a target sentence $\hat{S}$ compared to annotated target sentence $\bar{S}_\alpha$.

a point of exploration for future work. The significant improvement against the unsupervised methods (Shen et al., 2017; Lample et al., 2017) indicates the usefulness of the parallel text in PASTEL.

Table 7 shows output text $\hat{S}$ produced by our model given a source text S and a style α. We observe that the output text changes according to the set of styles.

6 Conclusion and Future Directions

We present PASTEL, a parallelly annotated stylistic language dataset. Our dataset is collected by human annotation using a proper denotation setting that preserves the meaning as well as maximizes the diversity of styles. Multiplicity of persona styles in PASTEL makes other style variables controlled (or fixed) except the target style for classification, which is a more accurate experimental design. Our simple supervised models with our parallel text in PASTEL outperforms the unsupervised style transfer models using non-parallel corpus. We hope PASTEL can be a useful benchmark to both train and evaluate models for style transfer and other related problems in text generation field.

We summarize some directions for future style researches:

- In our ablation study, salient features for style classification are not only syntactic or lexical features but also content words (e.g., love, food). This is a counterexample to the hypothesis implicit in much of recent style research: *style* needs to be *separately modeled* from *content*. We also observe that some texts remain similar across different annotator personas or across outputs from our transfer models, indicating that some content is stylistically invariant. Studying these and other aspects of the content-style relationship in PASTEL could be an interesting direction.
- Does any external variable co-varying with the text qualify to be a style variable/facet? What are the categories of style variables/facets? Do architectures which transfer well across one style variable (e.g gender) generalize to other style variables (e.g age)? We opine that these questions are largely overlooked by current style transfer work. We hope that our consideration of some of these questions in our work, though admittedly rudimentary, will lead to them being addressed extensively in future style transfer work.

Acknowledgements

This work would not have been possible without the ViST dataset and helpful suggestions with Ting-Hao Huang. We also thank Alan W Black, Dan Jurafsky, Wei Xu, Taehee Jung, and anonymous reviewers for their helpful comments.

Abstract

According to screenwriting theory, turning points (e.g., change of plans, major setback, climax) are crucial narrative moments within a screenplay: they define the plot structure, determine its progression and thematic units (e.g., setup, complications, aftermath). We propose the task of turning point identification in movies as a means of analyzing their narrative structure. We argue that turning points and the segmentation they provide can facilitate processing long, complex narratives, such as screenplays, for summarization and question answering. We introduce a dataset consisting of screenplays and plot synopses annotated with turning points and present an end-to-end neural network model that identifies turning points in plot synopses and projects them onto scenes in screenplays. Our model outperforms strong baselines based on state-of-the-art sentence representations and the expected position of turning points.

1 Introduction

Computational literary analysis works at the intersection of natural language processing and literary studies, aiming to evaluate various theories of storytelling (e.g., by examining a collection of works within a single genre, by an author, or topic) and to develop tools which aid in searching, visualizing, or summarizing literary content.

Within natural language processing, computational literary analysis has mostly targeted works of fiction such as novels, plays, and screenplays. Examples include analyzing characters, their relationships, and emotional trajectories (Chaturvedi et al., 2017; Iyyer et al., 2016; Elsner, 2012), identifying enemies and allies (Nalisnick and Baird, 2013), villains or heroes (Bamman et al., 2014, 2013), measuring the memorability of quotes (Danescu-Niculescu-Mizil et al., 2012), characterizing gender representation in dialogue (Agarwal et al., 2015; Ramakrishna et al., 2015; Sap et al., 2017), identifying perpetrators in crime series (Frermann et al., 2018), summarizing screenplays (Gorinski and Lapata, 2018), and answering questions about long and complex narratives (Kočiskỳ et al., 2018).

Turning Point	Description
1. Opportunity	Introductory event that occurs after the presentation of the setting and the background of the main characters.
2. Change of Plans	Event where the main goal of the story is defined. From this point on, the action begins to increase.
3. Point of No Return	Event that pushes the main character(s) to fully commit to their goal.
4. Major Setback	Event where everything falls apart (temporarily or permanently).
5. Climax	Final event of the main story, moment of resolution and the "biggest spoiler".

Table 1: Turning points and their definitions.

In this paper we are interested in the automatic analysis of narrative structure in screenplays. Narrative structure, also referred to as a storyline or plotline, describes the framework of how one tells a story and has its origins to Aristotle who defined the basic triangle-shaped plot structure representing the beginning (protasis), middle (epitasis), and end (catastrophe) of a story (Pavis, 1998). The German novelist and playwright Gustav Freytag modified Aristotle's structure by transforming the triangle into a pyramid (Freytag, 1896). In his scheme, there are five acts (*introduction, rising movement, climax, return*, and *catastrophe*). Several variations of Freytag's pyramid are used today in film analysis and screenwriting (Cutting, 2016).

In this work, we adopt a variant commonly employed by screenwriters as a practical guide for producing successful screenplays (Hague, 2017). According to this scheme, there are six stages (acts) in a film, namely *the setup*, *the new situation*, *progress*, *complications and higher stakes*, *the final push*, and *the aftermath*, separated by five *turning points* (TPs). TPs are narrative moments from which the plot goes in a different direction

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1707–1717, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

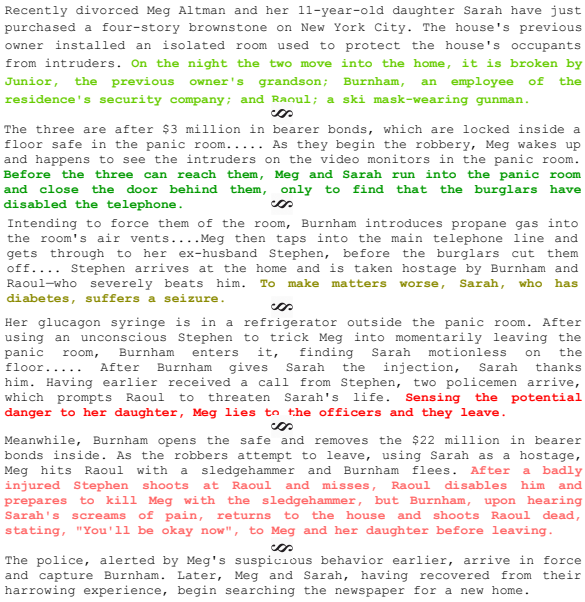

Figure 1: Example of turning point annotations (TP1, TP2, TP3, TP4, TP5, respectively) for the synopsis of the movie "Panic Room".

(Thompson, 1999), and by definition they occur at the junctions of acts. Aside from changing narrative direction, TPs define the movie's structure, tighten the pace, and prevent the narrative from drifting. The five TPs and their definitions are given in Table 1.

We propose the task of turning point identification in movies as a means of analyzing their narrative structure. TP identification provides a sequence of key events in the story and segments the screenplay into thematic units. Common approaches to summarization and QA of long or multiple documents (Chen et al., 2017; Yang et al., 2018; Kratzwald and Feuerriegel, 2018; Elgohary et al., 2018) include a retrieval system as the first step, which selects a subset of relevant passages for further processing. However, Kočiskỳ et al. (2018) demonstrate that these approaches do not perform equally well for extended narratives, since individual passages are very similar and the same entities are referred to throughout the story. We argue that this challenge can be addressed by TP identification, which finds the most important events and segments the narrative into thematic units. Downstream processing for summarization or question answering can then focus on those segments that are relevant to the task.

Problematically for modeling purposes, TPs are latent in screenplays, there are no scriptwriting conventions (like character cues or scene headings) to denote where TPs occur, and their exact manifestation varies across movies (depending on genre and length), although there are some rules of thumb indicating where to expect a TP (e.g., the Opportunity occurs after the first 10% of a screenplay, Change of Plans is approximately 25% in). To enable automatic TP identification, we develop a new dataset which consists of screenplays, plot synopses, and turning point annotations. To save annotation time and render the labeling task feasible, we collect TP annotations at the plot synopsis level (synopses are a few paragraphs long compared to screenplays which are on average 120 pages long). An example is given in Figure 1. We then project the TP annotations via distant supervision onto screenplays and propose an end-to-end neural network model which identifies TPs in full length screenplays.

Our contributions can be summarized as follows: (a) we introduce TP identification as a new task for the computational analysis of screen plays that can benefit applications such as QA and summarization; (b) we create and make publicly available the **TuRnIng POint Dataset** (TRIPOD) [1] which contains 99 movies (3,329 synopsis sentences and 13,403 screenplay scenes) annotated with TPs; and (c) we present an end-to-end neural network model that identifies turning points in plot synopses and projects them onto scenes in screenplays, outperforming strong baselines based on state-of-the-art sentence representations and the expected position of TPs.

2 Related Work

Recent years have seen increased interest in the automatic analysis of long and complex narratives. Specifically, Machine Reading Comprehension (MRC) and Question Answering (QA) tasks are transitioning from investigating single short and clean articles or queries (Rajpurkar et al., 2016; Nguyen et al., 2016; Trischler et al., 2016) to large scale datasets that consist of complex stories (Tapaswi et al., 2016; Frermann et al., 2018; Kočiskỳ et al., 2018; Joshi et al., 2017) or require reasoning across multiple documents (Welbl et al., 2018; Wang et al., 2018; Dua et al., 2019; Yang et al., 2018). Tapaswi et al. (2016) introduce a multi-modal dataset consisting of questions over 140 movies, while Frermann et al. (2018) attempt to answer a single question, namely who is the perpetrator in 39 episodes of the well-known crime series CSI, again based on multi-modal informa-

[1] https://github.com/ppapalampidi/TRIPOD

tion. Finally, Kočiskỳ et al. (2018) recently introduced a dataset consisting of question-answer pairs over 1,572 movie screenplays and books.

Previous approaches have focused on fine-grained story analysis, such as inducing character types (Bamman et al., 2013, 2014) or understanding relationships between characters (Iyyer et al., 2016; Chaturvedi et al., 2017). Various approaches have also attempted to analyze the goal and structure of narratives. Black and Wilensky (1979) evaluate the functionality of story grammars in story understanding, Elson and McKeown (2009) develop a platform for representing and reasoning over narratives, and Chambers and Jurafsky (2009) learn fine-grained chains of events.

In the context of movie summarization, Gorinski and Lapata (2018) automatically generate an overview of the movie's genre, mood, and artistic style based on screenplay analysis. Gorinski and Lapata (2015) summarize full length screenplays by extracting an optimal chain of scenes via a graph-based approach centered around the characters of the movie. A similar approach has also been adopted by Vicol et al. (2018), who introduce the MovieGraphs dataset consisting of 51 movies and describe video clips with character-centered graphs. Other work creates animated story-boards using the action descriptions of screenplays (Ye and Baldwin, 2008), extracts social networks from screenplays (Agarwal et al., 2014a), or creates *xkcd* movie narrative charts (Agarwal et al., 2014b).

Our work also aims to analyze the narrative structure of movies, but we adopt a high-level approach. We advocate TP identification as a precursor to more fine-grained analysis that unveils character attributes and their relationships. Our approach identifies key narrative events and segments the screenplay accordingly; we argue that this type of preprocessing is useful for applications which might perform question answering and summarization over screenplays. Although our experiments focus solely on the textual modality, turning point analysis is also relevant for multimodal tasks such as trailer generation and video summarization.

3 The TRIPOD Dataset

The TRIPOD dataset contains 99 screenplays, accompanied with cast information (according to IMDb), and Wikipedia plot synopses annotated with turning points. The movies were selected from the Scriptbase dataset (Gorinski and Lapata, 2015) based on the following criteria: (a) maintaining a variation across different movie genres (e.g., action, romance, comedy, drama) and narrative types (e.g., flashbacks, time shifts); and (b) including screenplays that are faithful to the released movies and their synopses as much as possible. In Table 2, we present various statistics of the dataset.

	Train	Test
movies	84	15
turning points	420	75
synopsis sentences	2,821	508
screenplay scenes	11,320	2,083
synopsis vocabulary	7.9k	2.8k
screenplay vocabulary	37.8k	16.8k
per synopsis		
tokens	729.8 (165.5)	698.4 (187.4)
sentences	35.4 (8.4)	33.9 (9.9)
sentence tokens	20.6 (9.5)	20.6 (9.3)
per screenplay		
tokens	23.0k (6.6)	20.9k (4.5)
sentences	3.0k (0.9)	2.8k (0.6)
scenes	133.0 (61.1)	138.9 (50.7)
per scene		
tokens	173.0 (235.0)	150.5 (198.3)
sentences	22.2 (31.5)	19.9 (26.9)
sentence tokens	7.8 (6.0)	7.6 (6.4)

Table 2: Statistics of the TRIPOD dataset; all means are shown with standard deviation in brackets.

Our motivation for obtaining TP annotations at the synopsis level (coarse-grained), instead of at the screenplay level (fine-grained) was twofold. Firstly, on account of being relatively short, synopses are easier to annotate than full-length screenplays, allowing us to scale the dataset in the future. Secondly, we would expect synopsis-level annotations to be more reliable and the degree of inter-annotator agreement higher; asking annotators to identify precisely where a turning point occurs might seem like looking for a needle in a haystack. An example of a synopsis with TP annotations is shown in Figure 1 for the movie "Panic Room". Each TP is colored differently, and both the chain of key events (colored text) and resulting segmentation (∞) are illustrated.

In an initial pilot study, the three authors acted as annotators for identifying TPs in movie synopses. They selected exactly one sentence per TP, under the assumption that all TPs are present. Based on the pilot, annotation instructions were devised and an annotation tool was created which allows to label synopses with TPs sentence-by-sentence. After piloting the annotation scheme on 30 movies, two new annotators were trained using our instructions and in a second study, they doubly annotated five movies. The remaining movies

in the dataset were then single annotated by the new annotators.

We computed inter-annotator agreement using two different metrics: (a) total agreement (TA), i.e., the percentage of TPs that two annotators agree upon by selecting the exact same sentence; and (b) annotation distance, i.e., the distance $d[p_i, tp_i]$ between two annotations for a given TP, normalized by synopsis length:

$$d[p_i, tp_i] = \frac{1}{N}|p_i - tp_i| \quad (1)$$

where N is the number of synopsis sentences and tp_i and p_i are the indices of the sentences labeled with TP i by two annotators. The mean annotation distance D is then computed by averaging distances $d[p_i, tp_i]$ across all annotated TPs.

The TA between the two annotators in our second study was 64.00% and the mean annotation distance was 4.30% (StDev 3.43%). The annotation distance per TP is presented in Table 5 (last line), where it is compared with the automatic TP identification results (to be explained later).

We also asked our annotators to annotate the screenplays (rather than synopses) for a subset of 15 movies. This subset serves as our goldstandard test set. Annotators were given synopses annotated with TPs and were instructed to indicate for each TP which scenes in the screenplay correspond to it. Six of the 15 movies were doubly annotated, so that we could measure agreement. Since annotators were allowed to choose a variable number of scenes for each TP, this changes slightly our agreement metrics.

Total Agreement (TA) now is the percentage of TP scenes the annotators agree on:

$$TA = \frac{1}{T \cdot L} \sum_{i=1}^{T \cdot L} \frac{|S_i \cap G_i|}{|S_i \cup G_i|} \quad (2)$$

where T, L are the TPs identified per annotator in a screenplay, and S_i and G_i are the indices of the scenes selected for TP i by the two annotators. Partial Agreement (PA) is the percentage of TPs where there is an overlap of at least one scene:

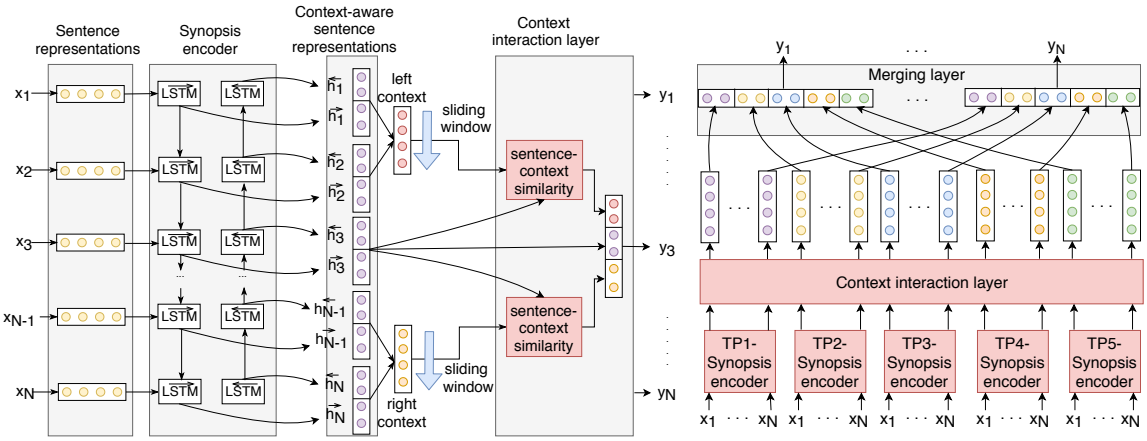
$$PA = \frac{1}{T \cdot L} \sum_{i=1}^{T \cdot L} [S_i \cap G_i \neq \emptyset] \quad (3)$$

And annotation distance D becomes the mean of the distances[2] $d[S_i, G_i]$ between two annotators normalized by M, the length of the screenplay:

$$d[S_i, G_i] = \frac{1}{M} \min_{(s \in S_i, g \in G_i)} |s - g| \quad (4)$$

The TA and PA between the two annotators were 35.48% and 56.67%, respectively. The mean annotation distance was 1.48% (StDev 2.93%). The TA shows that the annotators rarely indicate the same scenes, even if they are asked to annotate an event in the screenplay that is described by a specific synopsis sentence. However, they identify scenes which are in close proximity in the screenplay, as PA and annotation distance reveal. This analysis validates our assumption that annotating the synopses first limits the degree of overall disagreement.

[2]We compute the minimum distance between the two sets of scenes, since non-sequential scenes may be included in the same set. Hence, considering the center of the sets is not always representative of the TP scenes.



4 Turning Point Prediction Models

In this work, we aim to detect text segments which act as TPs. We first identify which *sentences* in plot synopses are TPs (Section 4.1); next, we identify which *scenes* in screenplays act as TPs via projection of *goldstandard* TP labels (Section 4.2); finally, we build an end-to-end system which identifies TPs in screenplays based on *predicted* TP synopsis labels (Section 4.3).

All models we propose in this paper have the same basic structure; they take text segments i (sentences or scenes) as input and predict whether these act as TPs or not. Since the sequence, number, and labels of TPs are fixed (see Table 1), we treat TP identification as a binary classification problem (where 1 indicates that the text is a TP and 0 otherwise). Each segment is encoded into a multi-dimensional feature space x_i which serves as input to a fully-connected layer with a single neuron representing the probability that i acts as a TP. In the following, we describe several models which vary in the way input segments are encoded.

4.1 Identifying Turning Points in Synopses

Context-Aware Model (CAM) A simple baseline model would compute the semantic representation of each sentence in the synopsis using a pretrained sentence encoder. However, classifying segments in isolation without considering the context in which they appear, might yield inferior semantic representations. We therefore obtain richer representations for sentences by modeling their surrounding context. We encode the synopsis with a Bidirectional Long Short-Term Memory (BiLSTM; Hochreiter and Schmidhuber 1997) network; and obtain contextualized representation cp_i

(a) Topic-Aware Model (TAM) (b) Multi-view TAM

Figure 2: Model overview for TP identification in synopses. On the left, sentence representations x_i are contextualized via a synopsis encoder (BiLSTM layer) and after interacting with the left and right windows in the context interaction layer, the final sentence representation y_i is computed. On the right, five different synopsis encoders are utilized, one per TP, and these different views of a synopsis sentence x_i are combined in the merging layer.

for sentence x_i by concatenating the hidden layers of the forward $\overrightarrow{h_i}$ and backward $\overleftarrow{h_i}$ LSTM, respectively: $cp_i = h_i = [\overrightarrow{h_i}; \overleftarrow{h_i}]$ (for a more detailed description, see the Appendix). Representation cp_i is the input feature vector for our binary classifier. The model is illustrated in Figure 2a.

Topic-Aware Model (TAM) TPs by definition act as boundaries between different thematic units in a movie. Furthermore, long documents are usually comprised of topically coherent text segments, each of which contains a number of text passages such as sentences or paragraphs (Salton et al., 1996). Inspired by text segmentation approaches (Hearst, 1997) which measure the semantic similarity between sequential context windows in order to determine topic boundaries, we enhance our representations with a *context interaction* layer. The objective of this layer is to measure the similarity of the current sentence with its preceding and following context, thereby encoding whether it functions as a boundary between thematic sections. The enriched model with the context interaction layer is illustrated in Figure 2a.

After calculating contextualized sentence representations cp_i, we compute the representation of the left lc_i and right rc_i contexts of sentence i (see Figure 2a, right-hand side). We select windows of fixed length l and calculate lc_i and rc_i by averaging the sentence representations within each window. Next, we compute the semantic similarity of the current sentence with each context representation. Specifically, we consider the element-wise product b_i, cosine similarity c_i and pairwise distance u_i as similarity metrics:

$$b_i = cp_i \odot lc_i \qquad c_i = \frac{cp_i \cdot lc_i}{\|cp_i\| \|lc_i\|} \tag{5}$$

$$u_i = \frac{cp_i \cdot lc_i}{\max(\|cp_i\|_2 \cdot \|lc_i\|_2)} \tag{6}$$

The interaction representation of sentence cp_i with its left context is the concatenation of cp_i, fl_i, and the above similarity values (i.e., b_i, c_i, u_i):

$$fl_i = [cp_i; lc_i; b_i; c_i; u_i] \tag{7}$$

The interaction representation fr_i for the right context rc_i is computed analogously. We obtain the final representation of sentence i via concatenating fl_i and fr_i: $y_i = [fl_i; fr_i; cp_i]$.

TP-Specific Information Another variation of our model is to use TP-specific encoders instead of a single one (see Figure 2b). In this case, we employ five different encoders for calculating five different representations for the current synopsis sentence x_i, each one with respect to a specific TP. These representations can be considered multiple views of the same sentence. We calculate the interaction of each view with the left and right context window, as previously, via the context interaction layer. Finally we compute the sentence representation y_i by concatenating its individual context-enriched TP representations.

Entity-Specific Information We also enrich our model with information about entities. We first apply co-reference resolution to the plot synopses using the Stanford CoreNLP toolkit (Manning et al.,

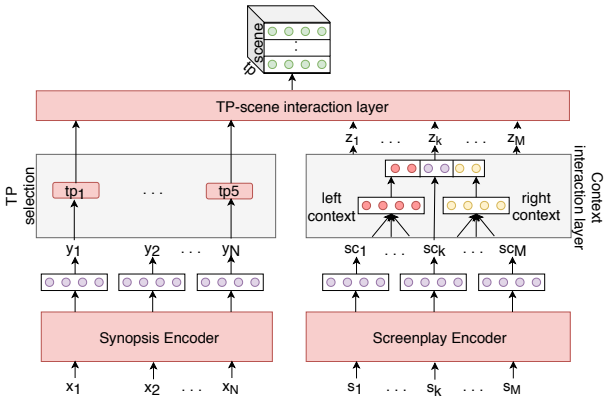


Figure 3: TAM overview for TP identification in screenplays. The synopsis and screenplay encoders contextualize synopsis sentences x_i and screenplay scenes s_i, respectively. TPs are selected from contextualized synopsis sentences y_i and a richer representation sc_i is computed for s_i via the context interaction layer. The similarity between sentence tp_i and scene z_i is computed by the TP–scene interaction layer.

2014) and substitute mentions of named entities whenever these are included in the IMDb cast list. We then obtain entity-specific sentence representations as follows. Our encoder uses a word embedding layer initialized with pre-trained entity embeddings and a BiLSTM for contextualizing word representations. We add an attention mechanism on top of the LSTM, which assigns a weight to each word representation. We compute the entity-specific representation e_i for synopsis sentence i as the weighted sum of its word representations (for more details, see the Appendix). Finally, entity enriched sentence representations x'_i are obtained by concatenating generic vectors x_i with entity-specific ones e_i: $x'_i = [x_i; e_i]$.

4.2 Identifying Turning Points in Screenplays

Identifying TPs in synopses serves as a testbed for validating some of the assumptions put forward in this work, namely that turning points mark narrative progression and can be identified automatically based on their lexical makeup. Nevertheless, we are mainly interested in the real-world scenario where TPs are detected in longer documents such as screenplays. Screenplays are naturally segmented into scenes, which often describe a self-contained event that takes place in one location, and revolves around a few characters. We therefore assume that scenes are suitable textual segments for signaling TPs in screenplays.

Unfortunately, we do not have any goldstandard information about TPs in screenplays. We provide distant supervision by constructing noisy labels based on goldstandard TP annotations in synopses (see the description below). Given sentences labeled as TPs in a synopsis, we identify scenes in the corresponding screenplay which are semantically similar to them. We formulate this task as a binary classification problem, where a sentence-scene pair is deemed either "relevant" or "irrelevant" for a given TP.

	TP1	TP2	TP3	TP4	TP5
theory	10.00	25.00	50.00	75.00	94.50
μ	11.39	31.86	50.65	74.15	89.43
σ	6.72	11.26	12.15	8.40	4.74

Table 3: Expected TP position based on screenwriting theory; mean position μ and standard deviation σ in goldstandard synopses of our training set.

Distant Supervision Based on the screenwriting scheme of Hague (2017), TPs are expected to occur in specific parts of a screenplay (e.g., the Climax is likely to occur towards the end). We exploit this knowledge as a form of distant supervision. We estimate the mean position for each TP using the gold standard annotation of the plot synopses in our training set (normalized by the synopsis length). The results are shown in Table 3, together with the TP positions postulated by screenwriting theory. We observe that our estimates agree well with the theoretical predictions, but also that some TPs (e.g., TP2 and TP3) are more variable in their position than others (e.g., TP1 and TP5). This leads us to the following hypothesis: each TP is situated within a specific window in a screenplay. Scenes that lie within the window are semantically related to the TP, whereas all other scenes are unrelated. In experiments we calculate a window $\mu \pm \sigma$ based on our data (see Table 3).

We compute scene representations based on the sequence of sentences that comprise it using a BiLSTM equipped with an attention mechanism (see Section 4.1). The final scene representation s is the weighted sum of the representations of the scene sentences. Next, the TP–scene interaction layer enriches scene representations with similarity values with each marked TP synopsis sentence tp as shown in Equations (5)–(7).

We again augment the above-described base model with contextualized sentence and scene representations using a synopsis and screenplay encoder. The synopsis encoder is the same one used for our sentence-level TP prediction task (see Section 4.1). The screenplay encoder works in a sim-

ilar fashion over scene representations.

Topic-Aware Model (TAM) TAM enhances our screenplay encoder with information about topic boundaries. Specifically, we compute the representations of the left lc_i and right rc_i context window of the i^{th} scene in the screenplay as described in Section 4.1. Next, we compute the final representation z_i of scene sc_i by concatenating the representations of the context windows lc_i and rc_i and the current scene sc_i: $z_i = [lc_i; sc_i; rc_i]$. There is no need to compute the similarity between scenes and context windows here as we now have goldstandard TP representations in the synopsis and employ the TP–scene interaction layer for the computation of the similarity between TPs and enriched scene representations z_i. Hence, we directly calculate in this layer a scene-level feature vector that encodes information about the scene, its similarity to TP sentences, and whether these function as boundaries between topics in the screenplay.

Entity-Specific information We can also employ an entity-specific encoder (see Section 4.1) for the representing the synopsis and scene sentences. Again, generic and entity-specific representations are combined via concatenation.

4.3 End-to-end TP Identification

Our ultimate goal is to identify TPs in screenplays without assuming any goldstandard information about their position in the synopsis. We address this with an end-to-end model which first predicts the sentences that act as TPs in the synopsis (e.g., TAM in Section 4.1) and then feeds these predictions to a model which identifies the corresponding TP scenes (e.g., TAM in Section 4.2).

5 Experimental Setup

Training We used the Universal Sentence Encoder (USE; Cer et al. 2018) as a pre-trained sentence encoder for all models and tasks; its performance was superior to BERT (Devlin et al., 2018) and other related pre-trained encoders (for more details, see the Appendix). Since the binary labels in both prediction tasks are imbalanced, we apply class weights to the loss function of our models. We weight each class by its inverse frequency in the training set (for more implementation details, see the Appendix).

Inference During inference in our first task (i.e., identification of TPs in synopses), we select one sentence per TP. Specifically, we want to track the five sentences with the highest posterior probability of being TPs and sequentially assign them TP labels based on their position. However, it is possible to have a cluster of neighboring sentences with high probability, even though they all belong to the same TP. We therefore constrain the sentence selection for each TP within the window of its expected position, as calculated in the distribution baseline (Section 4.2).

For models which predict TPs in screenplays, we obtain a probability distribution over all scenes in a screenplay indicating how relevant each is to the TPs of the corresponding plot synopsis. We find the peak of each distribution and select a neighborhood of scenes around this peak as TP-relevant ones. Based on the goldstandard annotation, each TP corresponds to 1.77 relevant scenes on average (StDev 1.23). We therefore consider a neighborhood of three relevant scenes per TP.

	TA	*D*

ther context-aware nor utilizes topic boundary information against CAM and TAM. We also show two variants of TAM enhanced with TP-specific encoders (+ TP views) and entity-specific information (+ entities). Model performance is measured using the evaluation metrics of Total Agreement (*TA*) and annotation distance (*D*), normalized by synopsis length (equation (1)).

The baseline model presents the lowest performance among all variants which suggests that state-of-the-art sentence representations on their own are not suitable for our task. Indeed, when contextualizing the synopsis sentences via a BiLSTM layer we observe an absolute increase of 4.00% in terms of *TA*. Moreover, the addition of a context interaction layer (see TAM row in Table 4a) yields an absolute *TA* improvement of 4.00% compared to CAM. Combining different TP views further improves by 3.00%, reaching a *TA* of 39.00%, and reducing *D* to 6.52%.

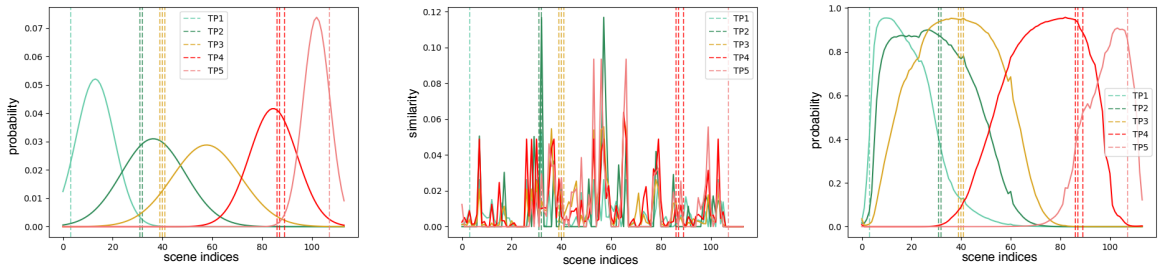

Table 4b shows our results on the test set. We compare TAM, our best performing model against two strong baselines. The first one selects sentences that lie on the expected positions of TPs according to screenwriting theory; while the second one selects sentences that lie on the peaks of the empirical TP distributions in the training set (Section 4.2). As we can see, TAM (+ TP views) achieves a *TA* of 38.57% compared to 22.00% for the distribution baseline. And although entity-specific information does not have much impact on the development set, it yields a 2.76% improvement on the test set. A detailed break down of results per TP is given in Table 5. Interestingly, our model resembles human behavior (see row *Human agreement*): TPs 1, 4, and 5 are easiest to distinguish, whereas TPs 2 and 3 are hardest and frequently placed at different points in the synopsis.

We also conducted a human evaluation experiment on Amazon Mechanical Turk (AMT). AMT workers were presented with a synopsis and "highlights", i.e., five sentences corresponding to TPs. We obtained highlights from goldstandard annotations, the distribution baseline, and TAM (+ TP views). AMT workers were asked to read the synopsis and rank the highlights from best to worst according to the following criteria: (1) the quality of the plotline that they form; (2) whether they include the most important events and plot twists of the movie; and (3) whether they provide some description of the events in the beginning and end of the movie. In Figure 4 we show, proportionally, how often our participants ranked each model 1st, 2nd, and so on. Perhaps unsurprisingly, goldstandard TPs were considered best (and ranked 1st 42% of the time). TAM is ranked best 30% of the time, followed by the distribution baseline which was only ranked first 26% of the time. Overall, the average ranking positions for the goldstandard, TAM, and the baseline are 1.87, 1.98, and 2.16, respectively. Human evaluation therefore validates that our model outperforms the position-based baselines.

TP Identification in Screenplays Our results are summarized in Table 6. For this task, we performed five-fold crossvalidation over our original goldstandard set to obtain a test-development split (recall we do not have goldstandard annotations for training). We report Total Agreement (*TA*), Partial Agreement (*PA*), and annotation distance *D*, normalized by screenplay length (Equations (2)–(4)).

Aside from the theory and distribution-based baselines, we also experimented[3] with a com-

[3]Common segmentation approaches such as TextTiling (Hearst, 1997) perform poorly on our task and we do not report them due to space constraints.

Distribution baseline tf*idf similarity TAM

Figure 5: Probability distributions over the scenes of the screenplay for the movie "Juno"; x-axis: scene indices, y-axis: probability that the scene is relevant to a specific TP. Vertical dashed lines are goldstandard TP scenes.

mon IR baseline which considers TP synopsis sentences as queries and retrieves a neighborhood of semantically similar scenes from the screenplay using tf*idf similarity. Specifically, we compute the maximum tf*idf similarity for all sentences included in the respective scene. We empirically observed that tf*idf's behavior can be erratic selecting scenes in completely different sections of the screenplay, and therefore constrain it by selecting scenes only within the windows determined by the position distributions ($\mu \pm \sigma$) for each TP. As far as our own models are concerned, we report results with goldstandard TP labels for CAM and TAM on their own and enriched with entity information. We also built and end-to-end system based on TP predictions from TAM.

As can be seen in Table 6, tf*idf approaches perform worse than position-related baselines. Overall, similar vocabulary across scenes and mentions of the same entities throughout the screenplay make tf*idf approaches insufficient for our tasks. The best performing model is TAM confirming our hypothesis that TPs are not just isolated key events, but also mark boundaries between thematic units and, therefore, segmentation-inspired approaches can be beneficial for the task. Results for entities are somewhat mixed; for CAM, the entity-specific information improves *TA* and *PA* but increases *D*, while it does not seem to make much difference for TAM. The performance of the end-to-end TAM model drops slightly compared to the same model using goldstandard TP annotations. However, it still remains competitive against the baselines, indicating that tracking TPs in screenplays fully automatically is feasible.

In Figure 5, we visualize the posterior distribution of various models over the scenes of the screenplay for the movie "Juno". The first panel shows the distribution baseline alongside goldstandard TP scenes (vertical lines). We observe that the distribution baseline provides a good approximation of relevant TP positions (which validates its use in the construction of noisy labels, Section 4.2), even though it is not always accurate. For example, TPs 1 and 3 lie outside the expected window in "Juno".

The second panel presents the TP predictions according to tf*idf similarity. We observe that scenes located in entirely different parts of the screenplay present high similarity scores with respect to a given TP due to vocabulary uniformity and mentions of the same entities throughout the screenplay. In the next panel we present the predictions of TAM. Adding synopsis and screenplay encoders yields smoother distributions increasing the probability of selecting TP scenes inside distinct regions of the screenplay, with sharper peaks and higher confidence.

7 Conclusions

We proposed the task of turning point identification in screenplays as a means of analyzing their narrative structure. We demonstrated that automatically identifying a sequence of key events and segmenting the screenplay into thematic units is feasible via an end-to-end neural network model. In future work, we will investigate the usefulness of TPs for summarization and question answering. We will also scale the TRIPOD dataset and move to a multi-modal setting where TPs are identified directly in video data.

Abstract

Despite detection of suicidal ideation on social media has made great progress in recent years, people's implicitly and anti-real contrarily expressed posts still remain as an obstacle, constraining the detectors to acquire higher satisfactory performance. Enlightened by the hidden "tree holes" phenomenon on microblog, where people at suicide risk tend to disclose their inner real feelings and thoughts to the microblog space whose authors have committed suicide, we explore the use of tree holes to enhance microblog-based suicide risk detection from the following two perspectives. (1) We build suicide-oriented word embeddings based on tree hole contents to strength the sensibility of suicide-related lexicons and context based on tree hole contents. (2) A two-layered attention mechanism is deployed to grasp intermittently changing points from individual's open blog streams, revealing one's inner emotional world more or less. Our experimental results show that with suicide-oriented word embeddings and attention, microblog-based suicide risk detection can achieve over 91% accuracy. A large-scale well-labelled suicide data set is also reported in the paper.

1 Introduction

Suicide is a growing problem in today's society. Each year nearly 800,000 people worldwide commit suicide, which is one person every 40 seconds, and there are many more who attempt it (Organization et al., 2014). Suicide prevention will conduce to human's well-being, of which timely sensing suicide ideation is an essential task.

Existing Solutions. Traditional suicide risk assessment like Suicide Probability Scale (Bagge and Osman, 1998), Adult Suicide Ideation Questionnaire (Fu et al., 2007), Suicidal Affect-Behavior-Cognition Scale (Harris et al., 2015), etc. requires respondents to either fill in a questionnaire or participate in a professional interview. However, they are applicable to a small group of people. Particularly for the people who are suffering but tend to hide inmost thoughts and refuse to seek helps from others, the approaches cannot function (Essau, 2005; Rickwood et al., 2007; Zachrisson et al., 2006).

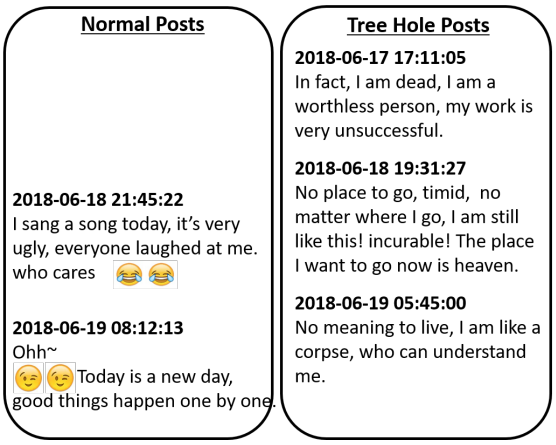

Figure 1: An example of one user's normal posts vs. his/her hidden tree hole posts on microblog.

Recently, the penetration of social media (like forums and microblogs) and its large-scale, low-cost, and open advantages enable researchers to overcome the limitation and timely detect individual's suicide ideation. Despite great efforts have been made (Alambo et al., 2019; Cheng et al., 2017; Du et al., 2018; Sawhney et al., 2018; Coppersmith et al., 2018; Viouls et al., 2018), the social media based detection performance is constrained due to implicitly and anti-real contrarily expressed posts from people who hide their inmost feelings and thoughts on social media. To illustrate, let's see a user's normal blogs vs. his/her hidden posts in a microblog tree hole in Figure 1. Usually, people of suicidal tendency (referred to as suicidal people in the study) tend to disclose their real inner feelings on the microblog space whose authors have committed suicide. Hundreds of such

	Normal Posts	Tree Hole Posts
Avg proportion of self-concern words per post	14%	50%
Avg proportion of others-concern words per post	68%	12%
Avg proportion of suicide-related words per post	5%	95%
Avg number of posts per user in a year	69.3	52.1
Total number of posts from all users in a year	252,901	190,087

Table 1: Statistics of suicidal users' normal posts and hidden tree hole posts on Microblog based on 3652 users from May 1, 2018 to April 30, 2019.

tree holes exist on Sina microblog. An example tree hole contains 1,700,000 posts from suicide attempts. In Figure 1, we can sense a severe hopelessness from the tree hole posts, but not from the normal posts, and the user even expresses an uplift feeling. After cross-examining suicidal users' normal and hidden posts as shown in table 1, we discover that users' hidden posts in the tree hole have more self-concerns, less others-concerns, and illustrate suicidal thoughts more directly. In comparison, suicidal users normal posts contain much less suicide-related words, and the users are reluctant to show their suicidal feelings in their normal posts. Moreover, the data of self-concern and others-concern shown in the first two rows even indicate that people with suicide risk are not willing to talk about themselves in their normal posts, which takes great challenges to detect suicide risk from users' open normal posts.

Our Work. The aim of the study is to break through the above limitation to achieve a new state-of-art performance on latent suicide risk detection from one's open normal microblogs. We leverage tree hole posts from the following two perspectives. (1) We construct suicide-oriented word embeddings based on tree hole contents to strength the sensibility of suicide-related lexicons and context based on tree hole contents. (2) A two-layered attention mechanism is deployed to grasp intermittently changing points from individual's open blog streams, revealing one's inner emotional world more or less. Our experimental results on 252,901 open normal microblogs show that with suicide-oriented word embeddings and two-layered attention, latent suicide risk detection can achieve over 91% accuracy.

In summary, the paper makes the following contributions.

- We build effective suicide-oriented word embeddings to better understand the implicit meanings of words contained in users' normal posts, and propose a two-layered attention model to capture the changing points which reveal suicide risk from individuals' blog streams. Our latent suicide risk detection from users normal posts not only outperforms the state-of-the-art approaches, but also are powerful enough in detecting implicitly and anti-real contrarily expressed posts.
- We construct a large-scale data set from 3652 suicidal people in the period of [May 1, 2018 to April 30, 2019], containing 252,901 normal posts on Sina microblog. The data set can further facilitate people's well-being studies in the computer science and psychology fields.

2 Related Work

2.1 Traditional Questionnaire-based Suicide Risk Assessment

Researchers have developed a number of psychological measurements to access individual's suicide risk (Pestian et al., 2017), such as Suicide Probability Scale (SPS) (Bagge and Osman, 1998), Depression Anxiety Stress Scales-21 (DASS-21) (Crawford and Henry, 2003; Henry and Crawford, 2005), Adult Suicide Ideation Questionnaire (Fu et al., 2007), Suicidal Affect-Behavior-Cognition Scale (Harris et al., 2015), functional Magnetic Resonance Imaging (fMRI) signatures (Just et al., 2017), and so on. While these measurements are professional and effective, they require respondents to either fill in a questionnaire or participate in a professional interview, constraining its touching to suicidal people who have low motivations to seek help from professionals (Essau, 2005; Rickwood et al., 2007; Zachrisson et al., 2006). A recent study found out that taking a suicide assessment may bring negative effect to individuals with depressive symptoms (Harris and Goh, 2017).

2.2 Suicide Risk Detection from Social Media

Recently, detection of suicide risk from social media is making great progress due to the advantages of reaching massive population, low-cost, and real-time (Braithwaite et al., 2016). Harris et al. (2014) reported that suicidal users tend to spend more time online, have greater likelihood of developing online personal relationships, and greater use of online forums.

Suicide Risk Detection from Suicide Notes. Pestian et al. (2010) built a suicide note classifier used machine learning techniques, which performs better than human psychologists in distinguishing fake online suicide notes from real ones. Huang et al. (2007) hunted suicide notes based on lexicon-based keyword matching on MySpace.com (a popular site for adolescents and young adults, particularly sexual minority adolescents with over 1 billion registered users worldwide) to check whether users have an intent to commit suicide.

Suicide Risk Detection from Community Forums. Li et al. (2013) applied textual sentiment analysis and summarization techniques to users' posts and posts' comments in a Chinese web forum in order to identify suicide expressions. Masuda et al. (2013) examined online forums in Japan, and discovered that the number of communities which a user belongs to, the intransitivity, and the fraction of suicidal neighbors in the social network contributed the most to suicide ideation. De Choudhury et al. (2016) built a logistic regression framework to analyze Reddit users' shift tendency from mental health sub-communities to a suicide support sub-community. heightened self-attentional focus, poor linguistic coherence and coordination with the community, reduced social engagement and manifestation of hopelessness, anxiety, impulsiveness and loneliness in shared contents are distinct markers characterizing these shifts. Based on the suicide lexicons detailing suicide indicator, suicide ideation, suicide behavior, and suicide attempt, Alambo et al. (2019) built four corresponding semantic clusters to group semantically similar posts on Reddit and questions in a questionnaire together, and used the clusters to assess the aggregate suicide risk severity of a Reddit post.

Suicide Risk Detection from Microblogs. Jashinsky et al. (2014) used search keywords and phrases relevant to suicide risk factors to filter potential suicide-related tweets, and observed a strong correlation between Twitter-derived suicide data and real suicide data, showing that Twitter can be viewed as a viable tool for real-time monitoring of suicide risk factors on a large scale. The correlation study between suicide-related tweets and suicidal behaviors was also conducted based on a cross-sectional survey (Sueki, 2015), where participants answered a self-administered online questionnaire, containing questions about Twitter use, suicidal behaviour, depression and anxiety, and demographic characteristics. The survey result showed that Twitter logs could help identify suicidal young Internet users.

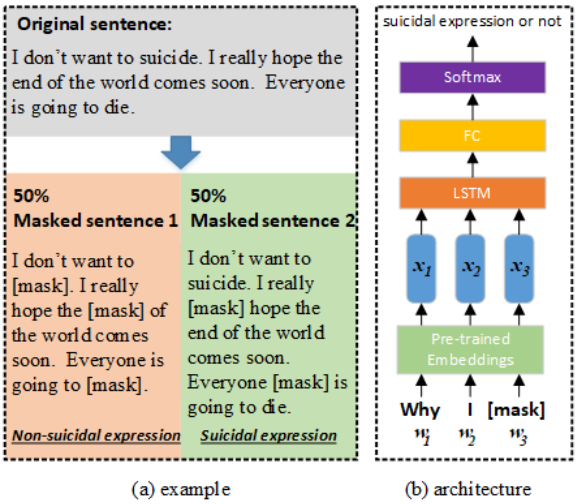
Based on eight basic emotion categories (joy, love, expectation, anxiety, sorrow, anger, hate, and surprise), Ren et al. (2015) examined three accumulated emotional traits (i.e., emotion accumulation, emotion covariance, and emotion transition) as the special statistics of emotions expressions in blog streams for suicide risk detection. A linear regression algorithm based on the three accumulated emotional traits was employed to examine the relationship between emotional traits and suicide risk. The experimental result showed that by combining all of three emotion traits together, the proposed model could generate more discriminative suicidal prediction performance.

Natural language processing and machine learning techniques, such as Latent Dirichlet Allocation (LDA), Logistic Regression, Random Forest, Support Vector Machine, Naive Bayes, Decision Tree, etc., were applied to identify users' suicidal ideation based on their linguistic contents and online behaviors on Sina Weibo (Guan et al., 2014; Zhang et al., 2014a; Huang et al., 2014; Zhang et al., 2014b; Huang et al., 2015; Guan et al., 2015; Cheng et al., 2017) and Twitter (Abboute et al., 2014; Burnap et al., 2015; O'Dea et al., 2015; Coppersmith et al., 2015). Deep learning based architectures like Convolutional Neural Network (CNN), Recurrent Neural Network (RNN), Long Short-Term Memory Neural Network (LSTM), etc., were also exploited to detect users' suicide risk on social media (Du et al., 2018; Sawhney et al., 2018; Coppersmith et al., 2018). Viouls et al. (2018) detected users' change points in emotional well-being on Twitter through a martingale framework, which is widely used for change detection in data streams.

Category	Suicide Ideation	Suicide behavior	Psychache	Mental illness	Hopeless
Number	586	88	403	48	188
Words/phrases	want to die escape	seppuku hypnotics	want to cry loneliness	depression hallucination	dead end despair

Table 2: Representative words/phrases of Chinese suicide dictionary

3 Suicide-oriented Word Embeddings



Although there are some good works on word embeddings (Mikolov et al., 2013; Pennington et al., 2014; Joulin et al., 2016; Devlin et al., 2018), lack of domain information limits their performance on suicide detection.

Given a serious of pre-trained word embeddings and suicide-related dictionary, we aim to generate suicide-related word embeddings which can strengthen the sensibility of suicide-related lexicons and context. In this study, we call them Suicide-oriented Word Embeddings, as we take advantage of the information from Tree Hole's data set which can be regarded as a kind of latent emotional expressions of individuals. As suicidal individuals in social media often use some suicide-related words/phrases in their posts, we employ Chinese suicide dictionary (Lv et al., 2015) to generate suicide domain associated embeddings. The Chinese suicide dictionary analyzes 1.06 million active blog users' posts and lists 2168 words/phrases related to suicidal ideation. These words/phrases belong to 13 categories and each word/phrase is assigned with a risk weight from 1 to 3 which indicates the relevance of suicide. We list 5 representative categories in table 2.

Since pre-trained word embeddings already contain rich semantic information and contextual information, we only need to enrich existing word embeddings with suicide-related information.

We employ a masked classification task to do this. Generally, a sentence should contains suicide-related words/phrases if it express suicidal ideation. Hence, We select 10,000 sentences[1] from Tree Hole's data set and ensure every sentence contains more than one word/phrase appeared in Chinese suicide dictionary.

Moreover, we utilize the selected sentences to do a suicidal expression classification. A sentence is regarded as suicidal expression only if it includes at least one suicide-related word/phrase. In this way, we do a sentence-level classification to refine pre-trained word embeddings and let them understand which word/phrase is relevant to suicide expression.

(a) example (b) architecture

Figure 2: An example of the strategy for embeddings training is shown on the left and the architecture of the masked classification task to train the suicide-oriented word embeddings is on the right.

In training details, for each epoch, we randomly select 50% sentences to replace all suicide-related words/phrases with "[mask]". Especially, for the rest 50% sentences, we randomly insert two "[mask]" into every sentence to avoid the suicidal expression classifier classifying sentence only based on whether it contains word "[mask]".

An example is given in Figure 2 (a). **Masked sentence 1** is the sentence that we replace all suicide-related words/phrases with "[mask]" and **Masked sentence 2** is the sentence that we randomly insert two "[mask]". We label **Masked sentence 1** as 0 (non-suicide) and **masked sentence 2** as 1 (suicide).

As there is no clear boundary between suicide-related words/phrases and others in pre-trained word embeddings, through this suicidal expression classification we force suicide-related words/phrases to be enriched with domain information and let all the suicide-related word/phrases

[1]Through out this work, a "sentence" can be a piece of text, rather than an actual linguistic sentence. It may contains more than one actual sentence.

contain the relationship with suicidal ideation. After classification model converge in Tree Hole's data set, we obtain suicide-oriented word embeddings which contain both semantic information from pre-trained word embeddings and suicide-information from suicide dictionary.

As illustrated in Figure 2, given a sentence $A = \{w_1, w_2, .., w_n\}$ written by a user in Tree Hole, where n is the length of a sentence, the aim of suicidal expression classification is to classify whether this sentence contains expression about suicidal ideation or not. In this case, we define $X = \{x_1, x_2, .., x_n\} \in R^{n \times d_e}$ as the word embeddings of A, where d_e is the dimension of embeddings. Figure 2 shows the architecture of the suicidal expression classification Model.

We employ a LSTM layer to extract text feature from A followed by a fully connected layer for classification. We feed the word embeddings X into the LSTM as following:

$$\begin{aligned} h_t &= \textbf{LSTM}(x_i, h_{t-1}), \\ [k_1, k_2] &= softmax((H^a W_1 + b_1)^T W_2 + b_2) \end{aligned} \tag{1}$$

where h_{t-1}, h_t represent the hidden states at time $t-1$ and t, $H^a = \{h_1, h_2, ..., h_n\} \in R^{n \times d_e}$ is sentence representation of A, $[k_1, k_2]$ stand for the possibility of whether the sentence contains expression about suicidal ideation or not. $W_1 \in R^{d_e \times 1}$, $W_2 \in R^{n \times 2}$, $b_1 \in R^{1 \times 1}$ and $b_2 \in R^{1 \times 2}$ are trainable parameters.

4 Suicide Detection Model (SDM) based on Suicide-oriented Word Embeddings and Attention Mechanism

Given a sequential of posts $\hat{T}$ from one user, $\hat{T} = \{(s_1, p_1), (s_2, p_2), ..., (s_m, p_m)\}$, where m denotes the number of posts, (s_i, p_i) stand for text and picture from i-th post. The aim is to detect whether the user at risk of suicide or not. Let $\hat{X} = \{x_1, x_2, .., x_n\} \in R^{n \times d_e}$ be the word embeddings of s_i, where n represents the length of s_i and d_e is the dimension of embeddings. Figure 3 shows the architecture of the proposed two-layered attention model.

4.1 Feature Extraction

Text Feature Extraction. We employ a LSTM layer and attention mechanism to extract text feature from s_i. We feed the word embeddings $\hat{X}$ into

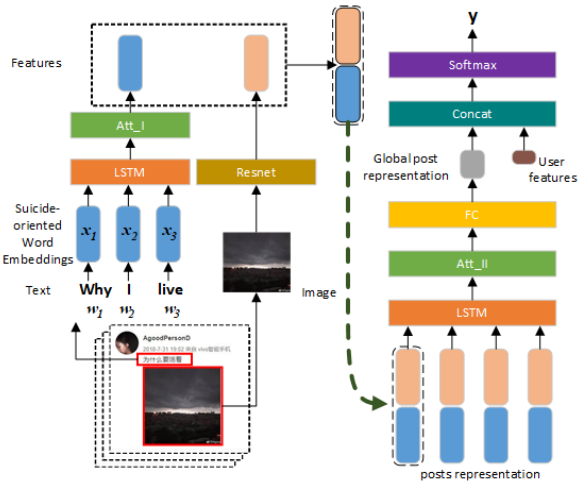


Figure 3: Architecture of the Suicide Risk Detection model.

the LSTM as following:

$$h_t = \textbf{LSTM}(x_t, h_{t-1}) \tag{2}$$

where h_{t-1}, h_t represent the hidden states at time $t-1$ and t. We obtain the primary textual representation $H_i^p = \{h_1, h_2, ..., h_n\} \in R^{n \times d_e}$ of s_i after LSTM layer. To gain the critical suicide-related textual information of H_i^p, we apply the **attention mechanism *Att_I*** :

$$Att_I = softmax(H_i^p W_3 + b_3) \tag{3}$$

where $Att_I \in R^{n \times 1}$ is the attention vector that demonstrates the distribution of the weights for each word of primary textual representation, $W_3 \in R^{d_e \times 1}$ and $b_3 \in R^{1 \times 1}$ are trainable parameters. Then we make multiplication between the attention vector Att_I and H_i^p to get the final textual representation $\hat{H}_i \in R^{d_e \times 1}$ of text s_i,

$$\hat{H}_i = (H_i^p)^T Att_I \tag{4}$$

Image Feature Extraction. We extract image features from a 34 layer pre-trained ResNet (He et al., 2016). For the convenience of calculation, we convert the last fully connected layer of ResNet from 512×1000 to $512 \times d_e$:

$$I_i = tanh(O\, W_4 + b_4) \tag{5}$$

where $O \in R^{1 \times 512}$ is the input of the last fc-layer, $W_4 \in R^{512 \times d_e}$ and $b_4 \in R^{1 \times d_e}$ are trainable parameters. Then, $I_i \in R^{1 \times d_e}$ is the visual representation of picture p_i.

User's Feature Extraction.

Feature	Dimension	Description
Gender	3	(1,0,0)for male, (0,1,0)for female and (0,0,1) for 'Unknown'.
Screen name length	1	The length of screen name.
Post Count	1	The number of posts.
Follower	1	The number of followers.
Following	1	The number of following.
Picture	1	The number of posts with picture.
Post time	4	The four dimensions are proportions of posts posted in (0:00-5:59), (6:00-11:59), (12:00-17:59), (18:00-23:59) of a day.

Table 3: Summary of user's features.

As illustrated in table 3, we extract 12 features $F \in R^{12\times1}$ from user' profile and posting behaviour. Since not every one has tree hole's data, in this study we do not consider tree hole's data in suicide risk detection model.

4.2 Suicide Risk Detection

Given textual representation $\hat{H}_i$ and visual representation I_i, we employ a concatenate operation $\oplus$ to obtain the post representation $E_i \in R^{2d_e\times1}$ for a single post (s_i, p_i):

$$E_i = \hat{H}_i \oplus I_i^T \tag{6}$$

Similar with above, we employ another LSTM layer and attention mechanism to generate global post representation $G \in R^{30\times1}$:

$$\begin{aligned} h_t &= \textbf{LSTM}(E_i, h_{t-1}), \\ Att_II &= softmax(H^g W_5 + b_5), \\ G &= tanh(((Att_II)^T \times H^g)W_6 + b_6), \end{aligned} \tag{7}$$

where h_{t-1}, h_t represent the hidden states at time $t-1$ and t. $H^g = \{h_1, h_2, ..., h_m\} \in R^{m\times d_e}$ represents the primary post representation of a user after LSTM layer. As not every post of a user expresses the ideation of suicide, we apply the **attention mechanism *Att_II*** to gain the high suicide risk post information of H^e. An attention vector $Att_II \in R^{m\times1}$ was computed to present the different risk weight of posts, where $W_5 \in R^{d_e\times1}$ and $b_5 \in R^{1\times1}$ stand for trainable parameters. Then based on attention Att_II, we obtain the global post representation G for a user, where $W_6 \in R^{d_e\times30}$ and $b_6 \in R^{1\times30}$ stand for trainable parameters.

Finally, we apply a concatenate operation to jointly consider G and F, and through a fully connected layer to compute the possibility of suicide:

	Users	Posts	Posts with image
suicide	3,652	252,901	93,461
non-suicide	3,677	491,130	260,667

Table 4: Statistic of suicide data set.

$$[y_1, y_0] = softmax((G \oplus F)^T W_7 + b_7) \tag{8}$$

where y_1, y_0 represent the possibility of a user at risk of suicide or not, $W_7 \in R^{42\times2}$ and $b_7 \in R^{1\times2}$ stand for trainable parameters.

5 Experiments

5.1 Data Collection

To make suicide risk detection via social media, we construct two data sets: one from Tree Hole and another from Weibo.

Tree Hole's data set. We studied a suicidal community which exists in the comments of a Chinese student's last posting before the student committed suicide. In March 17, 2012, this student which screen name is "Zoufan" left the last word on Weibo and then committed suicide. For the past seven years, More than 160,000 people gather here and write over 1,700,000 comments which is still continuing to grow. They express their suicidal thoughts, show their tragic experiences and demonstrate their plans of suicide behaviors. In psychology, we can understand this community as a Tree Hole. We crawled all comments from May 1,2018 to April 30, 2019 and selected top 4,000 active users. After that, four doctoral students major in computational mental healthcare were employed to annotate users that whether they are at risk of suicide or not. Specifically, We only decide the user "at suicide risk" based on self-report of

his/her tree hole posts. If a user express clear suicidal thoughts like *"At this moment, I especially want to die. I feel very tired. I really want to be free."* more than 5 times in different days, then we label him/her at suicide risk. Finally we get 190,087 sentences of 3,652 users and the average length per post is 11.96 words.

Suicide data set. To collect users at suicide risk, we crawl user's profile and all created posts in Weibo according to user list from Tree Hole' data set. Besides, we select the users who never submit any post containing expression about suicidal ideation and label them as non-suicide risk. In this case, we discard users whose fans more than 1,500 or posts more than 2,000 because that they may be public figure or organization. The statistic of suicide data set are illustrated in Table 4.

5.2 Data Preprocessing

We carry out the following data preprocessing procedures: 1) **Emoji**. We replace emoji with corresponding word like "happy", "cry" to facilitate our model to understand the emotion of user's post. 2) **URL.** As URL has no use for our detection, we simply remove them from sentences. 3) **Image.** All images posted by users were adjusted to 224×224 for normalized input.

5.3 Experimental Setup

In suicide detection task, we treat recent 100 posts from one user as one sample. After sum up D_2 and D_3, we obtain 7,329 microblog users and training set, validation set and test set contain 6,129, 600, 600 respectively. All sentences are padded to the length of the longest sentence in the data set with word "<PAD>". Batch size is 16 during training process and we use 0.001 as learning rate. Adam Kingma and Ba (2015) is adopted as the optimizer.

We compare suicide-oriented word embeddings with following well-developed word embeddings.

(1) **Word2vec**: The fundamental work for considering the local semantic information of words. We get pre-trained Word2vec word embeddings from Li et al. (2018).

(2) **GloVe**: Context-based unsupervised algorithm, which apply co-occurrence matrix to jointly consider the local and global semantic information. We apply open source tool [2] to train word embeddings on all sentences from Tree Hole's data set.

(3) **Fasttext**: A fast text classification and representation learning model based on Word2vec and hierarchical softmax. Pre-trained FastText word embeddings were obtained from official project [3].

(4) **Bert**: Latest language model based on transformer. We acquire pre-trained Bert model from official project[4] and generate word embedding of each word in a sentence dynamically.

Also, we compare our suicide risk detection model with following well-designed methods.

(1) **LSTM** (Coppersmith et al., 2018): An attention mechanism based Long Short-Term Memory model which can capture contextual information between suicide-related words and others.

(2) **Naive Bayesian (NB) and Support Vector Machine (SVM)** (Pedregosa et al., 2011): Two representative machine learning methods with well-designed features. We use SC-LIWC information (Cheng et al., 2017) as textual features, saturation, brightness, warm/clear color and five-color theme information (Shen et al., 2018) from picture as visual features and user's behaviour features from table 3.

5.4 Results

Three sets of tests were conducted to evaluate the performance of suicide risk detection model with suicide-oriented word embeddings.

5.4.1 Effectiveness of Suicide-oriented Word Embeddings

We compare the performance of LSTM and SDM with seven word embeddings as illustrated in table 5. We find that without suicide-related dictionary, Bert outperforms other three word embeddings with 2% higher accuracy and 1.5% higher F1-score on both models. After leveraging suicide-related dictionary, suicide-oriented word embeddings based on FastText achieves the best performance with accuracy 88.00% 91.33%, F1-score 88.14%, 90.92% on two models. Obviously, there is a gap between suicide-oriented word embeddings and normal word embeddings which can verify the effectiveness of the former.

