Most seq2seq models are *autoregressive*, meaning that they factorize the joint probability of the output sequence given the input sequence $P_\theta(\mathbf{y}|\mathbf{x})$ into the product of probabilities over the next token in the sequence given the input sequence and previously generated tokens:

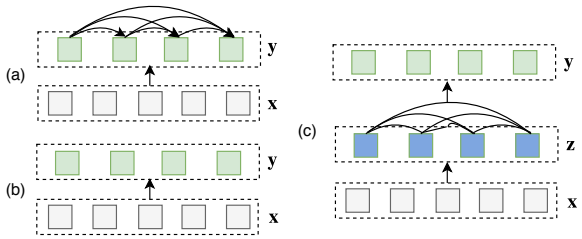

Figure 1: (a) Autoregressive (b) non-autoregressive and (c) our proposed sequence generation models. $\mathbf{x}$ is the source, $\mathbf{y}$ is the target, and $\mathbf{z}$ are latent variables.

$$P_\theta(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T} P_\theta(y_t|y_{<t}, \mathbf{x}). \quad (1)$$

Each factor, $P_\theta(y_t|y_{<t}, \mathbf{x})$, can be implemented by function approximators such as RNNs (Bahdanau et al., 2015) and Transformers (Vaswani et al., 2017). This factorization takes the complicated problem of *joint estimation* over an exponentially large output space of outputs $\mathbf{y}$, and turns it into a *sequence of tractable multi-class classification problems* predicting y_t given the previous words, allowing for simple maximum log-likelihood training. However, this assumption of left-to-right factorization may be sub-optimal from a modeling perspective (Gu et al., 2019; Stern et al., 2019), and generation of outputs must be done through a linear left-to-right pass through the output tokens using beam search, which is not easily parallelizable on hardware such as GPUs.

Recently, there has been work on non-autoregressive sequence generation for neural machine translation (NMT; Gu et al. (2018); Lee et al. (2018); Ghazvininejad et al. (2019)) and language modeling (Ziegler and Rush, 2019). Non-autoregressive models attempt to model the joint distribution $P_\theta(\mathbf{y}|\mathbf{x})$ directly, decoupling the dependencies of decoding history during generation.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4282–4292, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

A naïve solution is to assume that each token of the target sequence is independent given the input:

$$P_\theta(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T} P_\theta(y_t|\mathbf{x}). \quad (2)$$

Unfortunately, the performance of this simple model falls far behind autoregressive models, as seq2seq tasks usually do have strong conditional dependencies between output variables (Gu et al., 2018). This problem can be mitigated by introducing a latent variable $\mathbf{z}$ to model these conditional dependencies:

$$P_\theta(\mathbf{y}|\mathbf{x}) = \int_{\mathbf{z}} P_\theta(\mathbf{y}|\mathbf{z},\mathbf{x}) p_\theta(\mathbf{z}|\mathbf{x}) d\mathbf{z}, \quad (3)$$

where $p_\theta(\mathbf{z}|\mathbf{x})$ is the prior distribution over latent $\mathbf{z}$ and $P_\theta(\mathbf{y}|\mathbf{z},\mathbf{x})$ is the "generative" distribution (a.k.a decoder). Non-autoregressive generation can be achieved by the following independence assumption in the decoding process:

$$P_\theta(\mathbf{y}|\mathbf{z},\mathbf{x}) = \prod_{t=1}^{T} P_\theta(y_t|\mathbf{z},\mathbf{x}). \quad (4)$$

Gu et al. (2018) proposed a $\mathbf{z}$ representing fertility scores specifying the number of output words each input word generates, significantly improving the performance over Eq. (2). But the performance still falls behind state-of-the-art autoregressive models due to the limited expressiveness of fertility to model the interdependence between words in $\mathbf{y}$.

In this paper, we propose a simple, effective, and efficient model, **FlowSeq**, which models expressive prior distribution $p_\theta(\mathbf{z}|\mathbf{x})$ using a powerful mathematical framework called generative flow (Rezende and Mohamed, 2015). This framework can elegantly model complex distributions, and has obtained remarkable success in modeling continuous data such as images and speech through efficient density estimation and sampling (Kingma and Dhariwal, 2018; Prenger et al., 2019; Ma and Hovy, 2019). Based on this, we posit that generative flow also has potential to introduce more meaningful latent variables $\mathbf{z}$ in the non-autoregressive generation in Eq. (3).

FlowSeq is a *flow-based sequence-to-sequence* model, which is (to our knowledge) the first non-autoregressive seq2seq model utilizing generative flows. It allows for efficient parallel decoding while modeling the joint distribution of the output sequence. Experimentally, on three benchmark datasets for machine translation – WMT2014, WMT2016 and IWSLT-2014, FlowSeq achieves comparable performance with state-of-the-art non-autoregressive models, and almost constant decoding time w.r.t. the sequence length compared to a typical left-to-right Transformer model, which is super-linear.