5.4.2 Effectiveness of Suicide Risk Detection Model

We compare the performance of four model as shown in table 6. In this case, LSTM and SDM

LSTM	88.00	88.14	76.89	75.32
SDM	**91.33**	**90.92**	**85.51**	**84.77**

Table 6: Performance comparison between different suicide risk detection model, where Acc and F1 represent accuracy and F1-score respectively.

Inputs	Accuracy	F1-score
Text	88.56	87.99
Text+Image	89.22	89.22
Text+User's feature	90.66	90.17
Text+Image +User's feature	**91.33**	**90.92**

Table 7: Ablation test for SDM with different inputs.

employs So-FastText word embeddings as their input. SDM improves the accuracy by over 3.33% and obtains 2.78% higher F1-score on full data set.

5.4.3 Performance on *Harder sub-testset*

To verify the effectiveness of models in dealing with peoples implicit and anti-real contrary expressions on microblog posts, we filter out 130 suicide risk people from test set who do not show obvious suicidal ideation on normal posts. Those 130 people construct a subset of test set named *Harder sub-testset*. After observing the performance of four models as shown in table 6, SDM can keep 8% higher value both in accuracy and F1-score on *Harder sub-testset*, compared with other models, and the decline is smaller than other models. This suggests that SDM performs better than existing models in dealing with people's implicit and anti-real contrary expressions.

5.4.4 Ablation Test for Suicide Risk Detection Model

To show the contribution of different input to the final classification performance, we design an ablation test of SDM after removing different input. All SDMs are based on embedding So-Fasttext. Since not every post contains image and user's features contain missing value, we do not only use images nor user's feature as input of SDMs. As illustrated in table 7, we can see that textual information is a crucial input of our SDM. Besides, user's features play a more important role than visual information. The more modalities we use, the better performance we get.

5.5 Discovery

To further explore the correlation between normal posts and hidden posts from same user, we import *Pearson Correlation Coefficient* (Tutorials, 2014) to manage it. For each user, we obtain a normal vector $V_i^n = \{v_{i,Jan}^n, v_{i,Feb}^n, ..., v_{i,Dec}^n\} \in$

R^{12}, where $v^n_{i,Jan}$ shows the total number of times words/phrases appear in posts for user *i* in January. In a similar way we get a hidden vector $V^h_i = \{v^h_{i,Jan}, v^h_{i,Feb}, ..., v^h_{i,Dec}\} \in R^{12}$. For each normal posts, we also have an attention weight from Att_{II} which represents the suicide risk. Then, similar as above, an attention risk vector $V^a_i = \{v^a_{i,Jan}, v^a_{i,Feb}, ..., v^a_{i,Dec}\} \in R^{12}$ was computed, where $v^a_{i,Jan}$ shows the total suicide risk for user *i* in January. We donate the pearson correlation coefficient $\rho_{n,h,i}$ of V^n_i and V^h_i, $\rho_{a,h,i}$ of V^a_i and V^h_i as the correlation between normal posts and hidden posts , attention and hidden posts for user *i*.

As shown in figure 4, we find that there are high positive linear correlation between normal posts and hidden posts from user 1 with $\rho_{nh} = 0.84$ and high negative linear correlation from user 4 with $\rho_{nh} = -0.7$. For other two suicide risk users, there are not obvious linear correlations with $\rho_{nh} = 0.33, -0.12$ respectively. The phenomenon that correlations ρ_{ah} between attention and hidden posts from four users all higher than 0.6 which means high positive linear correlation, which verify the ability of the two-layered attention mechanism to reveal ones' inner emotional world.

6 Conclusion

In this paper, we explore the uses of tree holes to enhance microblog-based suicide risk detection. Suicide-oriented word embeddings based on tree hole contents are built to strengthen the sensibility of suicide-related lexicons and a two-layered attention mechanism is deployed to grasp intermittently changing points from individuals open blog streams. Based on above word embeddings and attention mechanism, we propose a suicide risk detection model which outperforms the well-designed approaches on benchmark data set. Through experimental results we also find that, our model also performs well on people's implicit and anti-real contrary expressions.

Deep Ordinal Regression for Pledge Specificity Prediction

Shivashankar Subramanian **Trevor Cohn** **Timothy Baldwin**

shivashankar@student.unimelb.edu.au {t.cohn,tbaldwin}@unimelb.edu.au

Abstract

Many pledges are made in the course of an election campaign, forming important corpora for political analysis of campaign strategy and governmental accountability. At present, there are no publicly available annotated datasets of pledges, and most political analyses rely on manual analysis. In this paper we collate a novel dataset of manifestos from eleven Australian federal election cycles, with over 12,000 sentences annotated with specificity (e.g., rhetorical vs. detailed pledge) on a fine-grained scale. We propose deep ordinal regression approaches for specificity prediction, under both supervised and semi-supervised settings, and provide empirical results demonstrating the effectiveness of the proposed techniques over several baseline approaches. We analyze the utility of pledge specificity modeling across a spectrum of policy issues in performing ideology prediction, and further provide qualitative analysis in terms of capturing party-specific issue salience across election cycles.

1 Introduction

Election manifestos play a critical role in structuring political campaigns. Campaign communication can influence a party's reputation, credibility, and competence, which are primary factors in voter decision making (Fernandez-Vazquez, 2014). Among the various campaign-related functions fulfilled by manifestos (Eder et al., 2017), perhaps the most important is the contract they represent between parties and voters in terms of pledges and prioritisation of political issues (Royed et al., 2019). Political scientists have long studied how specific pledges translate into government programs and actual policy (Royed, 1996; Thomson, 2001; Naurin, 2011; Schermann and Ennser-Jedenastik, 2014). Other work relates specific pledges to the issue clarity of a political party through selective emphasis, which complements salience theory (Robertson et al., 1976; Budge and Farlie, 1983; Praprotnik, 2017). For example:

> *we commit ... 30 per cent tax rebate or cash benefit on the cost of private health insurance premiums*

conveys the party's support for private health insurance, and is more verifiable than:

> *we will improve the health system.*

Issue clarity has also been shown to be influenced by a party's ideological position and its role in government (Praprotnik, 2017).

Although pledge specificity prediction is an important task for the analysis of party position, priorities, and post-election policy framing, to date, almost all research has relied on manual analysis. Subramanian et al. (2019) is a recent exception to this, in performing speech act classification over political campaign text, where the class schema includes the distinction between specific and vague pledges (binary specificity class).

In this paper, we perform fine-grained pledge specificity prediction, which is more expressive than binary levels (Li et al., 2016; Gao et al., 2019). We use a class schema proposed by Pomper and Lederman (1980) as detailed in Table 1, which captures seven levels of specificity, forming a non-linear increasing order of commitment and specificity (Pomper and Lederman, 1980). Given the non-linear nature of the scale, we use deep ordinal regression models for this task, with distributional loss (Imani and White, 2018), where we model the output as a uni-modal distribution (Beckham and Pal, 2017). Our goal is to capture the intuition that a pledge with specificity level k, has higher commitment than all the levels $< k$, producing a smoothly varying prediction over the ordinal classes. This can be modeled as a uni-modal

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1729–1740, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

distribution which has a probability mass that decreases on both sides of the most probable class. Lastly, as it is expensive to obtain large-scale annotations, in addition to developing a novel annotated dataset, we also experiment with a semi-supervised approach by using unlabeled text.

The contributions of this paper are as follows: (1) we develop and release a dataset[1] for fine-grained pledge specificity prediction based on election manifestos covering eleven Australian federal election cycles (1980–2016), from the two major political parties — Labor and Liberal; (2) we propose to use deep ordinal regression models for the prediction task, and evaluate the model under sparse supervision scenarios using the teacher–student framework; and (3) we evaluate the utility of pledge specificity towards ideology prediction, and provide further qualitative analysis by correlating model predictions with party-specific issue salience across major policy areas.

2 Related Work

Political manifesto text analysis is a relatively novel application, at the intersection of Political Science and NLP. Research has focused primarily on fine-grained policy topic classification and overall ideology prediction tasks (Volkens et al., 2017; Verberne et al., 2014; Zirn et al., 2016; Subramanian et al., 2018). Most work dealing with pledge specificity analysis in manifestos has been based on manual analysis, as outlined in Section 1.

Specificity is a pragmatic property of text which has been studied across various fields of research. In cognitive linguistics, Dixon (1987) showed that specificity of information in text impacts reading comprehension speed. In Political Science, it has been used to analyze salience, party position and post-election policy framing (see Section 1). There has also been research on the association between text specificity and communication style. In terms of automated specificity analysis, Cook (2016) found specificity in the context of congressional hearings to vary between speakers belonging to the same vs. different ideologies. Namely, it was shown that specificity increases as the ideological distance between the committee chair and the witness decreases. Subramanian et al. (2019) addressed two levels of pledge specificity, as part of speech act classification task. Specificity has also been studied in news (Louis and Nenkova, 2011) and classroom discussion domains (Luo and Litman, 2016; Lugini and Litman, 2017).

These studies have dealt with a restrictive coarse-level analysis (2–3 categories), whereas a fine-grained scale better captures and allows for comparison of election manifestos (Pomper and Lederman, 1980). Gao et al. (2019) was the first attempt at fine-grained text specificity prediction, in the context of social media posts. Here, we target the novel task of fine-grained pledge specificity prediction, which can be used in a range of downstream applications, including capturing party priorities (salience) and ideological position across election cycles.

All the text specificity analysis work in NLP has modeled the task as classification or regression. As the 7-step pledge specificity levels used in this research (Pomper and Lederman, 1980) do not form a single real-valued scale, we model it as an ordinal regression task. Some examples of ordinal regression tasks include sentiment rating prediction (Rosenthal et al., 2017), stages of disease prediction (Gentry et al., 2015), and age prediction (Eidinger et al., 2014). Recent work has shown that adding a distributional (auxiliary) loss alongside a regression loss, and using expectation to obtain the predicted value (Imani and White, 2018), provides label smoothing and improves regression performance (Gao et al., 2017). Approaches based on a uni-modal probability distribution (e.g., Poisson) as output (da Costa et al., 2008; Beckham and Pal, 2017) can be seen as related to the former approach (Imani and White, 2018) where the discrete probability mass function replaces the histogram density. We propose to use a uni-modal distributional loss-based ordinal regression for pledge specificity prediction.

Secondly, as it is difficult to obtain large amounts of labeled data, existing approaches have used semi-supervised learning (Li and Nenkova, 2015; Subramanian et al., 2019). Here we use a cross-view training approach (Clark et al., 2018; Subramanian et al., 2019), where we enforce consensus between the intermediate class distributions or the final real-valued output.

3 Pledge Specificity Dataset

We annotated 22 election manifestos from the Australian Labor and Liberal parties, covering eleven Australian federal election cycles from

[1] https://github.com/shivashankarrs/Pledge-Specificity

Category	Definition	Example	#
Not a pledge	Provide facts; greetings; approval or criticism of policies	*We have modernised Australia's industrial relations system, particularly through the 1996 Workplace Relations Act*	1
Rhetorical pledge	Based on moral values and applies to all irrespective of the party	*We will put our country first*	2
General pledge	Specify intangible goals, and also not the ways to achieve them	*Labor will build a stronger and more productive economy*	3
Continuity pledge	Commit to the maintenance of currently functioning policy	*We will retain the voluntary health insurance system which now covers the great majority of Australians*	4
Goal pledge	Provide tangible outcomes and goals, without providing the means to achieve them	*A Shorten Labor Government will create 2000 jobs in Adelaide*	5
Action pledge	Provide means to achieve the objective, but don't reveal specific details	*We pledge to support effective voluntary family planning, and to recognize officially the link between social and economic development and the willingness of the individual to limit family size*	6
Detailed pledge	Provide clear details of action to achieve an objective	*A re-elected Coalition Government will invest $1 million to support the Exeter Community Precinct*	7

Table 1: Pledge specificity category, definition, example manifesto sentence, and the corresponding specificity value (#).

Specificity	# Sentences	%	Avg. Length
1	8165	67.00	19.5
2	423	3.47	22.0
3	950	7.80	23.4
4	300	2.46	24.6
5	473	3.88	24.8
6	901	7.39	25.2
7	973	7.99	28.5

Table 2: Distribution and length statistics across specificity categories.

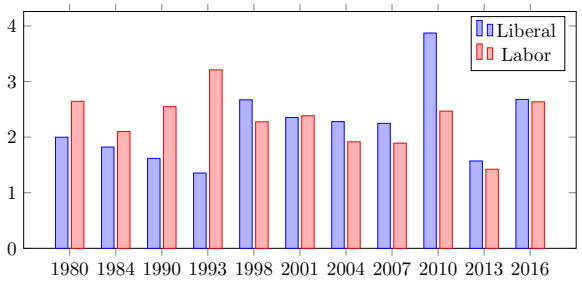

Figure 1: Average pledge specificity of Labor and Liberal parties over different election cycles

1980–2016. The dataset has 12,185 sentences annotated with seven levels of specificity (Pomper and Lederman, 1980). See Table 1 for class definitions and an example of each class. We obtained annotations using the Figure Eight crowdsourcing platform. For each sentence we provided the previous two sentences from the manifesto (as context), the party which published the manifesto, election year, and incumbent and opposition party details. Each sentence was annotated by at least 3 workers after passing quality control (at least 70% accuracy on test questions). After obtaining annotations, the label which has the highest confidence score is chosen for each sentence. Confidence is the level of agreement between multiple contributors, weighted by the contributors' trust scores. Overall agreement based on the Krippendorf's Alpha is $\alpha = 0.58$, indicating moderate agreement (Artstein and Poesio, 2008; Krippendorff, 2011), on par with related studies (Gao et al., 2019). The class distribution in the final dataset is given in Table 2, alongside the average sentence length in tokens. It can be seen that more specific pledge categories have higher average length. Average specificity values of Labor and Liberal party manifestos across elections are given in Figure 1. The length of the manifesto (in terms of number of sentences) influences average specificity values, with exceptions such as the Liberal party's 2010 election manifesto which is the shortest document but has the highest average pledge specificity value. Further detailed analysis, to decipher the pledge specificity trends in general, is a potential task for future work.

4 Proposed Approach

4.1 Base Model

We first obtain representations for each sentence via a sequence of word embeddings, to which we apply a bidirectional GRU ("biGRU": Cho et al. (2014)), and concatenate the final hidden state of both the forward and backward GRUs, $\mathbf{h}_i = \left[\overrightarrow{\mathbf{h}}_i, \overleftarrow{\mathbf{h}}_i\right]$. Rather than using a linear activation layer for the output, we study the effect of learning a distribution over ordinal classes, and using an expectation layer to get the final prediction, which we now expound upon.

4.2 Distributional Loss

Let us assume that the continuous target variable Y is normally distributed, conditioned on inputs $x \in \mathbb{R}^d$, $Y \sim \mathcal{N}(\mu = f(x), \sigma^2)$ for a fixed variance $\sigma^2 > 0$. In regression, the maximum likelihood function f for n samples $\{x_i, y_i\}$ corresponds to minimizing l_2 loss, such that $f(x) = \mathbb{E}(Y|x)$. Alternatively, we can learn a categorical distribution (q_x) over the ordinal classes $\mathcal{Y}$, and use the expected value as the prediction, $f(x)$ (Rothe et al., 2018). In this work, we follow the latter method, but parameterise the categorical distribution based on uni-modal probability distribution, a technique which has been shown to perform well for ordinal regression tasks (Beckham and Pal, 2017). This modification converts the problem to a more difficult (multi-task) problem, that promotes generalization and reduces over-fitting (Imani and White, 2018). The overall objective is to jointly minimize the squared loss for the regression task ($\mathcal{L}_S$), and cross-entropy for the distributional loss over $\mathcal{Y}$ ($\mathcal{L}_D$), based on the objective $\mathcal{L}_J = \alpha\mathcal{L}_S + \mathcal{L}_D$, where the hyper-parameter α is tuned using a validation set. We experiment with different distributions in generating the intermediate representations q_x, including categorical (as a baseline approach, see Section 5: Beckham and Pal (2016); Gao et al. (2017); Rothe et al. (2018)), discrete uni-modal (Binomial and Poisson: Beckham and Pal (2017)), and truncated Gaussian (Imani and White, 2018). The final prediction is obtained using expectation, which has been shown to be effective for various regression tasks in the vision domain. Here we study the use of uni-modal distributional loss-based ordinal regression approaches (Beckham and Pal, 2017; Imani and White, 2018) for text specificity analysis (Section 5 has results demonstrating its superiority over the other choices). We detail the different ways to obtain q_x, and the corresponding loss functions $\mathcal{L}_D$ below, and provide an overall summary in Figure 2.

4.2.1 BINOMIAL

With the biGRU model, we estimate the parameter (p) of the Binomial distribution (with a sigmoid output), based on which the distribution over classes can be obtained via the probability mass function,

$$p(k; K-1, p) = \binom{K-1}{k} p^k (1-p)^{K-1-k},$$

$k \in \{0, 1, \ldots K-1\}$, where $p \in [0, 1]$. As the final layers (post sigmoid) are under-parametrized, we have a softmax layer with τ after obtaining the probability masses,

$$q_k = \frac{\exp(\phi_k/\tau)}{\sum_{j=0}^{K-1} \exp(\phi_j/\tau)},$$

where $\tau \sim \text{SoftPlus}(\tau')$, and τ' is learned by the deep net, conditioned on the input (x). We then have an expectation layer to obtain the final output $f(x)$. Output of the softmax layer is fit to the one-hot encoded ordinal classes for each input ($\mathbf{y}$), by minimizing the cross-entropy loss ($\mathcal{L}_{\mathcal{D}\text{BINOMIAL}}$).

4.2.2 POISSON

POISSON is similar to the binomial case, in that we obtain the parameter (λ) of the Poisson distribution using the biGRU, with a SoftPlus activation. We then use the probability mass function of the Poisson distribution to get the probabilities over different classes, $k \in \mathcal{Y}$,

$$p(k; \lambda) = \frac{\lambda^k e^{-\lambda}}{k!},$$

which is again passed through a softmax layer to obtain q_x, fit by minimizing cross-entropy loss ($\mathcal{L}_{\mathcal{D}\text{POISSON}}$), and an expectation layer is used to obtain the final prediction.

4.2.3 Gaussian (GAUSS)

To compute $\mathbb{E}(Y|x)$ (μ of the Gaussian), here we fit the intermediate distribution q_x directly to histogram density of a truncated Gaussian distribution with support $[1, K]$ (target distribution: p_*). We achieve this by learning a prediction distribution with the biGRU model, $q_x : \mathcal{Y} \rightarrow [0, 1]$. For this, the ordinal label of training instances is transformed into a truncated Gaussian PDF. The mean

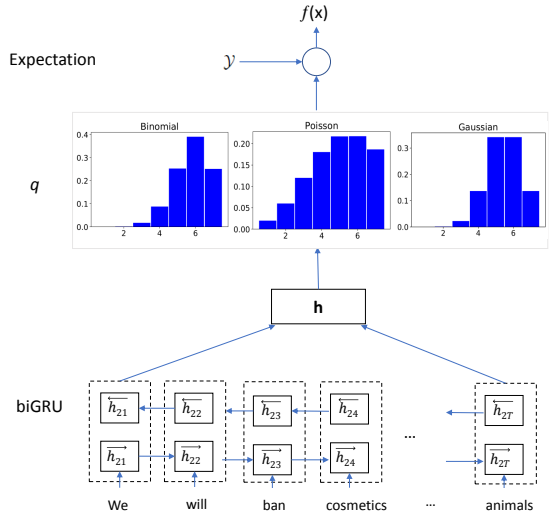

Figure 2: Illustration of the model architecture, comprising a biGRU over sentence tokens, to compute the parameter of one of the three distributions: p for Binomial (with $n = K-1$) and λ for Poisson. *Pmf* of these distributions are then used to define a categorical distribution over the ordinal classes $\mathcal{Y}$. For learning, we use the categorical cross-entropy against the gold *one-hot* y, as well as the squared error $(y - f(x))^2$, where $f(x)$ is given by expectation taken under the predicted categorical distribution q. Gaussian uses a different mechanism, as described in Section 4.2.3 where the categorical distribution (q) is predicted directly using a K-dimensional softmax output, and the cross-entropy is computed between q and a Gaussian histogram density centred at $\mu = y$, discretised by way of integration of the PDF between adjacent label indices.

μ for this Gaussian is the target y of each datapoint, with fixed variance σ^2, which we set to the radius of the bins in $\mathcal{Y}$ (1 in this case). The CDF for the chosen target distribution is computed as $\frac{1}{2}(1 + \text{erf}(\frac{x-\mu}{\sigma\sqrt{2}}))$ and p_* is obtained for each class, k $\in \mathcal{Y}$, as,

$$\frac{1}{2}\left(\text{erf}\left(\frac{k-\mu}{\sigma\sqrt{2}}\right) - \text{erf}\left(\frac{k-1-\mu}{\sigma\sqrt{2}}\right)\right).$$

This formulation allows efficient computation of divergence between p_* and q_x for optimization, which results in cross-entropy minimization ($\mathcal{L}_{\mathcal{D}\text{GAUSS}}$: Imani and White (2018)). Note that the training target p_* is uni-modal, and no constraints are *explicitly* enforced on the shape of q_x.

4.3 Incorporating Context

We incorporate context in the form of information from adjacent sentences following the approach of Liu et al. (2017): for each training sentence, we use the predicted (intermediate) probability distribution across ordinal classes of the previous L sentences as context. A new biGRU model is trained with the sentence and the additional contextual information, concatenated to $\mathbf{h}_i$. We refer to this model as biGRU$_{\text{ORD+CONTEXT}}$. In the test phase, biGRU$_{\text{ORD}}$ provides contextual information, and the newly trained model (biGRU$_{\text{ORD+CONTEXT}}$) is used to predict the test sentence output.

4.4 Semi-supervised Learning

As it is expensive to get large-scale specificity annotations we employ a cross-view training approach (Clark et al., 2018; Subramanian et al., 2019) for semi-supervised learning, which can leverage additional unlabeled text. Cross-view training is a kind of teacher–student method, whereby the model "teaches" a "student" model to classify unlabelled data. The student has a restricted view over the data, e.g., through the application of noise (Sajjadi et al., 2016; Wei et al., 2018). We use biGRU$_{\text{ORD+CONTEXT}}$ with word-level dropout and zero vector set to contextual information as the auxiliary model. This procedure regularizes the learning of the teacher to be more robust, as well as increasing its exposure to unlabeled text. We augment our dataset with over 32k sentences from UK and US election manifestos released from the same time period. On these unlabeled examples, the model's output is used to fit the auxiliary model by enforcing consensus in their predictions. This consensus loss $\mathcal{L}_{\text{U}}$ is added to the supervised training objective ($\mathcal{L}_J$). Under the semi-supervised setting, we evaluate the following approaches:

- MSE: use the final regression output of the teacher model ($f(x)$) to fit an auxiliary model, thereby enforcing consensus using a squared loss, MSE($\mathbb{E}_{q_\theta}[\mathcal{Y}], \mathbb{E}_{q_\omega}[\mathcal{Y}]$) where $\mathcal{Y}$ is a fixed class vector; denoted as "$\mathcal{L}_{\text{UMSE}}$".
- KLD: an intermediate distribution over targets $q_\theta(\mathcal{Y}|s)$ is used to fit an auxiliary model, $q_\omega(\mathcal{Y}|s)$, by minimising the Kullback-Leibler (KL) divergence, KL($q_\theta(\mathcal{Y}|s), q_\omega(\mathcal{Y}|s)$); denoted as "$\mathcal{L}_{\text{UKLD}}$".[2]
- EMD: $q_\theta(\mathcal{Y}|s)$ is again used to fit the auxiliary model, $q_\omega(\mathcal{Y}|s)$, by minimising the earth

[2]This is the closest setting to Subramanian et al. (2019), which minimizes KL divergence between output distributions in a classification setting. But the overall objective is different in our case, in that we have an expectation layer over q to obtain the target regression output.

Category	Approach	MMAE	ρ
	Majority	3	-
	Length	-	0.21
	Speciteller	-	0.18
	NN_{REG}	2.05	0.33
	$\text{biGRU}_{\text{REG}}$	1.83	0.47
	$\text{biGRU}_{\text{CLASS}}$	2.17	0.40
	$\text{biGRU}_{\text{REG}_{l_1}}$	1.99	0.46
Ordinal	$\text{biGRU}_{\text{CATEGORICAL}}$	1.80	0.48
Ordinal	$\text{biGRU}_{\text{BINOMIAL}}$	1.78	0.48
Ordinal	$\text{biGRU}_{\text{POISSON}}$	1.90	0.41
Ordinal	$\text{biGRU}_{\text{GAUSS}}$	1.72	**0.49**
Ordinal	$\text{biGRU}_{\text{GAUSS + CONTEXT}}$	**1.71**	**0.49**

Table 3: Specificity prediction performance; the best approach is given in bold.

mover's distance, $\text{EMD}(q_\theta(\mathcal{Y}|s),\ q_\omega(\mathcal{Y}|s))$; denoted as "$\mathcal{L}_{\text{UEMD}}$". EMD is defined as $\text{EMD}(q_\theta, q_\omega) = \frac{1}{K}^{\frac{1}{l}} \|\text{cmf}(q_\theta) - \text{cmf}(q_\omega)\|_l$, where $\text{cmf}(\cdot)$ is the cumulative mass function for the predicted (intermediate) probability distribution q, and we use $l = 2$. EMD considers distance between classes, and is more suitable for ordinal tasks (Hou et al., 2016).

5 Experimental Results

To evaluate model performance we use macro-averaged mean absolute error (MMAE: Rosenthal et al. (2017)) given the class imbalance, and Spearman's ρ. MMAE is given as $\frac{1}{|K|}\sum_{j=1}^{|K|}\frac{1}{|S_j|}\sum_{x_i \in S_j}|f(x_i) - y_i|$, where S_j denotes the subset of instances annotated with (true) ordinal class j. We consider the following baselines:

Majority: assign the majority class in the training set to all test instances.

Length: use sentence length as the specificity score.

Speciteller: co-training model of Li and Nenkova (2015), used by Cook (2016) for congressional hearings specificity analysis.

NN_{REG}: bag-of-words term-frequency representation, fed into a feed-forward neural network model (Gao et al., 2019).

$\text{biGRU}_{\text{REG}}$: biGRU model trained with a mean squared loss objective.

$\text{biGRU}_{\text{CLASS}}$: biGRU model trained with a cross-entropy objective (Subramanian et al., 2019).

$\text{biGRU}_{\text{REG}_{l_1}}$: biGRU regression model with mean absolute error objective (l_1 loss).

All the baseline and proposed biGRU models use ELMo embeddings (Peters et al., 2018). The regression models minimize l_2 loss, unless otherwise specified. We compare the average performance across five runs with an 80:20 train:test split. We randomly choose 10% of instances from the training set as validation data. We compare the baseline approaches with our proposed ordinal approaches, which have an intermediate distributional loss in conjunction with the final prediction loss: $\text{biGRU}_{\text{GAUSS}}$ (Section 4.2.3), $\text{biGRU}_{\text{BINOMIAL}}$ (Section 4.2.1), or $\text{biGRU}_{\text{POISSON}}$ (Section 4.2.2). We also evaluate $\text{biGRU}_{\text{CATEGORICAL}}$, where the softmax layer is fitted to one-hot encoded class labels (Gao et al., 2017; Rothe et al., 2018). Note that this is not uni-modal.

Gao et al. (2019) used a combination of bag-of-words representation, surface features, social-media-specific features (eg., Tweet mentions), and emotion-related features, with a support vector regression model which minimizes squared loss. Social media and emotion-related attributes are not relevant to our data, and other surface features did not provide improvements. Hence we show the performance of the bag-of-words representation with squared loss objective (NN_{REG} in Table 3). From the results in Table 3, we can see that sequential models with ELMo embeddings (biGRU) perform better than neural bag-of-words models (NN_{REG}). The l_2 regression model ($\text{biGRU}_{\text{REG}}$) performs better than l_1 regression ($\text{biGRU}_{\text{REG}_{l_1}}$) and classification ($\text{biGRU}_{\text{CLASS}}$).

With respect to deep ordinal approaches, $\text{biGRU}_{\text{POISSON}}$ performs better than classification ($\text{biGRU}_{\text{CLASS}}$), but does not improve upon regression ($\text{biGRU}_{\text{REG}}$). The Binomial performs better than the Poisson, consistent with previous work (Beckham and Pal, 2017; da Costa et al., 2008). $\text{biGRU}_{\text{CATEGORICAL}}$ performs better than $\text{biGRU}_{\text{REG}}$, but not over unimodal approaches ($\text{biGRU}_{\text{BINOMIAL}}$, $\text{biGRU}_{\text{GAUSS}}$). Overall, the model which fits intermediate distribution to a truncated Gaussian (histogram density) target distribution provides the best performance. It gives over 6% improvement in terms of MMAE, and over 4% in ρ, compared to $\text{biGRU}_{\text{REG}}$. Adding context to $\text{biGRU}_{\text{GAUSS}}$ ($\text{biGRU}_{\text{GAUSS+CONTEXT}}$) provides a slight reduction in error.

5.1 Semi-supervised Learning

We next compare the performance of $\text{biGRU}_{\text{GAUSS+CONTEXT}}$ (SUP) and the semi-

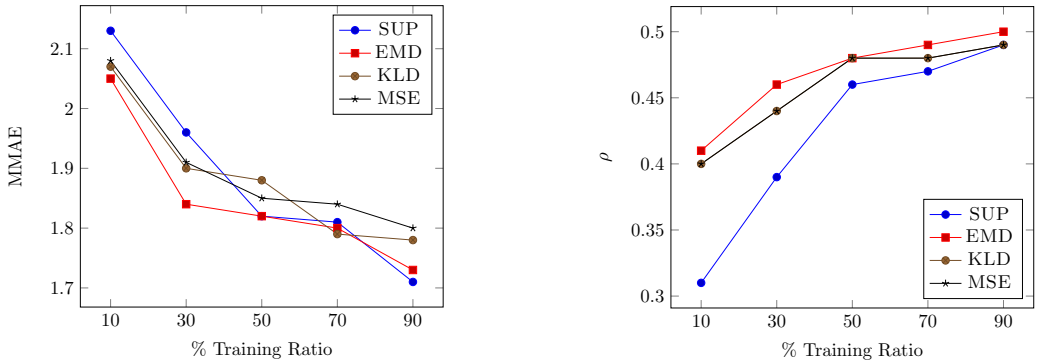

Figure 3: Prediction performance across different training ratios. Note that 90% = all the training data, as 10% is used for validation. The supervised ordinal model (SUP) and semi-supervised teacher–student models (MSE, KLD, EMD, given in Section 4.4) are compared on MMAE and Spearman's ρ.

supervised extensions of it (Section 4.4) which leverage additional unlabeled data: minimizing $\mathcal{L}_{\text{UMSE}}$ (MSE), $\mathcal{L}_{\text{UKLD}}$ (KLD), and $\mathcal{L}_{\text{UEMD}}$ (EMD). The amount of labeled data in the training split is varied from 10% to 90%. Results are presented in Figure 3 for MMAE and ρ. From the results, semi-supervised approaches provide large gains in terms of both MMAE and ρ, especially when training with fewer instances, ratio $\leq$ 30%. Overall, the semi-supervised learning approach which minimizes EMD performs best across all training ratios compared to both supervised and other semi-supervised approaches. It provides .10 and .06 absolute improvements in ρ under sparse supervision scenarios (10% and 30% of training data, resp.). Even under richer supervision settings ($\geq$ 70 %), it provides higher ρ.

6 Political Analysis Using the Models

Political scientists utilize pledge specificity for a variety of applications (see Section 1). Here, we extrinsically evaluate our specificity model using two tasks related to campaign strategy: (1) party position or ideology prediction (Section 6.1), and (2) issue salience analysis (Section 6.2). For both tasks, we compare the use of pledge specificity across policy issues vs. a count-based representation of policy mentions.

6.1 Ideology Prediction

Estimating the manifesto-level ideology score on the left–right spectrum using sentence-level policy topic annotations is a popular task (Slapin and Proksch, 2008; Lowe et al., 2011; Däubler and Benoit, 2017; Subramanian et al., 2018), for which the policy scheme provided by CMP (Volkens et al., 2017) is commonly used. It has 57 political themes, across 7 major categories. Among those approaches, the RILE index is the most widely adopted (Merz et al., 2016; Jou and Dalton, 2017), and has been shown to correlate highly with other popular scores (Lowe et al., 2011). RILE is defined as the difference between count of (pre-determined) right and left policy theme mentions across sentences in a manifesto (Volkens et al., 2013). Here we evaluate the effectiveness of using the proposed specificity modeling across those policy issues, compared to using RILE-based party position scores (Volkens et al., 2013).

We compute the specificity weight (Pomper and Lederman, 1980) from the average specificity score across sentences, $\frac{1}{|I|}\sum_{S_i \in I} \text{Spec}(S_i)$ for each policy issue (I). With specificity weight as the basic feature, we also model global signals such as party coalition and temporal dependencies across elections, which can enforce smoothness in manifesto positions (Greene, 2016; Subramanian et al., 2018) based on probabilistic soft logic.

6.1.1 Probabilistic Soft Logic

To address this, we propose an approach using hinge-loss Markov random fields ("HL-MRFs"), a scalable class of continuous, conditional graphical models (Bach et al., 2013). These models can be specified using Probabilistic Soft Logic ("PSL": Bach et al. (2017)), a weighted first order logical template language. An example of a PSL rule is $\lambda : \texttt{P(a)} \wedge \texttt{Q(a,b)} \rightarrow \texttt{R(b)}$, where P, Q, and R are predicates, a and b are variables, and λ is the weight associated with the rule. PSL uses soft

truth values for predicates in the interval $[0, 1]$. The degree of ground rule satisfaction is determined using the Lukasiewicz t-norm and its corresponding co-norm as the relaxation of the logical AND and OR, respectively. The weight of the rule indicates its importance in the HL-MRF probabilistic model, which defines a probability density function of the form:

$$P(\mathbf{Y}|\mathbf{X}) \propto \exp\left(-\sum_{r=1}^{M} \lambda_r \phi_r(\mathbf{Y}, \mathbf{X})\right),$$

where $\phi_r(\mathbf{Y}, \mathbf{X}) = \max\{l_r(\mathbf{Y}, \mathbf{X}), 0\}^{\rho_r}$ is a hinge-loss potential corresponding to an instantiation of a rule, and is specified by a linear function l_r and optional exponent $\rho_r \in \{1, 2\}$.

6.1.2 PSL Model

Here we elaborate on our PSL model based on manifesto content-based features (specificity weight across 57 policy issues), coalition information, and temporal dependencies. Our target `pos` (left–right position) is a continuous variable $[0, 1]$, where 1 indicates an extreme right position, 0 denotes an extreme left position, and 0.5 indicates center. We also model the social and economic positions explicitly (`socpos` and `econpos`), which influence the overall `pos`. Each instance of a manifesto, its party affiliation and policy issues, are denoted by the predicates `Manifesto`, `Party` and `Policy`. Other predicates are given as follows:

- **Specificity weight** of each policy issue in the given manifesto (`Specw`).
- **Relative specificity scale**: ratio of specificity weight for each policy issue given a party's manifesto, to maximum specificity weight for the same policy issue across parties from the same country and election (`SpecScale`).
- **Policy issue mapping**: 26 out of the 57 policy themes are categorized as social and economic left–right issues by Benoit and Laver (2007) (`IdeologyMap`).
- **Coalition**: captures the strength of ties between two parties, given by a logistic transformation of the number of times two parties have been in a coalition in the past (`Coalition`).
- **Temporal dependency** between a party's current manifesto position and its previous manifesto position (`PreviousManifesto`).

Representative rules of our PSL model, based on the predicates presented above, are given in Table 4. They include:

- **Specificity**: if a manifesto contains more specific pledges related to social (or economic) left/right policies, then it will more likely be a social (or economic) left/right-aligned manifesto.
- **Overall position**: social and economic position influences the overall position, and this allows the model to place different weights on the influence of social and economic policies on the overall position, which is found to be necessary by Benoit and Laver (2007).
- **Global signals**: coalition and temporal dependencies to enforce smoothness in manifesto positions.
- **Relative specificity**: `SpecScale` of a left (or right) policy during an election amplifies its overall position scores.

6.1.3 Evaluation

We use manifestos from Australia and UK for our analysis. We use data from Voter Survey (Cameron and McAllister, 2019) for Australia and CHES Expert Survey (Bakker et al., 2015) for the UK as the gold-standard party position. A primary step (related to the model given in Section 6.1.2) is to obtain policy topic classification for sentences in each manifesto. If annotations are not available from Volkens et al. (2017), one out of 57 political themes are predicted using the method of Subramanian et al. (2018). Specificity scores of sentences are obtained using the proposed ordinal regression approach (biGRU$_{\text{GAUSS+CONTEXT}}$). Using social, economic and a combined list of left–right policy themes (`IdeologyMap`), and with the RILE formulation, we bootstrap `socpos`, `econpos` and `pos`. We then use the PSL model (Table 4) to recalibrate the scores based on specificity scores and the global signals.

We compare the performance of bootstrapped `pos` (RILE or policy count-based) with the PSL model. Principal component analysis ("PCA": Gabel and Huber (2000)) on the frequency distribution, and projection on its principal component, is used as an additional baseline. Spearman's correlation (ρ) against the gold-standard positions is given in Table 5. Overall, pledge specificity, especially on a relative scale (which differentiates emphasis between parties) provides large gains, and global signals give only mild improvements.

Specificity Weight — Model I
$\texttt{Manifesto(x)} \wedge \texttt{Policy(I)} \wedge \texttt{Specw(x, I)} \wedge \texttt{IdeologyMap(I, social left/right)} \rightarrow \texttt{socpos(x)}$ $\texttt{Manifesto(x)} \wedge \texttt{Policy(I)} \wedge \texttt{Specw(x, I)} \wedge \texttt{IdeologyMap(I, economic left/right)} \rightarrow \texttt{econpos(x)}$
Overall position — Model II
$\texttt{Manifesto(x)} \wedge \texttt{socpos(x)} \rightarrow \texttt{pos(x)}$ $\texttt{Manifesto(x)} \wedge \texttt{econpos(x)} \rightarrow \texttt{pos(x)}$
Global signals — Model III
$\texttt{Manifesto(x)} \wedge \texttt{Party(x, a)} \wedge \texttt{Manifesto(y)} \wedge \texttt{Party(y, b)} \wedge \texttt{Coalition(a, b)} \wedge \texttt{pos(x)} \rightarrow \texttt{pos(y)}$ $\texttt{Manifesto(x)} \wedge \texttt{Party(x, a)} \wedge \texttt{PreviousManifesto(x, t)} \wedge \texttt{Party(t, a)} \wedge \texttt{pos(t)} \rightarrow \texttt{pos(x)}$
Relative specificity — Model IV
$\texttt{Manifesto(x)} \wedge \texttt{Policy(I)} \wedge \texttt{SpecScale(x, I)} \wedge \texttt{IdeologyMap(I, social left/right)} \rightarrow \texttt{socpos(x)}$ $\texttt{Manifesto(x)} \wedge \texttt{Policy(I)} \wedge \texttt{SpecScale(x, I)} \wedge \texttt{IdeologyMap(I, economic left/right)} \rightarrow \texttt{econpos(x)}$

Table 4: PSL Model: Representative rules. `left/right` in the `IdeologyMap` predicate indicates policy issues mapped to left/right categories, which is implemented as two separate rules — one for left and another for right.

Model	Aus	UK
bootstrapped pos	0.66	0.39
PCA	0.11	0.39
Model I + II	0.63	0.33
Model I + II + III	0.65	0.33
Model I + II + III + IV	**0.71**	**0.45**

Table 5: Spearman's ρ for prediction of party position based on the different models.

Policy Area	**C**	**S**
Health	824.92	905.19
Education	781.15	905.54
Environment	841.89	897.53
Tax	735.97	824.69
Economy	258.30	276.71

Table 6: Log-likelihood with pledges specificity weight (**S**) and count of sentences (**C**) across 57 policy themes as independent variables. Log-likelihood values using **S** are better than **C** across all the policy areas.

6.2 Capturing Issue Salience

For the Australian manifestos (from the Greens, Labor, Liberal, and National parties) we perform a qualitative study of specificity weight across policy themes, by correlating it against the salience of major policy areas given by the Voter Survey (Cameron and McAllister, 2019). Again we compare its utility over the use of counts across policy themes in a manifesto. Using sentences classified with policy themes and specificity scores using our proposed approach, we construct the following $|\text{Manifestos}| \times 57$ features — frequency distribution (**C**) and pledge specificity weight (**S**) across policy themes. The features are used as independent variables, and voter survey salience scores across major policy areas — health, education, environment, tax, and economy — are treated as dependent variables. Note that the voter survey scores are available for each party and election cycle across policy areas. We build separate multivariate linear regression models and compare them based on the goodness of fit (log-likelihood). Log-likelihood values are given in Table 6: across all policy areas, pledge specificity better captures salience than a count-based representation.

7 Conclusion and Future Work

In this work we present a new dataset of election campaign texts, annotated with pledge specificity on a fine-grained scale. We study the use of deep ordinal regression approaches using an auxiliary uni-modal distributional loss for this task. The proposed approaches provide large gains in performance under both supervised and semi-supervised settings. Specificity weight across policy issues benefits ideology prediction and also better captures issue salience, compared to the traditional policy theme count-based representation. This aligns with previous studies done based on manual annotations (Praprotnik, 2017). In future work, we aim to expand this study to multiple languages.

Abstract

Goal-oriented dialogue systems are now being widely adopted in industry where it is of key importance to maintain a rapid prototyping cycle for new products and domains. Data-driven dialogue system development has to be adapted to meet this requirement — therefore, reducing the amount of data and annotations necessary for training such systems is a central research problem.

In this paper, we present the Dialogue Knowledge Transfer Network (DiKTNet), a state-of-the-art approach to goal-oriented dialogue generation which only uses a few example dialogues (i.e. few-shot learning), none of which has to be annotated. We achieve this by performing a 2-stage training. Firstly, we perform *unsupervised dialogue representation pre-training* on a large source of goal-oriented dialogues in multiple domains, the MetaLWOz corpus. Secondly, at the *transfer stage*, we train DiKTNet using this representation together with 2 other textual knowledge sources with different levels of generality: ELMo encoder and the main dataset's source domains.

Our main dataset is the Stanford Multi-Domain dialogue corpus. We evaluate our model on it in terms of BLEU and Entity F1 scores, and show that our approach significantly and consistently improves upon a series of baseline models as well as over the previous state-of-the-art dialogue generation model, ZSDG. The improvement upon the latter — up to **10%** in Entity F1 and the average of **3%** in BLEU score — is achieved using only **10%** equivalent of ZSDG's in-domain training data.

1 Introduction

Machine learning-based dialogue systems, while still being a relatively new research direction, are experiencing increasingly wide adoption in industry. Large-scale dialogue assistant platforms such as *Google Assistant, Amazon Alexa, and Apple Siri* provide a unified conversational user interface (CUI) for third-party applications and services. Furthermore, products like *Google Dialogflow, Wit.ai, Microsoft LUIS, and Rasa* offer means for rapid development of a dialogue system's core modules. In addition, with the recently adopted technique of training dialogue systems end-to-end *data-efficiency* of such systems becomes the key question in their adoption in practical applications. Currently, while being extremely flexible and requiring little to no programming of in-domain business logic (see e.g. Ultes et al. (2018); Wen et al. (2017); Rojas-Barahona et al. (2017)), such systems have too high data consumption — including both collection and annotation effort — in order for them to be used in rapidly paced industrial product cycles. Therefore, approaches to training such systems with extremely limited data (i.e. zero-, one- and few-shot training) are a priority research direction in the dialogue systems area.

In this paper, we present the *Dialogue Knowledge Transfer Network* (or DiKTNet), a generative goal-oriented dialogue model designed for few-shot learning, i.e. training only using a small number of complete in-domain dialogues. The key underlying concept of this model is transfer learning: DiKTNet makes use of the latent text representation learned from several sources ranging from large-scale general-purpose textual corpora to similar dialogues in the domains different to the target one. We use the evaluation framework of Zhao and Eskénazi (2018) and the same dataset, and mainly compare our approach to theirs. While their method doesn't require complete in-domain dialogues and uses annotated utterances instead (and is therefore described as "zero-shot"), we show that our model achieves superior performance with roughly the same amount of data (with

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

respect to in-domain utterances) while requiring no annotations whatsoever.

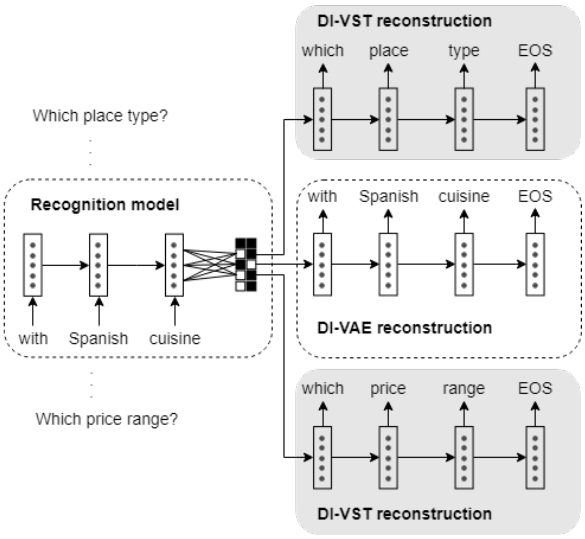

Figure 1: DI-VAE and DI-VST (DiKTNet Stage 1)

2 Related Work

The problem of data efficiency of dialogue systems has been extensively researched in the past. Starting with domain adaptation of a dialogue state tracker (Henderson et al., 2014) approached using Bayesian Processes (Gasic et al., 2017) and Recurrent Neural Networks (Mrksic et al., 2015), there has been significant work on training different dialogue system components using as little data as possible. As such, Williams et al. (2017) introduced a dialogue management model designed for bootstrapping from limited training data and further fine-tuning. A recent paper by Vlasov et al. (2018) introduced a dialogue management model which uses a unified embedding space for user and system turns allowing efficient cross-domain knowledge transfer.

There also exist approaches to end-to-end dialogue generation. Eshghi et al. (2017) proposed a linguistically informed model based on an incremental semantic parser (Eshghi et al., 2011) combined with a reinforcement learning-based agent. The parser was used for both maintaining the agent's state and pruning the agent's incremental, word-level generation actions (only the actions leading to syntactically correct word sequences were allowed for the agent to take). While outperforming end-to-end dialogue models on bAbI Dialog Tasks in a zero-shot setup (Shalyminov et al., 2017) due to its prior linguistic knowledge in the form of a dialogue grammar, this method inherited the limitations of it as well. Specifically, it's limited to a single domain until a wide-coverage grammar is available.

Meta-learning has also gained a lot of attention as a way to train models for maximally efficient adaptation to new data. As such, Qian and Yu (2019) presented such approach for fast adaptation of a dialogue model to a new domain. While highly promising, its main result was achieved on a synthetic dataset and would ideally need more testing on real data.

Finally, the method we directly compare our approach to is that of Zhao and Eskénazi (2018) who introduced the Zero-Shot Dialogue Generation (ZSDG) task and the corresponding model. In their work, they use a unified latent space for user utterances, system turns, and *domain descriptions* in the form of utterance-annotation pairs. Since they only used such utterances and no full dialogues for the target domain, they presented this approach as "zero-shot" learning. In our approach, we do use complete in-domain dialogues, but with significantly less data with respect to the number of in-domain utterances. Moreover, our method requires no annotation whatsoever.

Recent research in Natural Language Processing has shown that the transfer of text representation learned on larger data sources benefits target models' performance, just as was the case with ImageNet-based computer vision models (Deng et al., 2009).

For text, the main means for transfer was Word2Vec and GloVe embeddings (Mikolov et al., 2013; Pennington et al., 2014) recently extended with context-aware models like ELMo (Peters et al., 2018) and BERT (Devlin et al., 2018). Trained on large and diverse textual corpora, they were shown to improve target models' performance on a number of Natural Language Processing tasks. Although highly beneficial, those models' use may not be sufficient for the case of dialogue as response generation for goal-oriented dialogue from extremely limited data requires specialized tools. General-purpose embeddings lack specificity for close dialogue domains since they have been learned from very heterogeneously distributed data: in dialogue, the distribution of word sequences is highly specific to a given domain or task, i.e. word sequences in dialogue can take on an astonishingly wide variety of meanings in dif-

ferent contexts.

In this paper, we will work with *autoencoders*, a class of unsupervised text representation models working via reconstructing the input — specifically, a Variational Autoencoder (VAE) was considered the main means to learn robust text representations (Bowman et al., 2016). Although the model itself was challenging to train and was mainly used with plenty of workarounds, and recently there started to appear variants of this model with improved stability. One such model we will use in this paper is that of Zhao et al. (2018) (see Section 4.1 for more detail).

3 Few-Shot Dialogue Generation

We first describe the task we are addressing in this paper, and the corresponding base model. Specifically, we have a set of dialogues in source domains and just a few seed dialogues in the target domain. And the model's task is, having been trained on all the available *source data*, to fine-tune on the *target data* to be further evaluated on the full set of target-domain dialogues.

We are basing our model for this task on a Hierarchical Encoder-Decoder (HRED) architecture with attention-based copying (Merity et al., 2017). The base optimization objective is as follows:

$$\mathcal{L}_{\text{HRED}} = \log p_{\mathcal{F}^d}(\boldsymbol{x}_{\text{sys}} \mid \mathcal{F}^e(\boldsymbol{c}, \boldsymbol{x}_{\text{usr}})) \quad (1)$$

where $\boldsymbol{x}_{\text{usr}}$ is user's query, $\boldsymbol{x}_{\text{sys}}$ is the system's response, $\boldsymbol{c}$ is the dialogue context, and $\mathcal{F}^e$ and $\mathcal{F}^d$ are respectively hierarchical encoder and decoder.

We work with goal-oriented dialogues, so it's natural in our setting to take into account an underlying Knowledge Base (or API) providing results on the user's queries. Given that such KB information may contain unseen token sequences for the most part, especially in the target domain, we use a copy mechanism in order to be able to use this information in the system's responses. More specifically, we represent KB info as token sequences and concatenate it to the dialogue context similarly to CopyNet setup of Eric et al. (2017). Our copy mechanism's implementation is the Pointer-Sentinel Mixture Model (Merity et al., 2017; Zhao and Eskénazi, 2018):

$$p(w_t \mid s_t) = g p_{\text{vocab}}(w_t \mid s_t) + (1 - g) p_{\text{ptr}}(w_t \mid s_t) \quad (2)$$

In the formula above, w_t and s_t are respectively the output word and the decoder state at step t; p_{ptr} is the probability of attention-based copying of the word w_t, and g is the mixture weight:

$$p_{\text{ptr}}(w_t \mid s_t) = \sum_{k_j \in I(w, \boldsymbol{x})} \alpha_{k_j, t} \quad (3)$$

$$g = \text{Softmax}(u^T \tanh(W_\alpha s_i)) \quad (4)$$

where $\alpha_{k_j,t}$ is the attention weight for kth token in flattened dialogue context at the decoding step t and u is the sentinel vector — for more detail, see (Zhao and Eskénazi, 2018).

4 Dialogue Knowledge Transfer Network

Transfer learning is considered the key means for efficient training with minimal data, and our DiKTNet model essentially introduces several knowledge-transfer augmentations to the base HRED model described above. DiKTNet training is performed in two stages described below.

4.1 Stage 1. Dialogue representation pre-training

Dialogue structure — e.g. word sequences — is highly specific to a given domain or task, and the meaning of conversational utterances is highly contextual, i.e. similar utterances may have different meanings depending on the context. Nevertheless, there is a lot of similarity in dialogue structure — i.e. sequences of dialogue actions — across domains, e.g. a conversation normally starts with a mutual greeting and a question is very often followed by an answer. Here, we propose to exploit this phenomenon in the form of learning a latent dialogue action representation in order to better capture the dialogue structure by abstracting away from surface forms. Crucially, we learn such representation from MetaLWOz (Lee et al., 2019), a dataset specifically created for the purposes of meta-learning and transfer learning and consisting of human-human conversations in 51 unique domains (for more detail, see Section 6).

For this stage of training we use unsupervised, variational autoencoder-based (VAE) representation learning following the *Latent Action Encoder-Decoder (LAED)* approach of Zhao et al. (2018). LAED's underlying model is called *Discrete Information VAE (DI-VAE)*, a variant of a VAE with

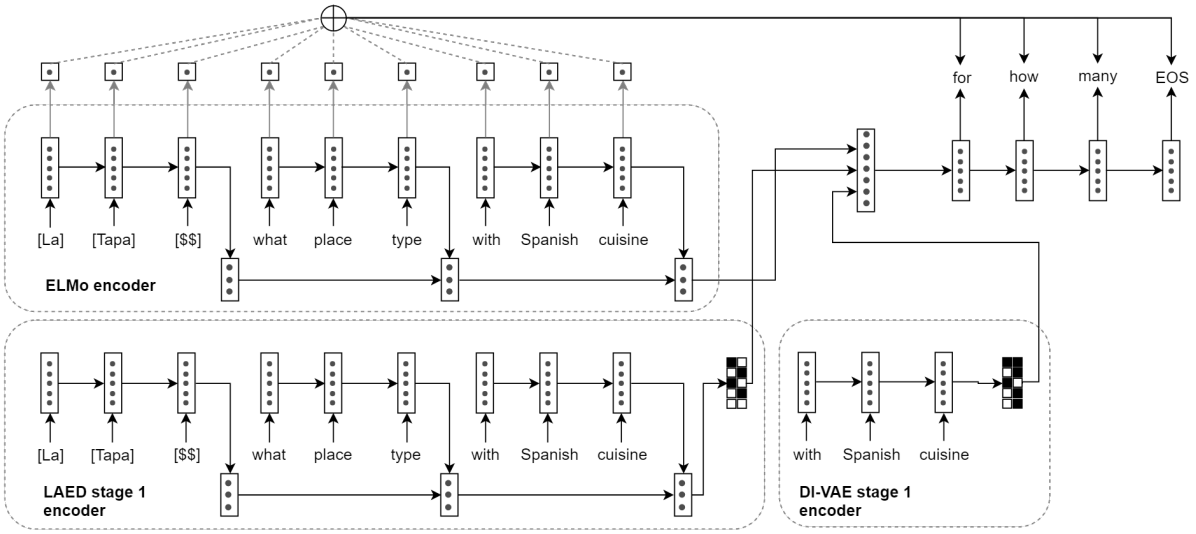

Figure 2: DiKTNet Stage 2 (tokens in brackets are KB data)

two modifications. Firstly, its optimization objective accounts for the mutual information I between the input and the latent variable which is implicitly discouraged in the original VAE objective (see Eqs. 5 and 6).

$$\begin{aligned}\mathcal{L}_{VAE} &= \mathbb{E}_x[\mathbb{E}_{q_\mathcal{R}(\boldsymbol{z}|\boldsymbol{x})}[\log p_\mathcal{G}(\boldsymbol{x} \mid \boldsymbol{z})] \\ &\quad - KL(q(\boldsymbol{z})\|p(\boldsymbol{z}))] = \\ &\quad \mathbb{E}_{q(\boldsymbol{z}|x)p(x)}[\log p_\mathcal{G}(\boldsymbol{x} \mid \boldsymbol{z})] \\ &\quad - I(Z, X) - KL(q(\boldsymbol{z})\|p(\boldsymbol{z})),\end{aligned} \tag{5}$$

$$\begin{aligned}\mathcal{L}_{DI\text{-}VAE} &= \mathcal{L}_{VAE} + I(Z, X) \\ &= \mathbb{E}_{q_\mathcal{R}(\boldsymbol{z}|\boldsymbol{x})p(\boldsymbol{x})}[\log p_\mathcal{G}(\boldsymbol{x} \mid \boldsymbol{z})] \\ &\quad - KL(q(\boldsymbol{z})\|p(\boldsymbol{z}))\end{aligned} \tag{6}$$

where $\boldsymbol{x}$ is the input utterance, $\boldsymbol{z}$ is the latent variable (X and Z corresponding to their batch-wise vectors), $\mathcal{R}$ and $\mathcal{G}$ are the recognition and generation models (implemented as RNNs) respectively, and $q(\boldsymbol{z}) = \mathbb{E}_x[q_\mathcal{R}(\boldsymbol{z} \mid x)]$.

Secondly, the latent variable $\boldsymbol{z}$ in DI-VAE is *discrete* as opposed to the continuous one in a vanilla VAE. The discrete latent code lends itself well to interpretation and can be viewed as a form of unsupervised dialogue act tagging. The discrete nature also makes the calculation of the KL-term more tractable via the *Batch Prior Regularization* technique (Zhao et al., 2018):

$$KL(q'(\boldsymbol{z})\|p(\boldsymbol{z})) = \sum_{k=1}^{K} q'(\boldsymbol{z}=k) \log \frac{q'(\boldsymbol{z}=k)}{p(\boldsymbol{z}=k)} \tag{7}$$

where K is the number of $\boldsymbol{z}$'s possible values and $q'(\boldsymbol{z})$ is the approximation to $q(\boldsymbol{z})$ over N data points:

$$q'(\boldsymbol{z}) = \frac{1}{N}\sum_{n=1}^{N} q_\mathcal{R}(\boldsymbol{z} \mid x_n) \tag{8}$$

In addition, we employ ***DI-VST***, DI-VAE's counterpart working in a Variational Skip-Thought manner (Hill et al., 2016) and reconstructing the input $\boldsymbol{x}$'s previous ($\boldsymbol{x_p}$) and next ($\boldsymbol{x_n}$) context utterances instead:

$$\begin{aligned}\mathcal{L}_{DI\text{-}VST} &= \\ &\mathbb{E}_{q_\mathcal{R}(\boldsymbol{z}|\boldsymbol{x})p(\boldsymbol{x})}[\log p^n_\mathcal{G}(\boldsymbol{x_n} \mid \boldsymbol{z}) p^p_\mathcal{G}(\boldsymbol{x_p} \mid \boldsymbol{z})] \\ &- KL(q(\boldsymbol{z})\|p(\boldsymbol{z}))\end{aligned} \tag{9}$$

DI-VAE and DI-VST models are visualized in Figure 1.

In the downstream DiKTNet model, we use DI-VAE autoencoder in order to obtain the representation of the user's query: $\boldsymbol{z}_{\text{usr}} = \text{DI-VAE}(\boldsymbol{x}_{\text{usr}})$.

In turn, DI-VST is used to obtain a prediction of the system's action $\boldsymbol{z}_{\text{sys}}$ in the discretized latent form given the user's input $\boldsymbol{x}_{\text{usr}}$ as well as the full dialogue context $\boldsymbol{c}$. For that, DI-VST autoencoder is used as part of a hierarchical, context-aware encoder-decoder response generation model (we refer to it as ***LAED*** itself). Its optimization

objective is as follows:

$$\mathcal{L}_{LAED}(\theta_{\mathcal{F}}, \theta_{\pi}) = \mathbb{E}_{q_{\mathcal{R}}(\boldsymbol{z}_{\text{sys}}|\boldsymbol{x}_{\text{sys}})p(\boldsymbol{x}_{\text{sys}},\boldsymbol{c})}[\log p_{\pi}(\boldsymbol{z}_{\text{sys}} \mid \boldsymbol{c}) + \log p_{\mathcal{F}}(\boldsymbol{x}_{\text{sys}} \mid \boldsymbol{z}_{\text{sys}}, \boldsymbol{c})] \quad (10)$$

where $\theta_{\mathcal{F}}$ is the set of parameters of the context-aware encoder and decoder, θ_{π} is the set of parameters of the policy θ_{π}. θ_{π} is the component trained to directly predict $\boldsymbol{z}_{\text{sys}}$ from the context $\boldsymbol{c}$.

We use different models for different aspects of the dialogue: DI-VAE for user's utterance representation, and DI-VST-based LAED — for the system's action prediction. In that, we follow the intuition of Zhao and Eskénazi (2018) who said that DI-VAE is better at capturing specific words of an utterance, while DI-VST represents the overall dialogue action better.

We train these two models on MetaLWOz in an unsupervised way with the objectives as described above, and use their discretized latent codes $\boldsymbol{z}_{\text{usr}}$ and $\boldsymbol{z}_{\text{sys}}$ respectively in the downstream model at the next stage of training.

4.2 Stage 2. Transfer

At this stage, we train directly for our target task, few-shot dialogue generation, and thus go back to the model described in Section 3. While the training procedure of this model naturally assumes *domain transfer*, we will provide it with more sources of textual and dialogue knowledge of varying generality described below.

As opposed to direct domain transfer, we incorporate domain-general dialogue understanding from the LAED representation trained on MetaLWOz at the previous stage. LAED captures the background top-down dialogue structure: sequences of dialogue acts in a cooperative conversation, latent dialog act-induced clustering of utterances, and the overall phrase structure of spoken utterances. We incorporate this information into the model by conditioning HRED's decoder on the combined latent codes from Stage 1 and refer to this model as ***HRED+LAED***.

$$\mathcal{L}_{\text{HRED+LAED}} = \mathbb{E}_{p(\boldsymbol{x}_{\text{usr}},\boldsymbol{c})p(\boldsymbol{z}_{\text{usr}}|\boldsymbol{x}_{\text{usr}})p_{\pi}(\boldsymbol{z}_{\text{sys}}|\boldsymbol{x}_{\text{usr}},\boldsymbol{c})}[\log p_{\mathcal{F}^d}(\boldsymbol{x}_{\text{sys}} \mid \{\mathcal{F}^e(\boldsymbol{x}_{\text{usr}}, \boldsymbol{c}), \boldsymbol{z}_{\text{usr}}, \boldsymbol{z}_{\text{sys}}\})]. \quad (11)$$

where $\boldsymbol{z}_{\text{usr}}$ and $\boldsymbol{z}_{\text{sys}}$ are respectively samples obtained from the DI-VAE user utterance model and LAED/DI-VST system action model, and $\{\}$ is the concatenation operator.