2 Background

As noted above, incorporating expressive latent variables $\mathbf{z}$ is essential to decouple the dependencies between tokens in the target sequence in non-autoregressive models. However, in order to model all of the complexities of sequence generation to the point that we can read off all of the words in the output in an independent fashion (as in Eq. (4)), the prior distribution $p_\theta(\mathbf{z}|\mathbf{x})$ will necessarily be quite complex. In this section, we describe generative flows (Rezende and Mohamed, 2015), an effective method for arbitrary modeling of complicated distributions, before describing how we apply them to sequence-to-sequence generation in §3.

2.1 Flow-based Generative Models

Put simply, flow-based generative models work by transforming a simple distribution (e.g. a simple Gaussian) into a complex one (e.g. the complex prior distribution over $\mathbf{z}$ that we want to model) through a chain of invertible transformations.

Formally, a set of latent variables $\boldsymbol{\upsilon} \in \Upsilon$ are introduced with a simple prior distribution $p_\Upsilon(\upsilon)$. We then define a bijection function $f : \mathcal{Z} \to \Upsilon$ (with $g = f^{-1}$), whereby we can define a generative process over variables $\mathbf{z}$:

$$\begin{aligned} \boldsymbol{\upsilon} &\sim p_\Upsilon(\boldsymbol{\upsilon}) \\ \mathbf{z} &= g_\theta(\boldsymbol{\upsilon}). \end{aligned} \quad (5)$$

An important insight behind flow-based models is that given this bijection function, the change of variable formula defines the model distribution on $\mathbf{z} \in \mathcal{Z}$ by:

$$p_\theta(\mathbf{z}) = p_\Upsilon(f_\theta(\mathbf{z})) \left| \det\left(\frac{\partial f_\theta(\mathbf{z})}{\partial \mathbf{z}}\right) \right|. \quad (6)$$

Here $\frac{\partial f_\theta(\mathbf{z})}{\partial \mathbf{z}}$ is the Jacobian matrix of f_θ at $\mathbf{z}$.

Eq. (6) provides a way to calculate the (complex) density of $\mathbf{z}$ by calculating the (simple) density of υ and the Jacobian of the transformation from $\mathbf{z}$ to υ. For efficiency purposes, flow-based models generally use certain types of transformations f_θ where both the inverse functions

g_θ and the Jacobian determinants are tractable to compute. A stacked sequence of such invertible transformations is also called a (normalizing) *flow* (Rezende and Mohamed, 2015):

$$\mathbf{z} \underset{g_1}{\overset{f_1}{\longleftrightarrow}} H_1 \underset{g_2}{\overset{f_2}{\longleftrightarrow}} H2 \underset{g_3}{\overset{f_3}{\longleftrightarrow}} \cdots \underset{g_K}{\overset{f_K}{\longleftrightarrow}} \boldsymbol{\upsilon},$$

where $f = f_1 \circ f_2 \circ \cdots \circ f_K$ is a flow of K transformations (omitting θs for brevity).

2.2 Variational Inference and Training

In the context of maximal likelihood estimation (MLE), we wish to minimize the negative log-likelihood of the parameters:

$$\min_{\theta \in \Theta} \frac{1}{N} \sum_{i=1}^{N} -\log P_\theta(\mathbf{y}^i|\mathbf{x}^i), \tag{7}$$

where $D = \{(\mathbf{x}^i, \mathbf{y}^i)\}_{i=1}^N$ is the set of training data. However, the likelihood $P_\theta(\mathbf{y}|\mathbf{x})$ after marginalizing out latent variables $\mathbf{z}$ (LHS in Eq. (3)) is intractable to compute or differentiate directly. Variational inference (Wainwright et al., 2008) provides a solution by introducing a parametric *inference model* $q_\phi(\mathbf{z}|\mathbf{y}, \mathbf{x})$ (a.k.a posterior) which is then used to approximate this integral by sampling individual examples of $\mathbf{z}$. These models then optimize the *evidence lower bound* (ELBO), which considers both the "reconstruction error" $\log P_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})$ and KL-divergence between the posterior and the prior:

$$\begin{aligned}\log P_\theta(\mathbf{y}|\mathbf{x}) \geq \mathrm{E}_{q_\phi(\mathbf{z}|\mathbf{y},\mathbf{x})}[\log P_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})] \\ - \mathrm{KL}(q_\phi(\mathbf{z}|\mathbf{y}, \mathbf{x})||p_\theta(\mathbf{z}|\mathbf{x})).\end{aligned} \tag{8}$$

Both inference model ϕ and decoder θ parameters are optimized according to this objective.

3 FlowSeq

We first overview FlowSeq's architecture (shown in Figure 2) and training process here before detailing each component in following sections. Similarly to classic seq2seq models, at both training and test time FlowSeq first reads the whole input sequence $\mathbf{x}$ and calculates a vector for each word in the sequence, the source encoding.

At training time, FlowSeq's parameters are learned using a variational training paradigm overviewed in §2.2. First, we draw samples of latent codes $\mathbf{z}$ from the current posterior $q_\phi(\mathbf{z}|\mathbf{y}, \mathbf{x})$. Next, we feed $\mathbf{z}$ together with source encodings into the decoder network and the prior flow to compute the probabilities of $P_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})$ and $p_\theta(\mathbf{z}|\mathbf{x})$ for optimizing the ELBO (Eq. (8)).

At test time, generation is performed by first sampling a latent code $\mathbf{z}$ from the prior flow by executing the generative process defined in Eq. (5). In this step, the source encodings produced from the encoder are used as conditional inputs. Then the decoder receives both the sampled latent code $\mathbf{z}$ and the source encoder outputs to generate the target sequence $\mathbf{y}$ from $P_\theta(\mathbf{y}|\mathbf{z}, \mathbf{x})$.

3.1 Source Encoder

The source encoder encodes the source sequences into hidden representations, which are used in computing attention when generating latent variables in the posterior network and prior network as well as the cross-attention with decoder. Any standard neural sequence model can be used as its encoder, including RNNs (Bahdanau et al., 2015) or Transformers (Vaswani et al., 2017).

3.2 Posterior

Generation of Latent Variables. The latent variables $\mathbf{z}$ are represented as a sequence of continuous random vectors $\mathbf{z} = \{\mathbf{z}_1, \ldots, \mathbf{z}_T\}$ with the same length as the target sequence $\mathbf{y}$. Each $\mathbf{z}_t$ is a d_z-dimensional vector, where d_z is the dimension of the latent space. The posterior distribution $q_\phi(\mathbf{z}|\mathbf{y}, \mathbf{x})$ models each $\mathbf{z}_t$ as a diagonal Gaussian with learned mean and variance:

$$q_\phi(\mathbf{z}|\mathbf{y}, \mathbf{x}) = \prod_{t=1}^{T} \mathcal{N}(\mathbf{z}_t|\mu_t(\mathbf{x}, \mathbf{y}), \sigma_t^2(\mathbf{x}, \mathbf{y})) \tag{9}$$

where $\mu_t(\cdot)$ and $\sigma_t(\cdot)$ are neural networks such as RNNs or Transformers.

Zero initialization. While we perform standard random initialization for most layers of the network, we initialize the last linear transforms that generate the μ and $\log \sigma^2$ values with zeros. This ensures that the posterior distribution as a simple normal distribution, which we found helps train very deep generative flows more stably.

Token Dropout. The motivation of introducing the latent variable $\mathbf{z}$ into the model is to model the uncertainty in the generative process. Thus, it is preferable that $\mathbf{z}$ capture contextual interdependence between tokens in $\mathbf{y}$. However, there is an obvious local optimum where the posterior network generates a latent vector $\mathbf{z}_t$ that only encodes the information about the corresponding target token y_t, and the decoder simply generates the

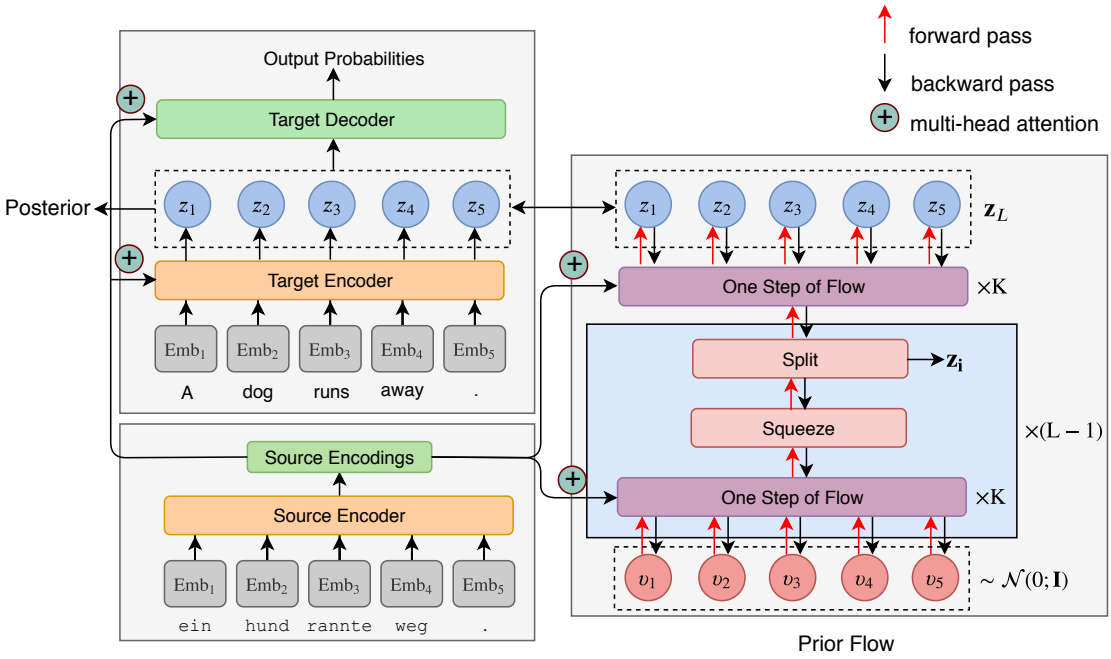

Figure 2: Neural architecture of FlowSeq, including the encoder, the decoder and the posterior networks, together with the multi-scale architecture of the prior flow. The architecture of each flow step is in Figure 3.