The last, most general source of knowledge we use is a pre-trained ELMo model (Peters et al., 2018). Apart from using an underlying bidirectional RNN encoder, ELMo captures both token-level and character-level information which is especially crucial in understanding unseen tokens and KB items in the underrepsesented target domain. HRED model with ELMo as the utterance-level encoder is referred to as ***HRED+ELMo***.

Finally, ***DiKTNet*** is HRED augmented with both ELMo encoder and LAED representation.

DiKTNet is visualized in Figure 2. The model (as well as its variants listed above) is implemented in PyTorch (Paszke et al., 2017), and the code is openly available[1].

5 Baselines

We perform an exhaustive ablation study of DiKTNet by comparing it to all its variations mentioned above: HRED, HRED+ELMo, and HRED+LAED. In addition to that, we have the ***HRED+VAE*** —a version of HRED+LAED for which we use a regular, continuous VAE behind DI-VAE and DI-VST in order to see the impact of discretized latent codes (see Eq 5 for the corresponding objective function).

Furthermore, we compare DiKTNet to the previous state-of-the-art approach, Zero-Shot Dialogue Generation (Zhao and Eskénazi, 2018). This model didn't use any complete in-domain dialogues but instead it relied on annotated utterances in all of the domains. We use it as-is (***ZSDG***) as well its variation as follows.

We make use of its central idea of 'domain descriptions' bridging dialogue understanding across domains, but instead of using manually annotated utterances, we employ automatic Natural Language Understanding markup. Our NLU annotations include:

- Named Entity Recognition — Stanford NER model ensemble of case-sensitive and caseless models (Finkel et al., 2005),
- date/time markup — Stanford SUTime (Chang and Manning, 2012),
- Wikidata entity linking — Yahoo FEL (Blanco et al., 2015; Pappu et al., 2017).

Table 1: Evaluation results. Marked with asterisks are individual results higher than ZSDG's performance which are achieved with the minimum amount of training data. In bold is the model consistently outperforming ZSDG in all domains and metrics with minimum data.

We serialize annotations from these sources into token sequences and make domain description tuples out of all the utterances in the source and target domains. This way, most of our domain descriptions share the structure and content of the original ones.

For example, for the phrase *'Will it be cloudy in Los Angeles on Thursday?'*, the original ZSDG annotation is of the form `"request #goal cloudy #location Los Angeles #date Thursday"`. Our NLU annotation for this phrase is `"LOCATION Los Angeles DATE Thursday"`.

We have two models in this setup, with (***NLU_ZSDG+LAED***) and without the use of LAED representation (***NLU_ZSDG***) respectively.

6 Datasets

Number of Domains:	51
Number of Dialogues:	40,388
Mean dialogue length:	11.91

Table 2: MetaLWOz dataset statistics

We use the Stanford Multi-Domain (SMD) dialogue dataset (Eric et al., 2017) containing human-human goal-oriented dialogues in three domains: appointment scheduling, city navigation, and weather information. Each dialogue has to do with a single task queried by the user and thus comes with additional knowledge base information coming from implicit querying of the underlying domain-specific API. Although sharing some common features (the setting of an intelligent in-car assistant and the use of the underlying KB), the dialogues differs significantly across domains which makes doamin transfer sufficiently challenging.

Statistic \ Domain	Navigation	Weather	Schedule
Dialogues	800	797	828
Utterances	5248	4314	3170
Avg. dialogue length	6.56	5.41	3.83

Table 3: Stanford multi-domain dataset statistics (trainset)

For the latent representation learning, we use MetaLWOz, a goal-oriented dialogue dataset containing human-human dialogues in diverse domains and several tasks in each of those. The dialogues are collected in a Wizard-of-Oz method where human participants were given a problem domain and a specific task in it, and were asked to complete the task via dialogue. No domain-specific APIs or knowledge bases were available

for the participants, and in the actual dialogues they were free to use fictional names and entities in a consistent way. The dataset's statistics are shown in Table 2. All the domains available in the MetaLWOz dataset are listed in the Table 6 of the Appendix A.

7 Experimental setup and evaluation

Our few-shot setup is as follows. Given the target domain, we first train LAED model(s) on the MetaLWOz data — here we exclude from training every domain that might overlap with the target one. Specifically, for the *Navigation* domain in SMD, it's *Store Details*, for *Weather* it's *Weather Check*, and for *Schedule* it's *Update Calendar* and *Appointment Reminder*.

In our final setup, at Stage 1 we used a DI-VST-based LAED and a DI-VAE, both of the size 10×5.

Next, having trained and frozen Stage 1 models, we train DiKTNet on all the source domains from the SMD dataset. We use a random sample of the target domain utterances together with their contexts and KB info, varying the amount of those from 1% to 10% of all available target data.

For the NLU_ZSDG setup, we annotated all available SMD data and randomly selected a subset of 1000 utterances from each source domain, and 200 utterances from the target domain. For source domains, this number amounts to roughly a quarter of all available training data — we chose it in order to make use of as much annotated data as possible while keeping the domain description task secondary. For the target domain, we made sure to keep under roughly the same in-domain data requirements as the ZSDG baseline.

For evaluation, we follow the approach of Zhao and Eskénazi (2018) and report BLEU and Entity F1 scores. Given the non-deterministic nature of our training setup, we report means and variances of our results over 10 runs with different random seeds.

We also perform an additional evaluation of DiKTNet's performance with extended amounts of target data and compare it to the original Key-Value Retrieval Network (***KVRet***) by Eric et al. (2017) which was originally trained with all the available data. In this case we average BLEU scores across all 3 SMD domains in order to be consistent with the form the corresponding results are presented in the original paper.

We train our models with the Adam optimizer (Kingma and Ba, 2014) with learning rate 0.001. Our hierarchical models' utterance encoder is an LSTM cell (Hochreiter and Schmidhuber, 1997) of size 256, and the dialog-level encoder is a GRU (Cho et al., 2014) of size 512.

8 Results and discussion

Our results are shown in Table 1 — our objective here is maximum accuracy with minimum training data required.

8.1 Results for the few-shot setup

It can be seen that few-shot models with LAED representation are the best performing models for this objective. While improvements upon ZSDG can already be seen with simple HRED in a few-shot setup, the use of the LAED representation and domain-general ELMo encoding helps significantly reduce the amount of in-domain training data needed: at 1% of in-domain dialogues, we see that DiKTNet consistently and significantly improves upon ZSDG in every domain. In SMD, with its average dialogue length of 5.25 turns, 1% of training dialogues amounts to approximately 40 in-domain training utterances. In contrast, the ZSDG setup used approximately 150 training utterance-annotation pairs for each domain, including the target one, totalling about *450 annotated* utterances.

Although in our few-shot approach we use full in-domain dialogues, we end up having significantly less in-domain training data, with the crucial difference that none of those has to be annotated for our approach. Therefore, the method we introduced attains state-of-the-art in both accuracy and data-efficiency.

In turn, the results of the ZSDG_NLU setup demonstrate that single utterance annotations, if not domain-specific and produced by human experts, don't provide as much signal as full dialogues, even without annotations at all. Even the significant number of such annotated utterances per domain didn't make a difference in this case.

We would also like to point out that, as can be seen in the table, our results have quite high variance — the main source of it is the nature of our training/evaluation setup where we average over 10 runs with 10 different sets of seed dialogues. However, in the majority of cases with comparable means, DiKTNet has a lower variance than

Domain		Context	Gold response	Predicted response
schedule	<usr>	Remind me to take my pills	Ok setting your medicine appointment for 7pm	Okay, setting *a reminder to take your pills at 7 pm.*
	<sys>	What time do you need to take your pills?		
	<usr>	I need to take my pills at 7 pm.		
navigate	<usr>	Find the address to a hospital	Have a good day	*No problem.*
	<sys>	Stanford Express Care is at 214 El Camino Real.		
	<usr>	Thank you.		
weather	<usr>	What is the weather forecast for the weekend?	For what city would you like to know that?	For what city would you like *the weekend forecast for?*

Table 4: DiKTNet's selected responses

Where can I go shopping?
Where does my friend live?
Where can I get Chinese food?
Where can I go to eat?
Can you please take me to a coffee house?
I'd like to set a reminder for my meeting at 2pm later this month please.
What is the time and agenda for my meeting, and who is attending?
Schedule a lab appointment with my aunt for the 7th at 1pm.
Schedule a calendar reminder for yoga with Jeff at 6pm on the 5th.
Car I'm desiring to do some shopping: which one is it the nearest shopping ...
... center? Anything within 4 miles?
Get the address to my friend's house that i could get to the fastest
Car I need to get to my friends house, it should be within 4 miles from here

Table 5: Selected clusters of utterances sharing the same LAED codes

the alternative models at the same percentage of seed data. And in the extreme case with 1% target data, DiKTNet improves on all the other models in terms of both means and variances.

8.2 Discussion of the latent representations

The comparison of the setups with different latent representations also gives us some insight: while the VAE-powered HRED model improves on the baseline in multiple cases, it lacks generalization potential compared to the LAED setup. The reason for that might be inherently more stable training of LAED due to its modified objective function which in turn results in a more informative representation providing better generalization. In order to have a glimpse into the LAED-produced clustering, in Table 5 we present a snippet of the utterance clusters sharing the same, most frequent latent codes throughout the dataset (the clustering is obtained with LAED model trained on every domain but 'Store details', i.e. the one for the evaluation on 'Navigate' SMD domain). From this snippet, it can be seen that those clusters work well for domain separation, as well as capturing dialogue intents.

8.3 Results with extended data

We performed an additional experiment with extended target data (see Figure 3 of Appendix A). It showed that DiKTNet, when trained with as little as 5% of target data, can outperform a KVRet trained using the entire dataset. Furthermore, with 50% of the target data, DiKTNet becomes more than twice as good as KVRet in terms of overall language generation.

However, goal-oriented metrics such as Entity F1 are more challenging to bootstrap. As such, DiKTNet outperforms KVRet on 'Weather' domain starting at 10% of the target data, but only has a trend on narrowing down the performance gap with KVRet on 'Navigate', and certainly needs more training data in 'Schedule' domain.

The explanation to that might be that most of the dialogue entities come from the KB snippets which are the least represented resource in our setup. They aren't available in MetaLWOz, and in SMD, KB snippets share little in common across domains. Therefore, in order to increase Entity F1, KB information should be directly copied to the output more efficiently — and increasing the robustness of the copy-augmented decoder is one of our future research directions.

8.4 Discussion of the evaluation metrics

We use BLEU as one of the main evaluation metrics in this paper — we do it in order to fully conform with the setup of Zhao and Eskénazi (2018) which we base our work on. But while being widely adopted as a general-purpose language generation metric, BLEU might not be sufficient in the dialogue settings (see Novikova et al. (2017) for a review). Specifically, we have observed several cases where the model would produce an overall grammatical response with the correct dialogue intent (e.g. "You are welcome! Anything else?"), but BLEU would output a lower score for it due to word mismatch (e.g. "You're welcome!"; see more examples in Table 4). This is a general issue in dialogue model evaluation since the variability of possible responses equivalent in meaning is very high in dialogue. In future work, we will put more emphasis on the meaning of utterances, for example by incorporating external dialogue act tagging resources in the evaluation setup which, together with general language generation metrics like perplexity, can make for more robust evaluation criteria than word overlap.

9 Conclusion and future work

In this paper, we have introduced DiKTNet, a model achieving state-of-the-art dialogue generation performance in a few-shot setup, without using any annotated data. By transferring latent dialogue knowledge from multiple sources of varying generality, we obtained a model with superior generalization to an underrepresented domain.

Specifically, we showed that our few-shot approach achieves state-of-the art results on the Stanford Multi-Domain dataset while being more data-efficient than the previous best model, by requiring significantly less data none of which has to be annotated.

While being state-of-the-art, the accuracy scores themselves still suggest that our technique is not ready for immediate adoption for real-world production purposes, and the task of few-shot generalization to a completely new dialogue domain remains an area of active research. In our own future work, we will try and find ways to improve the unsupervised representation (Shi et al., 2019) in order to increase the transfer potential. We will also explore ways to enable more efficient copying from the input which is crucial for correctly handling entities and therefore attaining high goal-oriented performance of the system.

Apart from that, we will consider alternative evaluation criteria to account for rich surface variability of natural speech.

Multi-Granularity Representations of Dialog

Shikib Mehri and Maxine Eskenazi
Language Technologies Institute, Carnegie Mellon University
{amehri,max+}@cs.cmu.edu

Abstract

Neural models of dialog rely on generalized latent representations of language. This paper introduces a novel training procedure which explicitly learns multiple representations of language at several levels of granularity. The multi-granularity training algorithm modifies the mechanism by which negative candidate responses are sampled in order to control the granularity of learned latent representations. Strong performance gains are observed on the next utterance retrieval task using both the MultiWOZ dataset and the Ubuntu dialog corpus. Analysis significantly demonstrates that multiple granularities of representation are being learned, and that multi-granularity training facilitates better transfer to downstream tasks.

1 Introduction

Producing generalized representations of language is a well-studied problem in natural language processing (NLP) (Montague, 1973; Davidson and Harman, 2012). Neural models typically encode an input into a latent vector, which is then used by upper layers. As such, improving the quality or generality of the learned representations will typically improve performance on the final task due to the increased representative power of the model.

Constructing meaningful representations of dialog is challenging. To effectively represent the dialog context, a latent dialog representation must contain the information necessary to (1) estimate a belief state over user goals (Williams et al., 2013), (2) track entity mentions (Zhao et al., 2017), (3) resolve anaphora co-references (Mitkov, 2014), (4) model the communicative purpose of an utterance (Core and Allen, 1997) and (5) resolve ambiguity in natural language. A large focus area of dialog research is the development of neural architectures which learn effective representations of the input (Zhou et al., 2016; Wu et al., 2016; Zhou et al., 2018). With the goal of training a model for next utterance retrieval, Zhou et al. (2018) use a deep self-attention network to produce a representation of each utterance within a dialog and follow it with an attention between utterances and 3-D convolutional layers.

Recent work has explored the use of large-scale self-supervised pre-training on very large corpora (Kiros et al., 2015; Peters et al., 2018; Devlin et al., 2018; Radford et al., 2018) as a means of improving natural language representations. These pre-trained models have yielded state-of-the-art results on several downstream NLP tasks (Wang et al., 2018): text classification, natural language inference, and question answering. Though such methods have proven useful across several downstream tasks (Wang et al., 2018), using them for dialog requires expensive fine-tuning of the complex models (Dinan et al., 2019; Alberti et al., 2019). The need for this fine-tuning is due to the pre-training procedure. First, the domain and style of dialog corpora differ significantly from the majority of the data used during pre-training. This necessitates fine-tuning in order to adapt the representations to more varied input. Second, the pre-trained representations, which are all obtained through various language modelling objectives, do not necessarily capture properties of dialog at several levels of granularity (e.g., belief state, entities, co-references, high-level user goals).

Though large-scale pre-training improves the strength and generality of latent representations, this effect is minimized when transferring to dialog tasks or out-of-domain data. To this end, this paper explores an alternate mechanism of learning strong and general representations for the task of next utterance retrieval (Lowe et al., 2015). We propose Multi-Granularity Training (MGT), which simultaneously trains multiple levels of representation. It later combines these latent repre-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1752–1761, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

sentations to obtain more general models of dialog. Different granularities of representation capture different properties of the input. For example, a high-granularity representation will capture specific words and entities mentioned in the dialog context. A low-granularity representation will instead capture more abstract properties of the dialog, such as the domain of the conversation or the high-level user goal. MGT combines representations at several levels of granularity, resulting in stronger and more general representations of dialog. The strength of representations is a consequence of learning the dedicated representations at each level of granularity. The generality results from learning several diverse representations across multiple granularities, thereby encompassing a wider amount of information. Since the representations are learned on dialog data and for the final task, this method does not suffer from the aforementioned shortcomings of pre-training.

The specific MGT procedure is motivated by the fact that observing different negative examples during training results in different representations. A model trained to select the correct response out of a set of lexically similar candidates will likely learn fine-grained representations of each word in an effort to identify minute differences between the candidates. On the other hand, a model trained to select a response from a set of topically diverse candidates will likely learn broader and more abstract representations of each utterance. Typically, negative examples are randomly sampled which results in learned representations that fit the average training example. MGT relies on an algorithm for controlled sampling of negative candidate responses, which allows for the construction of multiple training sets in order to learn multiple levels of granularity.

MGT is agnostic to the underlying model architecture. Though the majority of experiments in this paper are carried out with a dual encoder (Lowe et al., 2015) as the base model, MGT is also applied on top of Deep Attention Matching networks (Zhou et al., 2018) and obtains strong performance gains.

MGT is evaluated using the MultiWOZ dataset (Budzianowski et al., 2018) and the Ubuntu dialog corpus (Lowe et al., 2015) to train models for next utterance retrieval. Results show that MGT obtains better performance than ensembling (Perrone and Cooper, 1992) multiple baseline models. At the same time, it also serves as a better downstream representation of dialogs. The contributions of this paper are: (1) a training procedure which learns multiple granularities of latent representations for a task, (2) improved performance on next utterance retrieval across two diverse datasets, (3) an analysis significantly demonstrating that multiple granularities of representation have indeed been learned.

2 Related Work

This section discusses two areas of related work: language representations and the next utterance retrieval task.

2.1 Language Representations

Recent work has focused on improving latent representations of language through the use of large-scale self-supervised pre-training on very large corpora. Kiros et al. (2015) trains a sequence-to-sequence model (Sutskever et al., 2014) to predict the surrounding sentences, and uses the final encoder hidden state as a generic sentence representation. ELMo (Peters et al., 2018) trained a bi-directional language model on a large corpus in order to obtain strong contextual representations of words. OpenAI's GPT (Radford et al., 2018) produces latent representations of language by training a large transformer (Vaswani et al., 2017) with a language modelling objective. Devlin et al. (2018) further improves on this line of research by introducing the masked language modelling objective and a multi-tasking pre-training loss. Each of these methods has obtained state-of-the-art results on the GLUE benchmark (Wang et al., 2018), suggesting that they are strong and general representations of language.

These pre-trained representations of language have been applied to numerous tasks. Of particular interest are applications of these representations to dialog tasks. As part of the 2nd ConvAI challenge (Dinan et al., 2019), the best performing models on both human and automated evaluations (Wolf et al., 2019) were fine-tuned versions of OpenAI's GPT (Radford et al., 2018). Despite strong performance gains, transferring OpenAI's GPT required fine-tuning the full model because the dialog data was in a different domain and required different information to be contained in the representations. Recently, Mehri et al. (2019) introduce several dialog specific pre-training objec-

tives that obtain strong performance gains across multiple downstream dialog tasks.

2.2 Next Utterance Retrieval

Lowe et al. (2015) construct Ubuntu, the largest retrieval corpus for dialog, and present the dual encoder architecture as a baseline architecture. Kadlec et al. (2015) present several strong baseline architectures for this dataset. Zhou et al. (2016) present the Multiview architecture which, with the aim of constructing broader representation, learns both word-level representations and utterance-level representations. Sequential Matching Networks (SMN) (Wu et al., 2016) represent each utterance in the dialog context and construct segment-segment matching matrices between the response and each utterance in the context. Deep Attention Matching (DAM) (Zhou et al., 2018) uses deep transformers (Vaswani et al., 2017) to construct representations of each utterance in a dialog context, followed by cross-attention and convolutional layers.

Previous work on next utterance retrieval has proposed architectural modifications in an effort to improve the representative powers of the models. This paper presents a training algorithm applicable to any neural architecture, which explicitly forces the model to learn different granularities of representation.

3 Methods

This section describes three methods used for next utterance retrieval: a strong baseline dual encoder architecture, an ensemble of dual encoders, and an ensemble of dual encoders with multi-granularity training.

3.1 Dual Encoder

Given a dialog context, next utterance retrieval selects the correct response from a set of k candidates. The retrieval baselines presented by Kadlec et al. (2015) first encode the dialog context and a candidate response. Then they use the product of the latent representations to output a probability. This baseline architecture consists of two encoders, one to encode the context and one for the response.

Previous approaches using Ubuntu were trained for binary prediction (i.e., predict the probability of a particular response), and used during testing to select from a candidate set. To mitigate the discrepancy between training and testing, our baseline is *trained* to select the correct response from a candidate set. Since the Ubuntu training set consists of 0/1 labels, the training set was modified by considering only the positive-labeled examples, and uniformly sampling $k-1$ negative candidates.

Let $c_{1,\dots,N}$ denote the words of the dialog context, $r^i_{1,\dots,M_i}$ denote the words of the i-th candidate response and r_{gt} denote the ground-truth response. Given f_c, the LSTM encoder of the context, and f_r, the LSTM encoder of the candidate responses, the forward propagation of the dual encoder is described by:

$$\mathbf{c} = f_{\mathrm{c}}(c_i) \quad i \in [1, N] \tag{1}$$

$$\mathbf{r_i} = f_{\mathrm{r}}(r^i_j) \quad j \in [1, M_i] \tag{2}$$

$$\mathbf{r_{gt}} = f_{\mathrm{r}}(r^{gt}_j) \quad j \in [1, M_{gt}] \tag{3}$$

$$\alpha_{gt} = \mathbf{c}^T \mathbf{r_{gt}} \tag{4}$$

$$\alpha_i = \mathbf{c}^T \mathbf{r_i} \tag{5}$$

The final loss function is:

$$\begin{aligned}\mathcal{L} &= -\log p(r^i_{1,\dots,M_i} | c_{1,\dots,N}) \\ &= -\log\left(\frac{\exp(\alpha_{gt})}{\exp(\alpha_{gt}) + \sum_{j=1}^{K}\exp(\alpha_j)}\right)\end{aligned} \tag{6}$$

3.2 Ensemble of Dual Encoders

Ensembling multiple models (Perrone and Cooper, 1992) has been empirically shown to improve performance, since it maintains a low model bias while significantly reducing the model variance. In ensembling, multiple models are trained and their predictions are averaged during inference. Specifically, if α^l denotes the output of model $l \in [1, L]$, the output probability is defined as:

$$p(r^i_{1,\dots,M_i} | c_{1,\dots,N}) = \frac{1}{L}\sum_{l=1}^{L}\frac{exp(\alpha^l_i)}{\sum_{j=1}^{K} exp(\alpha^j_i)} \tag{7}$$

Since ensembling reduces the model variance while maintaining low bias, it is most effective when the models are diverse and each model excels at a particular type of input. In typical ensemble training, the different models are either obtained through different random initializations or at different checkpoints from the same training run. In such an approach, there is no mechanism which explicitly enforces diversity between the models.

3.3 Multi-Granularity Training

During baseline model training, the negative response candidates were uniformly sampled from R, the set of all responses in the training set. MGT is proposed in an effort to explicitly model different granularities of representation through a controlled method of sampling negative candidates.

Consider a training corpus consisting of a set of dialog contexts and ground-truth responses, $T = (C, R^{gt})$. In the baseline training, $k-1$ negative response candidates are uniformly sampled from the set of all responses, R:

$$T_i = (C_i, R_i^{gt}, [N_{i,1}, N_{i,2}, \ldots, N_{i,k-1}]) \quad (8)$$
$$\forall j \in [1, k-1] \quad N_{i,j} \sim \text{Uniform}(R)$$

MGT is motivated by the idea that observing different types of negative candidate response sets will result in different representations. Negative candidates which are lexically similar to the ground truth response should result in models that carefully consider each word in order to produce fine-grained representations and identify minute differences between candidate responses. On the other hand, very semantically distant candidate responses should result in very broad and abstract representations of language. While there may be many methods of sampling negative responses to influence what the model learns, this paper focuses on using the semantic similarity of the candidate responses as a means of controlling the granularity of learned representations.

Given the LSTM response encoder, f_r, the measure of semantic similarity is defined as:

$$\mathbf{r_i} = f_r(R_{i,j}) \quad j \in [1, M_i] \quad (9)$$
$$\mathbf{r_k} = f_r(R_{k,j}) \quad j \in [1, M_k] \quad (10)$$
$$d(R_i, R_k) = \frac{\mathbf{r_i}^T \mathbf{r_k}}{||\mathbf{r_i}|| \cdot ||\mathbf{r_k}||} \quad (11)$$

This approach relies on a cosine-similarity as a measure of semantic distance between dialog utterances. While not a perfect measure, for the purposes of the MGT algorithm it appears to be a sufficient measure. Since the training algorithm groups together similarly distant negative candidates, it is robust to noise in the measure of semantic distance. Future work may explore whether a better distance measure improves the MGT algorithm.

A distance matrix D is constructed between all of the responses in R, such that $D_{i,j} = d(R_i, R_j)$. The objective of MGT is to train L models at L different levels of granularity. For a particular response R_i, rather than sampling negative candidates from the entire set of R, the set of responses R is split into L segments based on distance from R_i. Define a function $\mathtt{b}(D_i, l)$ which considers a list of distances and returns the maximum distance in the l-th segment of a total of L segments. This is equivalent to sorting D_i and taking the $\left(|R| \times \frac{l}{L}\right)$-th value.

The distance matrix, D, is used to segment the set of potential negative candidates, R, for each training example (C_i, R_i^{gt}), into L buckets: $P_i^1, \ldots, P_i^L$. Given the definition of segmentation provided above, P_i^1 will consist of responses that are strictly closer (as defined by d) to R_i than the responses in P_i^2. When training the l-th model at the l-th level of granularity, the negative responses for R_i are sampled from P_i^l rather than R. P_i^l is constructed using $\mathtt{b}(D_i, l)$, which was defined to return the maximum value in the l-th segment.

This method is used to construct L different training corpora, $T^1, \ldots, T^L$. A particular T^l is constructed as follows:

$$T_i^l = (C_i, R_i^{gt}, [N_{i,1}^l, \ldots, N_{i,k-1}^l]) \quad (12)$$
$$P_i^l = \{r \in R \mid d(R_i, r) \in (\mathtt{b}(D_i, l-1), \mathtt{b}(D_i, l)\}$$
$$\forall j \in [1, k-1] \quad N_{i,j}^l \sim \text{Uniform}(P_i^l)$$

After the L different training corpora, L different models are trained. Models trained on closer candidate sets should learn more granular representations while models trained on more distant candidate sets should learn more abstract representations of dialog. Upon obtaining L different models, the output probability is produced by the ensembling method described in Equation 7.

4 Experiments

This section describes the datasets and presents experimental procedures aimed at evaluating the different approaches to next utterance retrieval.

4.1 Datasets

Two retrieval corpora, MultiWOZ (Budzianowski et al., 2018) and Ubuntu (Lowe et al., 2015) were used. MultiWOZ contains task-oriented conversations between a tourist and a Wizard-of-Oz, while

Ubuntu contains both open-domain and technical dialog snippets collected from Internet Relay Chat (IRC). The diversity of these two datasets provides insight into the general applicability of MGT.

4.1.1 MultiWOZ

The MultiWOZ dataset (Budzianowski et al., 2018) was converted into a retrieval corpus. MultiWOZ contains 8422 dialogs for training, 1000 for validation and 1000 for testing. There are 20 candidate responses for each dialog context.

4.1.2 Ubuntu Dialog Corpus

The original Ubuntu corpus (Lowe et al., 2015) has 1,000,000 training examples. Typical interactions include individuals asking for technical assistance in a conversational manner. The subject of conversation is not explicitly bounded and may be any topic. As described in Section 3.1, the training corpus is modified in order to train as a retrieval task rather than as a binary prediction task. Negative training examples (500,127) are filtered out. The size of the new training dataset is 499,873. There are a total of 10 candidate responses for each context. The validation and test sets remain unchanged, with 19,561 validation examples and 18,921 test examples.

4.2 Experimental Setup

Unless otherwise specified, the size of ensembles and the number of models in MGT is $L = 5$. For MGT, the highest performing checkpoint at each granularity is selected using the validation score. For the ensemble method, the top performing checkpoints are selected from a single run.

4.2.1 MultiWOZ Setup

Two distinct encoders are trained, one to encode the dialog context and the other for the candidate responses. Each encoder is a single layer, unidirectional LSTM with an embedding dimension of 50 and a hidden size of 150. These hidden sizes match the best performing hyperparameters identified by Budzianowski et al. (2018). The Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.005 is used to train the model for 20 epochs. The vocabulary is 1261 words, the batch size is 32, and gradients are clipped to 5.0. A checkpoint is saved after each epoch, and the best checkpoint is selected using performance on the validation set.

4.2.2 Ubuntu Setup

Each encoder is a single layer, uni-directional LSTM with an embedding dimension of 300 and a hidden size of 150. The Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.005 is used to train the model for 20 epochs. The vocabulary is 10002 words, the batch size is 128, and gradients are clipped to 5.0. Only the last 160 words of each dialog context are used. The word embeddings are initialized with pre-trained GloVe embeddings (Pennington et al., 2014). A checkpoint is saved after each epoch, and the best checkpoint is selected using performance on the validation set.

4.2.3 Deep Attention Matching Experiment

MGT is a training procedure which is agnostic to the underlying model architecture. Though the majority of the experiments presented in this paper use the dual encoder architecture (Lowe et al., 2015), MGT is applied on top of the state-of-the-art architecture for Ubuntu: the Deep Attention Matching Network (DAM) (Zhou et al., 2018). When applying MGT to DAM, the sampling of negative candidates is done using the baseline dual encoder architecture.

4.3 Multi-Granularity Training Example

Table 1 shows an example dialog context, ground-truth response and the negative candidate responses sampled at several levels of cosine distance, as per Equation 11. These negative candidate responses are retrieved by MGT's sampling algorithm, and are used to train multiple models at different levels of granularity.

The negative candidates for the higher granularity models are much closer to the ground-truth response than the candidates for the lower granularity models. As such, models trained at higher granularities will learn more granular representations of dialog in order to identify minute differences between responses. Examples for lower granularity models are more distant in meaning, and models may instead learn to represent higher-level attributes of the dialog.

5 Results

Multi-granularity training is proposed in order to learn strong and general latent representations of dialog. To evaluate the strength and generality of the learned representations, experiments are conducted to evaluate three different properties of

Dialog Context:
USER: i need an expensive place to dine in the center of town .
SYS: what type of food are you wanting at this restaurant ?
USER: type of food does not matter to me .
Ground-Truth Response:
SYS: yes there are 33 such restaurant -s . would you like me to book 1 for you ?
Closest Neg. Cand. (for Highest Granularity Model):
SYS: i have 5 indian restaurant -s in the west . if i may , might i suggest the rice boat . i can reserve a table for you if you would like .
2nd Closest Neg. Cand. (for 2nd Highest Granularity Model):
SYS: how about the avalon ?
3rd Closest Neg. Cand. (for 3nd Highest Granularity Model):
SYS: i would be happy to book that for you .are you travelling alone ?
2nd Furthest Neg. Cand. (for 2nd Lowest Granularity Model):
SYS: i apologize , there s been a misunderstanding . before we can book your taxi , we need to know which college . there are 18 colleges . what area are you looking for ?
Furthest Granularity Neg. Cand (for Lowest Granularity Model):
SYS: i need to know when you want to leave and arrival time in order for me to order you a taxi .

Table 1: An example dialog context from the training set. Along with the ground-truth response, negative candidates sampled at five different levels of semantic distance are shown. The retrieval models are trained to differentiate between the ground-truth response and the different negative candidates.

MGT: (1) improved performance on the task of next utterance retrieval, (2) explicit modelling of different granularities, and (3) improved generality and transferability to other dialog tasks.

5.1 Next Utterance Retrieval

Next utterance retrieval is reliant on latent representations of dialog. Several experiments are conducted to evaluate whether MGT improves the representative power of models and results in better performance on the task of next utterance retrieval. MGT is expected to outperform standard ensembling, since MGT explicitly models multiple granularities and trains more diverse models. The performance of MGT is evaluated using both MultiWOZ (Budzianowski et al., 2018) and Ubuntu (Lowe et al., 2015). Experiments are conducted using two different underlying architectures, a dual encoder baseline (Lowe et al., 2015) and a Deep Attention Matching network (Zhou et al., 2018).

5.1.1 MultiWOZ

Performance on the MultiWOZ retrieval task is evaluated with mean reciprocal rank (MRR), and Hits@1 (H@1). Mean reciprocal rank is defined as follows:

$$MRR = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{rank_i} \tag{13}$$

Hits@1 is equivalent to accuracy. It measures how often the ground-truth response is selected from the $K = 20$ candidates.

Model Name	MRR	Hits@1
Dual Encoder	79.55	66.13%
Ensemble (5)	81.53	69.47%
Multi-Granularity (5)	**82.74**	**72.18%**

Table 2: Performance on MultiWOZ. MGT is compared to a baseline dual encoder, and an ensemble of dual encoders with an identical number of parameters. All bold-face results are statistically significant to $p < 0.01$.

The results in Table 2 demonstrate the strong performance gains obtained with MGT. With $L = 5$ granularities, MGT outperforms a similarly sized ensemble of dual encoders. These results demonstrate that explicitly enforcing the policy that makes models learn multiple granularities of representation improves the representative power and performance on next utterance retrieval.

Model Name	MRR	$R_{10}@1$	$R_2@1$
Previous Research			
Dual Encoder (Lowe et al., 2015)	-	63.8	90.1
MV-LSTM (Pang et al., 2016)	-	65.3	90.6
Match-LSTM (Wang and Jiang, 2016)		65.3	90.4
Multiview (Zhou et al., 2016)	-	66.2	90.8
DL2R (Yan et al., 2016)	-	62.6	89.9
SMN (Wu et al., 2016)	-	72.6	92.6
DAM (Zhou et al., 2018)	-	**76.7**	**93.8**
Dual Encoder Experiments			
Dual Encoder (Lowe et al., 2015)	76.84	63.6	90.9
Ensemble (5)	78.91	66.9	91.7
Multi-Granularity (5)	**80.10**	**68.7**	**91.9**
Deep Attention Matching Experiments			
DAM (Zhou et al., 2018) (re-trained)	83.74	74.54	93.08
Ensemble (5)	84.03	74.95	93.27
Multi-Granularity (5)	**84.26**	**75.30**	**93.45**

Table 3: Results for next utterance retrieval on the Ubuntu dialog corpus. This table shows previous work, and experimental results with two underlying architectures: a dual encoder model and Deep Attention Matching networks. The results shown in the DAM experiments section are performed with the open-sourced implementation of Zhou et al. (2018), which obtains slightly worse performance than they report. All bold-face results are statistically significant to $p < 0.01$.

5.1.2 Ubuntu

Previous research used several variations of the $R_N@k$ metric to evaluate retrieval performance on the Ubuntu dialog dataset. $R_N@k$ refers to the percentage of the time that the ground truth response was within the top-k predictions for a candidate set size of N utterances. $R_{10}@1$ on Ubuntu is equivalent to Hits@1 and accuracy. In addition to MRR, we report $R_{10}@1$ and $R_2@1$, top-1 accuracy with a candidate set size of 10 and 2, respectively.

MGT is applied on top of the dual encoder baseline (Lowe et al., 2015) and Deep Attention Matching networks (Zhou et al., 2018). The results shown in Table 3 show the performance of MGT using two different underlying architectures, as well as previous work. Across both base architectures, MGT outperforms ensembling. The primary difference between these two methods is that MGT explicitly ensures that several granularities of representation are learned. As such, these results reaffirm the hypothesis that learning multiple granularities of representation leads to more diverse models, and more general representations of dialog.

Even with the dual encoder as the underlying model, MGT outperforms all previous work except for Sequential Matching Networks (SMN) (Wu et al., 2016) and Deep Attention Matching networks (DAM) (Zhou et al., 2018). The Deep Attention Matching experiment performs MGT using DAM[1] as the underlying architecture. MGT has good performance improvement on top of DAM, roughly double the improvement obtained by ensembling. This suggests that MGT can be used as a general purpose training algorithm which learns multiple-granularities of representation and thereby produces stronger and more general models.

5.2 Explicit Granularity Modelling

Multi-granularity training learns multiple granularities of representation. However, strong performance on next utterance retrieval, does not necessarily prove that several granularities are explicitly modelled. To analyze whether the models operate at different levels of granularity, the content of the representations must be considered. The $L = 5$ trained models, each at a different granularity, have their weights frozen. These frozen

[1]It should be noted that the open-source implementation provided by Zhou et al. (2018) was used, however performance was slightly lower than the results they reported. We speculate that given a DAM implementation that matches their reported results, MGT would obtain a similarly-sized improvement (+0.76 R@1).

Model Name	BoW (F-1)	DA (F-1)
Highest Abstraction	57.00	**19.24**
2nd Highest Abs.	57.69	19.14
Medium	58.49	18.31
2nd Highest Gran.	58.38	16.88
Highest Granularity	**59.43**	15.46

Table 4: Results of the granularity analysis experiment. $L = 5$ models trained to capture different granularities of representation. All bold-face results are statistically significant to $p < 0.01$.

models are then used to obtain a latent representation of all the dialog contexts in MultiWOZ. A linear layer is then trained on top of these representations for a downstream task. During this training, only the weights of the linear layer are updated. This evaluates the information contained in these learned representations.

Two different downstream tasks are considered; bag-of-words prediction and dialog act prediction. Bag-of-words prediction is the task of predicting a binary vector corresponding to the words present in the last utterance of the dialog context. This task requires very granular representations of language, and therefore the models trained to capture high granularity representations should have the highest performance. Dialog act prediction is the task of predicting the set of dialog acts for the next system response. This is a high-level task that requires abstract representations of language, therefore the models with the lowest granularity should do well.

The results in Table 4 confirm the hypothesis that MGT results in models that learn different granularities of representation. It is clear that higher granularity models better capture the information necessary for the bag-of-words task, while higher abstraction (lower granularity) models better capture information for dialog act prediction.

5.3 Generalizability and Task Transfer

One motivation of MGT is to improve the generality of representation, and facilitate easy transfer to various tasks. Truly general representations of language would require no fine-tuning of the model, and we would only need to learn a linear layer in order to extract the relevant information from the representation. Bag-of-words prediction and dialog act prediction are again used to evaluate the ability of MGT to transfer without any fine-tuning.

The results shown in Table 5 demonstrate

Model Name	BoW (F-1)	DA (F-1)
Dual Encoder	60.13	19.09
Ensemble (5)	64.11	22.39
Multi-Granularity (5)	**67.51**	**22.85**
Fine-tuned	90.33	28.75

Table 5: Experimental results demonstrating performance on two downstream tasks, without any fine-tuning of the latent representations. All bold-face results are statistically significant to $p < 0.01$.

Model Name	DA (F-1)
Random Init	28.75
Dual Encoder	32.63
Ensemble (5)	31.71
Multi-Granularity (5)	**33.46**

Table 6: Experimental results demonstrating performance on the downstream task of dialog act prediction, when the model is fine-tuned on all available data. All bold-face results are statistically significant to $p < 0.01$.

that MGT results in more general representations of language, thereby facilitating better transfer. However, there is room for improvement when comparing to models fine-tuned on the downstream task. This suggests that additional measures can be taken to improve the representative power of these models.

The results in Table 6 demonstrate that MGT learns general representations which effectively transfer to downstream tasks, especially more difficult tasks such as dialog act prediction. Fine-tuning the latent representations learned by MGT, results in improved performance on dialog act prediction.

6 Conclusions and Future Work

This paper presents multi-granularity training (MGT), a mechanism for learning strong and general representations for next utterance retrieval. Through the use of a sampling algorithm to select negative candidate responses, multiple granularities of representation are learned during training. Strong performance gains are observed on the task of next utterance retrieval on both MultiWOZ and Ubuntu. Experiments show that MGT is a generally applicable training procedure which can be applied to multiple underlying model architectures. Quantitative analytic experiments demonstrate that multiple granularities of representation

are in fact being learned, and that MGT facilitates better transfer to downstream tasks both with and without fine-tuning.

There are several avenues for future work. First, this method is general and broadly applicable, which suggests that it may improve performance on other tasks and domains. A particularly interesting application would be to generalize this method to language generation tasks. Second, a useful improvement on top of MGT would be a more sophisticated method of combining the multiple granularities of representations. Third, while this paper focuses on capturing multiple representations at different levels of granularity, it would be interesting to generalize MGT to learning multiple representations along several different axes (e.g., domains, styles, intents, etc.).

Abstract

Identity fraud detection is of great importance in many real-world scenarios such as the financial industry. However, few studies addressed this problem before. In this paper, we focus on identity fraud detection in loan applications and propose to solve this problem with a novel interactive dialogue system which consists of two modules. One is the knowledge graph (KG) constructor organizing the personal information for each loan applicant. The other is structured dialogue management that can dynamically generate a series of questions based on the personal KG to ask the applicants and determine their identity states. We also present a heuristic user simulator based on problem analysis to evaluate our method. Experiments have shown that the trainable dialogue system can effectively detect fraudsters, and achieve higher recognition accuracy compared with rule-based systems. Furthermore, our learned dialogue strategies are interpretable and flexible, which can help promote real-world applications.[1]

1 Introduction

Identity fraud is one person using another person's personal information or combining a few pieces of real data with bogus information to deceive a third person. Nowadays, identity fraud is becoming an increasingly prevalent issue and has left many financial firms nursing huge losses. Besides, for persons whose identities have been stolen, they may receive unexpected bills and their credit will also be affected. Although identity fraud is a very serious problem in modern society, there are no effective fraud detection methods at present and little attention has been paid to this problem.

Intuitively, a simple way to detect identity fraud in loan applications is directly asking applicants about their personal information. However, as shown in Fig. 1, this method is prone to errors because fraudsters may well know the fake information. Fortunately, we find fraudsters generally are not clear about answers to questions that are related to the fake information.[2] We refer to these questions as *derived questions*, which can be constructed based on triplets where the head entity is the personal information entity. For example, the first derived question about "Nanjing University" is based on (Nanjing University, FoundedDate, 1902). In Fig. 1, the applicant claims to graduate from "Nanjing University" but can not answer derived questions about this school. This fact indicates that the applicant is likely to be a fraudster.

The **fake** personal information of a loan applicant:

School	Company	Residence
Nanjing University	Baidu	No.3 Gulou Street

System: Which university did you graduate from?
Applicant: Nanjing University.
System: Which company do you work for?
Applicant: Baidu.
System: Where do you live?
Applicant: No.3 Gulou Street.
Decision: Non-Fraud (Wrong)

System: When was Nanjing University founded?
Applicant: I am not sure.
System: Which is the nearest subway station to Nanjing University?
Applicant: I am not quite clear.
Decision: Fraud (Correct)

Figure 1: Dialogue examples of two possible fraud detection methods. The first one is directly asking applicants about their personal information. The second one is asking applicants about questions that are related to their personal information.

Based on the above finding, we aim to design a

[1] https://github.com/Leechikara/Dialogue-Based-Anti-Fraud

[2] This finding is based on the premise that loan applicants answer questions without any help (e.g., using automatic QA systems or information retrieval tools). In fact, this premise is reasonable in many real scenarios, such as dialogue with video calls and phone calls in which we can monitor the applicants with a camera or require them to answer questions within few seconds (e.g., 5 seconds).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1762–1771, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

dialogue system to detect identity fraud by asking derived questions. However, there are three major challenges in achieving this goal.

First, designing derived questions requires a high-quality KG. However, owing to the sparseness problem (Ji et al., 2016; Trouillon et al., 2017) of the KG, many entities have no triplets for derived question generation. Second, randomly selecting triplets to generate questions is feasible but it is not the optimal questioning strategies to detect fraudsters. Third, because of privacy issues, evaluating anti-fraud systems with real applicants is not practical. And existing user simulation methods (Li et al., 2016; Georgila et al., 2006; Pietquin and Dutoit, 2006) do not apply to our task. Hence, how to evaluate our systems efficiently is a problem.

To address the above problems, we first complete an existing KG with geographic information in an electronic map (Section 2). In the new KG, nearly all personal information entities can find triplets for derived question generation. Then, based on the KG, we present structured dialogue management (Section 3) to explore the optimal dialogue strategy with reinforcement learning. Specifically, our dialogue management consists of (1) the *KG-based dialogue state tracker* (KG-DST) that treats embeddings of nodes in the KG as dialogue states and (2) the *hierarchical dialogue policy* (HDP) where high-level and low-level agents unfold the dialogue together. Finally, based on intuitive analysis, we find the applicants' behavior is related to some factors (Section 5.1). Thus, we introduce hypotheses to formalize the effect of these factors on the applicants' behavior and propose a heuristic user simulator to evaluate our systems.

Experiments have shown that the data-driven system significantly outperforms rule-based systems in the fraud detection task. Besides, the ablation study proves that the proposed dialogue management can improve the recognition accuracy and learning efficiency because of its ability to model structured information. We also analyze the behavior of our system and find the learned anti-fraud policy is interpretable and flexible.

To summarise, our main contributions are threefold: (1) As far as we know, this is the first work to detect identity fraud through dialogue interactions. (2) We point out three major challenges of identity fraud detection and propose corresponding solutions. (3) Experiments have shown that our approach can detect identity fraud effectively.

2 Knowledge Graph Constructor

There are four types of personal information in a Chinese loan application form: "School", "Company", "Residence" and "BirthPlace". To generate derived questions, we link all personal information entities to nodes in an existing Chinese KG[3] and crawl triplets that are directly related to them. However, owing to the fact that the KG is largely sparse, nearly a half of entities[4] cannot be linked. Thus we use wealthy geographic information about organizations and locations in electronic maps (e.g., Amap[5]) to complete the KG.

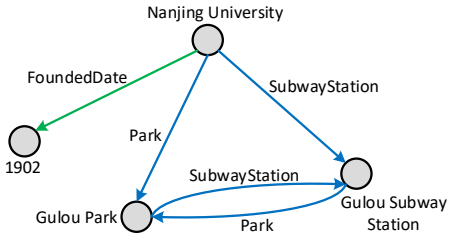

Figure 2: An example of the KG for Nanjing University. The green edge represents the triplet crawled from the existing KG and the blue edges represent the triplets generated based on a navigation electronic map.

Specifically, for each personal information entity, we first crawl its points of interest (POI[6]) within one kilometer and the POI types in the Amap. If there are multiple POI for the same type, we only keep the nearest one. Then we generate triplets in the form of ($Personal Information Entity$, $POI type$, POI) to indicate the fact that the nearest $POI type$ to the $Personal Information Entity$ is POI. Besides, for any two entities, if the distance between them is less than 100 meters, we generate two triplets to represent the bi-directional adjacency relation between them. In the end, as shown in Fig. 2, we combine triplets from the two information sources (the Chinese KG and the electronic map) to construct a new KG. In this KG, nearly all personal information entities can be linked. And for each relation[7], we design a language template for the question generation.

3 Dialogue System Design

The overview of our system is shown in Fig. 3. The core of the system is dialogue management

[3] https://www.ownthink.com

[4] Most of them are "Residence" and "BirthPlace".

[5] https://www.amap.com

[6] The POI are the specific locations (e.g., subway stations) that someone may find useful in navigation systems.

[7] After the data cleaning, there are 40 relations in all.

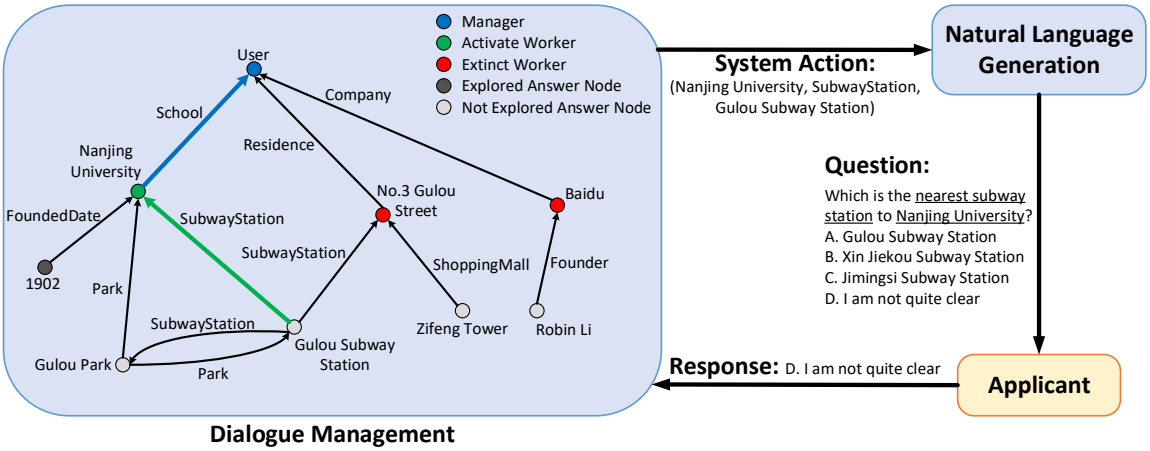

Figure 3: Overview of our approach. To build the directed graph for dialogue management, we reverse directions of all edges in the original personal KG to make the head entity read information from its tail entities. Besides, we add a special node "User" and new edges to represent the applicant's personal information. In this graph, the direction of each edge is the direction of message passing in KG-DST. The blue and green edges indicate that two agents select nodes to unfold the dialogue according to HDP.

which is organized as a directed graph $G(\mathbb{V}, \mathbb{E})$. In each turn, our system first infers dialogue states with the *KG-based dialogue state tracker* by computing embeddings of nodes. In this graph, the embedding of "User" node is the dialogue state of a high-level agent (manager), and the embeddings of nodes adjacent to "User" (named as personal information nodes) are the dialogue states of low-level agents (workers). Then our system unfolds the dialogue according to the *hierarchical dialogue policy*. Concretely, the manager first selects a personal information node (e.g., "Nanjing University") as the worker, and then the worker will select a node (e.g., "Gulou Subway Station") from its predecessors (named as answer nodes). After that, the sampled nodes of two agents form the final system action (a triplet). Next, based on the triplet and a predefined template, the natural language generation module will give a multiple-choice question to the applicant. After the applicant gives a response, the embeddings of all nodes will be updated to generate new dialogue states for the next turn.

3.1 KG-based Dialogue State Tracker

There are three types of nodes in $G(\mathbb{V}, \mathbb{E})$: the "User" node v_u, the personal information node $v_p \in \mathbb{V}_p$ and the answer node $v_a \in \mathbb{V}_a$. In the t-th turn, KG-DST first gives an initial embedding to $v \in \mathbb{V}_p \cup \mathbb{V}_a$. The initial embedding is the concatenation of *static features* and *dialogue features*. Then, v will gather information from its predecessors $N(v)$. After multiple *message passings*, we get its final embedding $E_t(v)$. Next, v_u will aggregate information from $\mathbb{V}_p$ to generate its embedding $E_t(v_u)$. Finally, $E_t(v_u)$ and $E_t(v_p)$ are the dialogue states of the manager and worker respectively.

Static Features. Specifically, for $v \in \mathbb{V}_p \cup \mathbb{V}_a$, the static features include the degree and type. Besides, for $v_a \in \mathbb{V}_a$, we use the "spread degree on the internet" to distinguish different answer nodes because we find there is an obvious correlation between this "spread degree" feature and applicants' behavior in our human experiments (Section 5.1). To get the "spread degree" feature, we first treat the answer node v_a and its adjacent personal information node v_p as the keyword[8], and then search it in the search engine. The number[9] of the retrieved results will be the "spread degree" feature of v_a. In the end, each static feature is encoded as a one-hot vector and they are concatenated to form a vector $S_t(v)$.

Dialogue Features. The dialogue features record the dynamic information of $v \in \mathbb{V}_p \cup \mathbb{V}_a$ during the dialogue. Specifically, dialogue features include whether the node has been explored by the manager or workers and whether the node appeared in the system action of the last turn. In addition, for $v_p \in \mathbb{V}_p$, the dialogue features include the interaction turns of the corresponding worker and the number of correctly/incorrectly answered questions about v_p. For $v_a \in \mathbb{V}_a$, the dialogue features

[8] In fact, the keyword is the head entity and tail entity of a triplet. For example, for the answer node "1902", the keyword is "Nanjing University 1902".

[9] If there are multiple keywords for an answer node (e.g., "Gulou Subway Station"), we take the average.

include whether applicants know v_a is the answer to a derived question. Similarly, dialogue features will be encoded as a one-hot vector $D_t(v)$.

Message Passing. In Fig. 3, the applicant does not know "Gulou Subway Station" is the nearest subway station to "Nanjing University". In such case, the personal information about "School" may be fake. Besides, for another question "What's the nearest park to Nanjing University?", the applicant may not know the answer because the distance between "Gulou Park" and "Gulou Subway Station" is less than 100 meters. Thus, we want the known information of "Gulou Subway Station" to be sent to its successors.

Specifically, for $v \in \mathbb{V}_p \cup \mathbb{V}_a$, we compute its embedding recursively as follows:

$$E_t^k(v) = \max_{v' \in N(v)} \tanh\left(\mathbf{W}^k E_t^{k-1}(v')\right) \quad (1)$$

where $E_t^k(v)$ is the depth-k node embedding in the t-th turn, $N(v)$ denotes the set of nodes adjacent to v, $\mathbf{W}^k$ is the parameter in the k-th iteration and the aggregate function is the element-wise max operation. The final node embedding is the concatenation of embeddings at each depth:

$$E_t(v) = \left[E_t^0(v), ..., E_t^K(v)\right] \quad (2)$$

where $E_t^0(v) = [S_t(v), D_t(v)]$ and K is a hyper-parameter.

After getting the embedding of $v_p \in \mathbb{V}_p$, we compute the embedding of v_u by aggregating information from $\mathbb{V}_p$:

$$E_t(v_u) = \max_{v_p \in \mathbb{V}_p} \tanh\left(\mathbf{W}^p E_t(v_p)\right) \quad (3)$$

where $\mathbf{W}^p$ is the parameter.

In the end, $E_t(v_p)$ is the worker's dialogue state which contains information of a part of the graph and $E_t(v_u)$ is the manager's dialogue state which contains information of the whole graph.

3.2 Hierarchical Dialogue Policy

After obtaining the dialogue states and node embeddings, our system will unfold the dialogue according to a hierarchical policy.

Specifically, the manager first selects $v_p \in \mathbb{V}_p$ as a worker to verify the identity state of v_p according to a high-level policy π^m. Then, the worker will choose some answer nodes from its predecessors $N(v_p)$ to generate questions about v_p according to a low-level policy π^w. If the worker gives the decision $d^w \in \{\text{Fraud}, \text{Non-Fraud}\}$ about the identity state of v_p, π^w will end and the manager will select a new worker again or give the final decision. If the manager gives the final decision $d^m \in \{\text{Fraud}, \text{Non-Fraud}\}$ about the applicant's identity state, π^m will end. Formally, π^m and π^w are defined as follows:

$$\begin{aligned}
\pi_t^m(v_p|E_t(v_u)) &\propto \exp\left(\mathbf{W}^m\left[E_t(v_u), E_t(v_p)\right] + b^m\right) \\
\pi_t^m(d^m|E_t(v_u)) &\propto \exp\left(\mathbf{W}^m\left[E_t(v_u), E(d^m)\right] + b^m\right) \\
\pi_t^w(v_a|E_t(v_p)) &\propto \exp\left(\mathbf{W}^w\left[E_t(v_p), E_t(v_a)\right] + b^w\right) \\
\pi_t^w(d^w|E_t(v_p)) &\propto \exp\left(\mathbf{W}^w\left[E_t(v_p), E(d^w)\right] + b^w\right)
\end{aligned} \quad (4)$$

where $\{\mathbf{W}^m, \mathbf{W}^w, b^m, b^w, E(d^m), E(d^w)\}$ are parameters, $E_t(v_u)$ and $E_t(v_p)$ are dialogue states of the manager and worker in the t-th turn, $E(d^m)$ is the encoding of the manager's terminal action which has the same dimension as $E_t(v_p)$, and $E(d^w)$ is the encoding of the worker's terminal action which has the same dimension as $E_t(v_a)$.

Besides, to prevent the two agents from making decisions in haste, domain rules are applied to their dialogue policies by "Action Mask" (Williams et al., 2017). Specifically, domain rules are defined as follows. First, only after all or at least three answer nodes related to a worker have been explored can the worker make the decision. Second, only after all workers have made decisions or at least one worker's decision is "Fraud" can the manager make the final decision.

4 Training

4.1 Reward Function

We expect the system can give correct decisions about applicants within minimum turns. Thus, at the end of each dialogue, the manager receives a positive reward r_{crt}^m for correct decision, or a negative reward $-r_{wrg}^m$ for wrong decision. If the manager selects a worker to unfold the dialogue in the t-th turn and the worker gives n_t^w questions to the applicant, the manager will receive a negative reward $-n_t^w * r_{turn}$. Besides, we provide an internal reward to optimize the low-level policy. Specifically, if the worker gives a correct decision about the corresponding personal information, it will receive a positive reward r_{crt}^w. Otherwise, it will receive a negative reward $-r_{wrg}^w$. And in each turn, the worker receives a negative reward $-r_{turn}$ to encourage shorter interactions.

4.2 Reinforcement Learning

The two agents can be trained with policy gradient (Williams, 1992) approach as follows:

$$\nabla \pi_t^m = \Big(R_t^m - V_t^m\big(E_t(v_u)\big)\Big) \nabla \log \pi_t^m\big(a_t^m | E_t(v_u)\big)$$
$$\nabla \pi_t^w = \Big(R_t^w - V_t^w\big(E_t(v_p)\big)\Big) \nabla \log \pi_t^w\big(a_t^w | E_t(v_p)\big) \tag{5}$$

where R_t^m and R_t^w are the discounted returns of two agents, a_t^m and a_t^w are their sampled actions, $V_t^m\big(E_t(v_u)\big)$ and $V_t^w\big(E_t(v_p)\big)$ are value networks which are optimized by minimizing mean-square errors to R_t^m and R_t^w respectively.

4.3 Pre-Training

Before reinforcement learning (RL), supervised learning (SL) is applied to mimic dialogues provided by a rule-based system. Rules are defined as follows. First, the manager selects a worker randomly. Then, the worker will select answer nodes randomly to generate questions. Let n_{crt}/n_{wrg} denotes the number of correctly/incorrectly answered questions in this worker's decision process. If $|n_{crt} - n_{wrg}| \geq 3$ or all answer nodes related to this worker have been explored, the worker will give its decision. If $n_{crt} < n_{wrg}$, the worker's decision will be "Fraud" and the manager's decision will be "Fraud" too. Otherwise, the worker's decision will be "Non-Fraud" and the manager will choose a new worker to continue the dialogue. In the end, if all workers' decisions are both "Non-Fraud", the manager's decision will be "Non-Fraud".

5 Experiments and Results

5.1 User Simulator and Human Experiments

Simulating users' behavior is an efficient way to evaluate dialogue systems. In our task, the applicants' behavior is answering derived questions. Thus, the key of user simulator is to estimate the probability $p(\boldsymbol{k}_i)$, where $\boldsymbol{k}_i$ is a binary random variable which denotes whether or not the applicant knows the triplet fact $\boldsymbol{t}_i$ behind a question $\boldsymbol{q}_i$.

Intuitively, $p(\boldsymbol{k}_i)$ depends on three factors. First, if the applicant's identity state is "Non-Fraud", $p(\boldsymbol{k}_i = 1)$ will be greater than $p(\boldsymbol{k}_i = 0)$. Second, the wider a triplet fact $\boldsymbol{t}_i$ spreads on the internet, the more likely applicants know it. For example, almost all of applicants know (Baidu, Founder, Robin Li) because there are a lot of web pages containing this fact on the internet. Third, if applicants know other triplets that are related to $\boldsymbol{t}_i$, they may well know $\boldsymbol{t}_i$ because it is easy to deduce $\boldsymbol{t}_i$ based on what they know. For example, if applicants know (Nanjing University, Park, Gulou Park) and (Gulou Park, SubwayStation, Gulou Subway Station), they may well know (Nanjing University, SubwayStation, Gulou Subway Station).

To formalize the effect of the three factors on applicants' behavior, we introduce three hypotheses: (1) For both fraudsters and normal applicants, $p(\boldsymbol{k}_i = 1)$ is proportional to the "spread degree" of $\boldsymbol{t}_i$. (2) The "spread degree" of $\boldsymbol{t}_i$ can be approximated by the number of retrieved results (denoted as $\text{Freq}(e_i^h, e_i^t)$) in search engine where the keyword is the head entity e_i^h and the tail entity e_i^t of $\boldsymbol{t}_i$. (3) For any three triplets, if they form a closed loop (regardless of directions) and applicants know two of them, the applicants must know all of them.

To generate simulated loan applicants, we first estimate the function relations between $p(\boldsymbol{k}_i = 1)$ and $\text{Freq}(e_i^h, e_i^t)$ via human experiments. Specifically, we ask 31 volunteers to answer derived questions[10] about their own and others' personal information. And then, for the question $\boldsymbol{q}_i$, we place it into a discrete bin according to the logarithm of $\text{Freq}(e_i^h, e_i^t)$. In each bin, we use the ratio of correctly answered questions to approximate $p(\boldsymbol{k}_i = 1)$. In the end, the relations are shown in Fig. 4. We can find that the statistical distributions of real behavior patterns of normal applicants and fraudsters are distinguishable and the results agree with our first two intuitions.

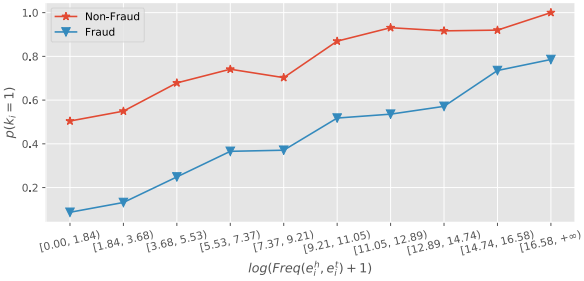

Figure 4: The relations between $\text{Freq}(e_i^h, e_i^t)$ and $p(\boldsymbol{k}_i)$ for two kinds of applicants. $\text{Freq}(e_i^h, e_i^t)$ is used to approximate the "spread degree" of $\boldsymbol{t}_i$. $p(\boldsymbol{k}_i = 1)$ indicates the probability that applicants know $\boldsymbol{t}_i$.

Then, we get simulated loan applicants[11] following a "*sampling and calibration*" manner. Specifically, given an applicant's personal information, we first sample the identity state randomly. If the

[10] There are 1516 derived questions in all.