"correct" token at each step t with $\mathbf{z}_t$ as input. In this case, FlowSeq reduces to the baseline model in Eq. (2). To escape this undesired local optimum, we apply token-level dropout to randomly drop an entire token when calculating the posterior, to ensure the model also has to learn how to use contextual information. This technique is similar to the "masked language model" in previous studies (Melamud et al., 2016; Devlin et al., 2018; Ma et al., 2018).

3.3 Decoder

As the decoder, we take the latent sequence $\mathbf{z}$ as input, run it through several layers of a neural sequence model such as a Transformer, then directly predict the output tokens in $\mathbf{y}$ individually and independently. Notably, unlike standard seq2seq decoders, we do not perform causal masking to prevent attending to future tokens, making the model fully non-autoregressive.

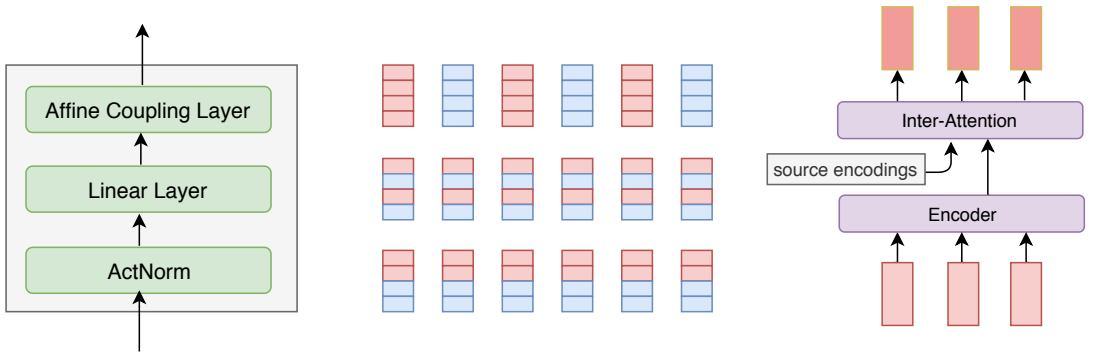
3.4 Flow Architecture for Prior

The flow architecture is based on Glow (Kingma and Dhariwal, 2018). It consists of a series of steps of flow, combined in a multi-scale architecture (see Figure 2.) Each step of flow consists three types of elementary flows – actnorm, invertible multi-head linear, and coupling. Note that all three functions are invertible and conducive to calculation of log determinants (details in Appendix A).

Actnorm. The activation normalization layer (actnorm; Kingma and Dhariwal (2018)) is an alternative for batch normalization (Ioffe and Szegedy, 2015), that has mainly been used in the context of image data to alleviate problems in model training. Actnorm performs an affine transformation of the activations using a scale and bias parameter per feature for sequences:

$$\mathbf{z}'_t = \mathbf{s} \odot \mathbf{z}_t + \mathbf{b}. \tag{10}$$

Both $\mathbf{z}$ and $\mathbf{z}'$ are tensors of shape $[T \times d_z]$ with time dimension t and feature dimension d_z. The parameters are initialized such that over each feature $\mathbf{z}'_t$ has zero mean and unit variance given an initial mini-batch of data.



Invertible Multi-head Linear Layers. To incorporate general permutations of variables along the feature dimension to ensure that each dimension can affect every other ones after a sufficient number of steps of flow, Kingma and Dhariwal (2018) proposed a trainable invertible 1×1 convolution layer for 2D images. It is straightforward to apply similar transformations to sequential data:

$$\mathbf{z}'_t = \mathbf{z}_t \mathbf{W}, \tag{11}$$

where $\mathbf{W}$ is the weight matrix of shape $[d_z \times d_z]$. The log-determinant of this transformation is:

$$\log \left| \det \left(\frac{\partial \text{linear}(\mathbf{z}; \mathbf{W})}{\partial \mathbf{z}} \right) \right| = T \cdot \log |\det(\mathbf{W})|$$

The cost of computing $\det(\mathbf{W})$ is $O(d_z^3)$.

(a) One step of flow. (b) Coupling layer splits. (c) NN function on the split of the coupling layer.

Figure 3: (a) The architecture of one step of our flow. (b) The visualization of three split pattern for coupling layers, where the red color denotes $\mathbf{z}_a$ and the blue color denotes zv_b. (c) The attention-based architecture of the NN function in coupling layers.

Unfortunately, d_z in Seq2Seq generation is commonly large, e.g. 512, significantly slowing down the model for computing $\det(\mathbf{W})$. To apply this to sequence generation, we propose a multi-head invertible linear layer, which first splits each d_z-dimensional feature vector into h heads with dimension $d_h = d_z/h$. Then the linear transformation in (11) is applied to each head, with $d_h \times d_h$ weight matrix $\mathbf{W}$, significantly reducing the dimension. For splitting of heads, one step of flow contains one linear layer with either row-major or column-major splitting format, and these steps with different linear layers are composed in an alternating pattern.

Affine Coupling Layers. To model interdependence across time steps, we use affine coupling layers (Dinh et al., 2016):

$$\begin{aligned} \mathbf{z}_a, \mathbf{z}_b &= \text{split}(\mathbf{z}) \\ \mathbf{z}'_a &= \mathbf{z}_a \\ \mathbf{z}'_b &= \text{s}(\mathbf{z}_a, \mathbf{x}) \odot \mathbf{z}_b + \text{b}(\mathbf{z}_a, \mathbf{x}) \\ \mathbf{z}' &= \text{concat}(\mathbf{z}'_a, \mathbf{z}'_b), \end{aligned}$$

where $\text{s}(\mathbf{z}_a, \mathbf{x})$ and $\text{b}(\mathbf{z}_a, \mathbf{x})$ are outputs of two neural networks with $\mathbf{z}_a$ and $\mathbf{x}$ as input. These are shown in Figure 3 (c). In experiments, we implement $\text{s}(\cdot)$ and $\text{b}(\cdot)$ with one Transformer decoder layer (Vaswani et al., 2017): multi-head self-attention over $\mathbf{z}_a$, followed by multi-head inter-attention over $\mathbf{x}$, followed by a position-wise feed-forward network. The input $\mathbf{z}_a$ is fed into this layer in one pass, without causal masking.

As in Dinh et al. (2016), the $\text{split}()$ function splits $\mathbf{z}$ the input tensor into two halves, while the concat operation performs the corresponding reverse concatenation operation. In our architecture, three types of split functions are used, based on the split dimension and pattern. Figure 3 (b) illustrates the three splitting types. The first type of split groups $\mathbf{z}$ along the time dimension on alternate indices. In this case, FlowSeq mainly models the interactions between time-steps. The second and third types of splits perform on the feature dimension, with continuous and alternate patterns, respectively. For each type of split, we alternate $\mathbf{z}_a$ and $\mathbf{z}_b$ to increase the flexibility of the split function. Different types of affine coupling layers alternate in the flow, similar to the linear layers.

Multi-scale Architecture. We follow Dinh et al. (2016) in implementing a multi-scale architecture using the squeezing operation on the feature dimension, which has been demonstrated helpful for training deep flows. Formally, each scale is a combination of several steps of the flow (see Figure 3 (a)). After each scale, the model drops half of the dimensions with the third type of split in Figure 3 (b) to reduce computational and memory cost, outputting the tensor with shape $[T \times \frac{d}{2}]$. Then the squeezing operation transforms the $T \times \frac{d}{2}$ tensor into an $\frac{T}{2} \times d$ one as the input of the next scale. We pad each sentence with EOS tokens to ensure T is divisible by 2. The right component of Figure 2 illustrates the multi-scale architecture.

3.5 Predicting Target Sequence Length

In autoregressive seq2seq models, it is natural to determine the length of the sequence dynamically by simply predicting a special EOS token. However, for FlowSeq to predict the entire sequence in parallel, it needs to know its length in advance to generate the latent sequence $\mathbf{z}$. Instead of predicting the absolute length of the target sequence, we predict the length difference between source

and target sequences using a classifier with a range of $[-20, 20]$. Numbers in this range are predicted by max-pooling the source encodings into a single vector,[2] running this through a linear layer, and taking a softmax. This classifier is learned jointly with the rest of the model.

3.6 Decoding Process

At inference time, the model needs to identify the sequence with the highest conditional probability by marginalizing over all possible latent variables (see Eq. (3)), which is intractable in practice. We propose three approximating decoding algorithms to reduce the search space.

Argmax Decoding. Following Gu et al. (2018), one simple and effective method is to select the best sequence by choosing the highest-probability latent sequence $\mathbf{z}$:

$$\begin{aligned} \mathbf{z}^* &= \operatorname*{argmax}_{\mathbf{z}\in\mathcal{Z}} p_\theta(\mathbf{z}|\mathbf{x}) \\ \mathbf{y}^* &= \operatorname*{argmax}_{\mathbf{y}} P_\theta(\mathbf{y}|\mathbf{z}^*, \mathbf{x}) \end{aligned}$$

where identifying $\mathbf{y}^*$ only requires independently maximizing the local probability for each output position (see Eq. 4).

Noisy Parallel Decoding (NPD). A more accurate approximation of decoding, proposed in Gu et al. (2018), is to draw samples from the latent space and compute the best output for each latent sequence. Then, a pre-trained autoregressive model is adopted to rank these sequences. In FlowSeq, different candidates can be generated by sampling different target lengths or different samples from the prior, and both of the strategies can be batched via masks during decoding. In our experiments, we first select the top l length candidates from the length predictor in §3.5. Then, for each length candidate we use r random samples from the prior network to generate output sequences, yielding a total of $l \times r$ candidates.