[11] Note that we can generate any number of simulated applicants based on one applicant's personal information.

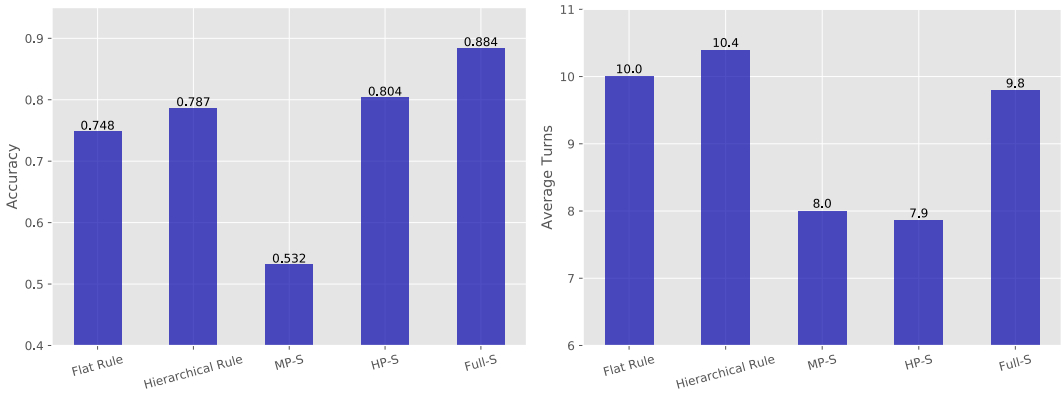

Figure 5: Performance of different systems. Tested on 10 epochs using the best model during training.

sampling result is "Fraud", we will sample $1 \sim 4$ information item(s) randomly to be the fake information. Generally, forging information about "School" and "Company" may result in a larger loan. Thus, when sampling the fake information, the sampling probability of "School" and "Company" is twice the sampling probability of "Residence" and "BirthPlace". Then, for each personal information and its related triplet $\boldsymbol{t_i}$, we sample $\boldsymbol{k_i}$ based on (1) whether the personal information is fake (2) Freq(e_i^h, e_i^t) and (3) the corresponding function relation in Fig. 4. Because the sampling results $\{\boldsymbol{k_1}, ..., \boldsymbol{k_n}\}$ are independent from each other, there may be the situations where the sampling results do not satisfy the rule defined in our third hypothesis. If that happens, we calibrate it until all sampling results agree with the hypothesis. Finally, if $\boldsymbol{k}_i = 1$, the applicant will give the correct answer to the question $\boldsymbol{q}_i$. Otherwise, the applicant's response is "D. I am not quite clear.".

5.2 Baselines

We compare our model (denoted as Full-S) with two rule-based baselines. In addition, to study the effect of message passing and hierarchical policy on the model training, we compare Full-S with two neural baselines for the ablation study.

- Flat Rule: The system selects 10 questions randomly to ask applicants. If the number of correctly answered questions is fewer than the number of incorrectly answered questions, the system's decision will be "Fraud". Otherwise, the system's decision will be "Non-Fraud".
- Hierarchical Rule: A rule-based system which uses a hand-crafted hierarchical policy to unfold dialogues. As shown in Section 4.3, we use this system to pre-train Full-S.
- MP-S: A neural dialogue system which uses message passing to infer dialogue states but uses a flat policy to unfold dialogues. That is, the manager selects answer nodes directly to generate derived questions.
- HP-S: A neural dialogue system which uses the hierarchical policy to unfold dialogues but does not use message passing to infer dialogue states. That is, K is 0 in Eq. 2.

5.3 Implementation Details

We collect 906 applicants' personal information, and randomly select 706 for training, 100 for dev, and 100 for test. In each batch, we sample 32 applicants' information for simulation. The maximum interaction turns of the system and the worker are 40 and 10 respectively. The iteration depth K is 2 in message passing. In the reward function, $r_{crt}^m = 3$, $r_{wrg}^m = 3$, $r_{crt}^w = 1$, $r_{wrg}^w = 1$, $r_{turn} = 0.1$. The discount factors are 0.999 and 0.99 for the manager and worker respectively. All neural dialogue systems are both pre-trained with rule-based systems for 20 epochs. We pre-train MP-S with Flat Rule because they both use the flat policy. Besides, we pre-train HP-S and Full-S with Hierarchical Rule because they both use the hierarchical policy. In the RL stage, all neural dialogue systems are trained for 300 epochs. When testing, we repeat 10 epochs and take the average.

5.4 Test Performance

We compare Full-S with baselines in terms of two metrics: recognition accuracy and average turns.

Fig. 5 shows the test performance. We can see that the accuracy of Flat Rule is lower than Hierarchical Rule, and the accuracy of the data-driven counterpart of Flat Rule (MP-S) is just slightly

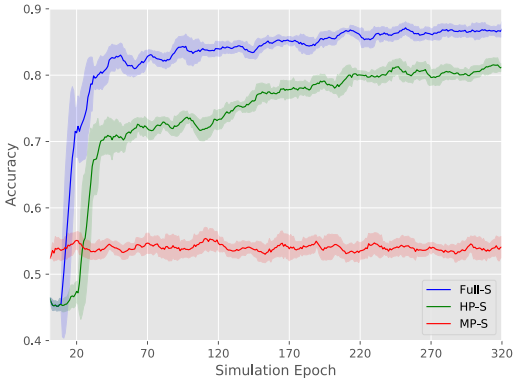

Figure 6: Accuracy curves of different neural models in dev set. The first "20 epochs" indicates the pre-training stage. The last "300 epochs" indicates the RL stage.

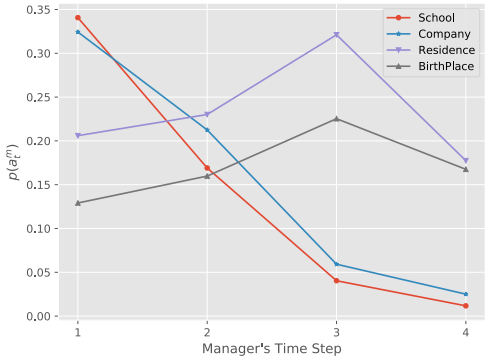

Figure 7: Manager's action probability curves. Each curve indicates the probability of selecting a piece of personal information to verify. For each curve, we take the average of all dialogues during testing.

higher than randomly guessing. It means that using the hierarchical policy to unfold dialogues is necessary for our task. Besides, HP-S achieves a higher accuracy than its rule-based counterpart (Hierarchical Rule) within much fewer turns. It proves that the data-driven system is more efficient than the rule-based system. Finally, equipped with message passing and hierarchical policy, Full-S achieves the best accuracy. And it is interesting to note that Full-S requires more turns but achieves much higher accuracy than HP-S. One possbile reason is that HP-S may easily trap in local optimum without message passing to infer dialogue states.

5.5 Ablation Study

To study the effect of message passing and hierarchical policy, we show the learning curves of three neural dialogue systems in Fig. 6. Each learning curve is averaged on 10 epochs.

We find that, compared with Full-S and HP-S, MP-S is unable to learn any useful dialogue policy during training. There are two reasons for this. First, the action space of flat policy is too large, which results that MP-S suffers from the sparse reward and long horizon issues. Second, without explicitly modeling the logic relation between the manager and workers, MP-S is prone to errors. Besides, we can see that the convergence speed of Full-S is faster than HP-S in both the pre-training and the RL stages. This is because message passing can model structured information of the KG, and hence Full-S is more efficient in policy learning.

5.6 Manager's Policy Analysis

To better understand the high-level dialogue policy, we analyze the manager's behavior in Full-S.

First, we show the manager's action probability curves in Fig. 7. We can see that selecting "School" and "Company" to verify personal information has a priority over "Residence" and "BirthPlace" in the first decision step. And in the following two decision steps, the probabilities of selecting "Residence" and "BirthPlace" will increase. This is because simulated applicants tend to forge personal information about "School" and "Company" for a larger loan. Consequently, to discover fake information faster, the manager learns to prioritize different information items.

Second, intuitively the manager's policy should follow two logic rules in our task:

Rule1: If a worker's decision is "Fraud" ($Cond1$), the dialogue should end immediately and the manager's decision will be "Fraud" ($RS1$).

Rule2: If all workers' decisions are both "Non-Fraud" ($Cond2$), the manager's decision will be "Non-Fraud" ($RS2$).

To test whether the manager follows the two rules, we calculate the probabilities of $RS1$ and $RS2$ under $Cond1$ and $Cond2$ respectively. Specifically, in the test data, $p(RS1|Cond1) = 0.95$ and $p(RS2|Cond2) = 0.96$. It proves that the manager will adopt workers' suggestions in most situations.

Meanwhile, we study cases where the manager does not follow the two rules and find some interesting phenomena. Specifically, if only one worker's decision is "Fraud" and the applicant can answer a few questions given by this worker, the manager's decision may be "Non-Fraud". Besides, if all workers' decisions are both "Non-Fraud" but the applicant can not answer most of the questions given

All triplets that are related to "Shanghai Sports University" (replaced with $School$ for short):

Decison: Fraud (Wrong)	Decison: Non-Fraud (Correct)

Table 1: Examples of the low-level policies in two systems. Note that the information about "School" is not fake.

by one worker, the manager's decision may still be "Fraud". In fact, when the two cases happen, the worker may make the wrong decision. However, the manager can still give the correct decision. It means the manager is robust to workers' mistakes.

5.7 Worker's Policy Analysis

To better understand the low-level dialogue policy and the effect of message passing on it, we compare workers' behaviors in HP-S and Full-S.

Table 1 shows an example of verifying personal information about "School" in HP-S and Full-S. We can see that the two systems give the same two questions in the first two turns. This is because the triplets behind the two questions are rarely known to fraudsters. It means that the low-level policies learn to give priority to such triplets for better distinguishing fraudsters from normal applicants. In the third turn, HP-S gives a question that is easy to answer for fraudsters and makes the wrong decision. However, Full-S notices the applicant gives the correct answer to a question that is hard to answer for fraudsters. Thus, Full-S does not make the decision in haste but continue the dialogue. Besides, it is worth noting that Full-S has not chosen ($School$, ConvenienceStore, HaoDe) to generate the derived question. This is because the message passing mechanism models the relation between "HaoDe" and "Xiao Liu Fruit". Specifically, because the two entities are closely related to each other, if applicants know "Xiao Liu Fruit", they may well know "HaoDe". Thus, there is no need to select this triplet anymore.

6 Related work

As far as we know, there is no published work about detecting identity fraud via interactions. We describe the two most related directions as follows:

Deception Detection. Detecting deception is a longstanding research goal in many artificial intelligence topics. Existing work has mainly focused on extracting useful features from non-verbal behaviors (Meservy et al., 2005; Lu et al., 2005; Bhaskaran et al., 2011), speech cues (Levitan et al., 2018; Graciarena et al., 2006) or both (Krishnamurthy et al., 2018; Pérez-Rosas et al., 2015) to train a classification model. In their work, the definition of deception is telling a lie. Besides, existing work requires labeled data, which is often hard to get. In contrast, we focus on detecting identity fraud through multi-turn interactions and use reinforcement learning to explore the anti-fraud policy without any labeled data.

Dialogue System. Our work is also related to task-oriented dialogue systems (Young et al., 2013; Wen et al., 2017; Li et al., 2017; Gašić et al., 2011; Wang et al., 2018, 2019). Existing systems have mainly focused on slot-filling tasks (e.g., booking a hotel). In such tasks, a set of system actions can be pre-defined based on the business logic and slots. In contrast, the system actions in our task are selecting nodes in the KG to generate questions. Thus, the structured information is important in our task. Besides, some works also try to model structured information in dialogue systems. For example, Peng et al. (2017) used hierarchical reinforcement learn-

ing (Vezhnevets et al., 2017; Kulkarni et al., 2016; Florensa et al., 2017) to design multi-domain dialogue management. Chen et al. (2018) used graph neural networks (Battaglia et al., 2018; Li et al., 2015; Scarselli et al., 2009; Niepert et al., 2016) to improve the sample-efficiency of reinforcement learning. He et al. (2017) used DynoNet to incorporate structured information in the collaborative dialogue setting. Compared with them, our method is a combination of the graph neural networks and hierarchical reinforcement learning, and experiments prove that they both work in the novel dialogue task.

7 Conclusion

This paper proposes to detect identity fraud automatically via dialogue interactions. To achieve this goal, we present structured dialogue management to explore anti-fraud dialogue strategies based on a KG with reinforcement learning and a heuristic user simulator to evaluate our systems. Experiments have shown that end-to-end systems outperform rule-based systems and the proposed dialogue management can learn interpretable and flexible dialogue strategies to detect identity fraud more efficiently. We believe that this work is a basic first step in this promising research direction and will help promote many real-world applications.

Hierarchy Response Learning for Neural Conversation Generation

Bo Zhang[1] and **Xiaoming Zhang**[1,2]

Abstract

The neural encoder-decoder models have shown great promise in neural conversation generation. However, they cannot perceive and express the intention effectively, and hence often generate dull and generic responses. Unlike past work that has focused on diversifying the output at word-level or discourse-level with a flat model to alleviate this problem, we propose a hierarchical generation model to capture the different levels of diversity using the conditional variational autoencoders. Specifically, a hierarchical response generation (HRG) framework is proposed to capture the conversation intention in a natural and coherent way. It has two modules, namely, an expression reconstruction model to capture the hierarchical correlation between expression and intention, and an expression attention model to effectively combine the expressions with contents. Finally, the training procedure of HRG is improved by introducing reconstruction loss. Experiment results show that our model can generate the responses with more appropriate content and expression.

1 Introduction

Neural conversation generation (Xu et al., 2017; Zhang et al., 2018), focusing on responding to humans intelligently on a variety of topics, has drawn great attention from both academic and industry. The sequence-to-sequence model (Seq2Seq) (Sutskever et al., 2014) is one type of neural generation model that maximizes the probability of generating a response given the dialogue context. It enables the incorporation of rich context to generate coherent responses in an unsupervised manner. However, it was found that Seq2Seq models suffer from so-called safe response problem (Xu et al., 2017) , i.e., they tend to generate some dull and generic repetitive responses (e.g., *"I think so"*, *"I don't know'*, etc.), rather than meaningful and conscious expression. Xu et al. (2017) ascribed this to the fundamental nature of statistical models since the distribution of most pieces of information are relatively sparser when compared to the safe response patterns in the open domain conversations. Some works attempted to improve the architecture of Seq2Seq models, including introducing reinforcement learning (Zhang et al., 2018), encouraging responses that have long-term payoff, etc. The other important reason is that the response generation model cannot express the intention and emotion internally. Thus, one line of research has focused on forcing the model to simulate some human's skills by augmenting the input with rich meta information. For example, some recent works biased the responses to some specific personas (Li et al., 2016b) or emotions (Huber et al., 2018).

Usually, in the process of human conversation, a speaker participates in the dialogue including the following steps. The speaker is firstly required to decide what the intention is to reflect the inner feelings or opinions. In the speaker's knowledge base, there may be varieties of appropriate expressions that can be found to represent his current intention. Therefore, a meaningful response can be produced by choosing one of the expressions and filling it with relevant content. For example, if a man wants to ask the way to the Park, he first needs to select an appropriate expression from a cluster of the expressions, e.g., *"Where is the . . . ?"*, *"How do I get to the . . . ?"* and *"Is the . . . far from here?"*, and then replaces ". . . " as the destination, i.e., the Park. As a crucial feature in natural conversation, **dialog acts** (Poesio and Traum, 1998) have been widely used in the dialogue managers to represent the intentions. Existing works introduce dialog acts to label a cluster of responses and a latent variable is learned to select a dialog act for response generation (Zhao et al., 2017; Serban

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1772–1781, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

et al., 2017a). However, it is not effective to capture the output diversity since the natural correlation between the expression patterns and dialog acts is not learnt. Intuitively, another latent level can be introduced to generate different expressions from the same dialog act, and a hierarchical structure can be used to model the response generation process. That is, the knowledge base is first constructed over the pairs of expressions and dialog acts to capture the latent correlation between them. Then, varieties of expressions can be selected from the knowledge base to be filled with the response content based on the latent correlation.

To learn the hierarchical model, it is quite challenging in large-scale conversation generation due to the following reasons. **First**, the semantic world is populated with a vast number of expressions, each of which corresponds to a specified label that reflects a kind of dialog act. Obtaining high-quality expression-act data is impractical particularly in open domain conversations. **Second**, it is difficult to incorporate expression and content into the generation model in a nature and coherent way because they have different semantic representation patterns. **Last**, this process cannot be efficiently optimized using stochastic gradient descent (SGD) akin to backpropagation on feedforward neural networks.

To tackle the challenges, we propose to take advantage of the hierarchical nature of response generation. In particular, we investigate: (1) how to automatically learn a hierarchical model to naturally capture the response generation process; (2) how to adaptively learn and adjust the influence ratio between expression and content. Our solutions to these questions result in a new architecture for neural response generation. In particular, a novel hierarchical response generation (HRG) framework is proposed to effectively capture the process of response generation. An expression reconstruction model with a two-level probability structure is introduced to randomly generate the expressions, and an expression attention model is proposed to effectively fill the expressions with content. Finally, an efficient training method is proposed to learn the model within the framework of conditional variational autoencoders (CVAE) (Doersch, 2016). The main contributions are outlined as:

- We propose to investigate the problem of generating variety and meaningful responses by imitating the human response process with a hierarchical response generation model.
- We propose an end-to-end framework to incorporate the expression and response content into the dialog generation. Our model is interpretable and even controllable compared to traditional generation model.
- We empirically demonstrate that our approach can generate responses with better expressions and content than traditional generation model.

2 Problem Statement

Our problem is formulated as follows: Given a dialog context C and a dialog act a of the response to be generated, the goal is to generate a response $y = (y_1, y_2, ..., y_n)$ that is coherent with the dialog act a. Essentially, the model estimates the probability: $P(y|C, a) = \prod_t P(y_t|y_{<t}, C, a)$. A simple implementation is to directly embed the act information into the Seq2Seq model. However, as shown in our experiments, it still suffers from safe response problem.

In this paper, we propose a novel hierarchical model to imitate the human thinking process in the conversation generation. The hierarchical generation process is: (1) for each dialog act a, a set $\Omega(a)$ is constructed to contain all the corresponding expressions of a; (2) to generate an expression, a dialog act a is first selected, and then an appropriate expression e is also selected from $\Omega(a)$; (3) a response is obtained by filling the expression e with relevant content according to the dialog context C. This hierarchical model allows us to express the responses with diverse expression templates of the same dialog act by drawing different samples from $\Omega(a)$. However, in addition to the difficulty of constructing high-quality set $\Omega(a)$, it is also needed to maximize the probability of each y in the training set with the objective: $P(y|C, a) = \int_{e \in \Omega(a)} P(y|C, e)\, de$, which is also difficult to compute by the numeric methods.

In our approach, the expression e is modeled as a conditional distribution over the dialog act a, i.e., $p_\theta(e|a)$. The response is then generated by feeding the expression e obtained based on $p_\theta(e|a)$ into the model, i.e., $P(y|C, e), e \sim p_\theta(e|a)$. Now, the training objective is simplified as follows:

$$P(y|C, a) = \int P(y|C, e)\, p_\theta(e|a)\, de. \quad (1)$$

This objective can be transformed as the variational lower bound of CVAE (Doersch, 2016), and thus can be optimized efficiently. Specifically, the variational approximation $q_\phi(e|y)$ is constructed to approximate the intractable posterior $p_\theta(e|a)$. Assuming that the meaning of expression e is independent of C, we train the model by maximizing the variational lower bound,

$$\begin{aligned} L(\theta, \phi; y, C, a) &= -KL(q_\phi(e|y)||p_\theta(e|a)) \\ &+ \mathbb{E}_{e\sim q_\phi(e|y)}[\log p_\theta(y|C, e, a)] \\ &\leq \log p(y|C, a) \end{aligned} \quad (2)$$

where $KL(\cdot||\cdot)$ is the Kullback-Leibler divergence to measure the distance between two distributions.

Note that in our problem statement, we assume that the dialog act of the to-be-generated response is given in advance, rather than predicted depending on the context. Many existing researches (Sacks et al., 1978; Young et al., 2013; Daniel Jurafsky, 2017) have explored dialog act interactions with dialog system and proposed some methods to decide the most appropriate dialog act for the response. In this paper, we only focus on response generation. During the testing process, we simply specify a dialog act to the model. We leave this study to our future work.

3 Hierarchical Response Generation

Building upon the encoder-decoder models (e.g., Seq2Seq, HRED(Serban et al., 2016)), a Hierarchical Response Generation (HRG) framework is proposed to effectively generate more diverse expressions for conversation generation. As shown in Figure 1, HRG contains two main modules: Expression Reconstruction model and Expression Attention model. A training method is proposed to learn the hierarchical HRG model in Section 3.3.

3.1 Expression Reconstruction

To maximize the objective Eq.(2), we are first required to model the networks $q_\phi(e|y)$ and $p_\theta(e|a)$. The task of network $q_\phi(e|y)$ is to capture the expression representations from the responses while $p_\theta(e|a)$ to sample an expression representation from the distributions associated with the specified dialog acts. As shown in Figure 2, in the framework of CVAE, the response is first encoded as a latent variable, and then a decoder is introduced to reconstruct the response. But this generation process is not interpretable and controllable. Thus, we

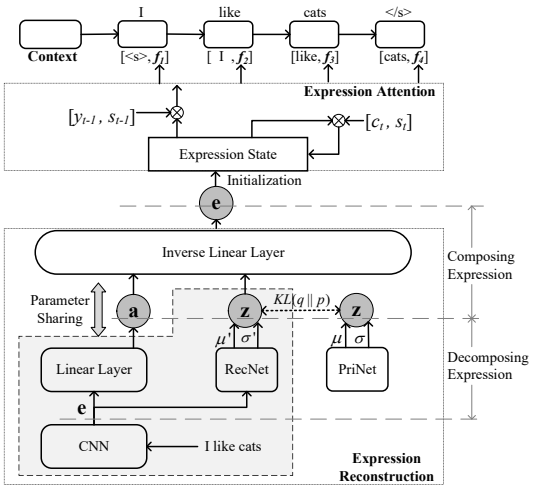

Figure 1: The overview of Hierarchical Response Generation (HRG). The components in the dashed box are removed during testing. The dialog act a is specified manually and the random variable z is generated by PriNet during testing.

propose a novel method to reconstruct the expression with multiple latent variables by establishing links between $q_\phi(e|y)$ and $p_\theta(e|a)$.

Modeling $q_\phi(e|y)$. It was found that the convolutional layer can extract the common patterns within the local regions of the input utterance (Kim, 2014). Therefore, the text convolutional network proposed in (Kim, 2014) is leveraged to mine the relationship between expression patterns and responses. Particularly, the network $q_\phi(e|y)$ consists of several convolutional filtering, local contrast normalization, and max-pooling layers, followed by several connected linear layers. Formally, given a response y, the expression representation can be described as

$$e = \text{CNN}(y). \quad (3)$$

In the experiments, we found that the convolutional layers can effectively extract the expression representation by discarding the content-related information.

Modeling $p_\theta(e|a)$. Given a dialog act a, the network $p_\theta(e|a)$ outputs an expression representation associated with a. To capture output diversity, it is also necessary to generate different expressions each time given the same dialog act. The classical models (e.g., linear layer) are not capable of representing this feature. Instead, the network $p_\theta(a|e)$ is easy to model by a linear layer, where

$$a = g(e) = \boldsymbol{W_f} \cdot e + \boldsymbol{b_f}. \quad (4)$$

Motivated by this observation, we propose an Inverse Linear Layer to model the network $p_\theta(e|a)$ where the dialog act a is mapped inversely into the expression representation e by solving g^{-1}.

Penrose Theorem (Ben-Lsrael and Greville, 1976) gives a general solution of equation $AX = B$ and proofs it. To solve g^{-1}, we simplify Penrose Theorem under an extra constraint and give a Corollary:

Corollary 1 *Let $A \in \mathbb{C}^{m\times n}$, $b \in \mathbb{C}^m$. The general solution of the equation $Ax = b$ is*

$$x = A^+b + (I - A^+A)z \tag{5}$$

for arbitrary $z \in \mathbb{C}^n$ (if $0 < rank(A) < n$), where A^+ is Moore–Penrose inverse of A and I is an identity matrix.

The transformation of Ax inevitably leads to the information loss of x and thus the random vector z should be supplemented to the solution.

According to Corollary 1, the expression e can be represented by an inverse linear layer as

$$e = g^{-1}(a, z) = \boldsymbol{W_f}^+(a - \boldsymbol{b_f}) + (I - \boldsymbol{W_f}^+\boldsymbol{W_f})z. \tag{6}$$

The expression is uniquely determined by two independent variables, i.e., the dialog act a and the latent variable z. Given the same or similar dialog context, there may exist many valid expressions for the responses with the same dialog act a, each corresponding to a certain configuration of z. This representation allows us to express responses with diverse expression templates of specified dialog act by drawing samples from the learned distribution of z. The network $p_\theta(e|a)$ can be easily computed by setting $p_\theta(a, z) = p_\theta(a)p_\theta(z)$, where a and z are uncorrelated.

Reconstructing Expression. As shown in Figure 1, during training, the expression representation e is first captured from the ground-truth response by the network $q_\phi(e|y)$. The expression e is decomposed into multiple independent variables, i.e., a and z, and then these variables are composed to reconstruct the expression e by the network $p_\theta(e|a)$. These variables provide different discourse-level information to force the decoder to focus on multiple global information simultaneously. As shown in Figure 2, different from CVAE, some variables (i.e., a) in HRG are interpretable to make the model controllable while some (i.e., z) are continuous to reflect the latent feature. During testing, the model is controllable by specifying an appropriate dialog act to express the intention.

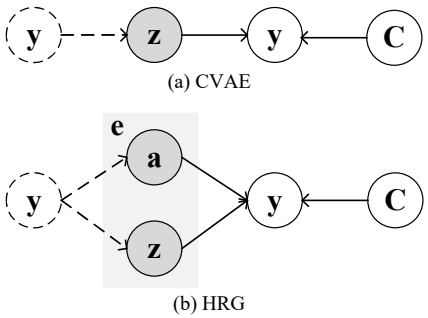

Figure 2: Graphical models for (a) CVAE and (b) HRG. Solid lines denote the generative models (a) $p(z)p(y|z, C)$ and (b) $p(e|a)p(y|e, C) = p(a)p(z)p(y|a, z, C)$; dashed lines denote the variational approximation (a) $q(z|y)$ and (b) $q(e|y) = q(a|y)q(z|y)$.

3.2 Expression Attention

There exist two main methods to incorporate the expression representation into the decoder. First, the concatenation of the context and expression representation e is used to initialize the recurrent of the decoder RNN with a nonlinear transformation. During the decoding, the decoder RNN decodes words based on the current state and previous word embeddings w. The second way is that the concatenation of fixed e and w is fed into decoder to update its state at each step. Formally, the first way updates its state only according to $[w, 0 \cdot e]$, while the second according to $[w, 1 \cdot e]$. However, these methods may cause that the content (expression) is so powerful that the responses are without any effective expression (meaningful content). In this paper, we propose an expression attention (EA) model to attend on different parts of expression representations each step by learning a vector $\alpha = \{\alpha_i \in (0, 1)\}$ adaptively. A balance between content and expression is effectively kept by feeding $[w, \alpha \cdot e]$ into decoder.

In particular, before decoding, an expression state is initialized as $q_0 = e$ to record the current expression representation. At step t, a strength gate β_t is computed based on the input of the previously decoded word y_{t-1} and the previous decoder state s_{t-1}. The expression state is weakened by a certain amount β_t at each step,

$$\beta_t = \text{Sigmoid}(\boldsymbol{W_s}[y_{t-1}, s_{t-1}]), \tag{7}$$

$$f_t = q_{t-1} \otimes \beta_t \tag{8}$$

where $\otimes$ is element-wise multiplication and $\text{Sigmoid}(x) = 1/(1 + exp(-x))$. The decoder updates its state conditioned on the previous token y_{t-1} and the current output f_t as follows:

$$s_t = \text{RNN}^d(s_{t-1}, [y_{t-1}, f_t]). \quad (9)$$

It is a dynamic process that the expression is adjusted adaptively according to the current environment and model behaviors compared to the two existing methods above. After step t, a self-update strategy is designed to update the expression state based on the context vector c_t (computed by Attention Mechanism (Luong et al., 2015)) and the current decoder state s_t. This process is formulated as

$$\gamma_t = \text{Sigmoid}(\boldsymbol{W_u}[c_t, s_t]), \quad (10)$$

$$q_t = q_{t-1} \otimes \gamma_t. \quad (11)$$

The expression representation is integrated into the decoder gradually until the expression state decays to zero through multiple iterations. The expression reconstruction and attention models respectively provide discourse-level and token-level randomness respectively, which can avoid the decoder generates the next token only depending on Neural Probabilistic Language Model instead of the dialog context and the current decoding state.

3.3 Reconstruction Training

The learnt parameters include the embeddings of vocabulary, and those in the encoder-decoder component and HRG. According to Section 3.1, we first identify two key assumptions that are essential: Both z and a are the indigenous properties of the expression e; The meaning of z is independent of the dialog act a. Based on them, we update the objective Eq.2 as

$$\begin{aligned} L(\theta, \phi; y, C, a) = & -KL(q_\phi(z|y)||p_\theta(z)) \\ & - KL(q_\phi(a|y)||p_\theta(a)) \\ & + \mathbb{E}_{z\sim q_\phi(z|y), a\sim q_\phi(a|y)}[\log p_\theta(y|C, a, z)]. \end{aligned} \quad (12)$$

Assuming that z follows isotropic Gaussian distribution, the prior network (PriNet) $p_\theta(z) = \mathcal{N}(\mu, \sigma^2\boldsymbol{I})$ and the recognition network (RecNet) $q_\phi(z|y) = \mathcal{N}(\mu', \sigma'^2\boldsymbol{I})$, where

$$\begin{bmatrix} \mu' \\ \log(\sigma'^2) \end{bmatrix} = \boldsymbol{W_r}\text{CNN}(y) + \boldsymbol{b_r}. \quad (13)$$

Now, the term $KL(q_\phi(z|y)||p_\theta(z))$ is a KL-divergence between two multivariate Gaussian distributions which can be computed in a closed form (Doersch, 2016). Different from z, the dialog act a follows discrete distribution. Minimizing the term $KL(q_\phi(a|y)||p_\theta(a))$ is much simpler than the continuous one, which can be evaluated by

$$\sum_{k=1}^{\mathcal{A}} q_\phi(a = k|y) \log \frac{q_\phi(a = k|y)}{p_\theta(a = k) + \epsilon} \quad (14)$$

where $\mathcal{A}$ is the number of dialog acts and $\epsilon = 10^{-6}$ is used to prevent division by zero. We denote the network $q_\phi(a|y)$ as the act classifier and its probability is evaluated by $softmax(\boldsymbol{W_f}\text{CNN}(y) + \boldsymbol{b_f})$. As shown in Figure 1, note here that the inverse linear layer shares the same parameters $\boldsymbol{W_f}$ and $\boldsymbol{b_f}$ with those in $q_\phi(a|y)$.

In the training process, by introducing the re-parameterization trick (Kingma and Welling, 2014), we obtain the variables z and a from RecNet $q_\phi(z|y)$ and act classifier $q_\phi(a|y)$, and then feed them into the inverse linear layer to capture expression representations. During testing, by specifying a dialog act a, the decoder generates the response according to the sample from the PriNet $p_\theta(z)$.

4 Experiment

4.1 Implementation Details

The dataset DailyDialog Corpus (Li et al., 2017b) is used to evaluate the proposed model. It contains 13,118 multi-turn human-human dialogs annotated with dialog acts and emotions, and covers 10 main topics about daily life. In this Corpus, the dialog act categories are {*Inform, Question, Directive, Commissive*}. In our experiments, HRG is combined into HRED model (Serban et al., 2016) as the expression-aware chatting machine (ECM). PyTorch[1] is used to implement the proposed model. All the RNN modules have 2-layer gated recurrent units (GRU) (Cho et al., 2014) structures with 500 hidden cells for each layer and are set with different parameters. Word embedding has size 300 and is initialized from Glove embedding[2]. The size of the latent variable z is set to be 300. The maximum dialog turn is 5 (10 utterances).

The models are trained end-to-end using Adam optimizer (Kingma and Ba, 2015) with batch size

[1] https://pytorch.org/

[2] https://nlp.stanford.edu/projects/glove/

of 30, learning rate of 0.001 and gradient clipping at 50. To overcome the *latent variable vanishing problem* in CVAE, we use the heuristic method (Bowman et al., 2016) to encode the meaningful information in z. That is, we multiply the first KL term in Eq.12 by a scalar, which starts at 0 and linearly increases to 1 over the first 10,000 batches.

4.2 Baselines

We compare our hierarchical model with two popular baselines: (1) **HAE**: a HRED-based model which we design to embed the dialog act information in the decoder; (2) **kgCVAE**: a knowledge-guided model that introduces dialog acts to guide the learning of the CVAEs (Zhao et al., 2017). A variant of the proposed model is implemented to verify the effectiveness of expression attention (EA) model. We denote the model without EA as **w/o EA**. The hyperparameters of the baselines and variants are the same as ECM.

As for **HAE**, we initialize the embedding of dialog acts using three different methods: (1) **RD** (random): initializing the embedding randomly; (2) **LG** (logic-related): training a Skip-Gram model (Mikolov et al., 2013) to maximize the co-occurrence probability among the acts that appear within a window, w, in the sequence of dialog acts for each dialog (set w to 1); (3) **CT** (content-related): training an act classifier $q_\phi(a|y)$ with the pairs of utterances and dialog acts in training set, and use each row in $\boldsymbol{W_f}$ as the embeddings. The size of act embeddings is set to 300, as the same with the output of EA. The concatenation of dialog act embedding and the previous word embedding is fed into the decoder of HRED to update its state at each step during decoding. HAE is trained to minimize the standard cross entropy loss of the decoder RNN model without any auxiliary loss.

4.3 Quantitative Analysis

Automatically evaluating the quality of the dialog model remains an open question. To evaluate how semantically relevant the response is, we report the results for three word embedding-based similarity metrics proposed by Liu et al. (2016): *Greedy Matching* (GDY), *Embedding Average* (AVG) and *Vector Extrema* (EXT). To evaluate whether the response follows the dialog act, we adopt act accuracy (ACC) as the agreement between the ground-truth dialog act and the dialog act predicted by an act classifier. We trained the act classifier and its precision and average recall in the testing set are 83.4% and 74.3% respectively.

In addition to automatic evaluation metrics, a manual evaluation metric (MUL) is also given to evaluate both the response content and expression, where three workers are employed to score a response in terms of *Content* (rating scale is 0,1,2) and *Act* (rating scale is 0,1). *Content* is evaluated based on whether the response is appropriate and natural to the dialog context, while *Act* based on whether the expression agrees with the ground-truth act. *Content* rating is a widely accepted metric proposed by Shang et al. (2015). And, the workers can easily evaluate *Act* rating based on the context since the number of acts is few in our experiment.

During testing, to efficiently measure output diversity, we generate N responses from HAE models by introducing beam search. For kgCVAE and ECM, we sample N times from the latent variable and only use greedy decoders. Meanwhile, for HAEs and ECM, we specify a as the act of the ground-truth response.

The automatic evaluation metrics focus on comparing the generated responses r_j with the ground truth g_i of the conversation. We compute the scores of models based on all the M test samples as follows:

$$AM = \frac{1}{M}\sum_{i=1}^{M}\max_{j\in[1,N]} d(g_i, r_j) \qquad (15)$$

where $d(\cdot)$ is one of automatic metrics described above, and N is empirically set to 10. Note here that the maximum metric in Eq.15 is more appropriate to measure the output diversity than average one. This is because that taking average metrics may cause that the safety responses get higher scores than meaningful and diverse responses if most of these valid responses are not related to the ground-truth. The maximum metric can greatly reduce the error by increasing the number of samples. The evaluation of MUL metric is unrelated to the ground truth responses. To evaluate MUL metric, we randomly selected 40 dialog contexts from the test set and then generate 400 responses for each model. Each response is evaluated with a rating of *Content-Act* by workers.

The automatic evaluation results are given in Table 1. According to the word embedding-based similarity metrics, responses generated by ECM are substantially more coherent and relevant to

Method (%)	GDY	AVG	EXT	ACC
HAE-RD	11.6	57.7	33.8	64.2
HAE-LG	14.7	66.0	30.0	74.2
HAE-CT	18.2	72.0	35.5	77.0
kgCVAE	23.6	75.3	**39.8**	—
ECM	**28.1**	**84.6**	37.9	80.4
w/o EA	20.6	78.0	34.8	**82.6**

Table 1: Automatic Evaluation Result.

the topic compared to HAE models and kgCVAE. ECM obtains higher act accuracy score than HAE as well since the second KL term of Eq.(12) forces the predicted act distribution to approximate the ground-truth. ECM without EA (w/o EA) achieves the best performance in act accuracy but poor performance in embedding-based similarity metrics. It indicates that EA is an efficient model to balance the expression and the content dynamically. On the other hand, HAE-CT gets higher scores both in embedding-based metrics and in accuracy than other HAE models, which suggests that the act classifier can preserve act-related information effectively. Note here that the act accuracy of kgCVAE is not given because the response act is an internal parameter predicted by the dialog context rather than an input during testing. Compared to ECM, kgCVAE may give the decoder a wrong direction to approximate the ground-truth responses with different dialog acts.

Method (%)	2-1	2-0	1-1	1-0	0-1	0-0
HAE-CT	13.5	8.0	23.5	9.0	31.5	14.5
ECM	26.5	15.5	32.0	7.0	16.0	3.0
w/o EA	21.0	6.0	29.0	10.0	28.5	5.5

Table 2: Manual evaluation result. The percentage of responses with the ratings of *Content-Act*. For instance, 2-1 means *Content* rating is 2 and *Act* rating is 1.

Table 2 shows the manual evaluation result where the content and expression are considered simultaneously. As we can see, responses generated by w/o EA tend to contain obvious act information but a little of content, while HAE generates the responses with lower scores of *Content-Act*. Compared to other methods, responses generated by ECM keep a good balance between *Content* and *Act*. In our experiment, we also find that HAE-CT still faces serious safe response problems. However, EA provides token-level randomness to avoid that the decoder generates the next token only depending on Neural Probabilistic Language Model.

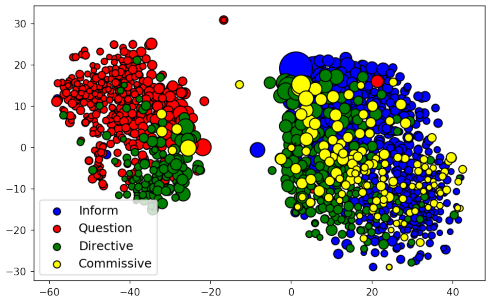

Figure 3: Visualization of expression representations for utterances with dialog acts. The size of circle represents the response length.

Discussion. ECM performs well than w/o EA not in automatic evaluation but also in manual evaluation obviously. Although ECM includes more trainable parameters in EA than w/o EA, the improvement of performance is mainly due to the effective architecture of EA. The EA model only involves two learnt matrices, i.e, $\boldsymbol{W_s}$ and $\boldsymbol{W_u}$, described in Section 3.2. Compared to the parameters in the multi-layer HRED, expression reconstruction, and the embedding of vocabulary, the number of parameters in EA can be ignored. Therefore, it can be concluded that EA plays a key role in improving output diversity with few parameters due to its efficient architecture.

4.4 Qualitative Analysis

Table 3 shows the responses generated by kgCVAE and ECM. In Example 1, speaker "A" begins with an open domain demand (directive). ECM generated highly diverse answers that cover multiple dialog acts which were fed into the model in advance during decoding. Further, we notice that the generated response with *inform* act (i.e., sample 1) has similar expression with the ground-truth one, implying that the latent z is able to capture the expression-sensitive variations. It verifies the effectiveness of the hierarchical generation process. ECM can obtain effective expression representation, and fill it with appropriate content obtained from the dialog context. Example 2 is a situation where the waiter "A" tells the customer "B" that the order has done. ECM takes the *directive* act as input and generate multiple responses to give "A" some suggestions (or commands). All the responses reflect the similar behaviors with different expression styles. On the contrary, kgCVAE is capable of generating some diverse responses, but cannot accurately understand the intention of

Example 1: **History** (Directive): **A**: Tell me a little bit about yourself , please . **Target** (Inform): **B**: My name is Dunlin and I live in Beijing . I was born in 1980 . I will graduate from Peking University this July .	
kgCVAE + z Samplings	**ECM** + Dialog Acts + z Samplings
1. i've been in china for two weeks .	1. (Inform) i graduated from hebes university .
2. how do you wish i can speak to the teacher's letter ?	2. (Commissive) of course , i ' ve been visiting a new company . i ' m looking for a job .
3. i'd like to speak a little more , but i know him .	3. (Question) yes , what ' s the matter ?
4. excuse me ?	4. (Directive) can you give me a example ?
Example 2: **History** (Inform): **waiter A**: good morning , sir . i ve got breakfast your ordered . **Target** (Directive): **customer B**: just put it on the table please .	
kgCVAE + z Samplings	**ECM** + *Directive* Act + z Samplings
1. oh , no .	1. put it on .
2. yes , i'd like to have a look . it s a good choice .	2. please check out this time .
3. that's ok . it's got wireless only , and we're over .	3. please . i am sorry to have kept you waiting .
4. good morning , thanks .	4. please wait a moment .

Table 3: Generated responses from kgCVAE and ECM in two examples.

"A" and thus the responses lack of coherency. The human-human dialogues in the dataset follow some dialog flow patterns, such as *Question-Inform*, *Directive-Commissive* (Li et al., 2017b). kgCVAE predicts the dialog act exactly in example 1 but wrongly in Example 2 since the pattern *Inform-Directive* is not common.

In our work, a CNN module is leveraged to filter the content-related information of utterances and get a discourse-level representation, i.e. expression vector, where meaningful expression information is preserved. CNN models have been shown to be efficient for NLP and have achieved excellent results in sentence modeling and classification. So we conjecture that the expression vectors are highly correlated with the dialog acts, and each one reflects a concrete expression representation of the specified dialog act. Figure 3 visualizes the expression vectors in the test dataset in 2D space using t-SNE (Der Maaten and Hinton, 2008). We find that the expression vectors are clustered into meaningful groups associated with the dialog acts, which confirms that CNN is an efficient tool to extract the expression information.

5 Related Works

Vanilla Seq2Seq model usually ends up with generic and dull responses. To tackle this problem, one line of research has focused on forcing the model to imitate some human's skills by augmenting the input with rich meta information. For example, some works separately gave chatbots the ability of emotions (Zhou et al., 2018), persona (Li et al., 2016b), vision (Huber et al., 2018; Wu et al., 2018) and thinking over the knowledge base (Liu et al., 2018; Zhu et al., 2017). In this work, we consider open domain dialogue generation with dialog acts. But, only a little works (Zhao et al., 2017; Serban et al., 2017a) on open domain end-to-end modeling take dialog acts into account.

On the other hand, many attempts have also been made to improve the architecture of Seq2Seq models by changing the training methods. Li et al. (2016a) attributed safe response problems to the use of MLE objective. Some works separately attempted to replace the MLE method with maximum mutual information (Li et al., 2016a), reinforcement learning (Zhang et al., 2018; Li et al., 2016c) and adversarial learning (Xu et al., 2017; Li et al., 2017a). Serban et al. (2017b) viewed the dialog context as prior knowledge and combined HRED model into the CVAE framework. Zhao et al. (2017) further introduced dialog acts to guide the learning of CVAE. In our paper, we use CVAE to learn the hierarchy generation model.

6 Conclusion and Future Work

In this paper, we investigate the problem of generating meaningful responses by imitating the hierarchical process of human response. Specifically, a hierarchical response generation model is proposed to hierarchically generate the expressions and fill them with appropriate content naturally and coherently. The experiment results show that HRED model equipped with HRG can generate responses appropriate not only in content but also in expression. Different from existing works, our model is interpretable and controllable.

In the future work, we will explore the act interactions with HRG. Instead of specifying a dialog act manually, the most appropriate one can be decided automatically.

Knowledge Aware Conversation Generation with Explainable Reasoning over Augmented Graphs

Zhibin Liu, Zheng-Yu Niu, Hua Wu, Haifeng Wang
Baidu Inc., Beijing, China
{liuzhibin05,niuzhengyu,wu_hua, wanghaifeng}@baidu.com

Abstract

Two types of knowledge, triples from knowledge graphs and texts from documents, have been studied for knowledge aware open-domain conversation generation, in which graph paths can narrow down vertex candidates for knowledge selection decision, and texts can provide rich information for response generation. Fusion of a knowledge graph and texts might yield mutually reinforcing advantages, but there is less study on that. To address this challenge, we propose a knowledge aware chatting machine with three components, an *augmented knowledge graph* with both triples and texts, knowledge selector, and knowledge aware response generator. For knowledge selection on the graph, we formulate it as a problem of *multi-hop graph reasoning* to effectively capture conversation flow, which is more explainable and flexible in comparison with previous work. To fully leverage long text information that differentiates our graph from others, we improve a state of the art reasoning algorithm with *machine reading comprehension technology*. We demonstrate the effectiveness of our system on two datasets in comparison with state-of-the-art models[1].

1 Introduction

One of the key goals of AI is to build a machine that can talk with humans when given an initial topic. To achieve this goal, the machine should be able to understand language with background knowledge, recall knowledge from memory or external resource, reason about these concepts together, and finally output appropriate and informative responses. Lots of research efforts have been devoted to chitchat oriented conversation generation (Ritter et al., 2011; Shang et al., 2015).

However, these models tend to produce generic responses or incoherent responses for a given topic, since it is quite challenging to learn semantic interactions merely from dialogue data without help of background knowledge. Recently, some previous studies have been conducted to introduce external knowledge, either unstructured knowledge texts (Ghazvininejad et al., 2018; Vougiouklis et al., 2016) or structured knowledge triples (Liu et al., 2018; Young et al., 2018; Zhou et al., 2018) to help open-domain conversation generation by producing responses conditioned on selected knowledge.

In the first research line, their knowledge graph can help narrowing down knowledge candidates for conversation generation with the use of prior information, e.g., triple attributes or graph paths. Moreover, these prior information can enhance generalization capability of knowledge selection models. But it suffers from information insufficiency for response generation since there is simply a single word or entity to facilitate generation. In the second line, their knowledge texts, e.g., comments about movies, can provide rich information for generation, but its unstructured representation scheme demands strong capability for models to perform knowledge selection or attention from the list of knowledge texts. Fusion of graph structure and knowledge texts might yield mutually reinforcing advantages for knowledge selection in dialogue systems, but there is less study on that.

To bridge the gap between the two lines of studies mentioned above, we present an Augmented Knowledge Graph based open-domain Chatting Machine (denoted as **AKGCM**), which consists of knowledge selector and knowledge aware response generator. This two-stage architecture and graph based knowledge selection make our system to be explainable. Explainability is very important

[1]Data and codes are available at https://github.com/PaddlePaddle/models/tree/develop/PaddleNLP/Research/EMNLP2019-AKGCM

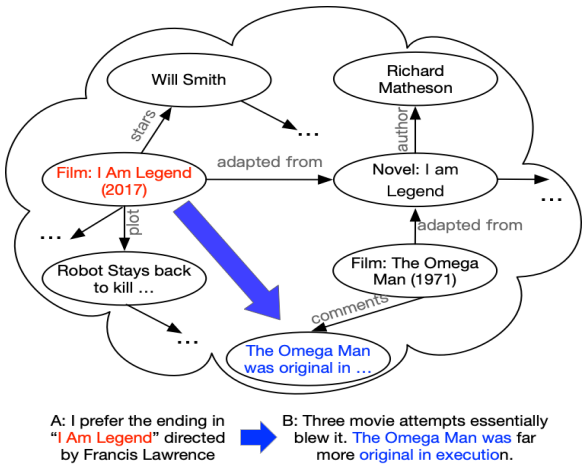

Figure 1: Sample conversation with explainable reasoning, reflecting conversation flow, on an augmented knowledge graph.

in e.g., information oriented chatting scenarios, where a user needs to know how new knowledge in chatbot's responses is linked to the knowledge in their utterances, or business scenarios, where a user cannot make a business decision without justification.

To integrate texts into a knowledge graph, we take a factoid knowledge graph (KG) as its backbone, and align unstructured sentences of non-factoid knowledge with the factoid KG by linking entities from these sentences to vertices (containing entities) of the KG. Thus we augment the factoid KG with non-factoid knowledge, and retain its graph structure. Then we use this augmented KG to facilitate knowledge selection and response generation, as shown in Figure 1.

For knowledge selection on the graph, we adopt a deep reinforcement learning (RL) based reasoning model(Das et al., 2018), MINERVA, in which the reasoning procedure greatly reflects conversation flow as shown in Figure 1. It is as robust as embedding based neural methods, and is as explainable as path based symbolic methods. Moreover, our graph differs from previous KGs in that: some vertices in ours contain long texts, not a single entity or word. To fully leverage this long text information, we improve the reasoning algorithm with machine reading comprehension (MRC) technology (Seo et al., 2017) to conduct fine-grained semantic matching between an input message and candidate vertices.

Finally, for response generation, we use an encoder-decoder model to produce responses conditioned on selected knowledge.

In summary, we make following contributions:

- This work is the first attempt that unifies knowledge triples and texts as a graph, and conducts flexible multi-hop knowledge graph reasoning in dialogue systems. Supported by such knowledge and knowledge selection method, our system can respond more appropriately and informatively.
- Our two-stage architecture and graph based knowledge selection mechanism provide better model explainability, which is very important for some application scenarios.
- For knowledge selection, to fully leverage long texts in vertices, we integrate machine reading comprehension (MRC) technology into the graph reasoning process.

2 Related Work

Conversation with Knowledge Graph: There are growing interests in leveraging factoid knowledge (Han et al., 2015; Liu et al., 2018; Zhu et al., 2017) or commonsense knowledge (Young et al., 2018; Zhou et al., 2018) with graph based representation for generation of appropriate and informative responses. Compared with them, we augment previous KGs with knowledge texts and integrate more explainable and flexible multi-hop graph reasoning models into conversation systems. Wu et al. (2018) used document reasoning network for modeling of conversational contexts, but not for knowledge selection.

Conversation with Unstructured Texts: With availability of a large amount of knowledge texts from Wikipedia or user generated content, some work focus on either modeling of conversation generation with unstructured texts (Ghazvininejad et al., 2018; Vougiouklis et al., 2016; Xu et al., 2017), or building benchmark dialogue data grounded on knowledge (Dinan et al., 2019; Moghe et al., 2018). In comparison with them, we adopt a graph based representation scheme for unstructured texts, which enables better explainability and generalization capability of our system.

Knowledge Graph Reasoning: Previous studies on KG reasoning can be categorized into three lines, path-based symbolic models (Das et al., 2017a; Lao et al., 2011), embedding-based neural models (Bordes et al., 2013; Wang et al., 2014), and models in unifying embedding and path-based

technology (Das et al., 2018; Lin et al., 2018; Xiong et al., 2017), which can predict missing links for completion of KG. In this work, for knowledge selection on a graph, we follow the third line of works. Furthermore, our problem setting is different from theirs in that some of our vertices contain long texts, which motivates the use of machine reading technology for graph reasoning.

Fusion of KG triples and texts: In the task of QA, combination of a KG and a text corpus has been studied with a strategy of late fusion (Gardner and Krishnamurthy, 2017; Ryu et al., 2014) or early fusion (Das et al., 2017b; Sun et al., 2018), which can help address the issue of low coverage to answers in KG based models. In this work, we conduct this fusion for conversation generation, not QA, and our model can select sentences as answers, not restricted to entities in QA models.

3 The Proposed Model

3.1 Problem Definition and Model Overview

Our problem is formulated as follows: Let $\mathcal{G} = \{\mathcal{V}, \mathcal{E}, \mathcal{L}^{\mathcal{E}}\}$ be an augmented KG, where $\mathcal{V}$ is a set of vertices, $\mathcal{E}$ is a set of edges, and $\mathcal{L}^{\mathcal{E}}$ is a set of edge labels (e.g., triple attributes, or vertex categories). Given a message $X = \{x_1, x_2, ..., x_m\}$ and $\mathcal{G}$, the goal is to generate a proper response $Y = \{y_1, y_2, ..., y_n\}$ with supervised models. Essentially, the system consists of two stages: (1) knowledge selection: we select the vertex that maximizes following probability as an answer, which is from vertex candidates connected to v_X:

$$v_Y = \arg\max_v P_{KS}(v|v_X, \mathcal{G}, X). \quad (1)$$

v_X is one of vertices retrieved from $\mathcal{G}$ using the entity or words in X, and it is ranked as top-1 based on text similarity with X. Please see Equation 8 and 10 for computation of $P_{KS}(*)$; (2) response generation: it estimates the probability:

$$P_{RG}(Y|X, v_Y) = \prod_{t=1}^{n} P(y_t|y_{<t}, X, v_Y). \quad (2)$$

The overview of our Augmented Knowledge Graph based Chatting Machine (AKGCM) is shown in Figure 2. The knowledge selector first takes as input a message $X = \{x_1, x_2, ..., x_m\}$ and retrieves a starting vertex v_X from $\mathcal{G}$ that is closely related to X, and then performs multi-hop graph reasoning on $\mathcal{G}$ and finally arrives at a vertex v_Y that has the knowledge being appropriate for response generation. The knowledge aware response generator produces a response $Y = \{y_1, y_2, ..., y_n\}$ with knowledge from v_Y. At each decoding position, it attentively reads the selected knowledge text, and then generates a word in the vocabulary or copies a word in the knowledge text.

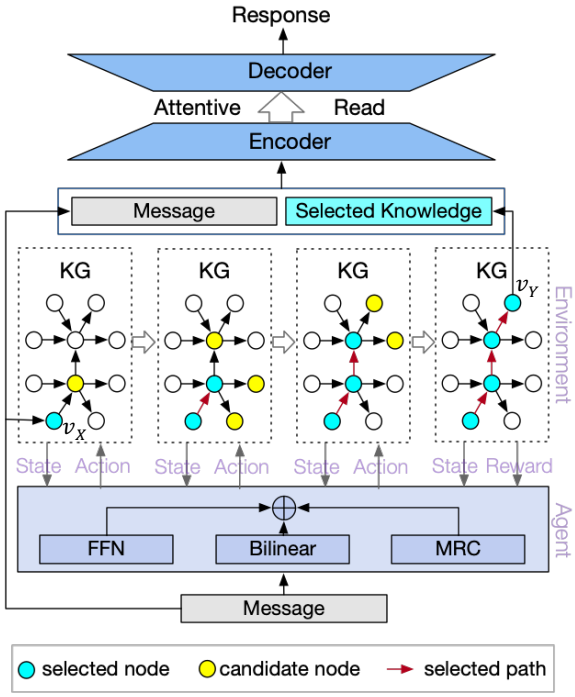

Figure 2: The architecture of AKGCM.

For model training, each pair of [message, response] in training data is associated with ground-truth knowledge and its vertex ID (ground-truth vertex) in $\mathcal{G}$ for knowledge grounding. These vertex IDs will be used as ground-truth for training of knowledge selector, while the triples of [message, knowledge text, response] will be used for the training of knowledge aware generator.

3.2 Augmented Knowledge Graph

Given a factoid KG and related documents containing non-factoid knowledge, we take the KG as a backbone, where each vertex contains a single entity or word, and each edge represents an attribute or a relation. Then we segment the documents into sentences and align each sentence with entries of the factoid KG by mapping entities from these sentences to entity vertices of the KG. Thus we augment the factoid KG with non-factoid knowledge, and retain its structured representation.

3.3 Knowledge Selection on the Graph

Task Definition: We formulate knowledge selection on $\mathcal{G}$ as a finite horizon sequential decision making problem. It supports more flexible multi-hop walking on graphs, not restricted to one-hop walking as done in previous work (Han et al., 2015; Zhou et al., 2018; Zhu et al., 2017).

As shown in Figure 2, we begin by representing the environment as a deterministic partially observed Markov decision process (POMDP) on $\mathcal{G}$ built in Section 3.2. Our RL based agent is given an input query of the form (v_X, X). Starting from vertex v_X corresponding to X in $\mathcal{G}$, the agent follows a path in the graph, and stops at a vertex that it predicts as the answer v_Y. Using a training set of known answer vertices for message-response pairs, we train the agent using policy gradients (Williams, 1992) with control variates.

The difference between the setting of our problem and previous KG reasoning lies in that: (1) the content of our input queries is not limited to entities and attributes; (2) some vertices in our graph contains long texts, while vertices in previous KGs just contain a single entity or short text. It motivates us to make a few improvements on previous models, as shown in Equation (5), (6), and (7).

Next we elaborate the 5-tuple $(\mathcal{S}, \mathcal{O}, \mathcal{A}, \delta, \mathcal{R})$ of the environment, and policy network.

States: A state $S_t \in \mathcal{S}$ at time step t is represented by $S_t = (v_t, v_X, X, v_{gt})$ and the state space consists of all valid combinations in $\mathcal{V}\times\mathcal{V}\times\mathcal{X}\times\mathcal{V}$, where v_t is current location of the RL agent, v_{gt} is the ground-truth vertex, and $\mathcal{X}$ is the set of all possible X.

Observations: The complete state of the environment cannot be observed. Intuitively, the agent knows its current location (v_t) and (v_X, X), but not the ground-truth one (v_{gt}), which remains hidden. Formally, the observation function $\mathcal{O} : \mathcal{S}\rightarrow\mathcal{V} \times \mathcal{V} \times \mathcal{X}$ is defined as $\mathcal{O}(S_t = (v_t, v_X, X, v_{gt})) = (v_t, v_X, X)$.

Actions: The set of possible actions $\mathcal{A}_{S_t}$ from a state S_t consists of all outgoing edges of the vertex v_t in $\mathcal{G}$. Formally $\mathcal{A}_{S_t} = \{(v_t, l_e, v_d) \in \mathcal{E} : S_t = (v_t, v_X, X, v_{gt}), l_e \in \mathcal{L}^{\mathcal{E}}, v_d \in \mathcal{V}\} \cup \{(S_t, \emptyset, S_t)\}$. It means an agent at each state has option to select which outgoing edge it wishes to take with the label of the edge l_e and destination vertex v_d. We limit the length of the action sequence (horizon length) up to a fixed number (e.g., T) of time steps. Moreover, we augment each vertex with a special action called 'NO_OP' which goes from a vertex to itself. This decision allows the agent to remain at a vertex for any number of time steps. It is especially helpful when the agent has managed to reach a correct vertex at a time step $t < T$ and can continue to stay at the vertex for the rest of the time steps.

Transition: The environment evolves deterministically by just updating the state to the new vertex according to the edge selected by the agent. Formally, the transition function $\delta : \mathcal{S} \times \mathcal{A}\rightarrow\mathcal{S}$ is defined by $\delta(S_t, A) = (v_d, v_X, X, v_{gt})$, where $S_t = (v_t, v_X, X, v_{gt})$ and $A = (v_t, l_e, v_d)$. l_e is the label of an edge connecting v_t and v_d, and v_d is destination vertex.

Rewards: After T time steps, if the current vertex is the ground-truth one, then the agent receives a reward of $+1$ otherwise 0. Formally, $\mathcal{R}(S_T) = I\{v_T = v_{gt}\}$, where $S_T = (v_T, v_X, X, v_{gt})$ is the final state.

Policy Network: We design a randomized non-stationary policy $\boldsymbol{\pi} = (\boldsymbol{d_0}, \boldsymbol{d_1}, ..., \boldsymbol{d_{T-1}})$, where $d_t = P(\mathcal{A}_{S_t})$ is a policy at time step t. In this work, for each d_t, we employ *a policy network with three components* to make the decision of choosing an action from all available actions $(\mathcal{A}_{S_t})$ conditioned on X.

The first component is a history dependent *feed-forward network* (FFN) based model proposed in (Das et al., 2018). We first employ a LSTM to encode the history $H_t = (H_{t-1}, A_{t-1}, O_t)$ as a continuous vector $\boldsymbol{h_t} \in \mathbb{R}^{2d}$, where H_t is the sequence of observations and actions taken. It is defined by:

$$\boldsymbol{h_t} = LSTM(\boldsymbol{h_{t-1}}, [\boldsymbol{a_{t-1}}; \boldsymbol{o_t}]), \qquad (3)$$

where $\boldsymbol{a_{t-1}}$ is the embedding of the relation corresponding to the label of the edge the agent chose at time $t-1$ and $\boldsymbol{o_t}$ is the embedding of the vertex corresponding to the agent's state at time t.

Recall that each possible action represents an outgoing edge with information of the edge relation label l_e and destination vertex v_d. So let $[\boldsymbol{l_e}; \boldsymbol{v_d}]$ denote an embedding for each action $A \in \mathcal{A}_{S_t}$, and we obtain the matrix $\boldsymbol{A_t}$ by stacking embeddings for all the outgoing edges. Then we build a two-layer feed-forward network with ReLU nonlinearity which takes in the current history representation h_t and the representation of X $(\boldsymbol{e_X^{new}})$. We use another single-layer *feed-forward network* for computation of $\boldsymbol{e_X^{new}}$, which accepts the original sentence embedding of X $(\boldsymbol{e_X})$ as input. The

updated FFN model for action decision is defined by:

$$P_{FFN}(\mathcal{A}_{S_t}) = \boldsymbol{A_t}(\boldsymbol{W_2}ReLU(\boldsymbol{W_1}[\boldsymbol{h_t}; \boldsymbol{o_t}; \boldsymbol{e_X^{new}}] + \boldsymbol{b_1}) + \boldsymbol{b_2}), \tag{4}$$

$$\boldsymbol{e_X^{new}} = ReLU(\boldsymbol{W_X}\boldsymbol{e_X} + \boldsymbol{b_X}). \tag{5}$$

Recall that in our graph, some vertices contain long texts, differentiating our graph from others in previous work. The original reasoning model (Das et al., 2018), MINERVA, cannot effectively exploit the long text information within vertices since it just learns embedding representation for the whole vertex, without detailed analysis of text in vertices. To fully leverage the long text information in vertices, we employ two models, *a machine reading comprehension model* (MRC) (Seo et al., 2017) and *a bilinear model*, to score each possible v_d from both global and local view.