Importance Weighted Decoding (IWD) The third approximating method is based on the *lower bound of importance weighted estimation* (Burda et al., 2015). Similarly to NPD, IWD first draws samples from the latent space and computes the best output for each latent sequence. Then, IWD ranks these candidate sequences with K importance samples:

$$\begin{aligned} \mathbf{z}_i &\sim p_\theta(\mathbf{z}|\mathbf{x}), \forall i = 1, \ldots, N \\ \hat{\mathbf{y}}_i &= \operatorname*{argmax}_{\mathbf{y}} P_\theta(\mathbf{y}|\mathbf{z}_i, \mathbf{x}) \\ \mathbf{z}_i^{(k)} &\sim q_\phi(\mathbf{z}|\hat{\mathbf{y}}_i, \mathbf{x}), \forall k = 1, \ldots, K \\ P(\hat{\mathbf{y}}_i|\mathbf{x}) &\approx \frac{1}{K}\sum_{k=1}^{K} \frac{P_\theta(\hat{\mathbf{y}}_i|\mathbf{z}_i^{(k)}, \mathbf{x}) p_\theta(\mathbf{z}_i^{(k)}|\mathbf{x})}{q_\phi(\mathbf{z}_i^{(k)}|\hat{\mathbf{y}}_i, \mathbf{x})} \end{aligned}$$

IWD does not rely on a separate pre-trained model, though it significantly slows down the decoding speed. The detailed comparison of these three decoding methods is provided in §4.2.

3.7 Discussion

Different from the architecture proposed in Ziegler and Rush (2019), the architecture of FlowSeq is not using any autoregressive flow (Kingma et al., 2016; Papamakarios et al., 2017), yielding a truly non-autoregressive model with efficient generation. Note that the FlowSeq remains non-autoregressive even if we use an RNN in the architecture because RNN is only used to encode a complete sequence of codes and all the input tokens can be fed into the RNN in parallel. This makes it possible to use highly-optimized implementations of RNNs such as those provided by cuDNN.[3] Thus while RNNs do experience some drop in speed, it is less extreme than that experienced when using autoregressive models.

4 Experiments

4.1 Experimental Setups

Translation Datasets We evaluate FlowSeq on three machine translation benchmark datasets: WMT2014 DE-EN (around 4.5M sentence pairs), WMT2016 RO-EN (around 610K sentence pairs) and a smaller dataset IWSLT2014 DE-EN (around 150K sentence pairs). We use scripts from fairseq (Ott et al., 2019) to preprocess WMT2014 and IWSLT2014, where the preprocessing steps follow Vaswani et al. (2017) for WMT2014. We use the data provided in Lee et al. (2018) for WMT2016. For both WMT datasets, the source and target languages share the same set of BPE embeddings while for IWSLT2014 we use separate embeddings. During training, we filter out sentences longer than 80 for WMT dataset and 60 for IWSLT, respectively.

[2] We experimented with other methods such as mean-pooling or taking the last hidden state and found no major difference in our experiments

Table 1: BLEU scores on three MT benchmark datasets for FlowSeq with argmax decoding and baselines with purely non-autoregressive decoding method. The first and second block are results of models trained w/w.o. knowledge distillation, respectively.

Modules and Hyperparameters We implement the encoder, decoder and posterior networks with standard (unmasked) Transformer layers (Vaswani et al., 2017). For WMT datasets, the encoder consists of 6 layers, and the decoder and posterior are composed of 4 layers, and 8 attention heads. and for IWSLT, the encoder has 5 layers, and decoder and posterior have 3 layers, and 4 attention heads. The prior flow consists of 3 scales with the number of steps $[48, 48, 16]$ from bottom to top. To dissect the impact of model dimension on translation quality and speed, we perform experiments on two versions of FlowSeq with $d_{model}/d_{hidden} = 256/512$ (base) and $d_{model}/d_{hidden} = 512/1024$ (large). More model details are provided in Appendix B.

Optimization Parameter optimization is performed with the Adam optimizer (Kingma and Ba, 2014) with $\beta = (0.9, 0.999)$ and $\epsilon = 1e-6$. Each mini-batch consist of 2048 sentences. The learning rate is initialized to $5e-4$, and exponentially decays with rate 0.999995. The gradient clipping cutoff is 1.0. For all the FlowSeq models, we apply 0.1 label smoothing and averaged the 5 best checkpoints to create the final model.

At the beginning of training, the posterior network is randomly initialized, producing noisy supervision to the prior. To mitigate this issue, we first set the weight of the KL term in ELBO to zero for 30,000 updates to train the encoder, decoder and posterior networks. Then the KL weight linearly increases to one for another 10,000 updates, which we found essential to accelerate training and achieve stable performance.

FlowSeq-large (NPD $n = 30$)	25.31	30.68	32.20	32.84

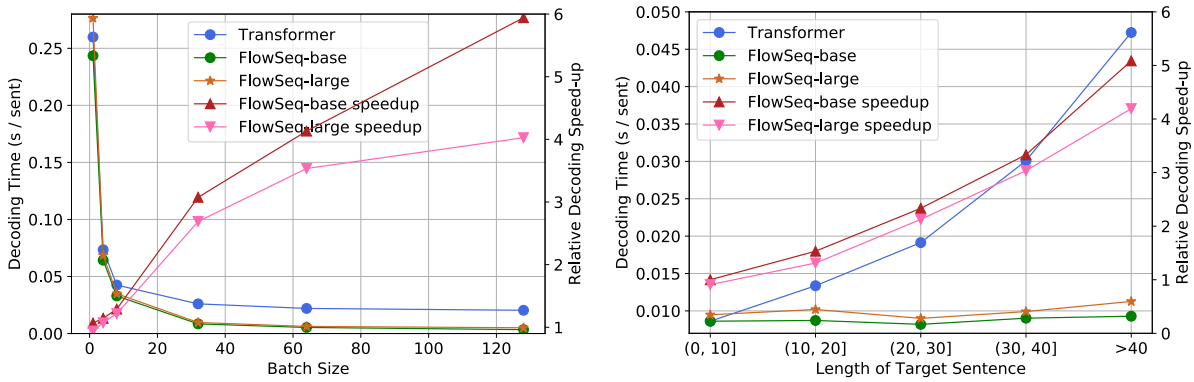

Table 2: BLEU scores on two WMT datasets of models using advanced decoding methods. The first block are Transformer-base (Vaswani et al., 2017). The second and the third block are results of models trained w/w.o. knowledge distillation, respectively. $n = l \times r$ is the total number of candidates for rescoring.

Knowledge Distillation Previous work on non-autoregressive generation (Gu et al., 2018; Ghazvininejad et al., 2019) has used translations produced by a pre-trained autoregressive NMT model as the training data, noting that this can significantly improve the performance. We analyze the impact of distillation in § 4.2.

4.2 Main Results

We first conduct experiments to compare the performance of FlowSeq with strong baseline models, including NAT w/ Fertility (Gu et al., 2018), NAT-IR (Lee et al., 2018), NAT-REG (Wang et al., 2019), LV NAR (Shu et al., 2019), CTC Loss (Libovický and Helcl, 2018), and CMLM (Ghazvininejad et al., 2019).

Table 1 provides the BLEU scores of FlowSeq with argmax decoding, together with baselines with purely non-autoregressive decoding methods that generate output sequence in one parallel pass. The first block lists results of models trained on raw data, while the second block are results using

(a) batch size

(b) target length

Figure 4: The decoding speed of Transformer (batched, beam size 5) and FlowSeq on WMT14 EN-DE test set (a) w.r.t different batch sizes (b) bucketed by different target sentence lengths (batch size 32).

knowledge distillation. Without using knowledge distillation, FlowSeq base model achieves significant improvement (more than 9 BLEU points) over CMLM-base and LV NAR. It demonstrates the effectiveness of FlowSeq on modeling the complex interdependence in target languages.

Towards the effect of knowledge distillation, we can mainly obtain two observations: i) Similar to the findings in previous work, knowledge distillation still benefits the translation quality of FlowSeq. ii) Compared to previous models, the benefit of knowledge distillation on FlowSeq is less significant, yielding less than 3 BLEU improvement on WMT2014 DE-EN corpus, and even no improvement on WMT2016 RO-EN corpus. The reason might be that FlowSeq does not rely much on knowledge distillation to alleviate the multi-modality problem.

Table 2 illustrates the BLEU scores of FlowSeq and baselines with advanced decoding methods such as iterative refinement, IWD and NPD rescoring. The first block in Table 2 includes the baseline results from autoregressive Transformer. For the sampling procedure in IWD and NPD, we sampled from a reduced-temperature model (Kingma and Dhariwal, 2018) to obtain high-quality samples. We vary the temperature within $\{0.1, 0.2, 0.3, 0.4, 0.5, 1.0\}$ and select the best temperature based on the performance on development sets. The analysis of the impact of sampling temperature and other hyper-parameters on samples is in § 4.4. For FlowSeq, NPD obtains better results than IWD, showing that FlowSeq still falls behind auto-regressive Transformer on model data distributions. Comparing with CMLM (Ghazvininejad et al., 2019) with 10 iterations of refinement, which is a contemporaneous work that achieves state-of-the-art translation performance, FlowSeq obtains competitive performance on both WMT2014 and WMT2016 corpora, with only slight degradation in translation quality. Leveraging iterative refinement to further improve the performance of FlowSeq has been left to future work.

4.3 Analysis on Decoding Speed

In this section, we compare the decoding speed (measured in average time in seconds required to decode one sentence) of FlowSeq at test time with that of the autoregressive Transformer model. We use the test set of WMT14 EN-DE for evaluation and all experiments are conducted on a single NVIDIA TITAN X GPU.

How does batch size affect the decoding speed? First, we investigate how different decoding batch size can affect the decoding speed. We vary the decoding batch size within $\{1, 4, 8, 32, 64, 128\}$. Figure. 4a shows that for both FlowSeq and Transformer decoding is faster when using a larger batch size. However, FlowSeq has much larger gains in the decoding speed w.r.t. the increase in batch size, gaining a speed up of 594% of base model and 403% of large model when using a batch size of 128. We hypothesize that this is because the operations in FlowSeq are more friendly to batching while the Transformer model with beam search at test time is less efficient in benefiting from batching.

How does sentence length affect the decoding speed? Next, we examine if sentence length is a major factor affecting the decoding speed. We bucket the test data by the target sentence length.