For scoring from global view, (1) we build a document by collecting sentences from all possible v_d, (2) we employ the MRC model to predict an answer span ($span_{aw}$) from the document, (3) we score each v_d by calculating a ROUGE-L score vector of v_d's sentence with $span_{aw}$ as the reference, shown as follows:

$$P_{MRC}(\mathcal{A}_{S_t}) = ROUGE(Text(V_d), span_{aw}). \tag{6}$$

Here, $Text(\cdot)$ represents operation of getting text contents, and $ROUGE(\cdot)$ represents operation of calculating ROUGE-L score. We see that the MRC model can help to determine which v_d is the best based on global information from the whole document.

For scoring from local view, we use another *bilinear model* to calculate similarity between X and v_d, shown as follows:

$$P_{Bi}(\mathcal{A}_{S_t}) = \boldsymbol{V_d}\boldsymbol{W_B}\boldsymbol{e_X}. \tag{7}$$

Finally, we calculate a sum of outputs of the three above-mentioned models and outputs a probability distribution over the possible actions from which a discrete action is sampled, defined by:

$$P(\mathcal{A}_{S_t}) = softmax(\alpha P_{FFN}(\mathcal{A}_{S_t}) + \beta P_{Bi}(\mathcal{A}_{S_t}) + \gamma P_{MRC}(\mathcal{A}_{S_t})), \tag{8}$$

$$A_t \sim Sample(P(\mathcal{A}_{S_t})), \tag{9}$$

$$P_{KS}(v_d|v_X, \mathcal{G}, X) = P(\mathcal{A}_{S_{T-1}}). \tag{10}$$

Please see Section 3.1 for definition of $P_{KS}(*)$. When the agent finally arrives at S_T, we obtain v_T as the answer v_Y for response generation.

Training: For the policy network (π_θ) described above, we want to find parameters θ that maximize the expected reward:

$$J(\theta) = \mathbb{E}_{(v_0,X,v_{gt})\sim D}\mathbb{E}_{A_0,\ldots,A_{T-1}\sim\pi_\theta}[\mathcal{R}(S_T)|S_0 = (v_0, v_0, X, v_{gt})], \tag{11}$$

where we assume there is a true underlying distribution D, and $(v_0, X, v_{gt}) \sim D$.

3.4 Knowledge Aware Generation

Following the work of Moghe et al. (2018), we modify a text summarization model (See et al., 2017) to suit this generation task.

In the summarization task, its input is a document and its output is a summary, but in our case the input is a [selected knowledge, message] pair and the output is a response. Therefore we introduce two RNNs: one is for computing the representation of the selected knowledge, and the other for the message. The decoder accepts the two representations and its own internal state representation as input, and then compute (1) a probability score which indicates whether the next word should be generated or copied, (2) a probability distribution over the vocabulary if the next word needs to be generated, and (3) a probability distribution over the input words if the next word needs to be copied. These three probability distributions are then combined, resulting in $P(y_t|y_{<t}, X, v_Y)$, to produce the next word in the response.

4 Experiments and Results

4.1 Datasets

We adopt two knowledge grounded multi-turn dialogue datasets for experiments, shown as follows:

EMNLP dialog dataset (Moghe et al., 2018) This Reddit dataset contains movie chats from two participants, wherein each response is explicitly generated by copying or modifying sentences from background knowledge such as IMDB's facts/plots, or Reddit's comments about movies. We follow their data split for training, validation and test[2]. Their statistics can be seen in Table 1.

ICLR dialog dataset (Dinan et al., 2019) This wizard-of-wiki dataset contains multi-turn conver-

[2]We use the single-reference mixed-short test set for evaluation. Please see their paper for more details.

sations from two participants. One participant selects a beginning topic, and during the conversation the topic is allowed to naturally change. The two participants are not symmetric: one will play the role of a knowledgeable expert while the other is a curious learner. We filter their training data and test data by removing instances without the use of knowledge and finally keep 30% instances[3] for our study since we focus on knowledge selection and knowledge aware generation. Their statistics can be seen in Table 1. For models (Seq2Seq, HRED) without the use of knowledge, we keep the original training data for them.

4.2 Experiment Settings

We follow the existing work to conduct both automatic evaluation and human evaluation for our system. We also compare our system with a set of carefully selected baselines, shown as follows.

Seq2Seq: We implement a sequence-to-sequence model (Seq2Seq) (Sutskever et al., 2014), which is widely used in open-domain conversational systems.

HRED: We implement a hierarchical recurrent encoder-decoder model (Serban et al., 2016).

MemNet: We implement an end-to-end knowledge-MemNet based conversation model (Ghazvininejad et al., 2018).

GTTP: It is an end-to-end text summarization model (See et al., 2017) studied on the EMNLP data. We use the code[4] released by Moghe et al. (2018), where they modify GTTP to suit knowledge aware conversation generation.

BiDAF+G: It is a Bi-directional Attention Flow based QA Model (BiDAF) (Seo et al., 2017) that performs best on the EMNLP dataset. We use the code[4] released by Moghe et al. (2018), where they use it to find the answer span from a knowledge document, taking the input message as the query. Moreover, we use a response generator (as same as ours) for NLG with the predicted knowledge span.

TMemNet: It is a two-stage transformer-MemNet based conversation system that performs best on the ICLR dataset (Dinan et al., 2019). We use the code[5] released by the original authors.

CCM: It is a state-of-the-art knowledge graph based conversation model (Zhou et al., 2018). We use the code[6] released by the original authors and then modify our graph to suit their setting by selecting each content word from long text as an individual vertex to replace our long-text vertices.

AKGCM: It is our two-stage system presented in Section 3. We implement our knowledge selection model based on the code[7] by(Das et al., 2018) and that[4] by (Moghe et al., 2018). We use BiDAF as the MRC module, shown in Equation (6), and we train the MRC module on the same training set for our knowledge selection model. We implement the knowledge aware generation model based on the code of GTTP[4] released by (Moghe et al., 2018). We also implement a variant AKGCM-5, in which top five knowledge texts are used for generation, and other setting are not changed.

4.3 Automatic Evaluations

Metrics: Following the work of (Moghe et al., 2018), we adopt BLEU-4 (Papineni et al., 2002), ROUGE-2 (Lin, 2004) and ROUGE-L (Lin and Och, 2004) to evaluate how similar the output response is to the reference text. We use Hit@1 (the top 1 accuracy) to evaluate the performance of knowledge selection.

[3] Their ground-truth responses should have high ROUGE-L scores with corresponding ground-truth knowledge texts.

TMemNet	0.04/0.50/0.46	0.05/0.36/0.59	0.01/0.25/0.74	0.01/0.21/0.78

Table 3: Results of human evaluations on the two datasets. AKGCM (or AKGCM-5) outperforms all the baselines significantly (sign test, p-value < 0.05) in terms of the two metrics.

Results: As shown in Table 2, AKGCM (or AKGCM-5) can obtain the highest score on test set in terms of Hit@1, and the second highest scores in terms of BLEU-4, ROUGE-2 and ROUGE-L, surpassing other models, except BiDAF, by a large margin. It indicates that AKGCM has a capability of knowledge selection better than BiDAF and TMemNet, and generates more informative and grammatical responses. We notice that from EMNLP dataset to ICLR dataset, there is a significant performance drop for almost all the models. It is probably due to that the quality of ICLR dataset is worse than that of EMNLP dataset. A common phenomenon of ICLR dataset is that the knowledge used in responses is loosely relevant to input messages, which increases the difficulty of model learning.

4.4 Human Evaluations

Metrics: We resort to a web crowdsourcing service for human evaluations. We randomly sample 200 messages from test set and run each model to generate responses, and then we conduct pair-wise comparison between the response by AKGCM and the one by a baseline for the same message. In total, we have 1400 pairs on each dataset since there are seven baselines. For each pair, we ask five evaluators to give a preference between the two responses, in terms of the following two metrics: (1) appropriateness (Appr.), e.g., whether the response is appropriate in relevance, and logic, (2) informativeness (Infor.), whether the response provides new information and knowledge in addition to the input message, instead of generic responses such as "This movie is amazing". Tie is allowed. Notice that system identifiers are masked during evaluation.

Annotation Statistics: We calculate the agreements to measure inter-evaluator consistency. For appropriateness, the percentage of test instances that at least 2 evaluators give the same label (2/3 agreement) is 98%, and that for at least 3/3 agreement is 51%. For informativeness, the percentage for at least 2/3 agreement is 98% and that for at

least 3/3 agreement is 55.5%.

Results: In Table 3, each score for win/tie/lose is the percentage of messages for which AKGCM (or AKGCM-5) can generate better/almost same/worse responses, in comparison with a baseline. We see that our model outperforms all the baselines significantly (sign test, p-value < 0.05) in terms of the two metrics on the two datasets. Furthermore, our model can beat the strongest baseline, BiDAF. It demonstrates the effectiveness of our graph reasoning mechanism that can use global graph structure information and exploit long text information. Our data analysis shows that both Seq2Seq and HRED tend to generate safe responses starting with "my favorite character is" or "I think it is". Both Memnet and TMemnet can generate informative responses. But the knowledge in their responses tends to be incorrect, which is a serious problem for knowledge aware conversation generation. Our results show that GTTP and BiDAF are very strong baselines. It indicates that the attention mechanism (from machine reading) for knowledge selection and the copy mechanism can bring benefits for knowledge aware conversation generation. Although CCM have the mechanisms mentioned above, this model is good at dealing with structured triples rather than long texts. It may explain the inferior performance of CCM in our problem setting.

We find that many responses are likely to be a simple copy of the selected knowledge, which is a reflection of the characteristics of the datasets. In the two datasets, some sentences in the background knowledge are directly used as responses to the messages. Therefore, the NLG module is likely to copy content from the selected knowledge as much as possible for generation. Moreover, the summarization model GTTP tends to copy words from its input message as its output due to its generation mechanism. Table 5 presents the examples in which AKGCM (AKGCM-5) performs better than other models on two dataset.

4.5 Model Analysis

AKGCM without (w/o) Non-factoid Knowledge: To verify contribution of non-factoid knowledge, we remove non-factoid knowledge from augmented KG in test procedure, and report the performance of our system with only factoid knowledge in Table 4. We see that without non-factoid knowledge from EMNLP dataset, the performance of our system drops significantly in terms of BLEU and ROUGE. It indicates that non-factoid knowledge is essential for knowledge aware conversation generation.

Model variant	BLEU-4 (%)	ROUGE-2 (%)	ROUGE-L (%)
w/o non-factoid knowledge	0.61	0.84	1.52
w/o Bilinear + MRC	15.12	14.15	21.09
w/o MRC	18.41	17.79	24.59
w/o Bilinear	28.62	28.19	32.84
Full model	30.84	29.29	34.72

Table 4: Results of ablation study for AKGCM on EMNLP dataset. We also include results of the full model for comparison.

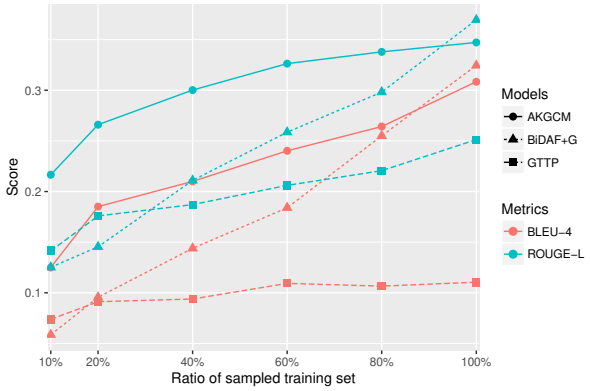

Figure 3: Results of how each model performs on EMNLP dataset when we gradually reduce the ratio of sampled training data from 100% to 10% (from right to left).

AKGCM w/o the MRC Model or Bilinear One: For ablation study, we implement a few variants of our system without the bilinear model or MRC for knowledge selection. Results of these variants are reported in Table 4. If we compare the performance of our full model with its variants, we find that both MRC and the bilinear model can bring performance improvement to our system. It indicates that the full interaction between messages and knowledge texts by their attention mechanism is effective to knowledge selection.

Model Generalization: As shown in Figure 3, we gradually reduce the size of training data, and then AKGCM can still manage to achieve acceptable performance, even when given extremely small training data (around 3,400 u-r pairs at the x-axis point of 10%). But the performance of

Dataset	EMNLP dataset (Movie Name: Monsters University)	ICLR dataset (Topic Name: Green)
Message	I love comic scene in movies though it makes me want to see it over again	How is green color produced?
Ground-truth response	I will be definitely be seeing it a second and possibly third time .	Green is evoked by light, a dominant wavelength of about 495570 nm. it is between blue and yellow.
Seq2seq	I think it 's just plain funny	Yellow is the color between green and orange on the spectrum of visible light
HRED	A stone cold classic !	There are different types of UNK there are different types of UNK
MemNet	I thought it was a great movie, but it is a great film.	It lies between violet and green on the spectrum of light.
GTTP	I think this movie was worth it , for i will be definitely be seeing it a second and possibly third time.	Yes , green is the color between blue and yellow on the visible spectrum .
CCM	I think it was a worth _UNK , but I still enjoyed it intense than the fraternities .	The energy is chemical on the Several minerals and tradition .
BiDAF+G	It not only serves as a great climax , but something that we can once again commend Pixar for telling great stories in out of the box thinking that we should think paying for the $ 10 dollar ticket is worth it .	It 's the color between blue and the color yellow .
Selected knowledge	It not only serves as a great climax, but something that we can once again commend Pixar for telling great stories in out of the box thinking that we should think paying for the $10 dollar ticket is worth it. And boy did I think this movie was worth it, ...	Green is the color between blue and yellow on the visible spectrum.
TMemNet	Man and i think this movie was worth it , i will definitely be seeing if it was a second time .	It ' s been around since the middle ages , it was associated with royalty .
AKGCM (AKGCM-5)	And boy did I think this movie was worth it , for I will be definitely be seeing it a second and possibly third time .	Green is evoked by light which has a dominant wavelength of roughly 495570 nm .
Selected knowledge	And boy did I think this movie was worth it, for I will be definitely be seeing it a second and possibly third time.	... It is evoked by light which has a dominant wavelength of roughly 495570 nm. Several minerals have a green color, including the emerald, ...

Table 5: Examples in which AKGCM performs better than other models on two dataset.

the strongest baseline, BIDAF+G, drops more dramatically in comparison with AKGCM. It indicates that our graph reasoning mechanism can effectively use the graph structure information for knowledge selection, resulting in better generalization capability of AKGCM.

Model Explainability: We check the graph paths traversed by our system for knowledge selection and try to interpret what heuristics have been learned. We find that our system can learn to visit different types of vertices conditioned on conversational contexts, e.g.. selecting comment vertices as responses for utterances starting with "what do you think". These results suggest that AKGCM may also be a good assistive tool for discovering new algorithms, especially in cases when the graph reasoning are new and less well-studied for conversation modeling.

5 Conclusion

In this paper, we propose to augment a knowledge graph with texts and integrate it into an open-domain chatting machine with both graph reasoning based knowledge selector and knowledge aware response generator. Experiments demonstrate the effectiveness of our system on two datasets compared to state-of-the-art approaches.

Abstract

Neural conversation systems generate responses based on the sequence-to-sequence (SEQ2SEQ) paradigm. Typically, the model is equipped with a single set of learned parameters to generate responses for given input contexts. When confronting diverse conversations, its adaptability is rather limited and the model is hence prone to generate generic responses. In this work, we propose an **Ada**ptive **N**eural **D**ialogue generation model, ADAND, which manages various conversations with conversation-specific parameterization. For each conversation, the model generates parameters of the encoder-decoder by referring to the input context. In particular, we propose two adaptive parameterization mechanisms: a context-aware and a topic-aware parameterization mechanism. The context-aware parameterization directly generates the parameters by capturing local semantics of the given context. The topic-aware parameterization enables parameter sharing among conversations with similar topics by first inferring the latent topics of the given context and then generating the parameters with respect to the distributional topics. Extensive experiments conducted on a large-scale real-world conversational dataset show that our model achieves superior performance in terms of both quantitative metrics and human evaluations.

1 Introduction

Open-domain dialogue models, usually called chit-chat systems, draw increasing attention from both academia and industry in recent years. Building on the successful sequence-to-sequence (SEQ2SEQ) paradigm (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015), contemporary mainstream open-domain dialogue generation models (Shang et al., 2015; Serban et al., 2016, 2017; Shen et al., 2017; Clark and Cao, 2017; Zhao et al., 2017; Xing et al., 2017; Zhao et al., 2018), trained on a large number of context-response pairs, attempt to generate an appropriate response for the given context based on a single set of the model parameters.

Because of its great potential in understanding and modeling conversations, SEQ2SEQ has been widely applied in different kinds of conversation scenarios including technical supporting, movie discussions, and social entertainment, etc. However, when confronting conversations with diverse topics or themes, SEQ2SEQ is usually prone to make generic meaningless responses due to its over-simplified parameterization. To tackle this issue, Xing et al. (2017) proposed a topic-aware response generation model, which utilizes a single encoder-decoder, augmented with topic information obtained from a pre-trained LDA model. Though effective, the model heavily relies on the outsourcing topic information to capture the topic variations of different conversations. Another approach, per-topic/theme encoder-decoder model (Choudhary et al., 2017), uses separate encoder-decoder model for each topic or theme. This method needs the preorganized topic/theme annotations for each conversation, which are prohibitively expensive to obtain. Furthermore, building multiple separate topic/theme-specific encoder-decoders not only weakens the applicability and efficiency of the system, but also prevents parameter sharing across domains, which leads to overparameterization due to the excessive amount of model parameters.

To gather the benefits of both approaches, in this paper, we propose an adaptive neural dialogue generation model which utilizes a single encoder-decoder for diverse conversations, meanwhile, the encoder-decoder is specifically parameterized according to each conversation. In particular, we propose two adaptive parameterization mechanisms: 1) context-aware parameterization directly generates parameters of the encoder-decoder model by capturing local semantics of the given context; 2)

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1793–1802, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

topic-aware parameterization enables parameter sharing among conversations with similar topic distributions by first inferring the latent topics of the input context, and then generating the parameters with respect to the inferred latent topics. Equipped with both the context-aware and topic-aware parameterization mechanisms, the model is capable of generating responses for diverse conversations with a single encoder-decoder through a more flexible and efficient approach. Moreover, our model is trained in an end-to-end fashion without any costly external or labeled topic annotations.

We empirically evaluate our approach on a large scale real-world conversational dataset. Extensive experiments show that our proposed ADAND outperforms existing dialogue generation models in terms of both the automatic evaluation metrics and human judgements.

2 Neural Dialogue Generation Model

Conventionally, neural dialogue generation model follows the encoder-decoder paradigm. Given the context $\mathbf{x} = \{x_1, x_2, \cdots, x_{T_\mathbf{x}}\}$ and the target response $\mathbf{y} = \{y_1, y_2, \cdots, y_{T_\mathbf{y}}\}$, the model learns to maximize the following conditional probability:

$$p(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T_\mathbf{y}} p(y_t|\mathbf{y}_{<t}, \mathbf{x}), \tag{1}$$

where $\mathbf{y}_{<t} = y_1 \cdots y_{t-1}$.

Typically, the probability $p(y_t|\mathbf{y}_{<t}, \mathbf{x})$ is modeled as follows:

$$p(y_t|\mathbf{y}_{<t}, \mathbf{x}) = p(y_t|s_{t-1}), \tag{2}$$

where s_{t-1} is the decoding hidden state up to time step $t-1$, depending on $\mathbf{y}_{<t}$ and $\mathbf{x}$. The s_t can be defined as:

$$s_t = \mathcal{F}(y_t, s_{t-1}, \mathcal{G}(\mathbf{x})), \tag{3}$$

where the encoder $\mathcal{G}$ and the decoder $\mathcal{F}$ can be implemented as recurrent neural networks such as LSTMs (Hochreiter and Schmidhuber, 1997) or GRUs (Cho et al., 2014), or the transformer (Vaswani et al., 2017) (with the attention mechanism (Bahdanau et al., 2015) or self-attention mechanism).

In this work, we employ the LSTM-based encoder-decoder dialogue generation model. The

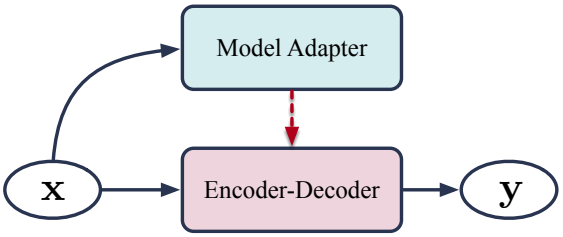

Figure 1: General model architecture. Black solid lines denote information flow, and the red dashed line indicates the adaptive parameterization operation.

LSTM unit is formulated as:

$$\begin{aligned}
i_t &= W_h^i h_{t-1} + W_x^i x_t + b^i \\
g_t &= W_h^g h_{t-1} + W_x^g x_t + b^g \\
f_t &= W_h^f h_{t-1} + W_x^f x_t + b^f \\
o_t &= W_h^o h_{t-1} + W_x^o x_t + b^o \\
c_t &= \sigma(f_t) \odot c_{t-1} + \sigma(i_t) \odot \tanh(g_t) \\
h_t &= \sigma(o_t) \odot \tanh(c_t),
\end{aligned} \tag{4}$$

where σ is the sigmoid operator and $\odot$ stands for Hadamard product. h_{t-1} is the previous hidden state and x_t is the input embedding at step t. $W = \{W_h^i, W_h^g, W_h^f, W_h^o, W_x^i, W_x^g, W_x^f, W_x^o\}$ and $b = \{b^i, b^g, b^f, b^o\}$ are the LSTM parameters. The model parameters are tuned on the training corpus.

When testing, given the input context, it generates a response with the learned parameters. This architecture shows great success in neural dialogue generation (Shang et al., 2015; Serban et al., 2016, 2017; Shen et al., 2017; Clark and Cao, 2017; Xing et al., 2017; Choudhary et al., 2017; Zhao et al., 2018). However, with a single set of model parameters and the oversimplified model architecture, the flexibility of the model is rather limited, especially when confronting conversations with diverse topics or themes.

3 Adaptive Neural Dialogue Generation Model

In this work, we propose an adaptive neural dialogue generation model which utilizes a single encoder-decoder model and a set of dynamical parameters to balance the model's flexibility and efficiency. As depicted in Figure 1, we utilize the model adapter to parameterize the encoder-decoder for each conversation. It takes the dialogue context as its input, and generates parameters of the encoder-decoder model through two adaptive parameterization mechanisms; and then the resultant

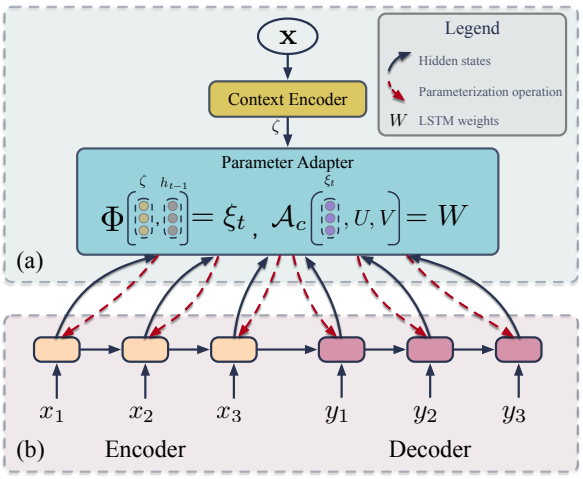

Figure 2: General architecture of the context-aware parameterization. (a) Context-aware parameter adapter. (b) One layer of the dialogue generation model. Black solid lines denote information flow, and red dashed lines indicate adaptive parameterization operations. $\mathcal{A}_c$ stands for the context-aware parameterization function (Eq.(7)).

encoder-decoder model generates the response with a specific set of model parameters.

3.1 Context-aware Parameterization

Context-aware parameterization parameterizes the dialogue encoder-decoder with respect to the local semantics of the given context. As shown in Figure 2, we first obtain the semantic representation of the context through a context encoder. Then, the parameter adapter dynamically adapts the parameters of the encoder-decoder at each time step. Here, we utilize a bidirectional LSTM to transform the input context into the semantic hidden representation ζ.

The parameter adapter then generates the weights of LSTM units as:

$$W = M^{[1:N_r]}\zeta, \tag{5}$$

where $W \in \mathbb{R}^{N_r \times N_c}$ and $M^{[1:N_r]} \in \mathbb{R}^{N_r \times N_c \times N_\zeta}$ is a tensor. $N_r = 4N_h$ and $N_c = N_h + N_x$, in which N_h is the hidden size of the LSTM and N_x is the embedding size. $\zeta \in \mathbb{R}^{N_\zeta}$ is the context representation. The product $M^{[1:N_r]}\zeta$ results in a weight matrix W, where each row is computed by one slice $j = 1, 2, \cdots, N_r$ of the tensor: $W_j = (M^j\zeta)^{\mathrm{T}}$.

Although such parameterization seems to be straightforward, due to the quadratic size of $M^{[1:N_r]}$, the parameter size of such parameter adapter is N_ζ times larger than the basic encoder-decoder model. Therefore, overfitting and expensive computational cost make it infeasible (Bertinetto et al., 2016; Ha et al., 2017). Following Flennerhag et al. (2018), we reduce the parameter space by factorizing the weights as:

$$\begin{aligned} W &= \mathcal{A}_c(\xi_t, U, V) \\ \xi_t &= \Phi(\zeta, h_{t-1}), \end{aligned} \tag{6}$$

where Φ is implemented as a LSTM unit, h_{t-1} is the previous encoder or decoder hidden state, and $\xi_t \in \mathbb{R}^{N_\zeta}$ is the context representation at time step t. $\mathcal{A}_c$ denotes the context-aware parameterization function, defined as:

$$\mathcal{A}_c(\xi_t, U, V) = U\xi_t V^{\mathrm{T}}, \tag{7}$$

where $U \in \mathbb{R}^{N_r \times N_\zeta}$ and $V \in \mathbb{R}^{N_c \times N_\zeta}$ are learnable weights.

The context-aware parameterization function $\mathcal{A}_c$ is reminiscent of the Singular Value Decomposition (SVD). Here, $\mathcal{A}_c$ composes a projection by adapting the dialogue context to the weight matrices and does not perform matrix decomposition actually. The number of parameters in this formulation is $L = N_r \times N_\zeta + N_c \times N_\zeta$ and the total parameter number of the model is linear with L, so that the total number of model parameters does not explode.

3.2 Topic-aware Parameterization

Context-aware parameterization adapts the encoder-decoder parameters regarding each input context. As a result, the adapted encoder-decoder is sensitive to the input context. To enable the parameter sharing among similar topics, we further propose a topic-aware parameterization mechanism. As shown in the Figure 3, the topic inferrer first distills the topic distribution θ from the context (Figure 3 (a)), and then the parameters of the encoder-decoder model are constructed upon θ (Figure 3 (b)).

3.2.1 Latent Topic Inference

We introduce a variational topic inferrer to infer the topic distribution θ of the conversation. Drawing inspirations from neural topic model (Miao et al., 2017), as illustrated in Figure 3 (a), the generation process of the variational topic inferrer is formulated as follows:

(i) A latent variable ν is inferred to convey the underlying semantics of the given context.

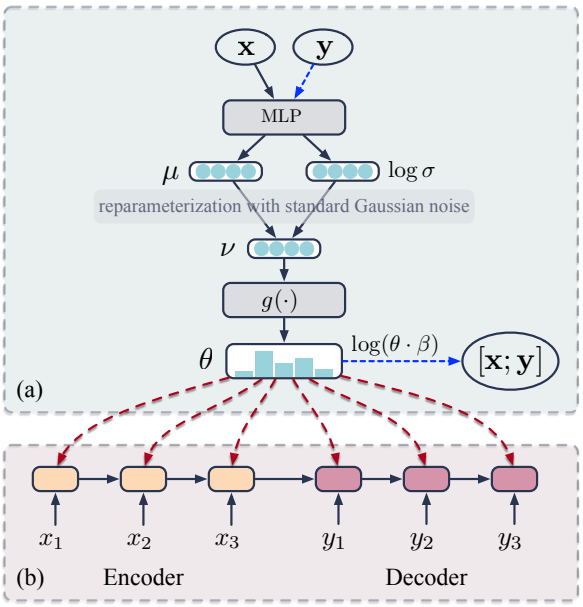

Figure 3: Illustration of the topic-aware parameterization. (a) Topic inferrer. (b) One layer of the dialogue generation model. Black solid lines denote information flow, blue dashed lines only appear in training, and red dashed lines indicate adaptive parameterization operations.

(ii) The topic distribution θ is constructed from the latent variable ν through a softmax function.

(iii) The dialogue $\mathbf{d}$, composing of a context-response pair $(\mathbf{x}, \mathbf{y})$, is drawn from the topic distribution over words $p(w_i|\beta_{z_i})$, where z_i is a topic assignment sampled from a multinomial distribution parameterized by the topic distribution θ, and β_{z_i} is the topic-word distribution of topic assignment z_i.

Given a context $\mathbf{x}$, the latent variable ν is sampled from $P(\nu|\mathbf{x}) = \mathcal{N}(\mu_{prior}, \sigma^2_{prior})$, and $\mathcal{N}(\mu_{prior}, \sigma^2_{prior})$ is the multivariate normal distribution with mean μ_{prior} and diagonal covariance matrix σ^2_{prior}. In practice, ν is reparameterized as: $\nu = \mu_{prior} + \epsilon \cdot \sigma_{prior}$ and ϵ is a standard Gaussian noise. The Gaussian parameters μ_{prior} and σ^2_{prior} are the outputs of multilayer perceptrons (MLP) given the bag-of-words (BoW) representation of the context as input. To reduce the encoding noise of stop words, here we choose the BoW instead of LSTM for context representations, following Miao et al. (2017). To implement neural variational inference, we utilize an inference network $Q(\nu|\mathbf{d}) = \mathcal{N}(\mu_{posterior}, \sigma^2_{posterior})$ to approximate the intractable true posterior $p(\nu|\mathbf{d})$, where $\mu_{posterior}$ and $\sigma^2_{posterior}$ are computed in the same way as the prior, taking the bag-of-words representation of dialogue $\mathbf{d}$ as input. The dialogue $\mathbf{d}$ consists of the context-response pair $(\mathbf{x}, \mathbf{y})$.

The topic distribution θ is constructed from the latent variable ν through a softmax function:

$$\theta = g(\nu) = \text{softmax}(\nu \cdot \mathbf{W}_\nu), \tag{8}$$

where $\mathbf{W}_\nu$ is a linear transformation and the bias terms are left out for brevity.

Then, the dialogue $\mathbf{d}$ is generated based on the topic distribution θ. Given θ, the marginal likelihood of a dialogue $\mathbf{d}$ is formulated as:

$$p(\mathbf{d}) = \int_\theta p(\theta) \prod_{i=1}^{|\mathbf{d}|} \sum_{z_i} p(w_i|\beta_{z_i}) p(z_i|\theta) d\theta. \tag{9}$$

In addition, the topic assignment z_i can be integrated out and the log-likelihood of a word w_i in dialogue $\mathbf{d}$ can be factorized as:

$$\begin{aligned} \log p(w_i|\beta, \theta) &= \log \sum_{z_i} [p(w_i|\beta_{z_i}) p(z_i|\theta)] \\ &= \log(\theta \cdot \beta^{\mathrm{T}}). \end{aligned} \tag{10}$$

The topic-word distribution β_k is defined by:

$$\beta_k = \text{softmax}(F \cdot \Lambda_k^{\mathrm{T}}), \tag{11}$$

where $F \in \mathbb{R}^{C \times H}$ is the topical word embedding matrix and $\Lambda \in \mathbb{R}^{K \times H}$ is the topic embedding matrix, K is the number of topics, C is the number of topical words, H is the embedding size and $\beta = \{\beta_1, \beta_2, \cdots, \beta_K\}$.

3.2.2 Parameterization with Latent Topics

We parameterize the encoder-decoder with the inferred topic distribution θ. In context-aware parameterization, the parameters of the encoder-decoder are adapted dynamically at each time step, whereas in topic-aware parameterization, as illustrated in Figure 3 (b), we generate only one set of parameters for each conversation.

Similar to the context-aware parameterization function in Eq.(7), given the topic distribution θ, the topic-aware parameterization function $\mathcal{A}_\kappa$ constructs the LSTM weight W as follows:

$$\begin{aligned} W &= \mathcal{A}_\kappa(\theta, U, V) \\ \mathcal{A}_\kappa(\theta, U, V) &= U\theta V^{\mathrm{T}}, \end{aligned} \tag{12}$$

where $U \in \mathbb{R}^{N_r \times K}$ and $V \in \mathbb{R}^{N_c \times K}$ are learnable parameters. K is the number of latent topics.

3.3 Parameterization with Both Context and Topics

Intuitively, context-aware parameterization is more adept at capturing local semantics of the input context while topic-aware parameterization enables parameter sharing between conversations with similar topic distributions. To benefit the model parameterization with both the local and global information, we further adapt parameters of the encoder-decoder by utilizing both the context representations ξ_t and the topic distribution θ. In particular, the LSTM weight W at time step t is adapted as follows:

$$\begin{aligned} W =& \Psi_t \mathcal{A}_c(\xi_t, U_c, V_c) + \\ & (1-\Psi_t)\mathcal{A}_\kappa(\theta, U_\kappa, V_\kappa) \\ \Psi_t =& \sigma(\xi_t, \theta), \end{aligned} \tag{13}$$

where Ψ_t is the gating function deciding whether the parameterization relies more on the context or the topics. U_c, V_c, U_κ and V_κ are learnable weights. $\mathcal{A}_c$ and $\mathcal{A}_\kappa$ denote the context-aware and topic-aware parameterization function respectively. σ is the sigmoid function.

3.4 Learning

To enable the joint optimization of latent topic inference, adaptive model parameterization, and response generation in ADAND, given the definitions in Eq.(9), similar to Kingma and Welling (2014) and Miao et al. (2017), we derive a variational lower bound for the generation likelihood:

$$\begin{aligned} \mathcal{J} =& \mathbb{E}_{Q(\theta|\mathbf{d})}[\sum_{i=1}^{|\mathbf{d}|}[\log \sum_{z_i}[p(w_i|\beta_{z_i})p(z_i|\theta)]] + \log p(\mathbf{y}|\mathbf{x})] \\ & - D_{KL}(Q(\theta|\mathbf{d})||P(\theta|\mathbf{x})) \\ =& \mathbb{E}_{Q(\theta|\mathbf{d})}[\sum_{i=1}^{|\mathbf{d}|}\log p(w_i|\beta,\theta) + \sum_{t=1}^{T_\mathbf{y}}\log p(y_t|s_{t-1})] \\ & - D_{KL}(Q(\theta|\mathbf{d})||P(\theta|\mathbf{x})) \\ =& \mathbb{E}_{Q(\nu|\mathbf{d})}[\sum_{i=1}^{|\mathbf{d}|}\log p(w_i|\beta,\nu) + \sum_{t=1}^{T_\mathbf{y}}\log p(y_t|s_{t-1})] \\ & - D_{KL}(Q(\nu|\mathbf{d})||P(\nu|\mathbf{x})) \\ \approx & \sum_{i=1}^{|\mathbf{d}|}\log p(w_i|\beta,\nu) + \sum_{t=1}^{T_\mathbf{y}}\log p(y_t|s_{t-1}) \\ & - D_{KL}(Q(\nu|\mathbf{d})||P(\nu|\mathbf{x})), \end{aligned} \tag{14}$$

where $\mathbf{y} = \{y_1, y_2, \cdots, y_{T_y}\}$, $P(\nu|\mathbf{x})$ is the prior estimation of the latent variable ν which approximates the posterior $Q(\nu|\mathbf{d})$. The prior $P(\theta|\mathbf{x}) = P(g(\nu)|\mathbf{x}) = P(\nu|\mathbf{x})$, and the posterior $Q(\theta|\mathbf{d}) = Q(g(\nu)|\mathbf{d}) = Q(\nu|\mathbf{d})$. The first term is the dialogue generation objective in the latent topic inferrer, the second term is the response generation objective, and the third term is the KL divergence between two Gaussian distributions. All the parameters are learned by optimizing Eq.(14) and updated with back-propagation.

The following previously proposed strategies (Bowman et al., 2016; Zhao et al., 2017) are adopted in training to alleviate the vanishing latent variable problem: (1) KL annealing: the weight of the KL divergence term is gradually increasing from 0 to 1 during training; (2) Bag-of-words loss: the bag-of-words loss requires the latent variable ν, together with the dialogue context, to reconstruct the response bag-of-words representation y_b.

4 Experiments

4.1 Dataset and Competitor Baselines

To ascertain the effectiveness of the proposed model, we construct an open-domain conversation corpus covering a broad range of resources including a movie discussions dataset collected from Reddit (Dodge et al., 2015), an Ubuntu technical corpus (Lowe et al., 2015), and a chit-chat dataset (Zhang et al., 2018). 87,468 context-response pairs were sampled for training, 4,460 for validation and 4,468 for testing.

The code and corpus are available at `http://github.com/hengyicai/AdaND`.

The following state-of-the-art models are adopted as our comparison systems.

SEQ2SEQ The attention-based sequence-to-sequence model (Bahdanau et al., 2015), which is a representative baseline.

CVAE A latent variable conversation model in which it incorporates a latent variable at the sentence-level to inject stochasticity and diversity (Clark and Cao, 2017; Zhao et al., 2017).

LAED A recurrent encoder-decoder conversation model using discrete latent actions for interpretable neural dialogue generation (Zhao et al., 2018).

TA-SEQ2SEQ TA-SEQ2SEQ incorporates the outsourcing topic information into the response generation, where the topics are learned from a separate LDA model to enrich the context (Xing et al., 2017).

DOM-SEQ2SEQ A domain-aware conversation model consisting of multiple domain-targeted

Models	Relevance (%)				Informativeness (%)

Table 1: Quantitative evaluation results (%).

SEQ2SEQ models for response generation (Choudhary et al., 2017).

4.2 Evaluation

Following the evaluation procedure in previous work (Li et al., 2016; Xing et al., 2017; Chen et al., 2018), experimental results of all models are reported in terms of the relevance and informativeness. To evaluate the semantic relevance between the generated response and the ground-truth response, we adopted the BLEU metric (Papineni et al., 2002) and three embedding-based similarity metrics proposed in Liu et al. (2016): Embedding Average (**Average**), Embedding Extrema (**Extrema**) and Embedding Greedy (**Greedy**). To measure informativeness and diversity of the response, we exploited the Distinct-1, Distinct-2 and Distinct-3 metrics. A higher ratio of distinct n-grams implies more informative and diverse responses.

4.3 Implementation and Reproducibility

We implemented our model with ParlAI (Miller et al., 2017). The sequence lengths are truncated at 50. We used Adam (Kingma and Ba, 2014) with an initial learning rate of 0.001 to optimize the model. For all the experiments, we employed a 2-layer bidirectional LSTM as the encoder and a unidirectional one as the decoder. The hidden size and the word embedding dimension are both set to 300. The latent variable size is set to 64. The topic number K in our model is set to 5 and the most frequent 3,159 words are taken as the topical words vocabulary by stemming, filtering stop-words from the training set. The batch size is set to 128 for all models. We trained a Twitter LDA model to obtain the topical words for TA-SEQ2SEQ and set its model-specific parameters following the original paper (Xing et al., 2017). For regularization and preventing over-fitting, a dropout of 0.1 is applied and the weight decay is set to 3×10^{-5}. We used the pretrained word embeddings (Pennington et al., 2014) of 300 dimensions, and the vocabulary size is set to 20,000. All models are trained with early stopping, i.e., if the loss does not decrease after 10 validations. The loss is computed on the validation set at every 0.5 epochs and we save the parameters for the top model on the validation set. We finally report evaluation scores on the test set from the saved model.

4.4 Overall Performance

Table 1 lists the performance of our system and the comparison systems. CVAE and LAED inject SEQ2SEQ with stochastic latent variable, resulting in more informative responses and better performance on Distinct-{1, 2, 3}. TA-SEQ2SEQ incorporates SEQ2SEQ with the outsourcing topic information from LDA. It is not surprising that it performs much better on the response relevance (BLEU, Average, Greedy, Extrema), while its improvements on the informativeness are limited. DOM-SEQ2SEQ builds multiple domain-specific encoder-decoders. It gains improvements on both the relevance metrics and informativeness metrics.

In general, with both the context-aware and topic-aware parameterization, our model outperforms all the competitive baselines in terms of the response relevance and informativeness.

4.5 Context-aware *vs* Topic-aware Parameterization

Context-aware parameterization captures local semantics of the given context, while topic-aware parameterization enables parameters sharing among conversations with similar topics. As shown in Ta-

Opponent	Win	Loss	Tie	Kappa
ADAND vs. SEQ2SEQ	62.5%	2.52%	34.98%	46.46
ADAND vs. CVAE	36.98%	7.56%	55.46%	51.59
ADAND vs. LAED	44.54%	6.72%	48.74%	55.57
ADAND vs. TA-SEQ2SEQ	54.62%	5.88%	39.5%	54.91
ADAND vs. DOM-SEQ2SEQ	32.78%	10.08%	57.14%	55.53

Table 2: The results of human evaluation.

Models	Speed (cases/ms)
SEQ2SEQ	0.740
CVAE	0.541
LAED	0.435
TA-SEQ2SEQ	0.172
DOM-SEQ2SEQ	0.106
ADAND	0.407

Table 3: Speed test.

ble 1, both parameterization mechanisms perform much better than the original SEQ2SEQ model, while context-aware parameterization is slightly better in terms of informativeness. When jointly utilizing both the context-aware and topic-aware parameterization mechanisms, we observe the best performance, indicating that these two mechanisms are both beneficial and complementary.

4.6 Human Evaluation

We conducted human evaluations on the test set to further validate the effectiveness of the model. We randomly selected 500 samples from the test set. Three well-educated students were invited to conduct the evaluation. For each case, we provided annotators with triplets (sample, response$_1$, response$_2$) whereby one response is generated by ADAND, and the other is generated by a competitor model. The annotators, who have no knowledge about which system the response is from, are then required to independently rate among win (response$_1$ is better), loss (response$_2$ is better) and tie (they are equally good or bad), considering four factors: context relevance, logical consistency, fluency and informativeness. Note that if annotators rate different options, this triplet will be counted as "tie". Table 2 reveals the results of subjective evaluation. The kappa scores indicate that the annotators came to a fair agreement in the judgment.

As expected, ADAND outperforms the other baselines and enjoys a large margin over the existing models. The relative performance of the competitors is consistent with the quantitative evaluation results, confirming the superior performance of our proposed method.

Table 4: Topics by the words (β in Eq.(10)) with top-10 highest probability discovered by the latent topic inferrer.

4.7 Speed Test

We conducted speed test to verify the efficiency of the ADAND model empirically in Table 3. Augmented with auxiliary components, all the extension models exhibit higher time cost than the original SEQ2SEQ model. We observe that the decoding speeds of CVAE and LAED are relatively comparable with our model. However, when comparing with TA-SEQ2SEQ and DOM-SEQ2SEQ that also elaborately and explicitly model conversations with diverse topics or themes, ADAND shows a clear superiority in decoding speed. For TA-SEQ2SEQ, it relies on an outside LDA model to obtain the topic information. The joint attention and copying mechanism also reduce its efficiency. For DOM-SEQ2SEQ, it is not surprising that the time complexity of multiple topic/theme-specific encoder-decoders is much higher than all-other comparison models. ADAND utilizes a single encoder-decoder and is parameterized dynamically regarding the input context, which ensures its flexibility and efficiency.

4.8 Analysis & Case Study

To get some insights of how topic-aware parameterization performs, we present the topics by the words (β in Eq.(10)) with top-10 highest probabilities in Table 4. The discernible clusters of the topical words (F in Eq.(11)) are illustrated in Figure 4. These evidences demonstrate that the topic inferrer in topic-aware parameterization effectively distills the latent topic distribution of each conversation, which enables the parameter sharing among conversations with similar topics.

We also investigate the orthogonality of the learned U and V matrices in Eq.(7) and Eq.(12). We trained our model multiple times with differ-

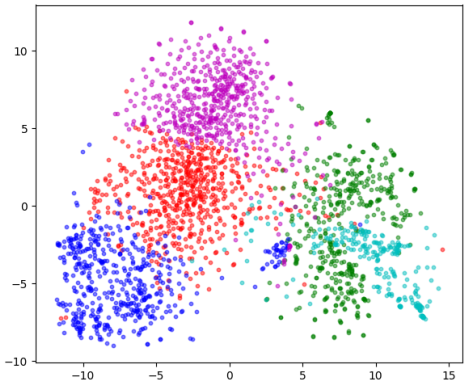

Figure 4: t-SNE (van der Maaten and Hinton, 2008) projection of topical word embeddings (F in Eq.(11)) in the latent topic inferrer. Words with similar topics are in the same color.

ent parameter initialization methods (drawn values from normal distribution or uniform distribution). We observe that UU^{T} and VV^{T} approximate identity matrices. We conjecture that such SVD-alike parameterization implicitly enforces orthogonality during training.

We list several examples generated by different models in Table 5. The inferred latent topic distributions are also presented in the table. It can be observed that responses generated by the original SEQ2SEQ model are more generic. Latent variable conversation models (CVAE and LAED) generate more diverse but sometimes irrelevant responses, TA-SEQ2SEQ tends to produce short responses while DOM-SEQ2SEQ does not perform obviously better than TA-SEQ2SEQ. The responses generated by ADAND are not only relevant but also informative.

5 Related Work

Our work is closely related to the research of dialogue generation in diverse conversations. Previous work relies on external pre-organized topic information (Xing et al., 2017; Wang et al., 2017) or predicted keywords (Yao et al., 2017; Wang et al., 2018) to boost the response informativeness and coherence. Choudhary et al. (2017) further leveraged the topic/theme annotations to build multiple separate encoder-decoder models for topic/theme-aware response generation. In contrast, we do not exploit any outsourcing or labeled topic information. The proposed model directly infers the latent topics of each conversation and is trained in an end-to-end manner. Another difference is that we maintain a single encoder-decoder for various conversations whereas the model is dynamically and specially parameterized.

The second line of related work is parameterization in NLP. Ha et al. (2017) proposed to train a small network to generate the parameters for another larger network. Such adaptive parameteriza-

Table 5: Test samples of our model (ADAND) and the baselines. The latent topic distributions inferred by ADAND are also presented. The reference is the ground-truth response in the dataset.

tion has been shown to be successful in many NLP tasks, including language modeling (Suarez, 2017; Flennerhag et al., 2018), sequence generation (Ha and Eck, 2018; Peng et al., 2019), and neural machine translation (Platanios et al., 2018). In our work, we parameterize the encoder-decoder with respect to both the context and the latent topics.

Regarding latent variable conversation models, prior researches strive to learn meaningful latent variables for dialogue systems, and reveal that latent variables befit the neural dialogue models with more diverse response generations (Serban et al., 2017; Zhao et al., 2017; Clark and Cao, 2017; Chen et al., 2018) and interpretable dialogue actions (Zhao et al., 2018). In our model, instead of directly injecting the latent variable into dialogue models, we distill the latent topics through neural variational inference, offering a more interpretable latent variable. Moreover, we parameterize the encoder-decoder with the inferred latent topics, which allows parameter sharing among conversations with similar topics.

6 Conclusion

This paper presents an adaptive neural dialogue generation model—ADAND, which allows the dynamical parameterization of the model to each conversation and enables the generation of appropriate responses in diverse conversations. Specially, we propose two adaptive parameterization approaches: context-aware parameterization which captures local semantics of the input context; and topic-aware parameterization which enables parameter sharing by first inferring the latent topics of the given context and then generating the parameters with the inferred latent topics. The proposed approaches are assessed on a large-scale conversational dataset and the results show that our model achieves superior performance and higher efficiency. It should be noted that our approach is not isolated to only LSTMs. We would like to explore the effectiveness of the approach regarding other structures in future work.

Abstract

In this paper, we propose a novel end-to-end framework called **KBRD**, which stands for **K**nowledge-**B**ased **R**ecommender **D**ialog System. It integrates the recommender system and the dialog generation system. The dialog system can enhance the performance of the recommendation system by introducing knowledge-grounded information about users' preferences, and the recommender system can improve that of the dialog generation system by providing recommendation-aware vocabulary bias. Experimental results demonstrate that our proposed model has significant advantages over the baselines in both the evaluation of dialog generation and recommendation. A series of analyses show that the two systems can bring mutual benefits to each other, and the introduced knowledge contributes to both their performances.[1]

1 Introduction

Dialog in e-commerce has great commercial potential. In conventional recommender systems, personalized recommendation is highly based on the previous actions of users, including searching, clicking and purchasing. These actions can be regarded as users' feedbacks that reflect users' interest. However, due to its implicitness, such feedback can only reflect a part of users' interest, causing inaccuracy in recommendation. Another information source about user preferences is the dialog between users and services. In such dialog, users often provide more information about their preferences. They often ask for tips or recommendation in the dialog. In this process, services can guide them to speak out their interests in order to solve users' problems and meet their requirements. Compared with the implicit feedback, the feedback from the dialog is more explicit and more related to users' preferences. Therefore, a recommender dialog system possesses high commercial potential.

USER:	Hello!
RECOMMENDER:	What kind of movies do you like?
USER:	I am looking for a movie recommendation. When I was younger I really enjoyed the *A Nightmare on Elm Street (1984)*.
BASELINE:	Have you seen *It (2017)*?
OURS:	I like horror movies too! Have your seen *Halloween (1978)* ?
HUMAN:	Oh, you like scary movies? I recently watched *Happy Death Day (2017)*.

Table 1: **An example of the outputs of recommender dialog systems.** The model recommends items (italic) while maintaining the dialog with the user. Compared with the baseline, our dialog system gives a more diverse and consistent response.

A recommender dialog system can be regarded as a combination of a recommender system and a dialog system. A dialog system should respond to users' utterances with informative natural language expressions, and a recommender system should provide high-quality recommendation based on the content of users' utterances. We demonstrate an example in Table 1. In brief, a recommender dialog system should perform well in both tasks.

An ideal recommender dialog system is an end-to-end framework that can effectively integrate the two systems so that they can bring mutual benefits to one another. In this setting, information from the recommender system can provide vital information to maintain multi-turn dialog, while information from the dialog system that contains implication of users' preferences can enhance the qual-

ity of recommendation. Besides, the incorporation of external knowledge can strengthen the connections between systems and enhance their performances. Therefore, driven by the motivations, we propose a novel end-to-end framework that integrates the two systems. We name it **KBRD**, standing for **K**nowledge-**B**ased **R**ecommender **D**ialog System.

Specifically, the dialog generation system provides contextual information about items to the recommender system. For instance, for a movie recommendation system, contextual information can be director, actor/actress and genre. Thus, even with no item mentioned in the dialog, the recommender system can still perform high-quality recommendation based on the contextual information. In return, the recommender system provides recommendation information to promote the dialog, such as recommendation-aware vocabulary bias. Furthermore, we incorporate external knowledge into our framework. The knowledge graph helps bridge the gap between systems and enhances both their performances.

We conduct a series of experiments that demonstrate the effects of our framework in both the evaluation of recommendation and dialog generation. Moreover, the analyses show that dialog information effectively tackles the cold-start problem in recommendation, and the recommendation-aware vocabulary bias from the recommender system improves the quality of generated dialogs. Also, the biased words can be parts of reasons to explain the system's decisions for recommendation.

2 Preliminary

Before we introduce our proposed framework, we provide an illustration of the basic framework of the recommender dialog system to show how the recommendation system and the dialog system are organized for end-to-end training.

2.1 Recommender System

Provided with a user's information, a recommender system is aimed at retrieving a subset of items that meet the user's interest from all the items. In a cold-start setting, the recommender system initially has no knowledge about the user. With the progress of the dialog, the recommender system accumulates user's information and builds a user profile. Thus, it can provide reasonable recommendation based on the user preferences reflected in the conversation.

To implement an effective recommender system in this task, it is available to build a recommender system based on conventional collaborative filtering algorithms (Sarwar et al., 2001) or based on neural networks (He et al., 2017). For example, Li et al. (2018) applies a user-based autoencoder (Sedhain et al., 2015) to recommend new items based on previously mentioned items in the dialog.

2.2 Dialog System

The dialog system in the basic framework is in charge of generating multi-turn dialog with a natural language generation model. The pioneering work (Li et al., 2018) on conversational recommendation task adopted Hierarchical Recurrent Encoder Decoder (HRED) (Sordoni et al., 2015b,a; Serban et al., 2016) for this part. The HRED is an encoder-decoder framework for sequence-to-sequence learning (Sutskever et al., 2014). In the framework, an encoder receives the dialog history as input and encodes it to high-level representation, while a decoder generates responses based on the encoded representation. By recursively encoding and decoding the previous information, the system makes utterances in the multi-turn dialog.

2.3 End-to-End System

In order to perform end-to-end training, we demonstrate the combination of the recommender system and conversation system. Specifically, the input of the recommender system is constructed based on the dialog history, which is a representation of mentioned items in the dialog. The output of the recommender system P_{rec}, which is a probability distribution over the item set, can be combined with the output of the dialog system $P_{\text{dialog}} \in \mathbb{R}^{|V|}$, where V refers to the vocabulary. A switching mechanism (Gulcehre et al., 2016) controls the decoder to decide whether it should generate a word from the vocabulary or an item from the recommender output at a certain timestep.

$$P(w) = p_s P_{\text{dialog}}(w) + (1 - p_s)\, P_{\text{rec}}(w) \quad (1)$$

$$p_s = \sigma\left(w_s o + b_s\right) \quad (2)$$

where w represents either a word from the vocabulary or an item from the item set, o is the hidden representation in the final layer of the dialog

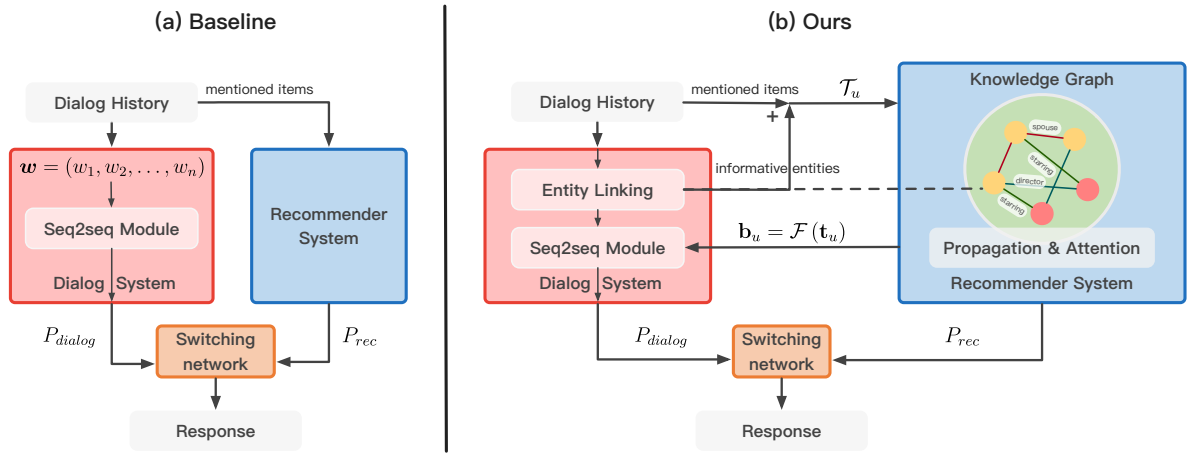

Figure 1: **Comparative illustration on modules of the existing baseline framework and our proposed KBRD framework.** (a) The connection between the recommender system and the dialog system in the baseline framework is weak. The dialog system takes the plain text of the dialog history as input and the recommender only considers mentioned items in the dialog. (b) Our framework enables interaction between the two systems. First, informative entities are linked to an external knowledge graph and sent to the recommender besides items. They are propagated on the KG via a relational graph convolutional network, enriching the representation of user interest. Second, the knowledge-enhanced user representation is sent back to the dialog system in the form of vocabulary bias, enabling it to generate responses that are consistent with the user's interest.

system. $w_s \in \mathbb{R}^d$ and $b_s \in \mathbb{R}$ are the switcher's parameters and σ refers to the sigmoid function. Therefore, the whole system can be trained in an end-to-end fashion.

3 Proposed Model

In this section, we introduce our proposed framework **KBRD** that integrates the recommender system and the dialog system effectively via knowledge propagation. We show how knowledge connects the two systems and how they bring mutual benefits to each other.

3.1 Dialog-Aware Recommendation with Knowledge

Recommendation of the basic framework is solely based on the mentioned items in the dialog history. Such recommendation ignores contextual information in dialog that often indicates users' preferences.

Here we propose to make use of the dialog contents, including the non-item information, in the process of recommendation. Furthermore, to effectively recommend items from the non-item information, we introduce an external knowledge graph from DBpedia (Lehmann et al., 2015) to our system. The knowledge can build a connection between dialog contents and items.

Incorporating Dialog Contents Specifically, we have a knowledge graph $\mathcal{G}$ consisting of triples (h, r, t) where $h, t \in \mathcal{E}$ and $r \in \mathcal{R}$. $\mathcal{E}$ and $\mathcal{R}$ denote the sets of entities and relations in the knowledge graph. We first match each item in the item set to entities in $\mathcal{E}$ by name.[2] We then perform entity linking (Daiber et al., 2013) on dialog contents and thus informative non-item entities appearing in dialog contents are matched to $\mathcal{E}$.[3] Therefore, we can represent a user as $\mathcal{T}_u = \{e_1, e_2, \cdots, e_{|\mathcal{T}_u|}\}$, where $e_i \in \mathcal{E}$. To be more specific, it is a set of mentioned items plus non-item entities extracted from the dialog contents, linked to the knowledge graph.

Relational Graph Propagation Inspired by Schlichtkrull et al. (2018), we apply Relational Graph Convolutional Networks (R-GCNs) to encode structural and relational information in the knowledge graph to entity hidden representations. An intuition behind this is that neighboring nodes in knowledge graph may share similar features that are useful for recommendation. For exam-

[2]For example, a movie item "star wars" is matched to http://dbpedia.org/resource/Star_Wars_(film) in the dbpedia knowledge graph.

[3]Utterance "I like science fiction movies." is associated with http://dbpedia.org/resource/Science_fiction_film. An utterance may be associated with one or multiple entities.

ple, when a user speaks of his/her preference on an actor/actress, the recommender should provide movies that have a close connection to that person. In addition, by taking different relations into consideration, the system models different types of neighbors more accurately.

Formally, at layer 0, we have a trainable embedding matrix $\mathbf{H}^{(0)} \in \mathbb{R}^{|\mathcal{E}| \times d^{(0)}}$ for nodes (i.e., entities) on the knowledge graph. Then, for each node v in $\mathcal{E}$ at layer l, we compute:

$$h_v^{(l+1)} = \sigma\left(\sum_{r \in \mathcal{R}} \sum_{w \in \mathcal{N}_v^r} \frac{1}{c_{v,r}} W_r^{(l)} h_w^{(l)} + W_0^{(l)} h_v^{(l)}\right)$$

where $h_v^{(l)} \in \mathbb{R}^{d^{(l)}}$ denotes the hidden representation of node v at the l-th layer of the graph neural network, and $d^{(l)}$ denotes the dimensionality of the representation at the layer. $\mathcal{N}_v^r$ denotes the set of neighbor indices of node v under relation $r \in \mathcal{R}$. W_r^l is a learnable relation-specific transformation matrix for vectors from neighboring nodes with relation r. W_0^l is a learnable matrix for transforming the nodes' representation at the current layer. $c_{v,r}$ is a normalization constant that can either be learned or chosen in advance (e.g., $c_{v,r} = |\mathcal{N}_v^r|$).

For each node on the graph, it receives and aggregates the messages from its neighboring nodes after relation-specific transformation. Then it combines the information with its hidden representation to form its updated representation at the next layer.

Finally, at the last layer L, structural and relational information is encoded into the entity representation $h_v^{(L)}$ for each $v \in \mathcal{E}$. We denote the resulting knowledge-enhanced hidden representation matrix for entities in $\mathcal{E}$ as $\mathbf{H}^{(L)} \in \mathbb{R}^{|\mathcal{E}| \times d^{(L)}}$. We omit the (L) in the following paragraphs for simplicity.

Entity Attention The next step is to recommend items to users based on knowledge-enhanced entity representations. While an item corresponds to an entity on the knowledge graph, a user may have interacted with multiple entities. Given $\mathcal{T}_u$, we first look up the knowledge-enhanced representation of entities in $\mathcal{T}_u$ from $\mathbf{H}$, and we have:

$$\mathbf{H}_u = (h_1, h_2, \cdots, h_{|\mathcal{T}_u|}) \tag{3}$$

where $h_i \in \mathbb{R}^d$ is the hidden vector of entity e_i. Here our objective is to encode this vector set of variable size to a vector of fixed size so that we can compute the similarity between user and item. Instead of simply averaging these vectors, we choose a linear combination of the $|\mathcal{T}_u|$ vectors. Specifically, we apply self-attention mechanism (Lin et al., 2017) that takes $\mathbf{H}_u$ as input and outputs a distribution α_u over $|\mathcal{T}_u|$ vectors:

$$\alpha_u = \text{softmax}\left(w_{a2} \tanh\left(W_{a1} \mathbf{H}_u^T\right)\right) \tag{4}$$

where $W_{a1} \in \mathbb{R}^{d_a \times d}$ is a weight matrix and w_{a2} is a vector of parameters with size d_a. The final representation of user u is computed as follows:

$$t_u = \alpha_u \mathbf{H}_u \tag{5}$$

This enables the recommender system to consider the importance of different items and non-item entities in the dialog. Finally, the output of our recommender is computed as follows:

$$P_{\text{rec}} = \text{softmax}(\text{mask}(t_u \mathbf{H}^T)) \tag{6}$$

where mask is an operation that sets the score of non-item entities to $-\infty$. The masking operation ensures that the recommendations are all items.

3.2 Recommendation-Aware Dialog

Instead of applying HRED, we introduce the Transformer framework to the dialog system in this task. Transformer (Vaswani et al., 2017) can reach significantly better performances in many tasks, such as machine translation (Vaswani et al., 2017; Ott et al., 2018), question answering (Rajpurkar et al., 2016; Yang et al., 2018; Ding et al., 2019) and natural language generation (Liu et al., 2018; Chen et al., 2019). In our preliminary experiments, we have found that Transformer can also achieve better performance than HRED in this task, and thus we apply this framework to the dialog system.

The Transformer is also an encoder-decoder framework for sequence-to-sequence learning. The Transformer encoder consists of an embedding layer and multiple encoder layers. Each encoder layer has a self-attention module and a Point-Wise Feed-Forward Network (FFN). The encoder encodes the dialog history $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)$ to high-level representations $\boldsymbol{s} = (s_1, s_2, \ldots, s_n)$. Similarly, the Transformer decoder contains an embedding layer and multiple decoder layers with self-attention and FFN. Moreover, each of them contains a multi-head context

attention to extract information from the source-side context. The decoder generates a representation o at each decoding time step.

In order to predict a word at each decoding time step, the top layer of the decoder, namely the output layer, generates a probability distribution over the vocabulary:

$$P_{\text{dialog}} = \text{softmax}\left(Wo + b\right) \tag{7}$$

where $W \in \mathbb{R}^{|V| \times d}$ and $b \in \mathbb{R}^{|V|}$ are weight and bias parameters, and V refers to the vocabulary.

However, so far the dialog system is completely conditioned on the plain text of the dialog contents. By further introducing the recommender system's knowledge of the items that have appeared in dialog, we guide the dialog system to generate responses that are more consistent with the user's interests. Specifically, we add a vocabulary bias b_u to the top layer of the decoder inspired by Michel and Neubig (2018). Different from their work, b_u is computed based on the recommender system's hidden representation of user u:

$$b_u = \mathcal{F}(t_u) \tag{8}$$

where $\mathcal{F} : \mathbb{R}^d \rightarrow \mathbb{R}^{|V|}$ represents a feed-forward neural network and t_u is the user representation in the recommendation context introduced in Equation 5.

Therefore, the computation of the top layer of the decoder becomes:

$$P_{\text{dialog}} = \text{softmax}\left(Wo + b + b_u\right) \tag{9}$$

So far, we have built an end-to-end framework that bridges the recommender system and the dialog system, which enables mutual benefits between the systems.

4 Experiments

In this section, we provide an introduction to the details of our experiments, including dataset, setting, evaluation as well as further analyses.

4.1 Dataset

REcommendations through DIALog (REDIAL) is a dataset for conversational recommendation. Li et al. (2018) collected the dialog data and built the dataset through Amazon Mechanical Turk (AMT). With enough instructions, the workers on the platform generated dialogs for recommendation on movies. Furthermore, in order to achieve and dialog-aware recommendation, besides movies, we introduce the relevant entities, such as director and style, from DBpedia. The number of conversations is 10006 and the number of utterances is 182150. The total number of users and movies are 956 and 51699 respectively.

4.2 Setting

We implement the models in PyTorch and train on an NVIDIA 2080Ti. For the recommender, both the entity embedding size $d^{(0)}$ and the hidden representation size $d^{(l)}$ are set to 128. We choose the number of R-GCN layers $L = 1$ and the normalization constant $c_{v,r}$ to 1. For Transformer, all input embedding dimensions and hidden sizes are set to 300. During training, the batch size is set to 64. We use Adam optimizer (Kingma and Ba, 2015) with the setting $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1 \times 10^{-8}$. The learning rate is 0.003 for the recommender and 0.001 for the Transformer. Gradient clipping restricts the norm of the gradients within [0, 0.1].

4.3 Evaluation Metrics

The evaluation of dialog consists of automatic evaluation and human evaluation. The metrics for automatic evaluation are perplexity and distinct n-gram. Perplexity is a measurement for the fluency of natural language. Lower perplexity refers to higher fluency. Distinct n-gram is a measurement for the diversity of natural language. Specifically, we use distinct 3-gram and 4-gram at the sentence level to evaluate the diversity. As to human evaluation, we collect ten annotators with knowledge in linguistics and require them to score the candidates on the consistency with the dialog history. We sample 100 multi-turn dialogs from the test set together with the models' corresponding responses, and require them to score the consistency of the responses.[4] The range of score is 1 to 3.

The evaluation for recommendation is Recall@K. We evaluate that whether the top-k items selected by the recommender system contain the ground truth recommendation provided by human recommenders. Specifically, we use Recall@1, Recall@10, and Recall@50 for the evaluation.

[4]Note that we did not provide the utterances of the baseline Transformer to annotators. Based on our observation, the generations of the Transformer-based models are significantly different from those of REDIAL. In case that annotators had knowledge about models, we did not require them to score the utterances of Transformer.

Model	R@1	R@10	R@50
REDIAL	2.3±0.2	12.9±0.7	28.7±0.9
KBRD (D)	2.7±0.2	14.0±0.6	30.6±0.7
KBRD (K)	2.6±0.2	14.4±0.9	31.0±1.2
KBRD	**3.0**±0.2	**16.3**±0.3	**33.8**±0.7

Table 2: **Evaluation of the recommender system.** We report the results of Recall@1, Recall@10 and Recall@50 of the models ($p \ll 0.01$). **KBRD (D)** stands for only incorporating the dialog contents. **KBRD (K)** stands for only incorporating knowledge. The results demonstrate that both the interaction with the dialog system and the external knowledge are helpful for the improvement of model performance, and our proposed model reaches the best performance on the three metrics.

Model	PPL	Dist-3	Dist-4	CSTC
REDIAL	28.1	0.11	0.13	1.73
Transformer	18.0	0.27	0.39	-
KBRD	**17.9**	**0.30**	**0.45**	**1.99**

Table 3: **Automatic and human evaluation of dialog generation.** For automatic evaluation, we evaluate the perplexity (PPL) and distinct n-gram (Dist-3 and Dist-4 refer to distinct 3-gram and 4-gram respectively) of the generated dialogs. For human evaluation, we ask human annotators to evaluate the consistency (CSTC) of the generated utterances with the dialog history. Our proposed method performs the best in all evaluations compared with the baselines.

4.4 Baselines

The baseline models for the experiments are illustrated in the following:

- **REDIAL** This is a basic model for conversational recommendation. It basically consists of a dialog generation system based on HRED (Sordoni et al., 2015a; Serban et al., 2016), a recommendation system based on autoencoder and a sentiment analysis module.

- **Transformer** We name our implemented baseline model Transformer. It is similar to REDIAL, but its dialog generation system is based on the model Transformer (Vaswani et al., 2017). Except for that, the others remain the same.

4.5 Results

In the following, we present the results of our experiments, including the model performances in recommendation and dialog generation.

Recommendation To evaluate the effects of our recommendation system, we conduct an evaluation of Recall@K. We present the results in Table 2. From the results, it can be found that our proposed model reaches the best performances in the evaluation of Recall@1, Recall@10 and Recall@50. Furthermore, we also demonstrate an ablation study to observe the contribution of the dialog system and the introduced knowledge. It can be found that either dialog or knowledge can bring improvement to the performance of the recommendation system. Their combination improves the performance the most by +0.7 Recall@1, +3.4 Recall@10 and +5.1 Recall@50, which are advantages of 30.4%, 26.4% and 17.8% respectively. This shows that the information from both sources is contributive. The dialog contains users' preferred items as well as attributes, such as movie director and movie style, so that the system can find recommendation based on these inputs. The knowledge contains important features of the movie items so that the system can find items with similar features. Further, the combination brings an advantage even greater than sum of the two parts, which proves the effectiveness of our model.

Dialog Table 3 shows the results of the evaluation of the baseline models and our proposed method in dialog generation. In the evaluation of perplexity, Transformer has much lower perplexity (18.0) compared to REDIAL (28.1), and **KBRD** can reach the best performance in perplexity. This demonstrates the power of Transformer in modeling natural language. In the evaluation of diversity, we find that the models based on Transformer significantly outperform REDIAL from the results of distinct 3-gram and 4-gram. Besides, it can be found that **KBRD** has a clear advantage in diversity over the baseline Transformer. This shows that our model can generate more diverse contents without decreasing fluency.

As to the human evaluation, we ask human annotators to score the utterances' consistency with their dialog history. Compared with REDIAL **KBRD** reaches better performance by +0.22 consistency score, which is an advantage of 15%. Moreover, considering the range is between 1 and 3, this is a large gap between the performances

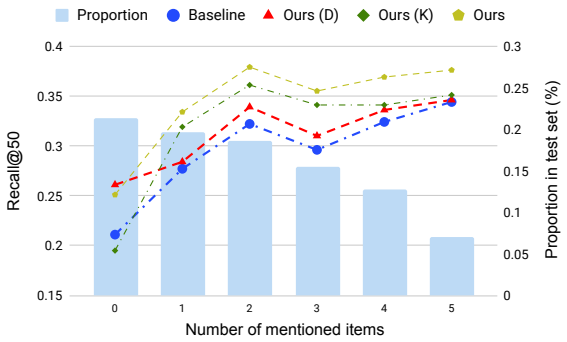

Figure 2: **Performance of the recommender system with different numbers of mentioned items.** The x-axis refers to the number of mentioned items in the dialog, the y-axis for the line chart (on the left) refers to the model performance on the Recall@50 evaluation, and the y-axis for the histogram (on the right) refers to proportion in the test set. This shows recommendation is much more difficult with few items mentioned (i.e., at the first few rounds in dialog). Leveraging dialog contents makes a great difference in this situation.

of the two models in this evaluation. To make a consistent response in a dialog, the model should understand the dialog history and better learn the user's preference. The baseline REDIAL does not have a strong connection between the dialog system and user representation. Instead, in our framework, the recommender system provides the recommendation-aware vocabulary bias b_u, which is based on the user representation t_u, to the dialog system. Thus the dialog system gains knowledge about the user's preference and generates a consistent response.

5 Discussion

In this section, we conduct a series of analyses to observe the effects of our proposed model. We discuss how dialog can improve the recommendation performance and how recommendation can enhance the dialog quality.

5.1 Does dialog help recommendation?

We first evaluate whether the dialog contents can benefit the recommendation system. The results of the evaluation are demonstrated in Figure 2. From the histogram in the figure, we observe that most of the dialogs contain only a few mentioned movies. The dialogs with only 0-2 mentioned movies take up a proportion of 62.8% of the whole testing dataset. Therefore, it is important for the system to perform high-quality recommendation with only a small number of mentioned movies. This also corresponds to the classical problem "cold start" (Schein et al., 2002) in the recommender system. In real applications, we also expect that the system can perform high-quality recommendation with fewer rounds. This represents the efficiency of the recommender system, which can save users' time and efforts.

Specifically, we demonstrate the performances of four systems in Figure 2. They are the basic framework, the one only with the interaction with the dialog system, the one only with the external knowledge and **KBRD** with both dialog and knowledge incorporation. From the figure, it can be found that while there is no mentioned item in the dialog, the baseline and the one only with knowledge perform the worst. In contrast, the two models with dialog incorporation perform significantly better. This shows that the context in the dialog contains much useful non-item information about users' preferences, such as director, actor/actress in movie recommendation. Therefore, while there is no mentioned item, the recommender system can still perform high-quality recommendation based on the contextual information. With the increase of mentioned items, the contribution of knowledge becomes more significant than the dialog. On average, the system with both information sources performs the best. Dialog introduces contextual information and knowledge introduces movie features and structural connection with other movies.

5.2 Does recommendation help dialog?

In Section 4.5, we present the performances of the baselines and our model **KBRD** in dialog generation. It can be found that the interaction with the recommendation system can enhance the performance of the dialog system in both automatic evaluation and human evaluation. Also, an example of the responses of different models is shown in Table 1. With the dialog history, the baseline REDIAL simply uses a generic response with a recommended movie. Instead, **KBRD** has more concern about the mentioned items apart from the plain text of dialog history. The user representation from our recommender system contains such information, which is sent to the dialog system to form a vocabulary bias. With such information, **KBRD** has a better understanding of both the dialog history as well as the user's preference, and thus generates a consistent response.

Movie	1	2	3	4	5	6	7	8
Star Wars	space	alien	sci-fi	star	sci	robot	smith	harry
The Shining	creepy	stephen	gory	horror	scary	psychological	haunted	thriller
The Avengers (2012)	marvel	superhero	super	dc	wait	batman	thor	take
Beauty and the Beast	cute	disney	animated	live	music	child	robin	kids

Table 4: **Examples of top 8 vocabulary bias**. Given a mentioned movie, we visualize words with high probability based on the recommendation-aware vocabulary bias. The examples show that the biased words have strong connections with their corresponding movies. While the vocabulary bias benefits the dialog system to generate responses that are more consistent with user interest, they also contribute to the explainability of recommendation.

To further study the effects of the recommender system on dialog generation, we display the top biased words from the vocabulary bias. Note that in **KBRD** a connection between the recommender system and dialog system is the recommendation-aware vocabulary bias b_u. To be specific, we compute the recommendation-aware bias b_u in dialog and select the components with the top-8 largest values.[5] Then we record the corresponding words and observe whether these words are related to the mentioned movies. We present several examples in Table 4. From the table, we observe that the words are highly related to the mentioned movies. For example, when "The Shining" is mentioned, some of the top biased words are "creepy", "gory" and "scary", which are consistent with the style of the horror movie, and "stephen", who is the original creator of the movie. Therefore, it can be suggested that the recommendation system conveys important information to the dialog system in the form of a vocabulary bias. Furthermore, these biased words can also serve as explicit explanation to recommendation results. From this perspective, this shows the interpretability of our model.

6 Related Work

Recommender systems aim to find a small set of items that meet users' interest based on users' historical interactions. Traditional recommender systems rely on collaborative filtering (Resnick et al., 1994; Sarwar et al., 2001), and recent advances in this field rely much on neural networks (Wang et al., 2015; He et al., 2017; Ying et al., 2018). To deal with the cold-start problem and the sparsity of user-item interactions which these methods usually suffer, researchers have proposed methods to incorporate external information, such as heterogeneous information networks (Yu et al., 2014), knowledge bases (Zhang et al., 2016; Wang et al., 2018a) and social networks (Jamali and Ester, 2010). Besides accuracy, explainability is also an important aspect when evaluating recommender systems (Zhang et al., 2014; Zhang and Chen, 2018; Wang et al., 2018b).

End-to-end dialog systems based on neural networks have shown promising performance in open-ended settings (Vinyals and Le, 2015; Sordoni et al., 2015b; Dodge et al., 2016; Wen et al., 2015) and goal-oriented applications (Bordes et al., 2017). Recent literature also explores the intersection of end-to-end dialog systems with other intelligence systems and creates new tasks such as visual dialog (Das et al., 2017; De Vries et al., 2017), conversational recommendation (Li et al., 2018). In particular, Li et al. (2018) collects a dataset of conversations focused on providing movie recommendations and proposes a baseline model for end-to-end training of recommender and dialog systems. Earlier studies in this field focus on different tasks such as minimizing the number of user queries (Christakopoulou et al., 2016), training the dialog agent to ask for facet values for recommendation (Sun and Zhang, 2018). Related literature can also be found in Thompson et al. (2004), Mahmood and Ricci (2009), Chen and Pu (2012), Widyantoro and Baizal (2014) and Liao et al. (2019).

7 Conclusion

In this paper, we propose a novel end-to-end framework, **KBRD**, which bridges the gap between the recommender system and the dialog system via knowledge propagation. Through a series of experiments, we show that **KBRD** can reach better performances in both recommendation and dialog generation in comparison with the baselines. We also discuss how the two systems benefit each other. Dialog information is effective for the recommender system especially in the setting of cold start, and the introduction of knowledge can strengthen the recommendation performance

[5] After stop words filtering.

significantly. Information from the recommender system that contains the user preference and the relevant knowledge can enhance the consistency and diversity of the generated dialogs.

Structuring Latent Spaces for Stylized Response Generation

Abstract

Generating responses in a targeted style is a useful yet challenging task, especially in the absence of parallel data. With limited data, existing methods tend to generate responses that are either less stylized or less context-relevant. We propose StyleFusion, which bridges conversation modeling and non-parallel style transfer by sharing a structured latent space. This structure allows the system to generate stylized relevant responses by sampling in the neighborhood of the conversation model prediction, and continuously control the style level. We demonstrate this method using dialogues from Reddit data and two sets of sentences with distinct styles (arXiv and Sherlock Holmes novels). Automatic and human evaluation show that, without sacrificing appropriateness, the system generates responses of the targeted style and outperforms competitive baselines. [1]

1 Introduction

A social chatbot designed to establish long-term emotional connections with users must generate responses that not only match the *content* of user input and context, but also do so in a desired target *style* (Zhou et al., 2018; Li et al., 2016b; Luan et al., 2016; Gao et al., 2019a). A conversational agent that speaks in a polite, professional tone is likely to facilitate service in customer relationship scenarios; likewise, an agent that sounds like an cartoon character or a superhero can be more engaging in a theme park. The master of response style is also an important step towards human-like chatbots. As highlighted in social psychology studies (Niederhoffer and Pennebaker, 2002a,b), when two people are talking, they tend to match linguistic style of each other, sometime even regardless of their intentions. Achieving this level of performance, however, is challenging. Lacking parallel data in different conversational styles, researchers often resort to what we will term *style datasets* that are in non-conversational format (e.g. news, novels, blogs). Since the contents and formats of these are quite different from conversation data, existing approaches tend to generate responses that are either less style-specific (Luan et al., 2017) or less context-relevant (Niu and Bansal, 2018).

We suggest that this trade-off between appropriateness and style stems from profound differences

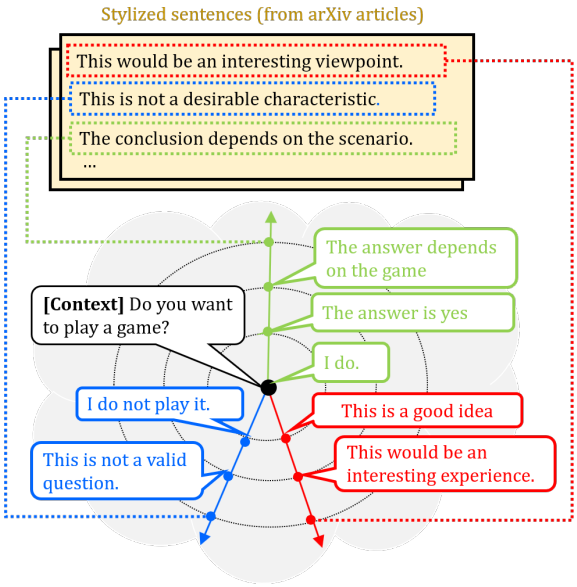

Figure 1: StyleFusion helps conversational model to distill style from non-conversational, non-parallel sentences by mapping them to points surrounding the related conversations in the structured latent space. Direction and distance from the model prediction (center black dot) roughly correspond to contents and style intensity, respectively, illustrated by examples taken from Table 2.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1814–1823, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

between conversation and style datasets in format, style and contents that impede joint learning. One approach has been to combine these only during decoding: Niu and Bansal (2018) trained two models separately, a Sequence-to-Sequence (S2S) (Sutskever et al., 2014) on a conversation dataset and a language model (LM) on a style dataset. At inference time, they take a weighted average of the token probability distribution of the two models to predict the next token. This forced bias, however, degrades output relevance. An alternative approach attempts to map the two datasets into the same latent space: Luan et al. (2017) use multi-task learning to train a S2S model on a conversation dataset and an autoencoder (AE) on a style dataset. Gao et al. (2019b) point out that the two datasets still form separate clusters in the latent space; below we observe that this leads to a low style intensity in generated responses (Section 5).

We propose to bridge conversation modeling and non-parallel style transfer by structuring a shared latent space using novel regularization techniques, that we dub StyleFusion. In contrast to Luan et al. (2017), the two datasets are well aligned in the latent space by generalizing SpaceFusion [2] (Gao et al., 2019b), an approach that aligns latent spaces for paired samples, to non-parallel datasets. In the structured shared latent space, stylized sentences are nudged adjacent to semantically related conversations, thereby allowing the system to generate style-specific relevant responses by sampling in the neighborhood of the model prediction. Distance and direction from the model prediction roughly match the style intensity and content diversity of generated responses, respectively, as illustrated in Fig. 1

We demonstrate this method using dialogues from Reddit data and two sets of sentences with distinct styles (arXiv and Sherlock Holmes novels). Automatic and human evaluation show that, without sacrificing appropriateness, our system can generate responses in a targeted style and outperforms competitive baselines.

Our contribution can be summarized thus: 1) We introduce an end-to-end approach that generates style-specific responses from conversational data and non-parallel non-conversation style data. 2) We generalize the SpaceFusion model of (Gao et al., 2019b) to non-parallel data by a new regularization method. 3) We present a visualization analysis that provides intuitive insights into the drawbacks of alternative approaches.

2 Related Work

Text style transfer is a related but distinct task. It usually preserves the content (Yang et al., 2018; Hu et al., 2017; Fu et al., 2018; Shen et al., 2017; Gong et al., 2019). In contrast, content of conversational responses in a given context can be semantically diverse. Various approaches have been proposed for non-parallel data setup. Fu et al. (2018) proposed to use separate decoders for different styles and a classifier to measure style strength. Shen et al. (2017) proposed to map texts of two different styles into a shared latent space where the "content" information is preserved and "style" information is discarded. An adversarial discriminator is used to align the latent spaces of two different styles. However, Yang et al. (2018) point out the difficulty of training an adversarial discriminator and proposed instead the use of language models as discriminator. Like Shen et al. (2017); Yang et al. (2018), we align latent spaces for different styles. However we also align latent spaces encoded by different models (S2S and AE).

Stylized response generation is a relatively new task. Akama et al. (2017) use a stylized conversation corpus to fine-tune a conversation model pretrained on a background conversation dataset. However, stylized texts are usually in non-conversational format, as in the present setting. Niu and Bansal (2018) proposed a method that takes the weighted average of the token probability distribution predicted by a S2S trained on background conversational dataset and that predicted by a LM trained on style dataset as the token probability. They observed reduced relevance and attributed this to the fact that the LM was not trained to attend to conversation context and S2S was not trained to learn style during training. In contrast, we jointly learn from conversation and style datasets during training. Niu and Bansal (2018) have proposed label-fine-tuning, but this is limited to scenarios where a reasonable portion of the conversational dataset is in the target style, which is not always the case.

Persona-grounded conversation modeling Li et al. (2016b); Luan et al. (2017) aim to generate responses mimicking a speaker. It is closely re-

lated to the present task, since persona is, broadly speaking, the manifestation of a type of style. Li et al. (2016b) feeds a speaker ID to the decoder to promote generation of response for that target speaker. However non-conversational data cannot be used. Luan et al. (2017) applied a multi-task learning approach to utilize non-conversational data. A S2S model, taking in conversational data, and an autoencoder (AE), taking in non-conversational data, share the decoder and are trained alternately. However, Gao et al. (2019b) observed that sharing the decoder may not truly allow S2S and AE to share the latent space, and thus S2S may not fully utilize what is learned by AE. Unlike Li et al. (2016b) using labelled persona IDs, Zhang et al. (2019) have proposed using a self-supervised method to extract persona features from conversation history. This allows modeling persona dynamically, which agrees with the fact that even the same person can speak in different style in different scenarios.

Multi-task learning McCann et al. (2018); Liu et al. (2019); Luan et al. (2017); Gao et al. (2019b); Zhang et al. (2017) aggregates the strengths of each specific task, and induces regularization effects (Liu et al., 2019) as the model is trained to learn a more universal representation. However a simple multi-task approach (Luan et al., 2017) may learn separate representations for each dataset (Gao et al., 2019b). To address this, in previous work (Gao et al., 2019b), we proposed the SPACEFUSION model featuring a regularization technique that explicitly encourages alignment of latent spaces for a universal representation. SPACEFUSION, however, is only designed for paired samples. We generalize SPACEFUSION to non-parallel datasets in this paper.

3 The STYLEFUSION Model

3.1 Problem statement

Let $\mathcal{D}_{conv} = [(x_0, y_0), (x_1, y_1), \cdots, (x_n, y_n)]$ denote a conversation dataset, where x_i and y_i are context sentences and a corresponding response, respectively. x_i consists of one or more utterances and y_i is only one utterance. $\mathcal{D}_{style} = [s_0, s_1, \cdots, s_m]$ denotes a non-conversational style dataset, where s_i is a sentence sampled from a corpus of the targeted style. Samples from $\mathcal{D}_{style}$ do not have a labelled corresponding relation with samples from $\mathcal{D}_{conv}$ (thus

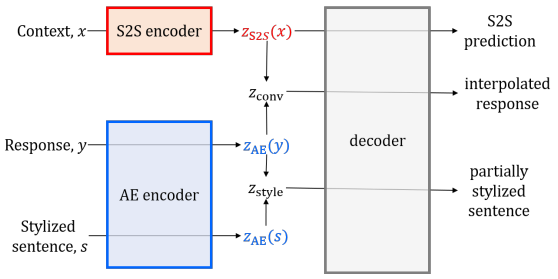

Figure 2: STYLEFUSION model architecture.

"non-parallel"). Our aim is to train a model jointly on $\mathcal{D}_{style}$ and $\mathcal{D}_{conv}$ to generate appropriate responses in the style similar to sentences from $\mathcal{D}_{style}$, to a given context. The iven context may or may not be in the target style.

3.2 Training

In contrast to SPACEFUSION(Gao et al., 2019b), which only fuses context-response pairs, our goal is to additionally map related stylized sentences to points surrounding the context in the shared latent representation space. The system can then generate relevant stylized responses by sampling in the neighborhood of the prediction based on the context.

Model overview. As illustrated in figure 2, the model consists of a sequence-to-sequence (S2S) module and an autoencoder (AE) module that shares a decoder. We use S2S to produce the prediction representation $z_{S2S}(x_i)$, and AE to obtain the representation of the corresponding responses $z_{AE}(y_i)$ and stylized sentences $z_{AE}(s_j)$. We use generalized regularization terms, fusion and smoothness, to align the three latent spaces $z_{S2S}(x_i)$, $z_{AE}(y_i)$, and $z_{AE}(s_j)$.

Fusion objectives encourage different latent spaces to be close to each other. Accordingly, we define the cross-latent-space distances to be minimized. For response appropriateness, as x_i and y_i are paired as context and response, we use their pair-wise dissimilarity, following Gao et al. (2019b)

$$d_{\text{conv}} = \sum_{i \in \text{batch}} \frac{d_E(z_{\text{S2S}}(x_i), z_{\text{AE}}(y_i))}{n\sqrt{l}} \quad (1)$$

where n is the batch size, l is the dimension of latent space , and we use d_E, the Euclidean distance in latent space, as the dissimilarity.

For style transfer, however, x_i and s_j is not paired. Thus, we instead minimize the distance

between a point and its nearest neighbor from another dataset to pull these two datasets close to each other in the shared latent space.

$$d_{\text{style}} = \frac{1}{2} d_{\text{NN}}^{\text{cross}}(\{z_{\text{S2S}}(x_i)\}, \{z_{\text{AE}}(s_i)\}) + \frac{1}{2} d_{\text{NN}}^{\text{cross}}(\{z_{\text{AE}}(s_i)\}, \{z_{\text{S2S}}(x_i)\}) \quad (2)$$

where $d_{NN}^{\text{cross}}(\{a_i\}, \{b_i\})$ is the batch average of the distance between a_i and $b_{\text{NN of } a_i}$ – the nearest neighbor (NN) of a_i from set $\{b_i\}$

$$d_{\text{NN}}^{\text{cross}}(\{a_i\}, \{b_i\}) = \sum_{i \in \text{batch}} \frac{d_E(a_i, b_{\text{NN of } a_i})}{n\sqrt{l}} \quad (3)$$

While minimizing the cross-latent-space distances, d_{conv} and d_{style}, we want the samples from the same latent space spread out, following Gao et al. (2019b). For this purpose, Gao et al. (2019b) maximized the average of capped distance between points from the same latent space. However, we found that the results are sensitive to the cap value. Instead, we define the following nearest-neighbor-based characteristic distance

$$d_{\text{spread-out}} = \min[d_{\text{NN}}^{\text{same}}(\{z_{\text{AE}}(y_i)\}), d_{\text{NN}}^{\text{same}}(\{z_{\text{AE}}(s_i)\}), d_{\text{NN}}^{\text{same}}(\{z_{\text{S2S}}(x_i)\})] \quad (4)$$

$$d_{\text{NN}}^{\text{same}}(\{a_i\}) = \sum_{i \in \text{batch}} \frac{d_E(a_i, a_{\text{NN of } a_i})}{n\sqrt{l}} \quad (5)$$

Combining these loss terms we have the following two objectives:

$$\mathcal{L}_{\text{fuse,conv}} = d_{\text{conv}} - d_{\text{spread-out}} \quad (6)$$

$$\mathcal{L}_{\text{fuse,style}} = d_{\text{style}} - d_{\text{spread-out}} \quad (7)$$

Smoothness objective encourages smooth semantic transition in the shared latent space. For response appropriateness, following Gao et al. (2019b), we encourage the interpolation between the prediction $z_{S2S}(x_i)$ and the target response $z_{AE}(y_i)$ to generate the target response y_i.

$$z_{\text{conv}} = (1-u) z_{\text{AE}}(y) + u z_{\text{S2S}}(x) + \epsilon \quad (8)$$

$$\mathcal{L}_{\text{smooth,conv}} = -\frac{1}{|y|} \log p(y|z_{\text{conv}}) \quad (9)$$

where $u \sim U(0,1)$ is a uniformly distributed random variable, and ϵ is a Gaussian noise with zero mean and covariance matrix of $\sigma^2 I$.

For style transfer, as we move from a non-stylized sentence $z_{\text{AE}}(x)$ to a random stylized sentence $z_{\text{AE}}(s)$, we expect to generate a partially stylized sentence and encourage the generated sentence to gradually change from x to s.

$$z_{\text{style}} = (1-u) z_{\text{AE}}(x) + u z_{\text{AE}}(s) + \epsilon \quad (10)$$

$$\mathcal{L}_{\text{smooth,style}} = -(1-u)\frac{1}{|x|} \log p(x|z_{\text{style}}) - u\frac{1}{|s|} \log p(s|z_{\text{style}}) \quad (11)$$

Training objective to be minimized is a combination of a vanilla S2S and the above regularization terms [3]. $\mathcal{L}_{\text{smooth,style}}$ and $\mathcal{L}_{\text{fuse,style}}$ are new terms not existing in (Gao et al., 2019b). A more compact definition $\mathcal{L}_{\text{conv}} = \mathcal{L}_{\text{smooth,conv}} + \mathcal{L}_{\text{fuse,conv}}$ and $\mathcal{L}_{\text{style}} = \mathcal{L}_{\text{smooth,style}} + \mathcal{L}_{\text{fuse,style}}$ yields

$$\mathcal{L} = -\frac{1}{|y|} \log p(y|z_{\text{S2S}}) + \mathcal{L}_{\text{conv}} + \mathcal{L}_{\text{style}} \quad (12)$$

For the case $\mathcal{D}_{style}$ is much smaller than $\mathcal{D}_{conv}$, as in the present work, the model may overfit on $\mathcal{D}_{style}$. We propose to firstly pretrain the model on $\mathcal{D}_{conv}$ only [4], then continue training on both $\mathcal{D}_{conv}$ and $\mathcal{D}_{style}$. Furthermore, to reduce overfitting, we applied a data augmentation technique by randomly mask tokens in s_i by a special out-of-vocab token. The masking probability of a token is inversely proportional to its frequency in training data.

3.3 Inference

Following (Gao et al., 2019b), we sample in the neighborhood of $z_{S2S}(x)$ by adding a noise r of a given length $|r|$ towards a direction randomly drawn from the uniform distribution.

$$z = z_{\text{S2S}}(x) + r \quad (13)$$

As r depends on l, the dimension of z, We define a normalized value

$$\rho = |r|/(\sigma\sqrt{l}) \quad (14)$$

As the stylized texts are usually sparse, it is possible to generate non-stylized hypothesis as we vary ρ along some direction. Thus we rank the hypotheses considering both relevance and style intensity.

$$\text{score}(h_i) = (1-\lambda) P(h_i|z_{\text{S2S}}(x)) + \lambda P_{\text{style}}(h_i) \quad (15)$$

[3] More generally, one may use a weighted sum of these terms instead. We set them equally weighted for simplicity

[4] by setting terms $\mathcal{L}_{\text{smooth,style}}$ and $\mathcal{L}_{\text{fuse,style}}$ as zero

where $\lambda = 0.5$ unless otherwise specified, $P(h_i|z_{\text{S2S}}(x))$ estimates the relevancy, and $P_{style}(h_i)$ is the probability of hypothesis h_i being targeted style predicted by pretrained classifiers.

We considered two style classifiers: a "**neural**" based on two stacked GRU (Cho et al., 2014) cells, and a "**ngram**" classifier which is a logistic regressor using ngram (n=1,2,3,4) multi-hot features. Both classifiers are trained using $\{y_i\}$ as negative samples and $\{s_i\}$ as positive samples. $P_{style}(h_i)$ is computed by taking average of the prediction of these two classifiers.

4 Experiment Setup

4.1 Tasks and datasets

We experiments with two tasks: generating arXiv-like and Holmes-like responses, respectively, using the datasets summarized in Table 1

Task	Training $\mathcal{D}_{\text{conv}}$	$\mathcal{D}_{\text{style}}$	Testing $\mathcal{D}_{\text{test}}$
arXiv-like	Reddit	arXiv	arXiv-like Reddit
Holmes-like	Reddit	Holmes	Holmes-like Reddit

Table 1: Summary of tasks and datasets

(i) *Reddit* is a conversation dataset constructed from posts and comments on Reddit.com [5] during 2011, consisting of 10M pairs of context and response . (ii) *arXiv* is a non-conversational dataset extracted from articles on arXiv.org [6] from 1998 to 2002, consisting of 1M sentences . (iii) *Holmes* refers to another non-conversational dataset extracted from Sherlock Holmes novel series[7] by Arthur Conan Doyle, with 38k sentences.

$\mathcal{D}_{\text{test}}$ is the test set with stylized reference responses, constructed by filtering the Reddit dataset from year 2013 using the trained neural and ngram classifiers. For each context, there are at least 4 reference responses approximately in the targeted style ($P_{\text{style}} > 0.3$). The style intensity of the context is not filtered.

4.2 Human evaluation

We designed the following two tasks.

Response appropriateness measurement task presents a context and a set of hypotheses (from the present and baseline systems), and for each hypothesis annotators choose from one of the following options that best fits the quality of the response: ok, marginal, bad (generic or irrelevant), and then map them to numerical score 1, 0.5, and 0, respectively.

Style classification task presents a hypothesis and two groups of example sentences, from Reddit and style corpus (Holmes or arXiv). Then crowdsourced annotators judge whether the hypothesis is more similar to the Reddit group, not sure, or more similar to the style corpus group. We then map these to numerical scores 0, 0.5, and 1, respectively.

For all tasks, the hypotheses of different systems of the same set of 500 randomly selected x_i are presented in random order and the identity of the system is invisible to annotators. Each sample is judged by 5 annotators individually.

4.3 Automatic evaluation

We measure relevance using multi-reference BLEU Papineni et al. (2002), and diversity by entropy 4-gram (Zhang et al., 2018), and distinct 1,2-gram (Li et al., 2016a).

For style intensity evaluation, besides the **neural** and **ngram** classifier prediction (Section 3.3), we also use simple word-counting (hereafter **count** metric) to minimize model-specific effects. We first construct a training corpus with balanced positive (from $\mathcal{D}_{\text{style}}$) and negative (responses sampled from $\mathcal{D}_{\text{conv}}$) samples. Then, for each word that appears in more than 5 sentences in the training corpus, we compute the average style intensity of sentences that contain this word. The top k words of highest style intensity are chosen as the keywords in this style. For a test corpus, we compute the average ratio of words that are keywords of a style, as its "count" style metric.

Besides the overall style comparisons (Reddit vs. Holmes, and Reddit vs. arXiv), we also crowdsourced three sets of sentences with human labeled levels in three finer styles: how formal, emotional, and technical each sentence is, and build the keyword list for the count metric.

4.4 Baselines

We compare the following baseline systems.

[5] using raw data collected by a third party http://files.pushshift.io/reddit/comments/

[6] from KDD 2003 http://www.cs.cornell.edu/projects/kddcup/datasets.html

[7] from https://gutenberg.org

The first category is generative models. (i) *MTask* refers to the vanilla multi-task learning model proposed in (Luan et al., 2017) trained on both $\mathcal{D}_{\text{conv}}$ and $\mathcal{D}_{\text{style}}$. (ii) *S2S+LM* refers to the method proposed by Niu and Bansal (2018)[8], which uses the weighted average of a S2S model, trained on $\mathcal{D}_{\text{conv}}$, and a LM model, trained on $\mathcal{D}_{\text{style}}$, as the token probability distribution at inference time.

The second category draws a training sample as hypothesis. (iii) *Retrieval* refers to a simple retrieval system which returns the sentence from $\mathcal{D}_{\text{style}}$ of highest generation probability by the MTask model. (iv) *Rand* is a system that randomly picks a sentence from $\mathcal{D}_{\text{style}}$. (v) *Human* refers to the system randomly picks one of the multiple reference responses in the given context from $\mathcal{D}_{\text{test}}$.

4.5 Model setup

StyleFusion and trainable baselines, MTask and S2S+LM, use two stacked GRU (Cho et al., 2014) cells for encoders and decoders with $l = 1000$. The word embedding is also 1000 dimension, trained from random initialization. The variance of the noise ϵ is set to $\sigma^2 = 0.1^2$. The state of the top layer of encoder GRU cell is used as z. z is used as the initial state of all layers of the decoder. All trainable models are trained with the ADAM method (Kingma and Ba, 2014) with a learning rate of 0.0003. For StyleFusion and MTask, we first train on $\mathcal{D}_{\text{conv}}$ for 2 epochs, and then continue the training on both $\mathcal{D}_{\text{conv}}$ and $\mathcal{D}_{\text{style}}$ until convergence [9]. For all systems except "Rand" and "Retrieval", we use the ranking method Eq 15 to select the top one hypothesis from 100 candidates.

5 Results and Analysis

5.1 Modulating the style

By leveraging the structure of the shared latent space, we can modulate the style intensity by ρ, as illustrated by examples in Table 2. For example, given the context *"Do you want to play a game"*, the hypothesis generated from $\rho = 0$ is *"I do"*, which is non-stylized. While moving towards z_{AE} of an arXiv-style sentence *"This would be an interesting viewpoint"*, the responses gradually change to "This would be an interesting experience" at $\rho = 1.0$, which remains relevant but is more similar to the target style. Similar trends can be observed when moving in the other direction *"The conclusion depends on the scenario"* and *"This is not a desirable characteristic"*. It also shows that the contents are affected by the direction, a desired property inherited from SpaceFusion models.

context	Do you want to play a game?
towards	The conclusion depends on the scenario .
$\rho = 0.0$	I do.
$\rho = 0.5$	The answer is yes.
$\rho = 1.0$	The answer depends on the game.
towards	This would be an interesting viewpoint.
$\rho = 0.4$	This is a good idea.
$\rho = 0.9$	This would be an interesting experience
towards	This is not a desirable characteristic.
$\rho = 0.5$	I don't play it.
$\rho = 1.0$	This is not a valid question.

Table 2: Example StyleFusion outputs for arXiv-like response generation task at different distance ρ and direction (towards z_{AE} of a given sentence)

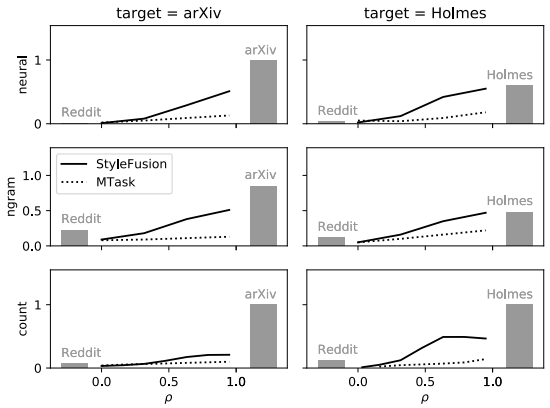

Figure 3: Change of the overall style intensity with ρ, as measured by two classifiers "neural" and "ngram" (Section 3.3) and the "count" metric. The "count" metric is normalized by the value of the target style corpus. The barplot shows the desired trend (from Reddit to arXiv or Holmes), and the lines the actual trends.

The relation between style intensity and ρ is further confirmed by automatic measurement. As illustrated in Fig. 3, as ρ increases, responses come to resemble the targeted style within the depicted range. In contrast, the style intensity of MTask outputs rises only slightly as ρ increases.

The increase of overall style intensity is coupled with change in the style's finer granularity, as illustrated in Fig. 4. Compared to Reddit, arXiv is less emotional, and more formal and technical. Consistent with this, StyleFusion outputs exhibit

[8] This method was referred as "Fusion" in (Niu and Bansal, 2018) but to avoid confusing readers with our StyleFusion method, we refer it as "S2S+LM"

[9] approximately one pass of arXiv and 5 passes of Holmes

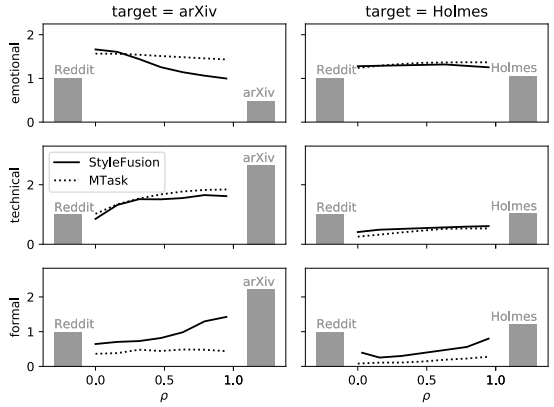

Figure 4: Change of the styles at finer granularity of ρ, measured by the "count" metric normalized by the value of Reddit dataset. The barplot shows the desired trend (from Reddit to arXiv or Holmes), and the lines the actual trends.

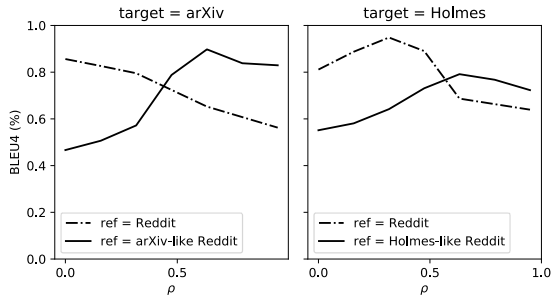

Figure 5: Relevancy of the StyleFusion outputs at different ρ as measured by BLEU4 with references of different styles

less emotion, but become much more technical and formal as ρ increases. MTask, however, tends only to show increased technical level, but fails to be less emotional and more formal, inconsistent with the target style. Where Holmes is the target, the emotional and technical levels do not significantly change compared to Reddit, but Holmes is stylistically more formal. StyleFusion captures these trends, whereas MTask outputs are insufficiently formal, shown in Fig. 4(lowest panel).

We also measured the BLEU4 score at different ρ as shown in Fig. 5. Besides $\mathcal{D}_{\text{test}}$ (stylized references), we also tested on held-out Reddit data (i.e. non-stylized references). We observed that at smaller ρ, the StyleFusion outputs are relevant to context and style is more similar to Reddit, indicated by the relatively high BLEU4 computed using non-stylized references. At greater radius, BLEU4 rises when calculated on arXiv-like and Holmes-like references, indicating that the responses generated remain relevant but are closer to the targeted style. Combined with the case at small radius, the implication is that, although the style gradually changes, the responses generated by StyleFusion remain relevant at a relatively wide range of radius.

context	Okay, but can we host it in the cloud?
StyleFusion	It would be an interesting experiment. It is a possibility.
S2S	I think it might be a bit of a stretch.
MTask	Yes, yes you can.
S2S+LM	The relevant question is , as to this , is you referring to the casimir energy program?
Retrieval	Even though this issue can be analyzed in more detail, we shall content ourselves with some simple statements.
rand	In particular, it involves the combination equation
human	To the cloud !
context	The universe has no edge.
StyleFusion	Does this mean the universe is expanding?
S2S	The universe is infinite.
MTask	The universe is finite.
S2S+LM	The universe can be on the infinite loop.
Retrieval	Is there really any difference in the low energy physics?
rand	In other words , the wave function in equation.
human	So... a sphere?

Table 3: Example system outputs on arXiv-like response generation task at $\rho = 1$

5.2 Fused latent space

As illustrated by the MDS (Borg and Groenen, 2003) visualization in Fig. 6, MTask cannot align different latent spaces, not only those from different model ($z_{\text{AE}}(y)$ and $z_{\text{S2S}}(x)$), but also for those from same model that have different styles ($z_{\text{AE}}(y)$ and $z_{\text{AE}}(s)$). SpaceFusion (Gao et al., 2019b) can align $z_{\text{AE}}(y)$ and $z_{\text{S2S}}(x)$ better, but $z_{\text{AE}}(s)$ forms a separate cluster, indicating that the conversation dataset and style dataset remain unaligned in the latent space. This is because SpaceFusion was not designed to align non-parallel samples. The separation between the conversation dataset and style dataset in latent space, as is the case for MTask and SpaceFusion, makes it difficult for the conversation model to use style knowledge. In contrast, StyleFusion aligns all three latent spaces well as evidenced by Fig. 6.

5.3 Human evaluation

Human evaluation results are presented in Table 5. As in the automatic evaluation results, StyleFusion and MTask show the highest appropriate-

context	First step: go check behind the cabinet and see what's back there.
STYLE-FUSION	I would advise against this.
S2S	I'm going to try this next time.
MTask	I'll be back in a few minutes.
S2S+LM	I've got a little time that i had not been engaged yet.
Retrieval	i was thinking the same thing.
Rand	Holmes shrugged his shoulders.
human	Then there would be nothing , and that would be the answer.
context	that 's a surprisingly large amount of police coming to see a *** teenager.
STYLE-FUSION	What is this crime you speak of?
S2S	I'm pretty sure that 's the only thing that 's going to happen.
MTask	I'm not sure what you mean by that.
S2S+LM	I should be on the same business.
Retrieval	well, yes.
Rand	I shall be back in an hour or two.
human	Must have feared what he was packin'

Table 4: Example system outputs on Holmes-like response generation task at $\rho = 1$

target	model	appropr-iateness	style intensity	harmonic mean
arXiv	STYLEFUSION	**0.17**	0.26	**0.20**
	MTask	**0.17**	0.11	0.14
	S2S+LM	0.09	0.51	0.15
	Retrieval	0.07	0.71	0.14
	Rand	0.04	**0.96**	0.07
	Human	0.51	0.28	0.36
Holmes	STYLEFUSION	**0.22**	0.28	**0.25**
	MTask	**0.23**	0.15	0.18
	S2S+LM	0.03	0.55	0.05
	Retrieval	0.14	0.30	0.19
	Rand	0.08	**0.69**	0.14
	Human	0.63	0.26	0.37

ness (not statistically different) apart from the Human system. However STYLEFUSION outputs are much more stylized. Rand, Retrieval and S2S+LM tend to generate stylized but irrelevant responses. To make the overall trends sharper, following (Gao et al., 2019b), we compute the harmonic mean of appropriateness and style intensity, in terms of which STYLEFUSION outperforms all baselines except the Human system. Additional examples of the system outputs and human responses are provided in Table 3 and Table 4

5.4 Ablation study and automatic evalution

The automatic evaluation results for arXiv-like and Holmes-like response generation tasks are presented in Table 6. In both instances, STYLEFUSION achieved relatively high BLEU, and showed high style intensity. The Rand baseline has the highest style intensity but lowest relevance. S2S+LM has the comparable style intensity to STYLEFUSION but BLEU is much lower, consistent with the observation made by (Niu and Bansal, 2018). MTask shows significantly less style intensity than STYLEFUSION. Moreover, MTask's diversity, as measured by entropy4 and distinct1,2, is much lower, indicating that outputs of this model tend to be bland. Adding $\mathcal{L}_{\text{conv}}$ regularization, which is SPACEFUSION, increases diversity, relevance and style intensity slightly, consistent with the finding in (Gao et al., 2019b). Style intensity is further boosted by the addition of term $\mathcal{L}_{\text{style}}$. relevancy and diversity are not significantly affected by the addition of $\mathcal{L}_{\text{style}}$.

6 Conclusion

We propose a regularized multi-task learning approach, STYLEFUSION, that bridges conversation models and non-parallel style transfer by structuring a shared latent space. This structure allows the system to generate stylized relevant responses by sampling in the neighborhood of the model prediction, and to continuously control style intensity by modulating the sampling radius. We demonstrate this method in two tasks: generating arXiv-like and Holmes-like conversational responses. Automatic and human evaluation show that, with-

Improving Open-Domain Dialogue Systems via Multi-Turn Incomplete Utterance Restoration

Abstract

In multi-turn dialogue, utterances do not always take the full form of sentences. These incomplete utterances will greatly reduce the performance of open-domain dialogue systems. Restoring more incomplete utterances from context could potentially help the systems generate more relevant responses. To facilitate the study of incomplete utterance restoration for open-domain dialogue systems, a large-scale multi-turn dataset *Restoration-200K*[1] is collected and manually labeled with the explicit relation between an utterance and its context. We also propose a "pick-and-combine" model to restore the incomplete utterance from its context. Experimental results demonstrate that the annotated dataset and the proposed approach significantly boost the response quality of both single-turn and multi-turn dialogue systems.

1 Introduction

Dialogue systems have attracted increasing attention due to the promising potentials on applications like virtual assistants or customer support systems (Hauswald et al., 2015; Poulami Debnath, 2018). However, studies (Carbonell, 1983) show that users of dialogue systems tend to use succinct language which often omits entities or concepts made in previous utterances. (also known as non-sentential utterances, (Fernández et al., 2005, 2007)). To make appropriate responses, dialogue systems must be equipped with the ability to understand these incomplete utterances.

Take Example 1 in Table 1 for instance, contents in parentheses are information omitted in the utterance. Humans are capable of comprehending those incomplete utterances based on previous utterances. For example, A_3 means what kind of *dessert* matches B's taste, instead of what kind of *shop* B likes. Failing to understand this utterance would be a disaster for dialogue systems to generate a relevant and coherent response. According to our survey (details in Table 2), in about 60% conversations, fully comprehending current utterance depends on previous context. We will refer conversation history (A_1 to B_2 in above example) as *previous utterances*, the utterance to be restored (A_3) as *original utterance*, and the complete form of A_3 as *restored utterance*.

Studies show that restoring the incomplete questions could help question-answering systems better understand users' intention (Raghu et al., 2015; Kumar and Joshi, 2017). It inspires us to improve the performance of open-domain dialogue systems via incomplete utterance restoration. However, most existing multi-turn dialogue datasets only provide sets of utterances, without any information about relations between utterances. In other words, they lack the necessary supervisions to restore the incomplete utterance.

To make dialogue systems better understand incomplete utterances, we collect a multi-turn conversation dataset from internet communities, and each of the conversations contains at least six utterances. Then we hire an annotation team to (1) label whether an utterance is related to its context or not, and (2) restore an incomplete utterance to a complete and context-free form based on its context. Finally, we get a high-quality and large-scale dataset with 200K annotated conversations. Such a dataset offers a new way of modelling utterance relations and improving the context-understanding ability of dialogue systems. We hope it would benefit the research of context understanding for multi-turn dialogue systems in the future.

With the annotated dataset above, we first attempt to restore the incomplete utterance using

Table 1: Examples from the dataset. If annotators judge the fifth utterance (A_3) omits concepts or entities made in previous utterances like Example 1 and 2, they rewrite the utterance as ground truth reference.

two vanilla models, Sequence-to-Sequence model (Seq2Seq) and Pointer Generative Network. Then a cascaded pick-and-combine model is further proposed to first "Pick" omitted words from context and then "Combine" them with the incomplete utterance. To better evaluate the restoration performance, an evaluation metric is also designed. In the experiment, both automatic metrics and human evaluation show that the proposed approach could achieve promising results and significantly improve the response relevance of both single-turn dialogue systems and multi-turn dialogue systems.

The proposed approach enables single-turn dialogue systems with the capability to comprehend the dialogue context. It also facilitates multi-turn dialogue systems to model the relation between the query (original utterance) and context (previous utterances) explicitly in a supervised manner, in contrast to modelling the relation implicitly and without extra guidance (Serban et al., 2016; Wu et al., 2017).

Our contributions are summarized as below:

1) A large-scale Chinese dataset with 200K multi-turn conversations are collected and manually labeled with the explicit relations between an utterance and its context.

2) A cascaded pick-and-combine model is proposed, which achieves promising results on both automatic metrics and human evaluation.

3) Experimental results demonstrate that the incomplete utterance restoration model could be complementary to existing dialogue systems and is conducive for improving response quality.

In the remaining part, we first describe the collected dataset in Section 2. In Section 3, several models and a new metric are presented for incomplete utterance restoration. Section 4 shows experimental results on both automatic metrics and human evaluation for the proposed method. In Section 5 the proposed model is applied to dialogue systems to evaluate its effectiveness. Section 6 introduces related work. We conclude our work and discuss future directions in Section 7.

2 Restoration-200K

2.1 Data Collection

We collect open-domain dialogues from Douban group[2], a well-known Chinese online community which is a common data source for dialogue systems (Wu et al., 2017). To determine if one utterance is complete or not, we take four utterances before it as the conversation context. Crawled conversations with less than six (extra one to assist annotation) utterances are filtered out. For conversations with more than six utterances, only the first six are reserved. We construct a conversation by the identification of reply tags in comments under each post.

2.2 Data Annotation

To ensure the annotation quality, five professional data annotators are hired to annotate the dataset instead of using crowd-sourcing platforms like MTurk. It took six months to finish the annotation. As shown in Figure 1, annotators first discern whether the original utterance (the fifth utterance in conversation) omits concepts or entities made in previous utterances. Since the boundary

[2]https://www.douban.com/group

	train	val	test
# conversations	194k	5k	5k
Incomplete ratio (%)	60.1	59.4	58.8
Vocabulary size	80k	15k	15k
Avg. context length	25.9	25.8	25.7
Avg. utterance length	8.62	8.53	8.60
Avg. reference length	12.4	12.3	12.4

Table 2: Statistics of Restoration-200K. The incomplete ratio refers to the ratio of conversations that contains the incomplete utterance. Vocabulary size is counted after Chinese word segmentation and the average length is counted on character level.

between yes and no is vague under certain circumstances, annotators are allowed to skip and discard the instance if it is hard to make a decision. The sixth utterance is also provided to assist annotators in comprehending the conversation. When restoration is needed, they rewrite the original utterance to a context-free restored utterance which contains all necessary information for utterance understanding, as shown in the last row of Table 1.

To reduce the diversity of rewritten sentences, annotators are instructed to use words from previous utterances wherever possible. A small commonly used word list is provided, and annotators could use those words to ensure the fluency of rewritten sentences. In other words, all words in the restored utterance come from previous and original utterances or the extra word list. Our survey shows only about 4.8% of conversations that need to be restored in the dataset do not satisfy such condition. All of them are discarded as well.

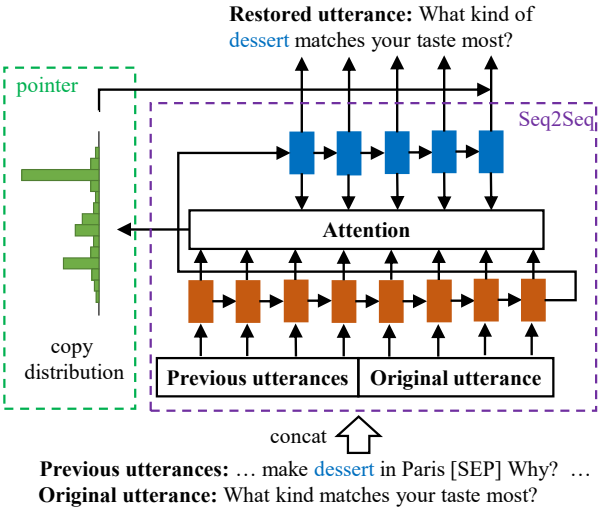
2.3 Data Statistics

The statistics of train, validation and test set are shown in Table 2. Kumar and Joshi (2016) collect 6K incomplete questions for QA systems, where each utterance only consists of 3.52 words on average[3]. In comparison, *Restoration-200K* has a longer utterance length, which indicates covering a broader range of topics and more informative contents.

3 Methodology

In this section, we try to tackle the incomplete utterance restoration problem by using the vanilla Seq2Seq model with attention and pointer generative network. Since these two models are easily dominated by a simple copy mechanism that directly regenerates the original utterance as the restored utterance, we further propose a cascaded pick-and-combine (PAC) model to restore the original utterance.

[3]The average sentence length is estimated based on the released test set.



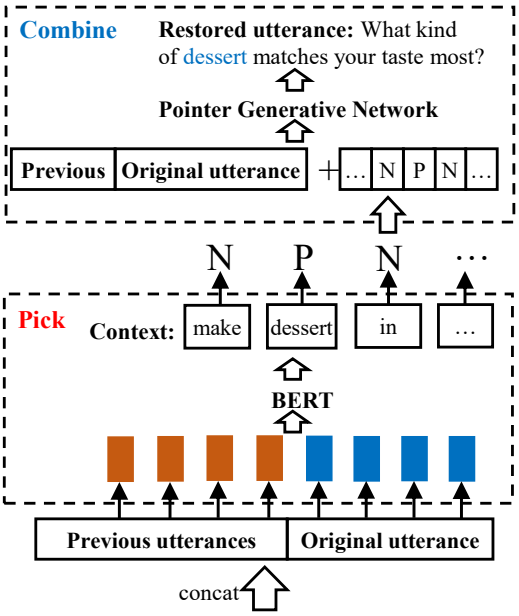


Figure 1: The architecture of Seq2Seq model and pointer generative network.

3.1 Vanilla Models

Seq2Seq Model with Attention: the Seq2Seq framework has been widely used in sequence generation tasks. The encoder encodes the input sequence into a vector representation c and the decoder generates the target sequence based on representation vector c, and all the previous words. As shown in Figure 1, to restore the incomplete utterance, we concatenate previous utterances C and the original utterance X as the input sequence. By inserting a special token $[sep]$ to separate C and X, the input sequence will be: $[c_1, \ldots, c_{t1}, [sep], x_1, \ldots x_{t2}]$.

Pointer Generative Network: as analyzed in Section 2.2, the incomplete utterance restoration problem has a unique characteristic: most generated words come from previous utterances or original utterance. To exploit this constraint, we propose using the pointer generative network to directly copy words from the input sequence. It has the capability of copying words from source sequence by directly taking the attention score a_k as prediction probability, as shown in the green part of Figure 1. The generation distribution P_{gen} can be calculated as: $P_{gen} = f(h_t^*, s_t, y_t)$, $p_{gen} = g(h_t^*, s_t, y_t)$. And the final vocabulary distribution

Previous utterances: … make dessert in Paris [SEP] Why?…

Original utterance: What kind matches your taste most?

Figure 2: The pick stage predicts which words in previous utterances are omitted by the original utterance. P represents the label of positive, namely the omitted words. In combine stage, the picking result is appended to original conversation as extra guidance for the complete utterance sequence generation.

P_{vocab} is defined as:

$$P_{vocab} = p_{gen} * P_{gen} + (1 - p_{gen}) * P_{copy}$$

3.2 Pick-and-Combine Model

For most utterances to be restored in the corpus, the reference only differs from the original utterance in few words. Our study shows on average only 17.7% words in previous utterances overlap with the restored utterance, while 100% words in the original utterance are included in the restored utterance. Such *unbalanced* probability makes models mentioned above tend to simply regenerate the original utterance to maximize the conditional probability of the generated sentence during the beam-search process. In other words, the Seq2Seq model and pointer generative network tend to regenerate the original utterance and cannot effectively restore the original utterance. The third conversation in Table 5 is a typical example.

To mitigate this problem, we propose to decompose the incomplete utterance restoration task into a cascaded process. The first stage is the *Pick* process that identifies omitted words in previous utterances. The second is the *Combine* stage that restores the original utterance based on the identified omitted words.

Pick: inspired by recent advances in transfer learning for language representation, we fine-tune the pre-trained deep bidirectional transformers for language understanding model (BERT) (Devlin et al., 2019) as a classifier to select omitted words from previous utterances. Specifically, instead of discrete classifications, we first formulate this word selection problem as a sequence tagging problem. Each word in previous utterances will be determined to be positive P (should be identified as an omitted word) or negative N (not an omitted word).

Combine: the combine stage is straightforward. The selected omitted words are appended to the input sequence as extra guidance. And the two sequences are taken as input of the pointer generative network mentioned in Section 3.1. We also tried to fine-tune the BERT to directly generate the restored utterance, but the result is far from satisfactory. Therefore, we directly append selected words to the original input sequence as extra guidance for generating restored sentences.

3.3 Task Evaluation

BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) are commonly used metrics in machine translation and summarization. However, for the task of incomplete utterance restoration, these metrics do not differentiate words in the original utterance from those in previous utterances, and each gram is equally important. The statistics in Table 2 show that most words in the reference overlap with words in the original utterance. Thus, a simple copy mechanism which regenerates the original utterance as restored utterance would achieve a high score on these metrics.