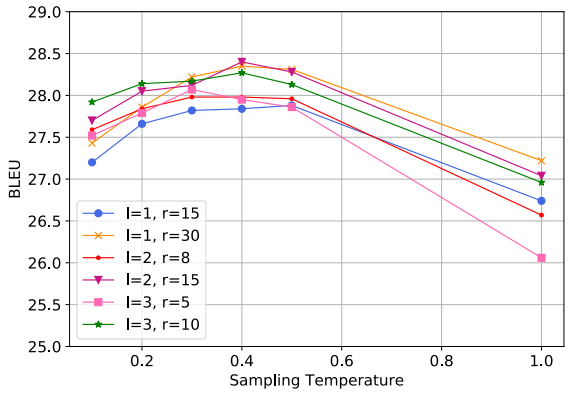

Figure 5: Impact of sampling hyperparameters on the rescoring BLEU on the dev set of WMT14 DE-EN. Experiments are performed with FlowSeq-base trained with distillation data. l is the number of length candidates. r is the number of samples for each length.

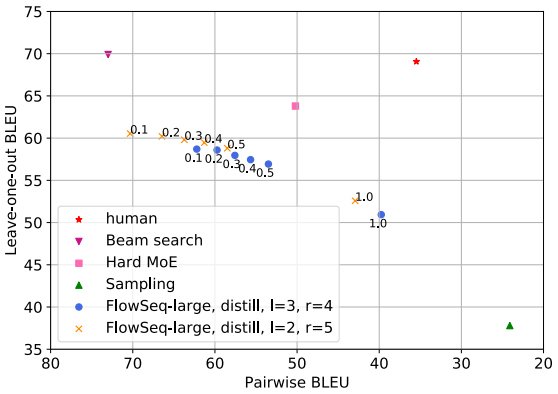

Figure 6: Comparisons of FlowSeq with human translations, beam search and sampling results of Transformer-base, and mixture-of-experts model (Hard MoE (Shen et al., 2019)) on the averaged leave-one-out BLEU score v.s pairwise-BLEU in descending order.

From Fig. 4b, we can see that as the sentence length increases, FlowSeq achieves almost constant decoding time while Transformer has a linearly increasing decoding time. The relative decoding speed up of FlowSeq versus Transformer linearly increases as the sequence length increases. The potential of decoding long sequences with constant time is an attractive property of FlowSeq.

4.4 Analysis of Rescoring Candidates

In Fig. 5, we analyze how different sampling hyperparameters affect the performance of rescoring. First, we observe that the number of samples r for each length is the most important factor. The performance is always improved with a larger sample size. Second, a larger number of length candidates does not necessarily increase the rescoring performance. Third, we find that a larger sampling temperature (0.3 - 0.5) can increase the diversity of translations and leads to better rescoring BLEU. However, the latent samples become noisy when a large temperature (1.0) is used.

4.5 Analysis of Translation Diversity

Following (Shen et al., 2019), we analyze the output diversity of FlowSeq. Shen et al. (2019) proposed pairwise-BLEU and BLEU computed in a leave-one-out manner to calibrate the diversity and quality of translation hypotheses. A lower pairwise-BLEU score implies a more diverse hypothesis set. And a higher BLEU score implies a better translation quality. We experiment on a subset of test set of WMT14-ENDE with ten references each sentence (Ott et al., 2018). In Fig. 6, we compare FlowSeq with other multi-hypothesis generation methods (ten hypotheses each sentence) to analyze how well the generation outputs of FlowSeq are in terms of diversity and quality. The right corner area of the figure indicates the ideal generations: high diversity and high quality. While FlowSeq still lags behind the autoregressive generations, by increasing the sampling temperature it provides a way of generating more diverse outputs while keeping the translation quality almost unchanged. More analysis of translation outputs and detailed results are provided in the Appendix D and E.

5 Conclusion

We propose FlowSeq, an efficient and effective model for non-autoregressive sequence generation by using generative flows. One potential direction for future work is to leverage iterative refinement techniques such as masked language models to further improve translation quality. Another exciting direction is to, theoretically and empirically, investigate the latent space in FlowSeq, hence providing deep insights of the model, even enhancing controllable text generation.

Compositional Generalization for Primitive Substitutions

Abstract

Compositional generalization is a basic mechanism in human language learning, but current neural networks lack such ability. In this paper, we conduct fundamental research for encoding compositionality in neural networks. Conventional methods use a single representation for the input sentence, making it hard to apply prior knowledge of compositionality. In contrast, our approach leverages such knowledge with two representations, one generating attention maps, and the other mapping attended input words to output symbols. We reduce the entropy in each representation to improve generalization. Our experiments demonstrate significant improvements over the conventional methods in five NLP tasks including instruction learning and machine translation. In the SCAN domain, it boosts accuracies from 14.0% to 98.8% in Jump task, and from 92.0% to 99.7% in TurnLeft task. It also beats human performance on a few-shot learning task. We hope the proposed approach can help ease future research towards human-level compositional language learning. Source code is available online[1].

1 Introduction

Humans learn language in a flexible and efficient way by leveraging *systematic compositionality*, the algebraic capacity to understand and produce large amount of novel combinations from known components (Chomsky, 1957; Montague, 1970). For example, if a person knows how to "step", "step twice" and "jump", then it is natural for the person to know how to "jump twice" (Figure 1). This compositional generalization is critical in human cognition (