To alleviate this issue, we propose the *restoration score* to evaluate the performance of incomplete utterance restoration model. This metric focuses on n-grams that contain at least one restored word, excluding other n-grams. Specifically, the n-gram restoration precision, recall, and F-score can be calculated as:

$$p_n = \frac{|\{\text{restored n-grams}\} \cap \{\text{n-grams in ref}\}|}{|\{\text{restored n-grams}\}|}$$

$$r_n = \frac{|\{\text{restored n-grams}\} \cap \{\text{n-grams in ref}\}|}{|\{\text{n-grams in ref}\}|}$$

$$f_n = 2 \cdot \frac{p_n \cdot r_n}{p_n + r_n}$$

Model	p_1	r_1	f_1	p_2	r_2	f_2	p_3	r_3	f_3	B_1	B_2	R_1	R_2
Syntactic	67.4	37.2	47.9	53.9	30.3	38.8	45.3	25.3	32.5	84.1	81.2	89.3	80.6
Seq2Seq	65.5	40.8	50.3	52.2	32.6	40.1	43.6	27.0	33.4	84.9	81.7	88.8	80.3
Pointer	66.6	40.4	50.3	54.0	33.1	41.1	**45.9**	28.1	34.9	84.7	81.7	89.0	80.9
PAC	**70.5**	**58.1**	**63.7**	**55.4**	**45.1**	**49.7**	45.2	**36.6**	**40.4**	**89.9**	**86.3**	**91.6**	**82.8**

Table 3: p, r, f here represent the restoration precision, recall and F-score that we propose in Section 3.3. B_n represents n-gram BLEU score and R_n represents n-gram ROUGE score.

where "restored n-grams" refer to the n-grams in restored utterance that contain at least one restored words, and "n-grams in ref" refer to the n-grams in reference that contain at least one restored words, $|X|$ refers to the number of elements in set X.

4 Experiment

4.1 Compared methods

We compare the performance of the following methods on the collected dataset:

- **Syntactic:** model proposed by Kumar (Kumar and Joshi, 2016). Specifically, they replace each out-of-vocabulary word in the corpus with a numbered unknown token. The number is based on its relative position in the conversation. The model itself is a Seq2Seq model with attention.
- **Seq2Seq:** the Seq2Seq model with attention introduced in Section 3.1.
- **Pointer:** the pointer generative network introduced in Section 3.1.
- **PAC:** the pick-and-combine model introduced in Section 3.2.

We adopt one layer unidirectional LSTM as the encoder and decoder of each model. During training, the vocabulary size is set to 10K. The size of each mini-batch is 64. Parameters are updated by Adam algorithm (P and Ba, 2014) with the betas set to 0.9 and 0.999 and the eps set to 1e-8. The learning rate is 0.25 and the clipping threshold of gradients is 0.1. The dropout rate is set to 0.5. The word embedding size, encoder hidden size and decoder hidden size are all set to 512. During the inference stage, the checkpoint with smallest validation loss is chosen and the beam-search size is set to 5 for all methods. For the pick stage in the proposed approach, we use a BERT model trained on 200G high-quality news data from Tencent AI Lab.

Method	Quality	Fluency
Syntactic	2.25	**2.58**
Seq2Seq	2.45	2.37
Pointer	2.53	2.50
PAC	**2.89**	2.51

Table 4: Human evaluation on the restoration quality and language fluency. The quality score adopts a 4-point scale, and fluency score adopts a 3-point scale. A higher score is better for both.

4.2 Evaluation metrics

The n-gram restoration score proposed in Section 3.3 is adopted as the automatic evaluation metrics. Then human evaluation is further conducted. Specifically, human annotators are instructed to evaluate the quality and fluency of restored utterances. The quality score evaluates if the restored utterances can be better understood without context than the original utterance. A restored utterance should be scored 4 if it can be perfectly understood without previous utterances, 3 if it is not perfect but still better than the original utterance, 2 if it hasn't been restored or it cannot help better the understanding, and 1 if it is worse than the original utterance. The fluency score is used to evaluate the fluency of a restored utterance. A 3-point scale is adopted and higher is better. We randomly select three hundred examples from the test set for human evaluation. Five professional annotators who have at least one year's experience on text annotation participate in the experiment.

4.3 Results

Automatic Metrics

Scores of each method on the automatic metric are shown on Table 3. PAC model achieves the best performance on the restoration precision, recall, and F-score from 1-gram to 3-grams. The restoration recall reflects how often does the model choose to restore the original utterance. As discussed in Section 3.2, Seq2Seq model and pointer

	Example 1	Example 2	Example 3
A_1	我这个样子也来相个亲喃 I am here for a blind date	晚上了在上**夜班** It's late. I am working in **night shift**	谁给你拍的 Who took it for you?
B_1	**会煮饭**加100分 **Being able to cook** will add 100 points for you	早安世界 Morning, the world	朋友抓拍 My friend took the snapshot
A_2	这个技能竟然100分 I can't believe this skill is worth 100 points	早 Morning	抓拍的够写意给了别人脑补的空间 The snapshot is so atmospheric that people could free their imagination
B_2	我喜欢**这个技能** I like **the skill**	乃是要通宵么 Are you going to work overnight?	**要的就是这个效果** **That is what I want**
A_3	我也喜欢希望能做好 I also like it and hope I could do well	上到8点钟 Until 8 a.m.	你确定吗我怎么觉得其实是没拍好 Are you sure? Why do I feel it was just a mistake
Reference	我也喜欢**会煮饭这个技能**希望能做好 I also like **the cooking skill** and hope I could do well	上**夜班**到8点钟 **The night shift** is until 8 a.m.	你确定**要的就是这种效果**吗我怎么觉得其实是没拍好 Are you sure **that is what you want**? Why do I feel it was just a mistake
PAC	我也喜欢**煮饭这个技能**希望能做好 I also like **the cooking skill** and hope I could do well	**夜班通宵**上到8点钟 **The night shift** requires **working overnight** until 8 a.m.	你确定**要的就是这种效果**吗我怎么觉得其实是没拍好 Are you sure **that is what you want**? Why do I feel it was just a mistake
Pointer	我也喜欢**这个技能**希望能做好 I also like **the skill** and hope I could do well	上到8点钟**通宵** **Working overnight** until 8 a.m.	你确定吗我怎么觉得其实是没拍好 Are you sure? Why do I feel it was just a mistake
Syntactic	我也喜欢**这个技能100分**希望能做好 I also like **the skill 100 points** and hope I could do well	上到8点钟 Until 8 a.m.	你确定吗我怎么觉得其实是没拍好 Are you sure? Why do I feel it was just a mistake
Seq2Seq	我也喜欢希望能做好 I also like it and hope I could do well	**通宵**上到8点钟 **Working overnight** until 8 a.m.	你确定吗我怎么觉得其实是没拍好 Are you sure? Why do I feel it was just a mistake

Table 5: Examples for incomplete utterance restoration. A_1 to B_2 are previous utterances and A_3 is the original utterance. The proposed PAC model could accurately identify pertinent words even those words appear at the beginning of the conversation like Example 2.

generative network tend to directly copy the original utterance, instead of taking risks to choose words from previous utterances. Restoration recall scores of these models can prove this claim. PAC model is also higher than other models in restoration precision. It demonstrates that the words selected by the PAC model are more accurate than that of other models.

We also report the BLEU and ROUGE score of each model. PAC model also achieves the highest scores in these metrics. However, scores of other models are comparatively high because these two metrics take each gram in the reference as equally important. It illustrates the necessity of the proposed evaluation metrics.

Human Evaluation

Results of the human evaluation are shown in Table 4. The proposed method has the highest quality score among all methods. We find the model with the higher score in human evaluation also has a higher restoration score. This tendency demonstrates that the proposed metric makes sense and is practical in this task. As for the fluency, all models except the Seq2Seq model achieve a similar score. The reason why the score of the PAC model is slightly lower than the syntactic model is that the fluency score follows a principle that the more you do, the more mistakes you make. Fluency of original utterances is high, so models with lower recall may get higher fluency.

4.4 Case study

Table 5 shows some examples of the incomplete utterance restoration among different models. At a closer look to the restored utterances, we find PAC model is capable of understanding the conversation context and correctly identify omitted concepts from multiple possible choices. In Example 1, none except PAC model can successfully restore the word "cooking" from previous utterances. In Example 2, most models can only extract the word "stay up" from previous utterances, and they fail to generate a fluent utterance. In contrast, the PAC model picks the correct words from previous utterances and generates a more fluent utterance. As for Example 3, only the PAC model can correctly restore the original utterance. This scenario also supports our analysis at the beginning of section 3.2 that vanilla models have a tendency to regenerate the original utterance.

We conclude an interesting phenomenon from this case study: only the PAC model owns the capability to extract omitted words from very early context. Other models merely choose words from the latest utterance exactly before the original one, namely the B_2 in Table 5. This great context comprehension ability is benefit from the pick process that identifies words from previous utterances.

5 Improving Existing Dialogue Systems

The main motivation for incomplete utterance restoration is to facilitate dialogue systems better

understanding conversation context and generate better responses. Thus, we conduct another experiment to evaluate if the response quality of single-turn and multi-turn dialogue systems improves after incomplete utterance restoration.

5.1 Settings

We applied the proposed PAC model to a single-turn and a multi-turn response generation model to evaluate its effectiveness on dialogue systems. Details are shown as follows:

- **MMI:** a state-of-the-art single-turn response generation model (Li et al., 2016). It adopts the maximum mutual information (MMI) as the objective function to prevent generating general responses. Note MMI model does not have access to the dialogue context. It only takes the original utterance as the input.

- **SMN:** the sequential matching network (SMN) is a state-of-the-art multi-turn reranking modeling proposed by Wu et al. (2017). The query expanded with keywords is used to retrieve top 100 response candidates. When reranking, SMN first matches a response with each utterance and distills matching information into a vector. The vectors are then accumulated through a recurrent neural network (RNN). The hidden states of the RNN is used to calculate the final matching score. In our experiments, SMN is applied to rerank candidates by taking the original utterance and conversation context as model inputs. The candidate with the highest matching score is chosen as the response.

- **MMI after Restoration:** The MMI model takes the restored utterance as the input.

- **SMN after Restoration:** The SMN model takes the restored utterance and conversation context as inputs.

Three hundred randomly selected conversations from the test set are selected and restored by all models. Five annotators are asked to evaluate whether responses to restored utterances are more relevant and appropriate than those of the original utterances. There are three choices for the annotators: better, similar or worse. If the response gets more appropriate *or* more relevant to the context, it will be judged as "better". If the response quality does not change much after the restoration, it will be regarded as "similar". Otherwise, it will be judged as "worse". Utterances that are not restored are judged as "Not Restored" (NR).

MMI	Better	Similar	Worse	NR
Syntactic	14.97	12.16	**2.81**	70.06
Seq2Seq	19.45	15.95	5.32	59.28
Pointer	21.25	16.51	5.35	56.89
PAC	**28.82**	21.95	6.12	**43.11**

Table 6: Human evaluation on response quality from the single-turn dialogue system after restoration. All numbers are in percentage (%), and NR represents *Not Restored*. Both are same for Table 7.

SMN	Better	Similar	Worse	NR
Syntactic	13.17	10.18	**6.59**	70.06
Seq2Seq	13.77	18.56	8.38	59.28
Pointer	16.17	16.76	10.18	56.89
PAC	**27.74**	17.37	11.78	**43.11**

Table 7: Human evaluation on response quality from the multi-turn dialogue system after restoration.

Note that we also train a generative multi-turn response generation model (Serban et al., 2016) on the collected dataset. But generated responses are not clear and coherent enough to understand. As a result, no human study is further conducted for such approach.

5.2 Results

Evaluation results of single-turn and multi-turn dialogue systems are shown in Table 6 and Table 7, respectively. Both systems get better responses after the restoration process, and PAC model is the most effective one. The PAC model achieves the lowest NR, which means it can restore more utterances than other models. Meanwhile, for single-turn dialogue systems, more than 50% queries get better responses when they are restored, and only 10% get worse responses. For multi-turn dialogue systems, although the SMN already has the ability to understand conversation context, the restoration still improves the response quality of nearly half of quires, and only about 20% responses get worse. The results prove that the proposed dataset and approach significantly improve the response quality.

	Example 1	Example 2	Example 3
A_1	下午去哪儿逛逛我的小单反 Where shall I go with my DSLR camera this afternoon	明天就直奔**西安**来了 Heading for **Xi'an** tomorrow	这是啤酒节啊 What a beer festival
B_1	火车站 Rail station	最近雨后会暴热 西安的定律 It''l become very hot after the rain. It''s a rule in Xi'an.	只有我一个人关注啤酒不错的吗 Am I the only one who finds the beer seems to be great?
A_2	不去那人太多了 No, there are too many people	要不要这么悲催的 How miserable it is	你也可以去的 You can go as well
B_2	哈哈**拍人头** Hah, you can **take photos of people**	肿么了你还没到 What, you haven't arrived yet?	**不喝酒** **No drinking**
A_3	(拍人头)不行不行镜头达不到 No, the lens is not good enough (for taking photos of people)	明早到(西安)呢现在在家 Will arrive (in Xi'an) tomorrow. Now I am home	(不喝酒)你可以去吃东西 (If no drinking,) You can go and eat something
MMI	你达不到？ Are you not good enough?	你在哪上班呢? Where do you work?	*没东西吃 *There is nothing to eat
MMI+PAC	*那就别拍了 *Then try to take photos of something else	*你在西安干嘛呢? *What are you doing in Xi'an?	我不喝酒的 I do not drink
SMN	不行呗 Just cannot do it	你现在好好的啊 You look cool now	*啥东西吃? *What to eat?
SMN+PAC	*不行也得行 *Yes, you can do it	*带你高校一日游外加兴庆公园赏雪哈哈 *I will take you to enjoy the one day trip to colleges and the beauty of snow in Park of Xingqing Palace	不喝酒那喝什么? What to drink if not the beer?

Table 8: A comparison between taking original and restored utterance as the input query to a response generation model. In A_3, words in parentheses are restored by PAC model. Responses annotated with * are better.

Some examples are shown in Table 8. Example 1 and 2 are cases where the response quality improves after incomplete utterance restoration. One interesting response is the one from *SMN+PAC* in Example 2. Note that the Park of Xingqing Palace is a famous historic relic in Xi'an. The dialogue system successfully generates a much more concrete and relevant response after restoring the city name *Xi'an*. There are also cases where responses become worse even if the model correctly restores omitted words, as shown in Example 3. One possible explanation is in this case the restored part is less important than the original utterance. This motivates us to find more strategies to alleviate this issue in future studies, such as training the restoration model and response generation model in an end-to-end manner or deploying a ranking model to choose the better response.

6 Related Work

6.1 Non-sentential Utterance Resolution

In addition to a further corpus and taxonomy study, Fernández et al. (2007) design a series of linguistic features to determine the NSU class. Dragone (2015); Dragone and Lison (2016) extend these features for NSU classification. Raghu et al. (2015) propose generating NSU resolution from templates. Poulami Debnath (2018) design a set of rules to classify and restore NSUs for customer support systems. All methods above heavily rely on the syntactic structure or frequent patterns observed empirically, which may not scale well for unseen domains. Kumar and Joshi (2016) approach NSU resolution as a Seq2Seq learning problem. One type of NSU that draws extra attention is ellipsis (Merchant, 2016; Kenyon-Dean et al., 2016; McShane and Babkin, 2016).

6.2 Multi-turn Dialogue Systems

Many efficient approaches have been proposed for developing intelligent dialogue systems (He et al., 2017; Shang et al., 2018; Tian et al., 2019; Cai et al., 2019). For multi-turn dialogue systems, Serban et al. (2016) and Xing et al. (2018) adopt hierarchical neural networks to model context. Tian et al. (2017) conduct an extensive comparison among existing methods and found context information is conducive for neural networks to generate longer, more meaningful and diverse replies. Wu et al. (2017) and Zhang et al. (2018) utilize the context information via a matching network and rerank the retrieved responses. Zhou et al. (2018) investigate matching a response with its multi-turn context using dependency information based entirely on attention. Most of these studies model the dialogue context information as an extra input in the response generation or response matching process. Our method, on the other hand, tries to understand the context by restoring the incomplete utterance to a context-free and complete form. It can be complementary to above studies.

7 Conclusion

In this paper, we propose to facilitate the comprehension of conversation context by restoring incomplete utterances. A large-scale dataset Restoration-200K, which consists of multi-turn

conversations for open-domain dialogue systems, is collected and manually annotated. Based on this dataset, the proposed pick-and-combine method achieves promising results on the incomplete utterance restoration task. Experimental results also demonstrate that the annotated dataset and the proposed approach significantly improve response quality for existing dialogue systems.

Abstract

Context modeling has a pivotal role in open domain conversation. Existing works either use heuristic methods or jointly learn context modeling and response generation with an encoder-decoder framework. This paper proposes an explicit context rewriting method, which rewrites the last utterance by considering context history. We leverage pseudo-parallel data and elaborate a context rewriting network, which is built upon the CopyNet with the reinforcement learning method. The rewritten utterance is beneficial to candidate retrieval, explainable context modeling, as well as enabling to employ a single-turn framework to the multi-turn scenario. The empirical results show that our model outperforms baselines in terms of the rewriting quality, the multi-turn response generation, and the end-to-end retrieval-based chatbots.

1 Introduction

Recent years have witnessed remarkable progress in open domain conversation (non-task oriented dialogue system) (Ji et al., 2014; Li et al., 2016a) due to the easy-accessible conversational data and the development of deep learning techniques (Bahdanau et al., 2014). One of the most difficult problems for open domain conversation is how to model the conversation context.

A conversation context is composed of multiple utterances, which raises some challenges not existing in the sentence modeling, including: 1) topic transition; 2) plenty of coreferences (he, him, she, it, they); and 3) long term dependency. To tackle these problems, existing works either refine the context by appending keywords to the last turn utterance (Yan et al., 2016), or learn a vector representation with neural networks (Serban et al., 2017b). However, these methods have drawbacks, for instance, correct keywords cannot be selected by heuristics rules, and a fix-length vector is not able to handle a long context.

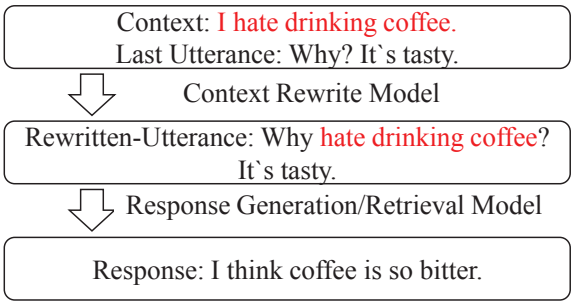

Figure 1: An Example of Context Rewriting.

We propose a context rewriting method, which explicitly rewrites the last utterance by considering the contextual information. Our goal is to generate a self-contained utterance, which neither has coreferences nor depends on other utterances in history. By this means, we change the input of chatbots from an entire conversation session to a rewritten sentence, which significantly reduces the difficulty of response generation/selection since the rewritten sentence is shorter and does not has redundant information. Figure 1 gives an example to further illustrate our idea.

The last utterance contains the word "it" which refers to the coffee in context. Moreover, "Why?" is an elliptical interrogative sentence, which is a shorter form of "Why hate drinking coffee?". We rewrite the context and yield a self-contained utterance "Why hate drinking coffee? It's tasty." Compared to previous methods, our method enjoys the following advantages: 1) The rewriting process is friendly to the retrieval stage of retrieval-based chatbots. Retrieval-based chatbots consists of two components: candidate retrieval and candidate reranking. Traditional works (Yan et al., 2016; Wu et al., 2017) pay little attention to the

*This work was done when the first author was an intern at Microsoft XiaoIce.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1834–1844, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

retrieval stage, which regards the entire context or context rewritten with heuristic rules as queries so noise is likely to be introduced; 2) It makes a step toward explainable and controllable context modeling, because the explicit context rewriting results are easy to debug and analyze. 3) Rewritten results enable us to employ a single-turn framework to solve the multi-turn conversation task. The single-turn conversation technology is more mature than the multi-turn conversation technology, which is able to achieve higher responding accuracy.

To this end, we propose a context rewriting network (CRN) to integrate the key information of the context and the original last utterance to build a rewritten one, so as to improve the answer performance. Our CRN model is a sequence-to-sequence network (Ilya Sutskever, 2014) with a bidirectional GRU-based encoder, and a GRU-based decoder enhanced with the CopyNet (Gu et al., 2016), which helps the CRN to directly copy words from the context. Due to the absence of the real written last utterance, unsupervised methods are used with two training stages, a pre-training stage with pseudo rewritten data, and a fine-tuning stage using reinforcement learning (RL) (Sutton et al., 1998) to maximize the reward of the final answer. Without the pre-training part, RL is unstable and slow to converge, since the randomly initialized CRN model cannot generate reasonable rewritten last utterance. On the other hand, only the pre-training part is not enough, since the pseudo data may contain errors and noise, which restricts the performance of our CRN.

We evaluate our method with four tasks, including the rewriting quality, the multi-turn response generation, the multi-turn response selection, and the end-to-end retrieval-based chatbots. Empirical results show that the outputs of our method are closer to human references than baselines. Besides, the rewriting process is beneficial to the end-to-end retrieval-based chatbots and the multi-turn response generation, and it shows slightly positive effect on the response selection.

2 Related Work

Recently, data-driven approaches for chatbots (Ritter et al., 2011; Ji et al., 2014) has achieved promising results. Existing work along this line includes retrieval-based methods (Hu et al., 2014; Ji et al., 2014; Wang et al., 2015; Yan et al., 2016; Zhou et al., 2016) and generation-based methods (Shang et al., 2015; Serban et al., 2016; Vinyals and Le, 2015; Li et al., 2016a,b; Xing et al., 2017; Serban et al., 2017a).

Early research into retrieval-based chatbots (Wang et al., 2013; Hu et al., 2014; Wang et al., 2015) only considers the last utterances and ignores previous ones, which is also called Short Text Conversation (STC). Recently, several studies (Lowe et al., 2015; Yan et al., 2016; Wu et al., 2017, 2018b) have investigated multi-turn response selection, and obtained better results in a comparison with STC. A common practice for multi-turn retrieval-based chatbots first retrieve candidates from a large index with a heuristic context rewriting method. For example, (Wu et al., 2017) and (Yan et al., 2016) refine the last utterance by appending keywords in history, and retrieve candidates with the refined utterance. Then, response selection methods are applied to measure the relevance between history and candidates.

A number of studies about generation-based chatbots have considered multi-turn response generation. Sordoni et al. (2015) is the pioneer of this type of research, it encodes history information into a vector and feeds to the decoder. Shang et al. (2015) propose three types of attention to utilize the context information. In addition, Serban et al. (2016) propose a Hierarchical Recurrent Encoder-Decoder model (HRED), which employs a hierarchical structure to represent the context. After that, latent variables (Serban et al., 2017b) and hierarchical attention mechanism (Xing et al., 2018) have been introduced to modify the architecture of HRED. Compared to previous work, the originality of this study is that it proposes a principle way instead of heuristic rules for context rewriting, and it does not depend on parallel data.

3 Model

Given a dialogue data set $\mathcal{D} = \{(U, r)_z\}_{z=1}^{N}$, where $U = \{u_0, \cdots, u_n\}$ represents a sequence of utterances and r is a response candidate. We denote the last utterance as $q = u_n$ for simplicity, which is especially important to produce the response, and other utterances as $c = \{u_0, \cdots, u_{n-1}\}$. The goal of our paper is to rewrite q as a self-contained utterance q^* using useful information from c, which can not only reduce the noise in multi-turn context but also leverage a more simple single-turn framework to solve the multi-turn end-to-end tasks. We focus on the

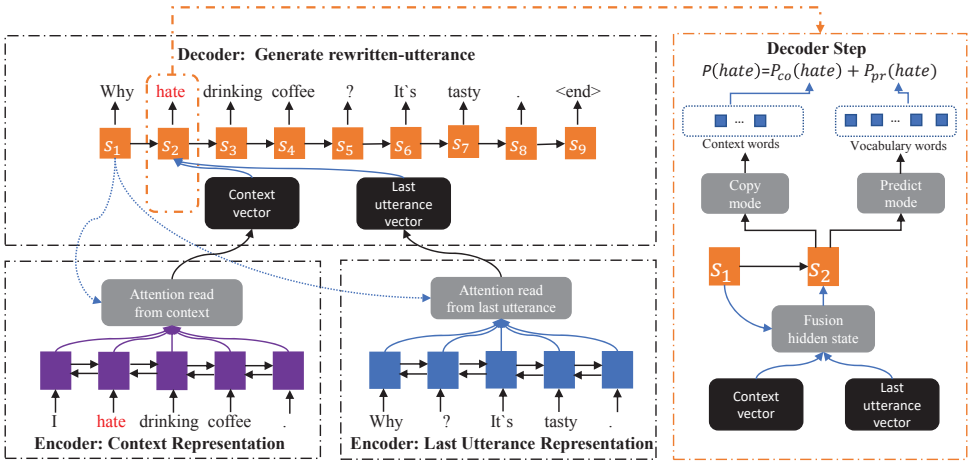

Figure 2: The Detail of CRN

multi-turn response generation and selection tasks.

To rewrite the last utterance q with the help of context c, we propose a context rewriting network (CRN), which is a popularly used sequence-to-sequence network, equipped with a CopyNet to copy words from the original context c (Section 3.1). Without the real paired data (pairs of the original and rewritten last utterance), our CRN model is firstly pre-trained with the pseudo data, generated by inserting extracted keywords from context into the original last utterance q (Section 3.2). To let the final response to influence the rewriting process, reinforcement learning is leveraged to further enhance our CRN model, using the rewards from the response generation and selection tasks respectively (Section 3.3).

3.1 Context Rewriting Network

As shown in Figure 2, our context rewriting network (CRN) follows the sequence to sequence framework, consisting of three parts: one encoder to learn the context (c) representation, another encoder to learn the last utterance (q) representation, and a decoder to generate the rewritten utterance q^*. Attention is also used to focus on different words in the last utterance q and the context c, and the copy mechanism is introduced to copy important words from the context c.

3.1.1 Encoder

To encode the context c and the last utterance q, bidirectional GRU is leveraged to take both the left and right words in the sentence into consideration, by concatenating the hidden states of two GRU networks in positive time direction and negative time direction. With the bidirectional GRU, the last utterance q is encoding into $H_Q = [h_{q_1}, \ldots, h_{q_{nq}}]$, and the context c is encoding into $H_C = [h_{c_1}, \ldots, h_{c_{nc}}]$.

3.1.2 Decoder

The GRU network is also leveraged as decoder to generate the rewritten utterance q^*, in which the attention mechanism is used to extract useful information from the context c and the last utterance q, and the copy mechanism is leveraged to directly copy words from the context c into q^*. At each time step t, we fuse the information from c, q and last hidden state s_t to generate the input vector z_t of GRU as following

$$z_t = W_f^T[s_t; \sum_{i=1}^{nq} \alpha_{q_i} h_{q_i}; \sum_{i=1}^{nc} \alpha_{c_i} h_{c_i}] + b \quad (1)$$

where [;] is the concatenation operation. W_f and b are trainable parameters, s_t is the last hidden state of decoder GRU in step t, α_q and α_c are the weights of the words in q and c respectively, derived by the attention mechanism as following

$$\alpha_i = \frac{exp(e_i)}{\sum_{j=1}^{n} exp(e_j)} \quad (2)$$

$$e_i = h_i W_a s_t \quad (3)$$

where h_i is the encoder hidden state of the i^{th} word in q or c, W_a is the trainable parameter.

The copy mechanism is used to predict the next target word according to the probability of $p(y_t|s_t, H_Q, H_C)$, which is computed as

$$\begin{aligned} p(y_t|s_t, H_Q, H_C) = & \, p_{pr}(y_t|z_t) \cdot p_m(pr|z_t) \\ & + p_{co}(y_t|z_t) \cdot p_m(co|z_t) \end{aligned} \quad (4)$$

where y_t is the $t-th$ word in response, pr and co stand for the predict-mode and the copy-mode, $p_{pr}(y_t|z_t)$ and $p_{co}(y_t|z_t)$ are the distributions of vocabulary word and context word which are im-

plemented by two MLP (multi layer perceptron) classifiers, respectively. And $p_m(\cdot|\cdot)$ indicates the probability to choose the two modes, which is a MLP (multi layer perceptron) classifier with softmax as the activation function:

$$p_m(pr|z_t) = \frac{e^{\psi_{pr}(y_t,H_Q,H_C)}}{e^{\psi_{pr}(y_t,H_Q,H_C)} + e^{\psi_{co}(y_t,H_Q,H_C)}} \tag{5}$$

where $\psi_{pr}(\cdot)$, $\psi_{co}(\cdot)$ are score functions for choosing the predict-mode and copy-mode with different parameters.

3.2 Pre-training with Pseudo Data

Instead of directly leverage RL to optimize our model CRN, which could be unstable and slow to converge, we pre-train our model CRN with pseudo-parallel data. Cross-entropy is selected as the training loss to maximize the log-likelihood of the pseudo rewritten utterance.

$$L_{MLE} = -\frac{1}{N}\sum_{i=1}^{n} \log(p(y_t|s_t, H_Q, H_C)) \tag{6}$$

The main challenge for the pre-training stage is how to generate good pseudo data, which can integrate suitable keywords from context and the original last utterance to form a better one to generate a good response. Given the context c, we extract keywords $w^*_{c_{1:n}}$ using pointwise mutual information (PMI) (in Section 3.2.1). With the extracted keywords $w^*_{c_{1:n}}$, language model is leveraged to find suitable positions to insert them into the original last utterance to generate rewritten candidates s^*, which will be re-ranked leveraging the information from following process (the response generation/selection) to get final pseudo rewritten utterance Q^* (in Section 3.2.2). In the following of this section, we will introduce our pseudo data creation method in detail.

3.2.1 Key Words Extraction

To penalize common and low frequent words, and prefers the "mutually informative" words, PMI is used to extract the keywords in the context c. Given a context word w_c, and a word w_r in response r, it is the divides the prior distribution $p_c(w_c)$ by the posterior distribution $p(w_c|w_r)$ as shown as:

$$\text{PMI}(w_c, w_r) = -\log\frac{p_c(w_c)}{p(w_c|w_r)} \tag{7}$$

In order to select the keywords which contribute to the response, and are suitable to be shown in the last utterance, we also calculate $\text{PMI}(w_c, w_q)$ between the context word w_c and any word w_q in the last utterance. The final contribution score $\text{PMI}(w_c, q, r)$ for the context word w_c to the last utterance q and the response r is calculated as

$$\text{norm}(\text{PMI}(w_c, q)) + \text{norm}(\text{PMI}(w_c, r)) \tag{8}$$

where $\text{norm}(\cdot)$ is the min-max normalization among all words in c, and $\text{PMI}(w_c, q)$ (similar for $\text{PMI}(w_c, r)$) is calculated as

$$\text{PMI}(w_c, q) = \sum_{w_q \in q} \text{PMI}(w_c, w_q). \tag{9}$$

The keywords w^*_c with top-20% contribution score $\text{PMI}(w_c, q, r)$ against r and q are selected to insert into the last utterance q.[1]

3.2.2 Pseudo Data Generation

Together with the extract candidate keyword, the words nearby are also extracted to form a continuous span to introduce more information, of which, at most 2 words before and after are considered. For one keyword, there are at most $C_3^1 * C_3^1 = 9$ span candidates. We apply a multi-layer RNN language model to insert the extracted key phrase to a suitable position in the last utterance. Top-3 generated sentences with high language model scores are selected as the rewritten candidates s^*.

With the information from the response, a rerank model is used to select the best one from the candidates s^*. For end-to-end generation task, the quality of candidates is measured with the cross-entropy of a single-turn attention based encoder-decoder model M_{s2s}, hoping that the good rewritten utterance can help to generate the proper response. For the end-to-end response selection task, the quality of the candidates is measured by the rank loss of a single-turn response selection model M_{ir}, hoping that the good one can distinguish the positive and negative responses.

$$L_{M_{s2s}}(r|s^*) = -\frac{1}{n}\sum_{i=1}^{n} \log p(r_1, \ldots, r_n|s^*) \tag{10}$$

$$L_{M_{ir}}(po, ne, s^*) = M_{ir}(po, s^*) - M_{ir}(ne, s^*) \tag{11}$$

In equation 10, r_i is the $i-th$ word in response. In equation 11 po is the positive response, and ne are the negative one.

[1] This threshold of PMI is based on the observation on the development set.

3.3 Fine-Tuning with Reinforcement Learning

Since the generated pseudo data inevitably contains errors and noise, which limits the performance of the pre-trained model, we leverage the reinforcement learning method to build the direct connection between the context rewrite model CRN and different tasks. We first generate rewritten utterance candidates q_r with our pre-trained model, and calculate the reward $R(q_r)$ which will be maximized to optimize the network parameters of our CRN. Due to the discrete choices of words in sequential generation, the policy gradient is used to calculate the gradient.

$$\nabla_\theta J(\theta) = E[R \cdot \nabla \log(P(y_t|x))] \quad (12)$$

For reinforcement learning in sequential generation task, instability is a serious problem. Similar to other works (Wu et al., 2018a), we combine MLE training objective with RL objective as

$$L_{com} = L^*_{rl} + \lambda L_{MLE} \quad (13)$$

where λ is a harmonic weight.

By directly maximizing the reward from end tasks (response generation and selection), we hope that our CRN can correct the errors in the pseudo data and generate better rewritten last utterance. Two different rewards are used to fine-tune our CRN for the tasks of response generation and selection respectively. We will introduce them in detail in the following.

3.3.1 End-to-end response generation reward

Similar as we do in Section 3.2.2, for end-to-end response generation task, we use the cross-entropy loss of a single-turn attention based encoder-decoder model M_{s2s} to evaluate the quality of rewritten last utterance q_r as

$$R_g(r, q^*, q_r) = L_{M_{s2s}}(r|q^*) - L_{M_{s2s}}(r|q_r) \quad (14)$$

where $L_{M_{s2s}}$ is defined in Equation 10, r is the response candidate, q_r is the generated candidate of our CRN, and q^* is the pseudo rewritten candidate as introduced in Section 3.2.2. If q_r can bring more useful information from context, it will get lower cross-entropy to generate r than the original pseudo rewritten one q^*.

3.3.2 End-to-end response selection reward

For end-to-end response selection task, we use a single-turn response selected model M_{ir} to evaluate the quality of the generated candidate q_r by the rank loss, it is calculated as

$$\begin{aligned} R_{ir}(po, ne, q^*, q_r) = L_{M_{ir}}(po, ne, q_r) \\ - L_{M_{ir}}(po, ne, q^*) \end{aligned} \quad (15)$$

where $L_{M_{ir}}$ is defined in Equation 11, q_r is the generated candidate of our model, and q^* is the pseudo candidate as introduced in Section 3.2.2. Similar to Equation 14, if q_r can bring more useful information, it will do better to distinguish the negative and positive responses.

4 Experiment

We conduct four experiments to validate the effectiveness of our model, including the rewriting quality, the multi-turn response generation, the multi-turn response selection, and the end-to-end retrieval-based chatbots.

We crawl human-human context-response pairs from Douban Group which is a popular forum in China and remove duplicated pairs and utterances longer than 30 words. We create pseudo rewritten context as described in Section 3.1. Because most of the responses are only relevant with the last two turn utterances, following Li et al. (2016c), we remove the utterances beyond the last two turns. We finally split 6,844,393 (c_i, q_i, q^*_i, r_i) quadruplets for training[2], 1000 for validation and 1074 for testing, and the last utterance in test set are selected by human and they all require rewriting to enhance information[3]. In the data set, the ratio between rewritten last utterance and un-rewritten[4] the last utterance is $1.426:1$. The average length of context c_i, last utterance q_i, response r_i, and rewritten last utterance q^*_i are 12.69, 11.90, 15.15 and 14.27 respectively.

We pre-train the CRN with the pseudo-parallel data until it coverages, then we use the reinforcement learning technique described in Section 3.3 to fine-tune the CRN. The specific details of the model hyper-parameters and optimization algorithms can be found in the **Supplementary**.

4.1 Rewriting Quality Evaluation

The detail of the training process is the same as Section 4.2.1. We evaluate the rewriting quality by calculating the BLEU-4 score (Papineni et al.,

[2]The data in the training set do not overlap with the test data of the four tasks.

[3]Our human-annotated test set is available at https://github.com/lovelife/chat

[4]Un-rewritten ones can handle utterances do not rely on their contexts.

	BLEU-4
Last Utterance	34.2
Last Utterance + Context	37.1
Last Utterance + Keyword	49.8
CRN	50.9
CRN + RL	**54.2**

Table 1: The result of rewriting quality.

2002), a sequence order sensitive metric, between the system outputs and human references. Such references are rewritten by a native speaker who considers the information in context. It is required that the rewritten last utterance is self-contained.

We compare our models CRN with three baselines. Firstly, we report the BLEU-4 scores of the origin last utterance and the combination of the last utterance and context. Additionally, following Wu et al. (2017), we append five keywords to the last utterance, where the keywords are selected from the context by TF-IDF weighting, which is named by Last Utterance + Keyword. The IDF score is computed on the entire training corpus.

Table 1 shows the experiment result, which indicates that our rewriting method outperforms heuristic methods. Moreover, a 54.2 BLEU-4 score means that the rewritten sentences are very similar to the human references. CRN-RL has a higher score than CRN-Pre-train on BLEU-4, it proves reinforcement learning promotes our model effectively.

4.2 Multi-turn Response Generation

Section 4.1 demonstrates the outputs of our model are more similar to the human rewritten references. In this part, we will show the influence of the context rewriting for response generation.

We use the same test data in Section 4.1 to evaluate our model in the multi-turn response generation task. The multi-turn response generation is defined as, given an entire context consisting of multiple utterances, a model should generate informative, relevant, and fluent responses. We compare against the following previous works:

S2SA: We adopt the well-known Seq2Seq with attention (Bahdanau et al., 2014) model to generate responses by feeding the last utterances q as source sentences.

HRED: Serban et al. (2016) propose using a hierarchical encoder-decoder model to handle the multi-turn response generation problem, where each utterance and the entire session are represented by different networks.

Dynamic, Static: Zhang et al. (2018) propose two state-of-the-art hierarchical recurrent attention networks for response generation. The dynamic model dynamically weights utterances in the decoding process, while the static model weights utterances before the decoding process.

4.2.1 Implementation Details

Given a context c and last utterance q, we first rewrite them with the CRN. Then the rewritten last utterance q' is fed to a single-turn generation model. The details of the model can be found in **Supplementary** and we set the same sizes of hidden states and embedding in all models. We regard two adjacent utterances in our training data to construct the training dataset (5,591,794 utterance-response pairs) for the single-turn generation model. We do not use the rewritten context as the input in the training phase, since we would like to guarantee the gain only comes from the rewriting mechanism at the inference stage.

4.2.2 Evaluation Metrics

We regard the human response as the ground truth, and use the following metrics:

Word overlap based metrics: We report BLEU score (Papineni et al., 2002) between model outputs and human references.

Embedding based metrics: As BLEU is not correlated with the human annotation perfectly, following (Liu et al., 2016), we employ embedding based metrics, Embedding Average (Average), Embedding Extrema (Extrema), and Embedding Greedy (Greedy) to evaluate results. The word2vec is trained on the training data set, whose dimension is 200.

Diversity: We evaluate the response diversity based on the ratios of distinct unigrams and bigrams in generated responses, denoted as Distinct-1 and Distinct-2 (Li et al., 2016a).

Human Annotation: We ask three native speakers to annotate the quality of generated responses. We compare the quality of our model with HRED and S2SA. We conduct 5-scale rating: +3, +2, +1, 0 and -1. +3: the response is natural, informative and relevant with context; +2: the response is natural, informative, but might not be relevant enough; +1: the response is natural, but might not be informative and relevant enough (e.g., I don't know); 0: The response makes no sense, irrelevant, or grammatically broken; -1: The response or utterances cannot be understood.

	BLEU-1	BLEU-2	BLEU-3	Average	Extrema	Greedy	Distinct-1	Distinct-2
S2SA	5.72	2.80	1.37	11.14	8.58	13.15	25.55	58.89
HRED	10.10	5.53	2.75	27.45	21.71	27.43	15.22	32.19
Dynamic	7.05	3.54	1.75	17.77	14.20	18.94	6.22	15.08
Static	9.31	5.01	2.77	21.32	17.36	22.49	6.59	17.31
CRN	13.26	8.43	4.64	32.31	26.97	33.59	**31.48**	**67.02**
CRN + RL	**13.63**	**8.69**	**4.88**	**33.14**	**27.49**	**34.68**	31.42	65.10

Table 2: Automatic evaluation results.

	3	2	1	0	-1	avg
S2SA	14.48%	**48.56%**	31.01%	5.48%	0.46%	1.72
HRED	13.28%	16.90%	**65.00%**	3.99%	0.46%	1.40
CRN+S2SA	37.05%	31.01%	25.07%	6.04%	0.46%	1.99
CRN+S2SA+RL	**42.43%**	29.25%	15.04%	**12.63%**	0.46%	**2.02**

Table 3: The distribution of human evaluation in response generation model.

4.2.3 Evaluation Results

Table 2 presents the automatic evaluation results, showing that our models outperform baselines on relevance and diversity. Table 3 gives the human annotation results, which also demonstrates the superiority of our models. Our models significantly improve response diversity, mainly because the rewritten sentence contains rich information that is capable of guiding the model to generate a specific output. After reinforcement learning our model promotes on BLEU and embedding metrics, it is because reinforcement learning can build the connection between the utterance-rewrite model with the response generation model for exploring better rewritten-utterance. But our model drops a little on the diversity metrics after reinforcement learning, this owes to the fact that the reward is biased to relevance rather than diversity. The similar phenomenon can be observed in the comparison of HRED and S2SA, which means that although relevance can increase by considering context information, general responses become more frequently concurrently.

Table 3 presents the distribution of score in human evaluation, we can observe that most of the responses generated by HRED and S2SA get 1 or 2 in human evaluation, while most of the responses generated by our model can get 2 or 3. It proves that our model can reduce noisy from context and construct an informative utterance to generate high-quality response. However, after reinforcement learning our model gets more 0 and 3 score, that is because after reinforcement learning, our model becomes unstable and prefers to extract more words from context. The score of one candidate will increase or decrease a lot if useful keywords or wrong keywords are inserted into the last utterance, respectively. In fact, more utterances are rewritten better after reinforcement learning so the average evaluation score improves.

4.3 Multi-turn Response Selection

We also evaluate the multi-turn response selection task of retrieval-based chatbots, which aims to select proper responses from a candidate pool by considering the context. We use the Douban Conversation Corpus released by Wu et al. (2017), which is created by crawling a popular Chinese forum, the Douban Group [5], covering various topics. Its training set contains 0.5 million conversational sessions, and the validation set contains 50,000 sessions. The negative instances in both sets are randomly sampling with a 1:1 positive-negative ratio. The test set contains 1000 conversation contexts, and each context has 10 response candidates with human annotations.

We split the last utterance from each context in the training data, and forms 0.5 million of (q, r) pairs. Subsequently, we train a single-turn Deep Attention Matching Network (Zhou et al., 2018) consuming the pair as an input, which is denoted as DAM$_{single}$. The DAM$_{single}$ model is treated as a rank model in Section 3.2.2 and a reward function in Section 3.3.2. In the testing stage, we use the CRN and the DAM$_{single}$ to assign a score for each candidate. Notably, the original DAM takes a context-response pair as an input, which is set as a baseline method. The parameters of the DAM is the same as its original paper.

	Win	Loss	Tie
CRN vs baseline	51.3%	29.7%	19.0%
CRN + RL vs baseline	35.7%	21.8%	42.5%

Table 5: The result of end-to-end response selection subjective evaluation.

4.3.1 Evaluation Results

Table 4 shows the response selection performances of different methods. We can see that our model achieves a comparable performance with state-of-the-art DAM model, but only consuming a rewritten utterance rather than the whole context. This indicates that our model is able to recognize important content in context and generate a self-contained sentence. This argument is also verified by 1 point promotion compared with DAM_{single} which only uses the last utterance as an input. Additionally, DAM_{single} just underperforms DAM 1 point, meaning that the last utterance is very important for response selection. It supports our assumption that the last utterance is important which is a good prototype for context rewriting.

4.4 End-to-End Multi-turn Response Selection

In practice, a retrieval-based chatbot first retrieves a number of response candidates from an index, then re-ranks the candidates with the aforementioned response selection methods. Previous works pay little attention to the retrieval stage, which just appends some keywords to the last utterance to collect candidates (Wu et al., 2017).

Because our model is able to rewrite context and generate a self-contained sentence. We expect it could retrieve better candidates at the first step, benefiting to the end-to-end performance. Since it is hard to evaluate the retrieval-stage, we evaluate the end-to-end response selection performance. Specifically, we first rewrite the contexts in the test set with CRN, and then retrieve 10 candidates with the rewritten context from the index[6]. DAM_{single} is employed to compute relevance scores with the rewritten utterance and the candidates. The candidate with the top score is selected as the final response. The baseline model appends keywords from context to the last utterance for retrieval and use the original DAM with all context as the input to select final response.

We recruit three annotators to do a side-by-side evaluation, and the model outputs are shuffled before human evaluation. The majority of the three judgments are selected as a result. If both outputs are hard to distinguish, we choose Tie as the result.

4.4.1 Evaluation Results

We list the side-by-side evaluation results in Table 5. Human annotators prefer the outputs of our model. On account of the reranking modules are comparable, we can infer that the gain comes from the better retrieval candidates. However, reinforcement learning does not have a positive effect on this task. We find our reinforced model becomes more conservative, it tends to generate shorter rewritten utterance than our pre-training model. That may be beneficial for response rerank, but if wrong keywords or noise words are extracted from context. It will reduce the quality of retrieved candidates, leading to an undesired end-to-end result.

[6]The authors (Wu et al., 2017) share their index data with us

Context	我十九号昆明飞厦门 I will fly from Kunming to Xiamen in 19th	上了豆瓣更无聊 Douban is so boring	你5点半下班? Do you go off duty in 5:30?
Last Utterance	我也想去 I want to go, too	好像是这样的 Yes	是的呀，坐上班车了都 Yes, I am in bus now
Rewritten-Utterance	昆明飞厦门我也想去 I want to fly from Kunming to Xiamen, too	豆瓣好像是这样的 Yes, Douban is.	是的呀，坐上班车了都下班? Yes, I am now in bus off duty?
Rewritten-Utterance+RL	我也想去厦门 I want to go to Xiamen, too	好像是这样的豆瓣更无聊 Yes, Douban is so boring	是的呀5点半下班，坐上班车了都 Yes, go off duty in 5:30, I am now in bus

Table 6: The examples of end-to-end response generation.

4.5 Case Study

We list the generated examples of our models and baseline models for End-to-end Generation Chatbot and Retrieval Chatbot. Because the submission space is quite limited, we put the case study of Retrieval Chatbot in the Supplementary Material.

4.5.1 End-to-end Generation Chatbots

Table 6 presents the generated examples of our models and baselines, our model can extract the keywords from the context which is helpful to generate an informative response, but the HRED model often generates safe responses like "$Metoo$" or "Yes". It is because the input information from context and last utterance contain so much noise, some of the context words are useless for the last utterance to generate responses. Our model can extract important keywords from noisy context and insert them into the last utterance, it is not only easy to control and explain in a chat-bot system, but also transmit useful information directly to last utterance. The input of S2SA model is the last utterance, so it can generate diverse response due to less noise, but its relevancy with context is low. Our model succeeds fusing advantage from both models and get a significant promotion. Comparing the generated responses by our pre-training model and reinforced model, the rewritten-utterance inferred by our pre-training model may be more informative, but the final generated response may be unrelated to context and last utterance. It is because reinforcement learning can build the connection between the utterance-rewrite model with response generation model for exploring better rewritten-utterance. A better rewritten-utterance should be helpful to generate a context-related response, Too much information inserted will add noise and too little will be useless.

5 Conclusion

This paper investigates context modeling in open domain conversation. It proposes an unsupervised context rewriting model, which benefits to candidate retrieval and controllable conversation. Empirical results show that the rewriting contexts are similar to human references, and the rewriting process is able to improve the performance of multi-turn response selection, multi-turn response generation, and end-to-end retrieval chatbots.

Abstract

This paper proposes a dually interactive matching network (DIM) for presenting the personalities of dialogue agents in retrieval-based chatbots. This model develops from the interactive matching network (IMN) which models the matching degree between a context composed of multiple utterances and a response candidate. Compared with previous *persona* fusion approaches which enhance the representation of a context by calculating its similarity with a given persona, the DIM model adopts a dual matching architecture, which performs interactive matching between responses and contexts and between responses and personas respectively for ranking response candidates. Experimental results on PERSONA-CHAT dataset show that the DIM model outperforms its baseline model, i.e., IMN with *persona* fusion, by a margin of 14.5% and outperforms the current state-of-the-art model by a margin of 27.7% in terms of top-1 accuracy **hits**@1.

1 Introduction

Building a conversation system with intelligence is challenging. Response selection, which aims to select a potential response from a set of candidates given the context of a conversation, is an important technique to build retrieval-based chatbots (Zhou et al., 2018). Many previous studies on single-turn (Wang et al., 2013) or multi-turn response selection (Lowe et al., 2015; Zhou et al., 2018; Gu et al., 2019) rank response candidates according to their semantic relevance with the given context.

With the emergence and popular use of personal assistants such as Apple Siri, Google Now and Microsoft Cortana, the techniques of making personalized dialogues has attracted much research attention in recent years (Li et al., 2016; Zhang et al., 2018; Mazaré et al., 2018). Zhang et al. (2018) constructed a PERSONA-CHAT dataset for building personalized dialogue agents, where each *persona* was represented as multiple sentences of profile description. An example dialogue conditioned on given profiles from this dataset is given in Table 1 for illustration.

A persona fusion method for personalized response selection was also proposed by Zhang et al. (2018). In this method, given a context and a persona composed of several profile sentences, the similarities between the context representation and all profile sentences are computed first using attention to get the persona representation. Then, the persona representation is applied to enhance the context representation by a simple concatenation or addition operation. Finally, the enhanced context representation is used to rank response candidates. This method has two main deficiencies. First, the context is treated as a whole for calculating its attention towards profile sentences. However, each context is composed of multiple utterances and these utterances may play different roles when matching different profile sentences. Second, the interactions between the persona and each response candidate are ignored when deriving the persona representation.

In this paper, the interactive matching network (IMN) (Gu et al., 2019) is adopted as the fundamental architecture to build our baseline and improved models for personalized response selection. The baseline model follows the persona fusion method proposed by Zhang et al. (2018) and two improved models are then proposed. First, an IMN-based persona fusion model with fine-grained context-persona interaction is designed. In this model, each utterance in a context, instead of the whole context, is used to calculate its similarity with each profile sentence in a persona. Second, a dually interactive matching network (DIM) is proposed by formulating the task of personalized response selection as a dual matching problem,

	Persona 1		Persona 2
Original	I just bought a brand new house. I like to dance at the club. I run a dog obedience school. I have a big sweet tooth. I like taking and posting selkies.	Original	I love to meet new people. I have a turtle named timothy. My favorite sport is ultimate frisbee. My parents are living in bora bora. Autumn is my favorite season.
Revised	I have purchased a home. Just go dancing at the nightclub, it is fun! I really enjoy animals. I enjoy chocolate. I pose for pictures and put them online.	Revised	I like getting friends. Reptiles make good pets. I love to run around and get out my energy. My family lives on a island. I love watching the leaves change colors.

Dialogue
Person 1: Hello, how are you doing tonight?
Person 2: I am well an loving this interaction how are you?
Person 1: I am great. I just got back from the club.
Person 2: This is my favorite time of the year season wise.
Person 1: I would rather eat chocolate cake during this season.
Person 2: What club did you go to? Me an timothy watched tv.
Person 1: I went to club chino. What show are you watching?
Person 2: LOL oh okay kind of random.
Person 1: I love those shows. I am really craving cake.
Person 2: Why does that matter any? I went outdoors to play frisbee.
Person 1: It matters because I have a sweet tooth.
Person 2: So? LOL I want to meet my family at home in bora.
Person 1: My family lives in alaska. It is freezing down there.
Person 2: I bet it is oh I could not.

Table 1: An example dialogue from the PERSONA-CHAT dataset.

i.e., finding a response that can properly match the given context and persona simultaneously. The DIM model calculates the interactions between the context and the response, and between the persona and the response in parallel, in order to derive the final matching feature for response selection.

We test our proposed methods on the PERSONA-CHAT dataset (Zhang et al., 2018). Results show that the IMN-based utterance-level persona fusion model and the DIM model can obtain a top-1 accuracy **hits**@1 improvement of 2.4% and 14.5%, respectively, over the baseline model, i.e., the IMN-based context-level persona fusion model. Finally, our proposed DIM model outperforms the current state-of-the-art model by a margin of 27.7% in terms of top-1 accuracy **hits**@1 on the PERSONA-CHAT dataset.

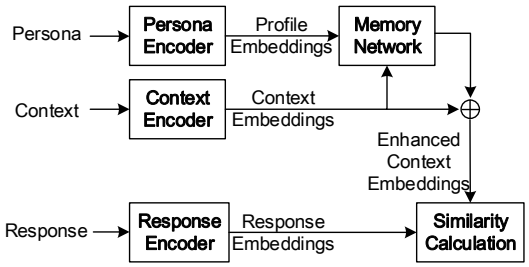
In summary, the contributions of this paper are three-fold. (1) An IMN-based fine-grained persona fusion model is designed in order to consider the utterance-level interactions between contexts and personas. (2) A dually interactive matching network (DIM) is proposed by formulating the task of personalized response selection as a dual matching problem, aiming to find a response that can properly match the given context and persona simultaneously. (3) Experimental results on the PERSONA-CHAT dataset demonstrate that our proposed models outperform the baseline and state-of-the-art models by large margins on the accuracy of response selection.

2 Related Work

2.1 Response Selection

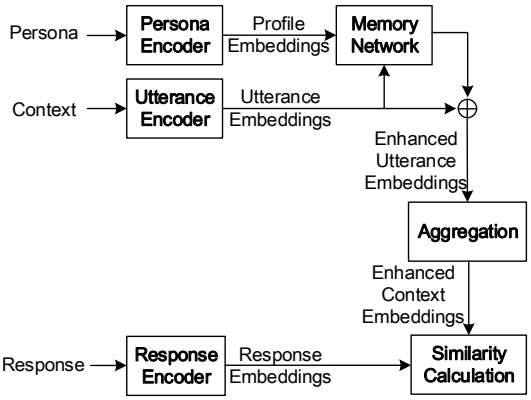
Response selection is an important problem in building retrieval-based chatbots. Existing work on response selection can be categorized into single-turn (Wang et al., 2013) and multi-turn dialogues (Lowe et al., 2015; Zhou et al., 2018; Gu et al., 2019). Early studies have been more on single-turn dialogues, considering only the last utterance of a context for response matching. More recently, the research focus has been shifted to multi-turn conversations, a more practical setup for real applications. Wu et al. (2017) proposed the sequential matching network (SMN) which first matched the response with each context utterance and then accumulated the matching information by a recurrent neural network (RNN). Zhou et al. (2018) proposed the deep attention matching network (DAM) to construct representations at different granularities with stacked self-attention. Gu et al. (2019) proposed the interactive matching network (IMN)

to enhance the representations of the context and response at both the word-level and sentence-level, and to perform the bidirectional and global interactions between the context and response in order to derive the matching feature vector.



2.2 Persona for Chatbots

Chit-chat models suffer from a lack of a consistent personality as they are typically trained over many dialogues, each with different speakers, and a lack of explicit long-term memory as they are typically trained to produce an utterance given only a very recent dialogue history. Li et al. (2016) proposed a persona-based neural conversation model to capture individual characteristics such as background information and speaking style. Miller et al. (2016) proposed the key-value memory network, where the keys were dialogue histories, i.e., contexts, and the values were next dialogue utterances. Zhang et al. (2018) proposed the profile memory network by considering the dialogue history as input and then performing attention over the persona to be combined with the dialogue history. Mazaré et al. (2018) proposed the fine-tuned persona-chat (FT-PC) model which first pretrained a model using a large-scale corpus with external knowledge and then fine-tuned it on the PERSONA-CHAT dataset.



In general, all these methods adopted a context-level persona fusion strategy, which first obtained the embedding vector of a context and then computed the similarities between the whole context and each profile sentence to acquire the persona representation. However, such persona fusion is relatively too coarse. The utterance-level representations of contexts are not leveraged. The interactions between the persona and each response candidate are also ignored when deriving the persona representation.

3 Task Definition

Given a dialogue dataset $\mathcal{D}$ with personas, an example of the dataset can be represented as (c, p, r, y). Specifically, $c = \{u_1, u_2, ..., u_{n_c}\}$ represents a context with $\{u_m\}_{m=1}^{n_c}$ as its utterances and n_c as the utterance number. $p = \{p_1, p_2, ..., p_{n_p}\}$ represents a persona with $\{p_n\}_{n=1}^{n_p}$ as its profile sentences and n_p as the profile number. r represents a response candidate. $y \in \{0, 1\}$ denotes a label. $y = 1$ indicates that r is a proper response for (c, p); otherwise, $y = 0$.

(a) Context-level persona fusion

(b) Utterance-level persona fusion

Figure 1: Comparison of the model architectures for (a) context-level persona fusion and (b) utterance-level persona fusion.

Our goal is to learn a matching model $g(c, p, r)$ from $\mathcal{D}$. For any context-persona-response triple (c, p, r), $g(c, p, r)$ measures the matching degree between (c, p) and r. A softmax output layer over all response candidates is adopted in this model. The model parameters are trained by minimizing a multi-class cross-entropy loss function on $\mathcal{D}$.

4 IMN-Based Persona Fusion

The model architecture used by previous methods with persona fusion (Zhang et al., 2018; Mazaré et al., 2018) is shown in Figure 1(a). It first obtains the context representation and then computes the similarities between the whole context and each profile sentence in a persona. Attention weights are calculated for all profile sentences to obtain the persona representation. Finally, the persona representation is combined with the context representation through concatenation or addition operations.

Formally, the representations of the whole context which is the concatenation of utterances, the context utterances, and the profile sentences are denoted as $\mathbf{c}$, $\{\mathbf{u}_m\}_{m=1}^{n_c}$ and $\{\mathbf{p}_n\}_{n=1}^{n_p}$ respectively,

where $\mathbf{c}$, $\mathbf{u}_m$ and $\mathbf{p}_n \in \mathbb{R}^d$. In previous context-level persona fusion methods, the enhanced context representation $\mathbf{c}^+$ fused with persona information is calculated as

$$\mathbf{c}^+ = \mathbf{c} + \sum_n \textbf{Softmax}(\mathbf{c} \cdot \mathbf{p}_n)\mathbf{p}_n. \quad (1)$$

Then, the similarity between $\mathbf{c}^+$ and the response representation are computed to get the matching degree of (c, p, r).

In this paper, we build our baseline model based on IMN (Gu et al., 2019). After the context and response embeddings are obtained in the IMN model, the context-level persona fusion architecture shown in Figure 1(a) is applied to integrate persona information. All model parameters are estimated in an end-to-end manner. This baseline model is denoted as IMN$_{ctx}$ in this paper.

Considering each context is composed of multiple utterances and these utterances may play different roles when matching different profile sentences, we propose to improve the baseline model by fusing the persona information at a fine-grained utterance-level as shown in Figure 1(b). This model is denoted as IMN$_{utr}$ in this paper. First, the similarities between each context utterance and each profile sentence are computed and the enhanced representation $\mathbf{u}_m^+$ of each context utterance is calculated as

$$\mathbf{u}_m^+ = \mathbf{u}_m + \sum_n \textbf{Softmax}(\mathbf{u}_m \cdot \mathbf{p}_n)\mathbf{p}_n. \quad (2)$$

Then, these enhanced utterance representations are aggregated into the enhanced context representation as

$$\mathbf{c}^+ = \textbf{Aggregation}(\{\mathbf{u}_m^+\}_{m=1}^{n_c}), \quad (3)$$

where either RNN or attention-based aggregation (Gu et al., 2019) can be employed.

5 Dually Interactive Matching Network

5.1 Model Overview

Previous studies on personalized response selection treat personas as supplementary information to enhance context representations by attention-based interaction. In this paper, we formulate the task of personalized response selection as a dual matching problem. The selected response is expected to properly match the given context and persona respectively. Here, personas are considered as equally important counterparts to contexts for ranking response candidates. The interactive matching between the context and response, and that between the persona and response constitute the dually interactive matching network (DIM).

The DIM model is composed of five layers. Figure 2 shows an overview of the architecture. Details about each layer are provided in the following subsections.

5.2 Word Representation Layer

We follow the setting used in IMN (Gu et al., 2019), which constructs word representations by combining general pre-trained word embeddings, those estimated on the task-specific training set, as well as character-level embeddings, in order to deal with the out-of-vocabulary issue.

Formally, embeddings of the *m*-th utterance in a context, the *n*-th profile sentence in a persona and a response candidate are denoted as $\mathbf{U}_m = \{\mathbf{u}_{m,i}\}_{i=1}^{l_{u_m}}$, $\mathbf{P}_n = \{\mathbf{p}_{n,j}\}_{j=1}^{l_{p_n}}$ and $\mathbf{R} = \{\mathbf{r}_k\}_{k=1}^{l_r}$ respectively, where l_{u_m}, l_{p_n} and l_r are the numbers of words in $\mathbf{U}_m$, $\mathbf{P}_n$ and $\mathbf{R}$ respectively. Each $\mathbf{u}_{m,i}$, $\mathbf{p}_{n,j}$ or $\mathbf{r}_k$ is an embedding vector of *d*-dimensions.

5.3 Sentence Encoding Layer

The context utterances, profile sentences and response candidate are encoded by bidirectional long short-term memories (BiLSTMs) (Hochreiter and Schmidhuber, 1997). We denote the calculations as follows,

$$\bar{\mathbf{u}}_{m,i} = \textbf{BiLSTM}(\mathbf{U}_m, i), i \in \{1, ..., l_{u_m}\}, \quad (4)$$
$$\bar{\mathbf{p}}_{n,j} = \textbf{BiLSTM}(\mathbf{P}_n, j), j \in \{1, ..., l_{p_n}\}, \quad (5)$$
$$\bar{\mathbf{r}}_k = \textbf{BiLSTM}(\mathbf{R}, k), k \in \{1, ..., l_r\}, \quad (6)$$

where $\bar{\mathbf{U}}_m = \{\bar{\mathbf{u}}_{m,i}\}_{i=1}^{l_{u_m}}$, $\bar{\mathbf{P}}_n = \{\bar{\mathbf{p}}_{n,j}\}_{j=1}^{l_{p_n}}$ and $\bar{\mathbf{R}} = \{\bar{\mathbf{r}}_k\}_{j=1}^{l_r}$. The parameters of these three BiLSTMs are shared in our implementation.

5.4 Matching Layer

The interactions between the context and the response and those between the persona and the response can provide useful matching information for deciding the matching degree between them. Here, the DIM model adopts the same strategy as in the IMN model (Gu et al., 2019) which considers the global and bidirectional interactions between two sequences.

Take the context-response matching as an example. First, the context representation $\bar{\mathbf{C}} = \{\bar{\mathbf{c}}_i\}_{i=1}^{l_c}$ with $l_c = \sum_{m=1}^{n_c} l_{u_m}$ is formed by

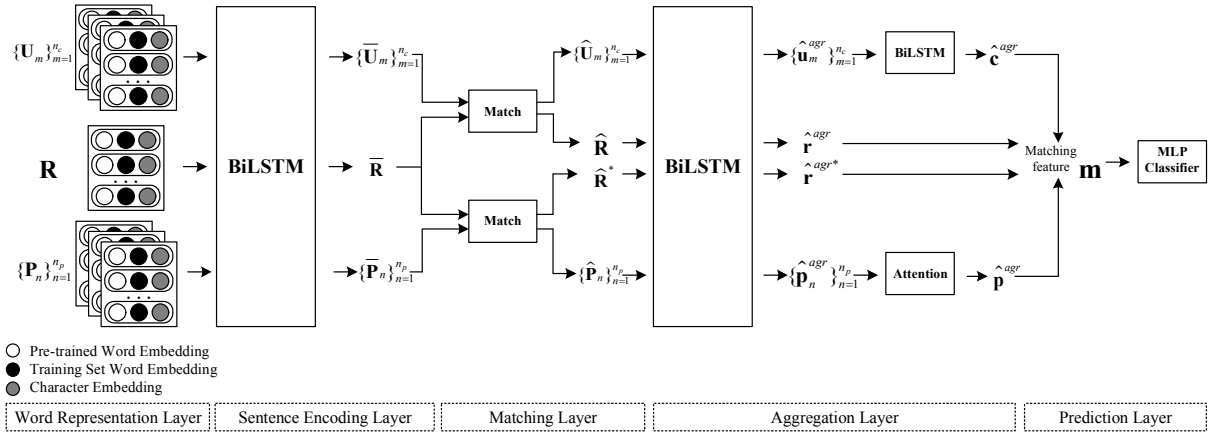


Figure 2: An overview of our proposed DIM model.

concatenating the set of utterance representations $\{\bar{\mathbf{U}}_m\}_{m=1}^{n_c}$. Then, a soft alignment is performed by computing the attention weight between each tuple $\{\bar{\mathbf{c}}_i, \bar{\mathbf{r}}_k\}$ as

$$e_{ik} = (\bar{\mathbf{c}}_i)^\top \cdot \bar{\mathbf{r}}_k. \quad (7)$$

After that, local inference is determined by the attention weights computed above to obtain the local relevance between a context and a response bidirectionally. For a word in the context, its relevant representation carried by the response is identified and composed using e_{ik} as

$$\tilde{\mathbf{c}}_i = \sum_{k=1}^{l_r} \frac{exp(e_{ik})}{\sum_{l=1}^{l_r} exp(e_{il})} \bar{\mathbf{r}}_k, i \in \{1, ..., l_c\}, \quad (8)$$

where the contents in $\{\bar{\mathbf{r}}_k\}_{k=1}^{l_r}$ that are relevant to $\bar{\mathbf{c}}_i$ are selected to form $\tilde{\mathbf{c}}_i$. Then, we define $\tilde{\mathbf{C}} = [\tilde{\mathbf{c}}_1, ..., \tilde{\mathbf{c}}_{l_c}]$. The same calculation is performed for each word in the response to form its relevant representation carried by the context as

$$\tilde{\mathbf{r}}_k = \sum_{i=1}^{l_c} \frac{exp(e_{ik})}{\sum_{l=1}^{l_c} exp(e_{lk})} \bar{\mathbf{c}}_i, k \in \{1, ..., l_r\}, \quad (9)$$

and we define $\tilde{\mathbf{R}} = [\tilde{\mathbf{r}}_1, ..., \tilde{\mathbf{r}}_{l_r}]$. To further enhance the collected information, the differences and element-wise products between $\{\bar{\mathbf{C}}, \tilde{\mathbf{C}}\}$ and between $\{\bar{\mathbf{R}}, \tilde{\mathbf{R}}\}$ are computed, and are then concatenated with the original vectors to obtain the enhanced representations as follows,

$$\widehat{\mathbf{C}} = [\bar{\mathbf{C}}; \tilde{\mathbf{C}}; \bar{\mathbf{C}} - \tilde{\mathbf{C}}; \bar{\mathbf{C}} \odot \tilde{\mathbf{C}}], \quad (10)$$

$$\widehat{\mathbf{R}} = [\bar{\mathbf{R}}; \tilde{\mathbf{R}}; \bar{\mathbf{R}} - \tilde{\mathbf{R}}; \bar{\mathbf{R}} \odot \tilde{\mathbf{R}}]. \quad (11)$$

So far we have collected the relevant information between the context and response. The enhanced context representation $\widehat{\mathbf{C}}$ is further converted back to matching matrices of separated utterances as $\{\widehat{\mathbf{U}}_m\}_{m=1}^{n_c}$.

The persona-response matching is conducted identically to the context-response matching introduced above, where the representations of profile sentences $\{\bar{\mathbf{P}}_n\}_{n=1}^{n_p}$ are used, instead of the representations of context utterances $\{\bar{\mathbf{U}}_m\}_{m=1}^{n_c}$. The results of persona-response matching are denoted as $\{\widehat{\mathbf{P}}_n\}_{n=1}^{n_p}$ and $\widehat{\mathbf{R}}^*$.

5.5 Aggregation Layer

The aggregation layer converts the matching matrices of context utterances, profile sentences and response into a final matching feature vector.

First, each matching matrix $\widehat{\mathbf{U}}_m, \widehat{\mathbf{R}}, \widehat{\mathbf{P}}_n$ and $\widehat{\mathbf{R}}^*$ are processed by BiLSTMs as

$$\hat{\mathbf{u}}_{m,i}^{utr} = \textbf{BiLSTM}(\widehat{\mathbf{U}}_m, i), i \in \{1, ..., l_{u_m}\}, \quad (12)$$

$$\hat{\mathbf{r}}_k^{utr} = \textbf{BiLSTM}(\widehat{\mathbf{R}}, k), k \in \{1, ..., l_r\}, \quad (13)$$

$$\hat{\mathbf{p}}_{n,j}^{utr} = \textbf{BiLSTM}(\widehat{\mathbf{P}}_n, j), j \in \{1, ..., l_{p_n}\}, \quad (14)$$

$$\hat{\mathbf{r}}_k^{utr*} = \textbf{BiLSTM}(\widehat{\mathbf{R}}^*, k), k \in \{1, ..., l_r\}, \quad (15)$$

where the four BiLSTMs share the same parameters in our implementation. Then, the aggregated embeddings are calculated by max pooling and last-hidden-state pooling operations as

$$\hat{\mathbf{u}}_m^{agr} = [\hat{\mathbf{u}}_{m,max}^{utr}; \hat{\mathbf{u}}_{m,l_{u_m}}^{utr}], m \in \{1, ..., n_c\}, \quad (16)$$

$$\hat{\mathbf{r}}^{agr} = [\hat{\mathbf{r}}_{max}^{utr}; \hat{\mathbf{r}}_{l_r}^{utr}], \quad (17)$$

$$\hat{\mathbf{p}}_n^{agr} = [\hat{\mathbf{p}}_{n,max}^{utr}; \hat{\mathbf{p}}_{n,l_{p_n}}^{utr}], n \in \{1, ..., n_p\}, \quad (18)$$

$$\hat{\mathbf{r}}^{agr*} = [\hat{\mathbf{r}}_{max}^{utr*}; \hat{\mathbf{r}}_{l_r}^{utr*}]. \quad (19)$$

Next, the sequences of $\hat{\mathbf{u}}_m^{agr}$ and $\hat{\mathbf{p}}_n^{agr}$ are further aggregated to get the embedding vectors for the context and the persona respectively.

Context aggregation As the utterances in a context are chronologically ordered, the utterance embeddings $\widehat{\mathbf{U}}^{agr} = \{\hat{\mathbf{u}}_m^{agr}\}_{m=1}^{n_c}$ are sent into another BiLSTM following the chronological order of utterances in the context. Combined max pooling and last-hidden-state pooling operations are then performed to obtain the context embeddings as

$$\hat{\mathbf{u}}_m^{ctx} = \textbf{BiLSTM}(\widehat{\mathbf{U}}^{agr}, m), m \in \{1, ..., n_c\}, \tag{20}$$

$$\hat{\mathbf{c}}^{agr} = [\hat{\mathbf{u}}_{max}^{ctx}; \hat{\mathbf{u}}_{n_c}^{ctx}]. \tag{21}$$

Persona aggregation As the profile sentences in a persona are independent to each other, an attention-based aggregation is designed to derive the persona embeddings as follows,

$$\alpha_n = \textbf{ReLU}(\mathbf{w}^\top \cdot \hat{\mathbf{p}}_n^{agr} + b), \tag{22}$$

$$\hat{\mathbf{p}}^{agr} = \sum_{n=1}^{n_p} \frac{e^{\alpha_n}}{\sum_{k=1}^{n_p} e^{\alpha_k}} \hat{\mathbf{p}}_n^{agr}, \tag{23}$$

where $\mathbf{w}$ and b are parameters need to be estimated during training.

Last, the final matching feature vector is the concatenation of context, persona and response embeddings as

$$\mathbf{m} = [\hat{\mathbf{c}}^{agr}; \hat{\mathbf{r}}^{agr}; \hat{\mathbf{p}}^{agr}; \hat{\mathbf{r}}^{agr*}], \tag{24}$$

where the first two features describe the context-response matching, and the last two describe the persona-response matching.

5.6 Prediction Layer

The final matching feature vector is then sent into a multi-layer perceptron (MLP) classifier with softmax output. Here, the MLP is designed to predict whether a (c, p, r) triple match appropriately based on the derived matching feature vector. Finally, the MLP returns a probability to denote the matching degree.

6 Experiments

6.1 Dataset

We tested our proposed methods on the PERSONA-CHAT dataset (Zhang et al., 2018) which contains multi-turn dialogues conditioned on personas. The dataset consists of 8939 complete dialogues for training, 1000 for validation, and 968 for testing. Response selection is performed at every turn of a complete dialogue, which results in 65719 dialogues for training, 7801 for validation, and 7512 for testing in total. Positive responses are true responses from humans and negative ones are randomly sampled. The ratio between positive and negative responses is 1:19 in the training, validation, and testing sets. There are 955 possible personas for training, 100 for validation, and 100 for testing, each consisting of 3 to 5 profile sentences. To make this task more challenging, a version of revised persona descriptions are also provided by rephrasing, generalizing, or specializing the original ones. Since the personas of both speakers in a dialogue are available, the response selection task can be conditioned on the speaker's persona ("self persona") or the dialogue partner's persona ("their persona") respectively.

6.2 Evaluation Metrics

We used the same evaluation metrics as in the previous work (Zhang et al., 2018). Each model aimed to select the best-matched response from available candidates for the given context c and persona p. We calculated the recall of the true positive replies, denoted as **hits**@1. In addition, the mean reciprocal rank (**MRR**) (Voorhees, 1999) metric was also adopted to take the rank of the correct response over all candidates into consideration.

6.3 Training Details

For building the IMN, IMN$_{ctx}$, IMN$_{utr}$ and DIM models, the Adam method (Kingma and Ba, 2015) was employed for optimization with a batch size of 16. The initial learning rate was 0.001 and was exponentially decayed by 0.96 every 5000 steps. Dropout (Srivastava et al., 2014) with a rate of 0.2 was applied to the word embeddings and all hidden layers. A word representation is a concatenation of a 300-dimensional GloVe embedding (Pennington et al., 2014), a 100-dimensional embedding estimated on the training set using the Word2Vec algorithm (Mikolov et al., 2013), and 150-dimensional character-level embeddings with window sizes {3, 4, 5}, each consisting of 50 filters. The word embeddings were not updated during training. All hidden states of the LSTM have 200 dimensions. The MLP at the prediction layer have 256 hidden units with ReLU (Nair and Hinton, 2010) activation. The maximum number of characters in a word, that of words in a context utterance, of utterances in a context, and of words in a response were set to be 18, 20, 15, and

	hits@1	**MRR**
IR baseline	21.4	-
Starspace	31.8	-
Profile	31.8	-
KV Profile	34.9	-
IMN	63.8	75.8

Table 2: Evaluation results of the IMN model and previous methods on PERSONA-CHAT dataset without using personas. All the results except ours are copied from Zhang et al. (2018).

20, respectively. We padded with zeros if the number of utterances in a context was less than 15; otherwise, we kept the last 15 utterances. For the IMN$_{ctx}$, IMN$_{utr}$ and the DIM models, the maximum number of words in a profile sentence and that of profile sentences in a persona were set to be 15 and 5, respectively. Similarly, we padded with zeros if the number of profile sentences in a persona was less than 5. The development set was used to select the best model for testing.

All code was implemented in the TensorFlow framework (Abadi et al., 2016) and is published to help replicate our results [1].

6.4 Experimental Results

Table 2 presents the evaluation results of our reproduced IMN model (Gu et al., 2019) and previous methods on PERSONA-CHAT dataset without using personas. It can be seen that the IMN model outperformed other models on this dataset by a margin larger than 28.9% in terms of **hits**@1. As introduced above, our proposed models for personalized response selection were all built on IMN.

Table 3 presents the evaluation results of our proposed and previous methods on PERSONA-CHAT under various persona configurations. The t-test shows that the differences between our proposed models, i.e., IMN$_{utt}$ and DIM, and the baseline model, i.e. IMN$_{ctx}$, were both statistically significant with p-value < 0.01. We can see that the fine-grained persona fusion at the utterance level rendered a **hits**@1 improvement of 2.4% and an **MRR** improvement of 1.9% by comparing IMN$_{ctx}$ and IMN$_{utr}$ conditioned on original self personas. The DIM model outperformed its baseline IMN$_{ctx}$ by a margin of 14.5% in terms of **hits**@1 and 10.5% in terms of **MRR**. Compared with the FT-PC model (Mazaré et al., 2018) which was first pretrained using a large-scale corpus and then fine-tuned on the PERSONA-CHAT dataset, the DIM model outperformed it by a margin of 10.0% in terms of **hits**@1 conditioned on revised self personas. Another advantage of DIM is that it was trained in an end-to-end mode without pre-training and using any external knowledge. Lastly, the DIM model outperforms previous models by margins larger than 27.7% in terms of **hits**@1 conditioned on original self personas.

Improvement of Using Personas Examining the numbers which indicate the gains or losses after adding persona conditions in Table 3, we can see that the context-level persona fusion improves the performance of previous models significantly when original self personas are used. However, the gain achieved by the IMN$_{ctx}$ model is limited. One possible reason is that the IMN model performs attention-based interactions between the context and the response in order to get their matching feature for response selection. Thus, the context embeddings shown in Fig. 1(a) contained the information from both the context and the response, which may be inappropriate for the following context-level persona fusion shown in Eq. (1). The improvement achieved by the DIM model is much higher because it adopts a dual matching framework to address this issue.

Original vs. Revised Comparing with using original personas, it is more difficult for the models conditioned on the revised personas to extract useful persona information, as shown by the limited improvement achieved by the previous models shown in Table 3. One possible reason is that there are fewer shared words between the response and the persona revised by rephrasing, generalizing, or specializing, which increases the difficulty of understanding the persona and its relationships with the response. For example, it is easier for models to judge the matching degree between the original profile "*Autumn is my favorite season.*" and the response "*This is my favorite time of the year season wise.*" than between the revised profile "*I love watching the leaves change colors.*" and the response. On the contrary, our proposed DIM model still obtains a **hits**@1 improvement of 6.9% and an **MRR** improvement of 5.4% when conditioned on the revised self personas, which can be attributed to the direct and interactive

IMN$_{utr}$	66.7 (+2.9)	78.1 (+2.3)	64.0 (+0.2)	76.0 (+0.2)	63.9 (+0.1)	75.9 (+0.1)	63.7 (-0.1)	75.7 (-0.1)
DIM	**78.8 (+15.0)**	**86.7 (+10.9)**	**70.7 (+6.9)**	**81.2 (+5.4)**	**64.0 (+0.2)**	**76.1 (+0.3)**	**63.9 (+0.1)**	**76.0 (+0.2)**

Table 3: Performance of the proposed and previous methods on the PERSONA-CHAT under various persona configurations. The meanings of "Self Persona", "Their Persona", "Original", and "revised" can be found in Section 6.1. All results except ours are copied from Zhang et al. (2018); Mazaré et al. (2018). Numbers in parentheses indicate the gains or losses after adding the persona conditions.

persona-response matching used in this model.

Self vs. Their As shown in Table 3, no significant gains can be obtained when the models are conditioned on the personas of dialogue partners. Note that there are no significant performance losses with our proposed methods, while the losses of previous models are 2.4% to 7.3% in terms of **hits**@1.

7 Analysis

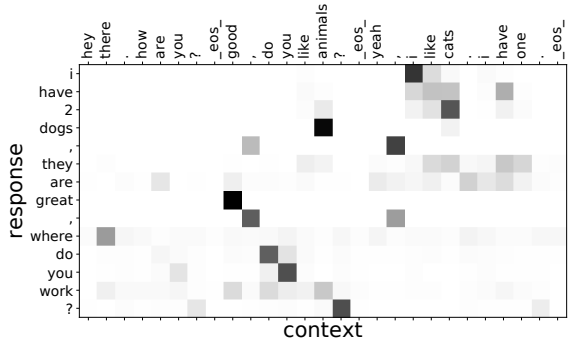
7.1 Ablations

	hits@1	**MRR**
DIM	78.8	86.7
- persona	63.8	75.8
- context	48.8	60.9

Table 4: Ablation tests of removing either persona-response matching or context-response matching in the DIM model conditioned on original self personas.

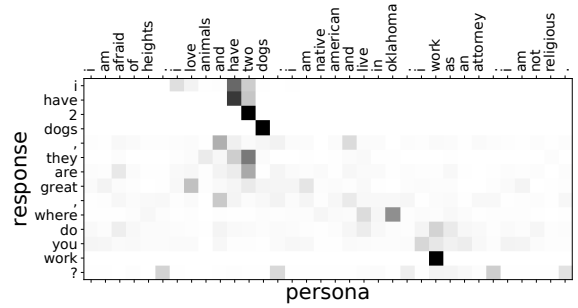
To demonstrate the importance of the dual matching framework followed by our proposed DIM model, ablation tests were performed using the original self personas and the results are shown in Table 4. We can see that both the persona-response matching and the context-response matching contribute to the performance of the DIM model. It is reasonable that the context-persona matching is more important because contexts provide the fundamental semantic descriptions for response selection. On the other hand, the single persona-response matching can also achieve a **hits**@1 of 48.8% and an **MRR** of 60.9%, which shows the usefulness of utilizing persona information to select the best-matched response.

7.2 Interactive Matching in DIM



In order to investigate the effectiveness of the interaction matching between the context and the response and that between the persona and the response in the DIM model, a case study was conducted by visualizing the response-to-context and response-to-persona attention weights used in Eq. (9). The results are shown in Fig. 3. We can see that some important words such as "*dogs*" in the response selected its relevant words such as "*animals*" in the context to derive the context-response matching features. Some important profile texts such as "*I love animals and have two dogs.*" also obtained large attention weights for getting the persona-response matching features. This experimental result confirms our formulation of the task of personalized response selection as a dual matching problem.

7.3 Transfer Test



Train \ Test	Original	Revised
Original	78.8	66.3
Revised	77.6	70.7

Table 5: **hits**@1 results of transfer tests on the DIM model.

Transfer tests were conducted by training and evaluating the DIM model using mismatched types of personas. The results are reported in Table 5. It shows that the DIM model achieved a better performance when testing on the same type of personas as training. Meanwhile, the model trained on the revised personas and tested on the original personas achieved less loss than the ones trained

(a) Response-to-context attention weights

(b) Response-to-persona attention weights

Figure 3: Visualizations of (a) response-to-context or (b) response-to-persona attention weights at the matching layer for a test sample. The darker units correspond to larger values.

on the original personas and tested on the revised personas, which shows that the revised personas can provide a better generalization ability to the DIM model than the original ones.

8 Conclusions

In this paper, we formulate the task of personalized response selection as a dual matching problem to search for a response that can properly match the given context and persona simultaneously. A new model named Dually Interactive Matching Network (DIM) is proposed, which performs the interaction matching between the context and response as well as between the persona and response in parallel, in order to derive the final matching features for personalized response selection. Experimental results show that DIM improves over the IMN models with context-level or utterance-level persona fusion, outperforming previous methods and achieving a new state-of-the-art performance on the PERSONA-CHAT dataset. In the future, we will explore models to make better use of dialogue partners' persona for response selection.

DyKgChat: Benchmarking Dialogue Generation Grounding on Dynamic Knowledge Graphs

Yi-Lin Tuan Yun-Nung Chen Hung-yi Lee
National Taiwan University, Taipei, Taiwan
pascaltuan@gmail.com y.v.chen@ieee.org hungyilee@ntu.edu.tw

Abstract

Data-driven, knowledge-grounded neural conversation models are capable of generating more informative responses. However, these models have not yet demonstrated that they can zero-shot adapt to updated, unseen knowledge graphs. This paper proposes a new task about how to apply dynamic knowledge graphs in neural conversation model and presents a novel TV series conversation corpus (DyKgChat) for the task. Our new task and corpus aids in understanding the influence of dynamic knowledge graphs on responses generation. Also, we propose a preliminary model that selects an output from two networks at each time step: a sequence-to-sequence model (Seq2Seq) and a multi-hop reasoning model, in order to support dynamic knowledge graphs. To benchmark this new task and evaluate the capability of adaptation, we introduce several evaluation metrics and the experiments show that our proposed approach outperforms previous knowledge-grounded conversation models. The proposed corpus and model can motivate the future research directions[1].

1 Introduction

In the chit-chat dialogue generation, neural conversation models (Sutskever et al., 2014; Sordoni et al., 2015; Vinyals and Le, 2015) have emerged for its capability to be fully data-driven and end-to-end trained. While the generated responses are often reasonable but *general* (without useful information), recent work proposed knowledge-grounded models (Eric et al., 2017; Ghazvininejad et al., 2018; Zhou et al., 2018b; Qian et al., 2018) to incorporate external facts in an end-to-end fashion without hand-crafted slot filling. Effectively combining text and external knowledge

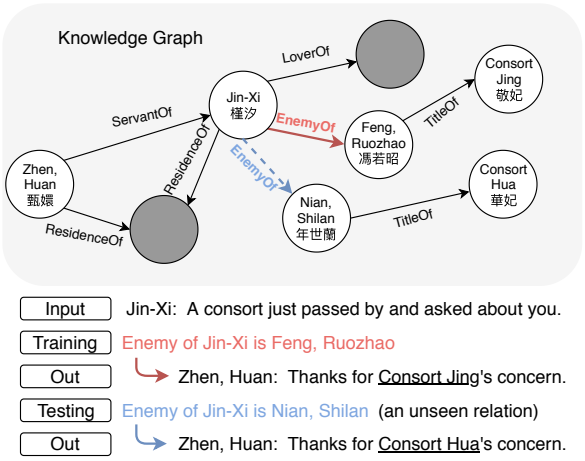

Figure 1: An example of an ideal conversation model with dynamic knowledge graphs.

graphs have also been a crucial topic in *question answering* (Yin et al., 2016; Hao et al., 2017; Levy et al., 2017; Sun et al., 2018; Das et al., 2019). Nonetheless, prior work rarely analyzed the model capability of zero-shot adaptation to dynamic knowledge graphs, where the states/entities and their relations are temporal and evolve as a single time scale process. For example, as shown in Figure 1, the entity *Jin-Xi* was originally related to the entity *Feng, Ruozhao* with the type *EnemyOf*, but then evolved to be related to the entity *Nian, Shilan*.

The goal of this paper is to facilitate knowledge-grounded neural conversation models to learn and zero-shot adapt with dynamic knowledge graphs. To our observation, however, there is no existing conversational data paired with dynamic knowledge graphs. Therefore, we collect a TV series corpus—*DyKgChat*, with facts of the fictitious life of characters. DyKgChat includes a Chinese palace drama *Hou Gong Zhen Huan Zhuan (HGZHZ)*, and an English sitcom *Friends*,which contain dialogues, speakers, scenes (e.g., the places and listeners), and the corresponded knowl-

HGZHZ	**Zhen-Huan**: She must be frightened. It should blame me. I should not ask her to play chess. **甄嬛**: 姐姐定是嚇壞了。都怪臣妾不好，好端端的來叫梅姐姐下棋做什麼。 **Doctor-Wen**: Relax, **Concubine-Huan madame**. **Lady Shen** is just injured but is fine. **溫太醫**: **莞嬪娘娘**請放心，**惠貴人**的精神倒是沒有大礙，只是傷口燒得有些厲害。
Friends	**Joey**: C' mon , you're going out with the guy! There's gotta be something wrong with him! **Chandler**: Alright **Joey**, be nice. So does he have a hump? A hump and a hairpiece?

Table 1: Examples of DyKgChat corpus.

edge graphs including explicit information such as the relations *FriendOf*, *EnemyOf*, and *ResidenceOf* as well as the linked entities. Table 1 shows some examples from DyKgChat.

Prior graph embedding based knowledge-grounded conversation models (Sutskever et al., 2014; Ghazvininejad et al., 2018; Zhu et al., 2017) did not directly use the graph structure, so it is unknown how a changed graph will influence the generated responses. In addition, key-value retrieved-based models (Yin et al., 2016; Eric et al., 2017; Levy et al., 2017; Qian et al., 2018) retrieve only *one-hop* relation paths. As fictitious life in drama, realistic responses often use knowledge entities existing in multi-hop relational paths, e.g., the residence of a friend of mine. Therefore, we propose a model that incorporates multi-hop reasoning (Lao et al., 2011; Neelakantan et al., 2015; Xiong et al., 2017) on the graph structure into a neural conversation generation model. Our proposed model, called quick adaptive dynamic knowledge-grounded neural conversation model (Qadpt), is based on a Seq2Seq model (Sutskever et al., 2014) with a widely-used copy mechanism (Gu et al., 2016; Merity et al., 2017; He et al., 2017; Xing et al., 2017; Zhu et al., 2017; Eric et al., 2017; Ke et al., 2018). To enable multi-hop reasoning, the model factorizes a transition matrix for a *Markov chain*.

In order to focus on the capability of producing reasonable knowledge entities and adapting with dynamic knowledge graphs, we propose two types of automatic metrics. First, given the provided knowledge graphs, we examine if the models can generate responses with proper usage of multi-hop reasoning over knowledge graphs. Second, after randomly replacing some crucial entities in knowledge graphs, we test if the models can accordingly generate correspondent responses. The empirical results show that our proposed model has the desired advantage of zero-shot adaptation with dynamic knowledge graphs, and can serve as a preliminary baseline for this new task. To sum up, the contributions of this paper are three-fold:

- A new task, *dynamic knowledge-grounded conversation generation*, is proposed.
- A newly-collected TV series conversation corpus *DyKgChat* is presented for the target task.
- We benchmark the task by comparing many prior models and the proposed quick adaptive dynamic knowledge-grounded neural conversation model (Qadpt), providing the potential of benefiting the future research direction.

2 Task Description

For each single-turn conversation, the input message and response are respectively denoted as $x = \{x_t\}_{t=1}^{m}$ and $y = \{y_t\}_{t=1}^{n}$, where m and n are their lengths. Each turn (x, y) is paired with a knowledge graph $\mathcal{K}$, which is composed of a collection of triplets (h, r, t), where $h, t \in \mathcal{V}$ (the set of entities) and $r \in \mathcal{L}$ (the set of relationships). Each word y_t in a response belongs to either generic words $\mathcal{W}$ or knowledge graph entities $\mathcal{V}$. The task is two-fold:

1. Given an input message x and a knowledge graph $\mathcal{K}$, the goal is to generate a sequence $\{\hat{y}_t\}_{t=1}^{n}$ that is not only as similar as possible to the ground-truth $\{y_t\}_{t=1}^{n}$, but contains *correct knowledge graph entities* to reflect the information.
2. After a knowledge graph is updated to $\mathcal{K}'$, where some triplets are revised to (h, r, t') or (h, r', t), the generated sequence should contain *correspondent knowledge graph entities* in $\mathcal{K}'$ to reflect the updated information.

2.1 Evaluation Metrics

To evaluate dynamic knowledge-grounded conversation models, we propose two types of evaluation metrics for validating two aspects described above.

2.1.1 Knowledge Entity Modeling

There are three metrics focusing on the knowledge-related capability.

Knowledge word accuracy (KW-Acc). Given the ground-truth sentence as the decoder inputs, at each time step, it evaluates how many knowledge graph entities are correctly predicted.

$$\text{KW-Acc} = \sum_{t=1}^{n} P(\hat{y}_t = y_t \mid y_1 y_2 \dots y_{t-1}, y_t \in \mathcal{V}).$$

For example, after perceiving the partial ground-truth response "*If Jin-Xi not in*" and knowing the next word should be a knowledge graph entity, KW-Acc measures if the model can predict the correct word "*Yongshou Palace*".

Knowledge and generic word classification (KW/Generic). Given the ground-truth sentence as the decoder inputs, at each time step, it measures the capability of predicting the correct class (a knowledge graph entity or a generic word) and adopts micro-averaging. The true positive, false negative and false positive are formulated as:

$$\begin{aligned}
\text{TP} &= |\{t \mid \hat{y}_t \in \mathcal{V}, y_t \in \mathcal{V}\}|, \\
\text{FN} &= |\{t \mid \hat{y}_t \in \mathcal{W}, y_t \in \mathcal{V}\}|, \\
\text{FP} &= |\{t \mid \hat{y}_t \in \mathcal{V}, y_t \in \mathcal{W}\}|, \\
\hat{y}_t &\sim P(\cdot \mid y_1 y_2 \dots y_{t-1}).
\end{aligned}$$

Generated knowledge words (Generated-KW). Considering the knowledge graph entities in the reference $y = \{y_t\}_{t=1}^{n}$ as positives, in the inference stage, we use the generated knowledge entities to compute true positive, false positive, and true negative, and adopt micro-averaging.

$$\begin{aligned}
\text{TP} &= |\{\hat{y}_t \in \{y_t \in \mathcal{V}\}_{t=1}^{n}, \hat{y}_t \in \mathcal{V}\}_{t=1}^{n}|, \\
\text{FN} &= |\{y_t \notin \{\hat{y}_t \in \mathcal{V}\}_{t=1}^{n}, y_t \in \mathcal{V}\}_{t=1}^{n}|, \\
\text{FP} &= |\{\hat{y}_t \notin \{y_t \in \mathcal{V}\}_{t=1}^{n}, \hat{y}_t \in \mathcal{V}\}_{t=1}^{n}|, \\
\hat{y}_t &\sim P(\cdot \mid \hat{y}_1 \hat{y}_2 \dots \hat{y}_{t-1}).
\end{aligned}$$

For example, after input a sentence "*Where's* **JinXi***?*", if a model generates "*Hi,* **Zhen-Huan***,* **JinXi** *is in* **Yangxin-Palace**." when reference is "**JinXi** *is in* **Yongshou-Palace**.", where bolded words are knowledge entities. Recall is $\frac{1}{2}$ and precision is $\frac{1}{3}$.

2.1.2 Adaptation of Changed Knowledge Graphs

Each knowledge graph is randomly changed by (1) shuffling a batch (*All*), (2) replacing the predicted entities (*Last1*), or (3) replacing the last two steps of paths predicting the generated entities (*Last2*). We have two metrics focusing on the capability of adaptation.

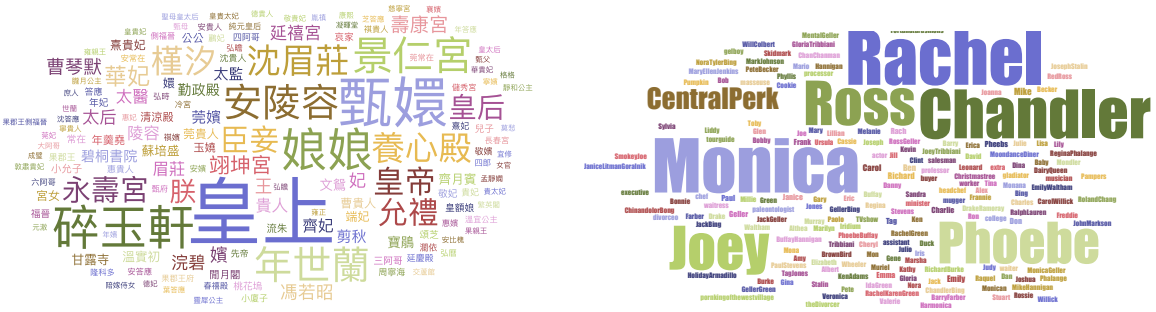
Metrics	HGZHZ	Friends
# Dialogues	1247	3092
Total # turns	17,164	57,757
Total # tokens	462,647	838,913
Avg. turns per dialogue	13.76	18.68
Avg. tokens per turn	26.95	14.52
Total unique tokens	3,624	19,762
# KG entities	174	281
# KG relation types	9	7
total # KG entities appear	46,059	176,550
# Dialogues w/ KG entities	1,166	2,373
# turns w/ KG entities	10,110	9,199

Table 2: The details of collected DyKgChat.

	Relation Type (Percentage)
HGZHZ	IsAliasOf (25%), IsChildOf (5%), IsLoverOf (6%), IsParentOf (5%), IsResidenceOf (16%), IsSiblingOf (2%), IsTitleOf (30%), IsEnemyOf (8%), IsServantOrMasterOf (3%)
Friends	IsLoverOf (12%), IsWorkplaceOf (2%), IsOccupationOf (8%), IsNameOf (47%), IsRelativeOf (8%), IsFriendOf (4%), IsNicknameOf (19%)

Table 3: The included relation types in the collect knowledge graphs, and their percentages.

Change rate. It measures if the responses are different from the original ones (with original knowledge graphs). The higher rate indicates that the model is more sensitive to a changed knowledge graph. Therefore, the higher rate may not be better, because some changes are worse. The following metric is proposed to deal with the issue, but *change rate* is still reported.



Accurate change rate. This measures if the original predicted entities are replaced with the hypothesis set, where this ensures that the updated responses generate knowledge graph entities according to the updated knowledge graphs. (1) In *All*, the hypothesis set is the collection of all entities in the new knowledge graph. (2) In *Last1* and *Last2*, the hypothesis set is the randomly-selected substitutes.

3 DyKgChat Corpus

This section introduces the collected DyKgChat corpus for the target knowledge-grounded conversation generation task.

3.1 Data Collection

To build a corpus where the knowledge graphs would naturally evolves, we collect TV series conversations, considering that TV series often contain complex relationship evolution, such as

(a) The word cloud of HGZHZ. (b) The word cloud of Friends.

Figure 2: The knowledge entity counts of HGZHZ are more balanced than ones of Friends.

friends, jobs, and residences. We choose TV series with different languages and longer episodes. We download the scripts of a Chinese palace drama "*Hou Gong Zhen Huan Zhuang*" (HGZHZ; with 76 episodes and hundreds of characters) from *Baidu Tieba*, and the scripts of an English sitcom "*Friends*" (with 236 episodes and six main characters)[2]. Their paired knowledge graphs are manually constructed according to their wikis written by fans[3][4]. Noted that the knowledge graph of HGZHZ is mainly built upon the top twenty-five appeared characters.

The datasets are split 5% as validation data and 10% as testing data, where the split is based on multi-turn dialogues and balanced on speakers. The boundaries of dialogues are annotated in the original scripts. The tokenization of HGZHZ considers Chinese characters and knowledge entities; the tokenization of Friends considers space-separated tokens and knowledge entities. The data statistics after preprocessing is detailed in Table 2. The relation types $r \in \mathcal{L}$ of each knowledge graph and their percentages are listed in Table 3, and the knowledge graph entities are plotted as word clouds in Figure 2.

3.2 Subgraph Sampling

Due to the excessive labor of building dynamic knowledge graphs aligned with all episodes, we currently collect a fixed knowledge graph $\mathcal{G}$ containing all information that once exists for each TV series. To build the aligned dynamic knowledge graphs, we sample the top-five shortest paths on knowledge graphs from each source to each target, where the sources are knowledge entities in the input message and the scene $\{x_t \in \mathcal{V}\}$, and the targets are knowledge entities in the ground-truth response $\{y_t \in \mathcal{V}\}$. We manually check whether the selected number of shortest paths are able to cover most of the used relational paths. The dynamic knowledge graphs are built based on an ensemble of the following possible subgraphs:

- The sample for each single-turn dialogue.
- The sample for each multi-turn dialogue.
- The manually-annotated subgraph for each period.

While the first rule is adopted for simplicity, the preliminary models should at least work on this type of subgraphs. The subgraphs are defined as the dynamic knowledge graphs $\{\mathcal{K}\}$, which are updated every single-turn dialogue.

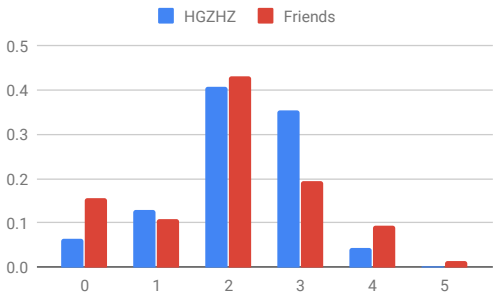


Figure 3: The distribution of lengths of shortest paths.

3.3 Data Analysis

Data imbalance. As shown in Table 2, the turns with knowledge graph entities are about 58.9% and 15.93% of HGZHZ and Friends respectively. Apparently in Friends, the training data with knowledge graph entities are too small, so fine-

[2] https://github.com/npow/friends-chatbot

[4] https://friends.fandom.com/wiki/Friends_Wiki

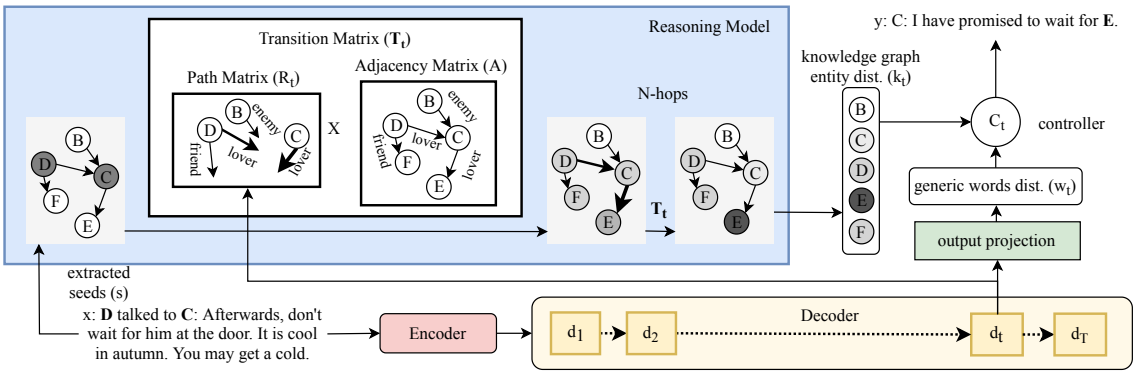

Figure 4: The framework of the proposed model. The node E here is the symbol for the emperor.

tuning on this subset with knowledge graph entities might be required.

Shortest paths. The lengths of shortest paths from sources to targets are shown in Figure 3. Most probabilities lie on two and three hops rather than zero and one hop, so key-value extraction based text generative models (Eric et al., 2017; Levy et al., 2017; Qian et al., 2018) are not suitable for this task.On the other hand, multi-hop reasoning might be useful for better retrieving correct knowledge graph entities.

Dynamics. The distribution of graph edit distances among dynamic knowledge graphs are 57.24 ± 24.34 and 38.16 ± 15.99 for HGZHZ and Friends respectively, revealing that the graph dynamics are spread out: some are slightly changed while some are largely changed, which matches our intuition.

4 Qadpt: Quick Adaptative Dynamic Knowledge-Grounded Neural Conversation Model

To our best knowledge, no prior work focused on dynamic knowledge-grounded conversation; thus we propose *Qadpt* as the preliminary model. As illustrated in Figure 4, the model is composed of (1) a Seq2Seq model with a controller, which decides to predict knowledge graph entities $k \in \mathcal{V}$ or generic words $w \in \mathcal{W}$, and (2) a reasoning model, which retrieves the relational paths in the knowledge graph.

4.1 Sequence-to-Sequence Model

Qadpt is based on a Seq2Seq model (Sutskever et al., 2014; Vinyals and Le, 2015), where the encoder encodes an input message x into a vector $\mathbf{e}(x)$ as the initial state of the decoder. At each time step t, the decoder produces a vector $\mathbf{d}_t$ conditioned on the ground-truth or predicted $y_1 y_2 \dots y_{t-1}$. Note that we use gated recurrent unit (GRU) (Cho et al., 2014) in our experiments.

$$\mathbf{e}(x) = \mathbf{GRU}(x_1 x_2 \dots x_m) \quad (1)$$

$$\mathbf{d_t} = \mathbf{GRU}(y_1 y_2 \dots y_{t-1}, \mathbf{e}(x)) \quad (2)$$

Each predicted $\mathbf{d}_t$ is used for three parts: *output projection*, *controller*, and *reasoning*. For output projection, the predicted $\mathbf{d}_t$ is transformed into a distribution $\mathbf{w}_t$ over generic words $\mathcal{W}$ by a projection layer.

4.2 Controller

To decide which vocabulary set (knowledge graph entities $\mathcal{V}$ or generic words $\mathcal{W}$) to use, the vector $\mathbf{d}_t$ is transformed to a controller c_t, which is a widely-used component (Eric et al., 2017; Zhu et al., 2017; Ke et al., 2018; Zhou et al., 2018b; Xing et al., 2017) similar to copy mechanism (Gu et al., 2016; Merity et al., 2017; He et al., 2017). The controller c_t is the probability of choosing from knowledge graph entities $\mathcal{V}$, while $1 - c_t$ is the probability of choosing from generic words $\mathcal{W}$. Note that we take the controller as a special symbol KB in generic words, so the term $1 - c_t$ is already multiplied to $\mathbf{w}_t$. The controller here can be flexibly replaced with any other model.

$$P(\{KB, \mathcal{W}\} \mid y_1 y_2 \dots y_{t-1}, \mathbf{e}(x)) = \text{softmax}(\phi(\mathbf{d}_t)), \quad (3)$$

$$\mathbf{w}_t = P(\mathcal{W} \mid y_1 y_2 \dots y_{t-1}, \mathbf{e}(x)), \quad (4)$$

$$c_t = P(KB \mid y_1 y_2 \dots y_{t-1}, \mathbf{e}(x)), \quad (5)$$

$$\mathbf{o}_t = \{c_t \mathbf{k}_t; \mathbf{w}_t\}, \quad (6)$$

where ϕ is the output projection layer, and $\mathbf{k}_t$ is the predicted distribution over knowledge graph entities $\mathcal{V}$ (detailed in subsection 4.3), and $\mathbf{o}_t$ is the produced distribution over all vocabularies.

4.3 Reasoning Model

To ensure that Qadpt can zero-shot adapt to dynamic knowledge graphs, instead of using attention mechanism on graph embeddings (Ghazvininejad et al., 2018; Zhou et al., 2018b), we leverage the concept of multi-hop reasoning (Lao et al., 2011). The reasoning procedure can be divided into two stages: (1) forming a transition matrix and (2) reasoning multiple hops by a Markov chain.

In the first stage, a transition matrix $\mathbf{T}_t$ is viewed as multiplication of a path matrix $\mathbf{R}_t$ and the adjacency matrix $\mathbf{A}$ of a knowledge graph $\mathcal{K}$. The adjacency matrix is a binary matrix indicating if the relations between two entities exist. The path matrix is a linear transformation θ of $\mathbf{d}_t$, and represents the probability distribution of each head $h \in \mathcal{V}$ choosing each relation type $r \in \mathcal{L}$. Note that a relation type *self-loop* is added.

$$\mathbf{R}_t = \text{softmax}(\theta(\mathbf{d}_t)), \tag{7}$$

$$\mathbf{A}_{i,j,\gamma} = \begin{cases} 1, & (h_i, r_j, t_\gamma) \in \mathcal{K} \\ 0, & (h_i, r_j, t_\gamma) \notin \mathcal{K} \end{cases}, \tag{8}$$

$$\mathbf{T}_t = \mathbf{R}_t \mathbf{A}, \tag{9}$$

where $\mathbf{R}_t \in \mathbb{R}^{|\mathcal{V}|\times 1\times|\mathcal{L}|}$, $\mathbf{A} \in \mathbb{R}^{|\mathcal{V}|\times|\mathcal{L}|\times|\mathcal{V}|}$, and $\mathbf{T}_t \in \mathbb{R}^{|\mathcal{V}|\times|\mathcal{V}|}$.

In the second stage, a binary vector $\mathbf{s} \in \mathbb{R}^{|\mathcal{V}|}$ is computed to indicate whether each knowledge entity exists in the input message x. First, the vector $\mathbf{s}$ is multiplied by the transition matrix. A new vector $\mathbf{s}^\intercal \mathbf{T}_t$ is then produced to denote the new probability distribution over knowledge entities after one-hop reasoning. After N times reasoning[5], the final probability distribution over knowledge entities is taken as the generated knowledge entity distribution $\mathbf{k}_t$:

$$\mathbf{k}_t = \mathbf{s}^\intercal (\mathbf{T}_t)^N. \tag{10}$$

The loss function is the cross-entropy of the predicted word $\mathbf{o}_t$ and the ground-truth distribution:

$$\mathcal{L}(\psi, \phi, \theta) = -\sum_{t=1}^{n} \log \mathbf{o}_t(y_t), \tag{11}$$

where ψ is the parameters of GRU layers. Compared to prior work, the proposed reasoning approach explicitly models the knowledge reasoning path, so an updated knowledge graphs will definitely change the results without retraining.

[5]We choose $N = 6$ because of the maximum length of shortest paths in Figure 3

4.4 Inferring Reasoning Paths

Because this reasoning method is stochastic, we compute the probabilities of the possible reasoning paths by the reasoning model, and infer the one with the largest probability as the retrieved reasoning path.

5 Related Work

The proposed task is motivated by prior knowledge-grounded conversation tasks (Ghazvininejad et al., 2018; Zhou et al., 2018b), but further requires the capability to adapt to dynamic knowledge graphs.

5.1 Knowledge-Grounded Conversations

The recent knowledge-grounded conversation models (Sordoni et al., 2015; Ghazvininejad et al., 2018; Zhu et al., 2017; Zhou et al., 2018b) generated responses conditioned on conversation history and external knowledge. Ghazvininejad et al. (2018) used memory networks (Weston et al., 2015b,a; Sukhbaatar et al., 2015) to attend on external facts, and added the encoded information to the decoding process.Zhu et al. (2017) added a copy mechanism (Gu et al., 2016; Merity et al., 2017; He et al., 2017) for improving its performance. Zhou et al. (2018b) presented two-level graph attention mechanisms (Veličković et al., 2018) to produce more informative responses.

For knowledge from unstructured texts, Ghazvininejad et al. (2018) used bag-of-word representations and Long et al. (2017) applied a convolutional neural network to encode the whole texts. With structured knowledge graphs, Zhu et al. (2017) and Zhou et al. (2018b) utilized graph embedding methods (e.g., TransE (Bordes et al., 2013)) to encode each triplet.

The above methods generated responses without explicit relationship to each external knowledge triplet. Therefore, when a triplet is added or deleted, it is unknown whether their generated responses can change accordingly. Moon et al. (2019) recently presented a similar concept, walking on the knowledge graph, for response generation. Nonetheless, their purpose is to find explainable path on a large-scaled knowledge graph instead of adaptation with the changed knowledge graphs. Hence, the proposed attention-based graph walker may suffer from the same issue as previous embedding-based methods.

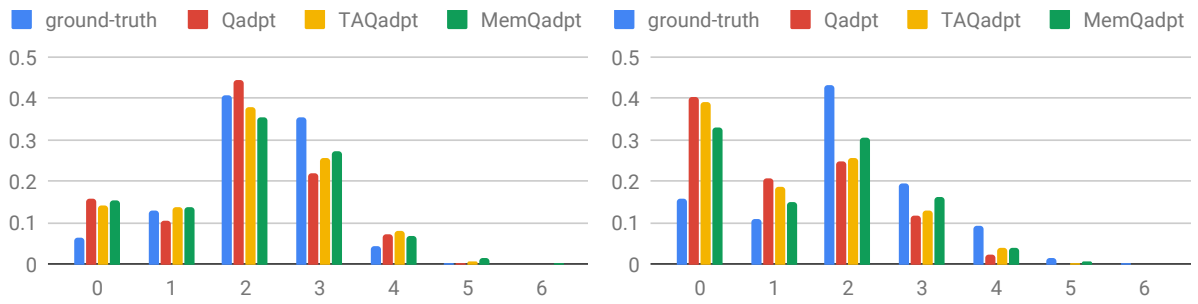
5.2 Multi-Hop Reasoning

We leverage multi-hop reasoning (Lao et al., 2011) to allow our model to quickly adapt to dynamic knowledge graphs. Recently, prior work used convolutional neural network (Toutanova et al., 2015), recurrent neural network (Neelakantan et al., 2015; Das et al., 2017), and reinforcement learning (Xiong et al., 2017; Das et al., 2018; Chen et al., 2018; Shen et al., 2018) to model multi-hop reasoning on knowledge graphs, and has proved this concept useful in link prediction. These reasoning models, however, have not yet explored on dialogue generation. The proposed model is the first attempt at adapting conversations via a reasoning procedure.

6 Experiments



For all models, we use gated recurrent unit (GRU) based Seq2Seq models (Cho et al., 2014; Chung et al., 2014; Vinyals and Le, 2015). Both encoder and decoder for HGZHZ are 256 dimension with 1 layer; ones for Friends are 128 dimension with 1 layer.

We benchmark the task, *dynamic knowledge-grounded dialogue generation*, and corpus *DyKgChat* by providing a detailed comparison between the prior conversational models and our proposed model as the preliminary experiments. We evaluate their capability of quick adaptation by randomized whole, last 1, last 2 reasoning paths as described in Section 2.1.2. We evaluate the produced responses by sentence-level BLEU-2 (Papineni et al., 2002; Liu et al., 2016), perplexity, distinct-n (Li et al., 2016), and our proposed metrics for predicting knowledge entities descrin section 2.1.1.

Because of the significant data imbalance of *Friends*, we first train on whole training data, and then fine-tune the models using the subset containing knowledge entities. Early stopping is adopted in all experiments.

6.1 Baselines

We compare our model with prior knowledge-grounded conversation models: the memory network (Ghazvininejad et al., 2018) and knowledge-aware model (KAware) (Zhu et al., 2017; Zhou et al., 2018b). We also leverage the topic-aware model (TAware) (Xing et al., 2017; Wu et al., 2018; Zhou et al., 2018a) by attending on knowledge graphs and using two separate output projection layers (generic words and all knowledge graph entities). In our experiments, MemNet is modified for fair comparison, where the memory pool of MemNet stores TransE embeddings of knowledge triples (Zhou et al., 2018b). The maximum number of the stored triplets are set to the maximum size of all knowledge graphs for

Table 6: The results of responses generation with BLEU, perplexity (PPL), distinct scores (1-gram to 4-gram).

each dataset (176 for hgzhz and 98 for friends). The multi-hop version of MemNet (Weston et al., 2015b) is also implemented (MemNet+multi)[6]. To empirically achieve better performance, we also utilize the attention of MemNet for TAware and KAware. Moreover, we empirically find that multi-hop MemNet deteriorate the performance of KAware (compared to one-hop), while it could enhance the performance of TAware. A standard Seq2Seq model (Vinyals and Le, 2015) is also shown as a baseline without using external knowledge. We also leverage multi-hop MemNet and the attention of TAware to strength Qadpt (+multi and +TAware).

6.2 Results

As shown in Table 4, MemNet, TAware and KAware significantly change when the knowledge graphs are largely updated (*All*) and can also achieve good accurate change rate. For them, the more parts updated (*All* $>>$ *Last2* $>$ *Last1*), the more changes and accurate changes. However, when the knowledge graphs are slightly updated (*Last1* and *Last2*), the portion of accurate changes over total changes (e.g., the *Last1* score $1.17/31.78$ for HGZHZ with MemNet model) is significantly low. Among the baselines, KAware has better performance on *Last1*. On the other hand, Qadpt outperforms all baselines when the knowledge graphs slightly change (*Last1* and *Last2*) in terms of accurate change rate. The proportion of accurate changes over total changes also show significantly better performance than the prior models. Figure 5 shows the distribution of lengths of the inferred relation paths for Qadpt models. After combining TAware or MemNet, the distribution becomes more similar to the test data.

Table 5 shows the results of the proposed metrics for correctly predicting knowledge graph entities. On both HGZHZ and Friends, TAware+multi and Qadpt significantly outperform MemNet for KW-Acc and KW/Generic, and MemNet outperforms all other models by KW/Generic precision (100%). This demonstrates that these models can better predict knowledge graph entities, but are slightly worse at making good choices of when to predict generic words (KW/Generic).

Table 6 presents the BLEU-2 scores (as recommended in the prior work (Liu et al., 2016)), perplexity (PPL), and distinct scores. The results show that all models have similar levels of BLEU-2 and PPL, while Qadpt+multi has slightly better distinct scores. The results suggest the same claim as Liu et al. (2016) that BLEU scores are not suit-

[6]Note that *multi-hop* here indicates re-attention on the triplet embeddings of a knowledge graph.

Model	HGZHZ						Friends					
	Fluency			Information			Fluency			Information		
	Win	Lose	Kappa	Win	Lose	Kappa	Win	Lose	Kappa	Win	Lose	Kappa

able for dialogue generation.

7 Human Evaluation

To perform human evaluation, we randomly select examples from the knowledge-related outputs of all models, because it is difficult for human to distinguish which generic response is better. We recruit fifteen annotators to judge the results. Each annotator was randomly assigned with 20 examples, and was guided to rank the results of five models: Seq2Seq, MemNet, TAware, KAware, and Qadpt. They were asked to rank all results according to two criteria: (1) fluency and (2) information. *Fluency* measures which output is more proper as a response to a given input message. *Information* measures which output contains more correct information (in terms of knowledge words here) according to a given input message and a referred response. The evaluation results are classified into "win", "tie", and "lose" for comparison.

The human evaluation results and the annotator agreement in the form of Cohen's kappa (Cohen, 1960) are reported in Table 7. According to a magnitude guideline (Landis and Koch, 1977), most agreements are substantial (0.6-0.8), while some agreements of Friends are moderate (0.4-0.6). In most cases of Table 7, Qadpt outperforms other four models. However, in Friends, Qadpt, MemNet, and TAware tie closely. The reason might be the lower agreements of Friends, or only the similar trend with automatic evaluation metrics. There are two extra spots. First, Qadpt wins MemNet and TAware less times than winning Seq2Seq and KAware, which aligns with Table 5 and Table 6. Second, Qadpt wins baselines more often by fluency than by information, and much more ties happen in the infomation fields than the fluency fields. This is probably due to the selection of knowledge-contained examples. Hence there is no much difference when seeing the information amount of models. Overall, the human evaluation results can be considered as reference because of the substantial agreement among annotators and the similar trend with automatic evaluation.

8 Discussion

The results demonstrate that MemNet, TAware and Qadpt generally perform better than than the other two baselines, and they excel at different aspects. MemNet can successfully incorporate knowledge graphs and generate sentences with both appropriate knowledge entities and generic words. In contrast, TAware and Qadpt predict more correct knowledge entities but tend to diminish generic words.

For the scenario of zero-shot adaptation, MemNet and TAware show their ability to update responses when the knowledge graphs are largely changed. On the other hand, Qadpt is better to capture minor dynamic changes (*Last1* and *Last2*) and updates the responses according to the new knowledge graphs. Some examples are given in Appendix. This demonstrates that MemNet and TAware attend on the whole graph instead of focusing on the most influential part.

9 Conclusion

This paper presents a new task, *dynamic knowledge-grounded conversation generation*, and a new dataset *DyKgChat* for evaluation. The dataset is currently provided with a Chinese and an English TV series as well as their correspondent knowledge graphs. This paper also benchmarks the task and dataset by proposing automatic evaluation metrics and baseline models, which can motivate the future research directions.

Retrieval-guided Dialogue Response Generation via a Matching-to-Generation Framework

Abstract

End-to-end sequence generation is a popular technique for developing open domain dialogue systems, though they suffer from the *safe response problem*. Researchers have attempted to tackle this problem by incorporating generative models with the returns of retrieval systems. Recently, a skeleton-then-response framework has been shown promising results for this task. Nevertheless, how to precisely extract a skeleton and how to effectively train a retrieval-guided response generator are still challenging. This paper presents a novel framework in which the skeleton extraction is made by an interpretable matching model and the following skeleton-guided response generation is accomplished by a separately trained generator. Extensive experiments demonstrate the effectiveness of our model designs.

1 Introduction

Sequence-to-sequence (seq2seq) neural models (Shang et al., 2015; Vinyals and Le, 2015; Sordoni et al., 2015; Serban et al., 2016; Li et al., 2016a) have been popular for single-turn dialogue response generation. However, many of the generated responses (e.g., "I don't know" and "I think so") appear to be generic and dull (safe response problem) (Li et al., 2016a). This problem is avoided in traditional retrieval systems (Ji et al., 2014; Hu et al., 2014) by preceding the selection of informative and engaging responses.

It is of interest to benefit from both the generalization capacity of the seq2seq models and the information richness of the retrieved responses. Following the standard encoder-decoder framework, early attempts have either used an extra encoder for the retrieved response (Song et al., 2016; Pandey et al., 2018; Wu et al., 2019) or a unified encoder for the concatenation of the query and the retrieved response (Weston et al., 2018). To prevent the inflow of erroneous information, Cai et al. (2019) proposed a general framework that first extracts a skeleton from the retrieved response and then generates the response based on the extracted skeleton. Despite their differences, a common issue is that the generation model easily learns to ignore the retrieved response entirely and collapses to a vanilla seq2seq model. As shown in Figure 1, this happens with improper training instances. Given the large space of possible responses, it happens frequently that a retrieved response (extracted skeleton) is suitable for responding to the query, but inconsistent with the current target response.[1] The generation model is thus mistakenly led to be inclined to neglect the retrieval.

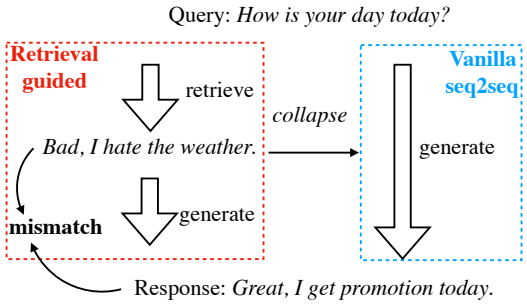

Figure 1: The common problem for training a retrieval-guided generation model in previous work. The model is forced to neglect the retrieved response even though it is a proper response, due to the mismatch between the retrieved response and the target response.

To address the above problem, we present the matching-to-generation method, a more flexible

[1]Previous studies (Weston et al., 2018; Wu et al., 2019; Cai et al., 2019) alleviated the problems by putting hard constraints on the data, which, however, greatly reduces the amount of usable data (e.g., Cai et al. (2019) required the Jaccard distance between the retrieved response and the target response should be in the range [0.3, 0.7]).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 1866–1875, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

framework for retrieval-guided response generation. This framework consists of an interpretable matching model for skeleton extraction and a skeleton-guided response generator for response generation. One novel characteristic of our proposed framework is that the training of the skeleton extractor (i.e., the matching model) and the response generator is decoupled, yet they work cooperatively under the help of a retrieval system. Figure 2 depicts the training and inference procedures of our framework. During training, the skeleton-guided response generator is trained in a similar manner as the denoising autoencoder (Vincent et al., 2008), where the model learns to recover an input pattern that is partially corrupted. Specifically, we employ a random mechanism for generating the skeletons used for training. The generated skeletons are extracted from their corresponding responses with some deliberate disturbance. In this way, we circumvent the aforementioned problem of improper training instances in previous work. Meanwhile, the random mechanism also simulates the actual inference environment where the quality of the input skeleton varies among different queries due to the instability of the retrieval system and the skeleton extractor. The diversity of the training skeletons helps produce a robust response generator that is capable of handling different situations.

Note the separation of the training of skeleton extraction and response generation requires an additional training objective for the skeleton extractor. Given there is no explicit response skeleton in general query-response pairs for training, we propose to use an interpretable matching model for *matching skeleton* extraction. We consider that the matching skeleton for a given query-response pair should be the sub-sequence of the response that is particularly useful in matching the query. The designed interpretable matching model is able to reveal the fine-grained matching scores at token-level whereas it is trained by ordinary query-response pairs.

Experiments show that our method significantly improves the informativeness of the generated responses as well as their relevance to the corresponding queries. In addition, we conduct extensive ablation studies to quantify the improvement from different model designs.

To summarize, our contributions are as follows:

- We propose a flexible framework for retrieval-guided dialogue response generation. The training of our approach is independent of the underlying retrieval system.
- We propose an interpretable matching model for matching skeleton extraction.
- We propose to train a skeleton-guided response generator that can handle skeletons with different qualities.
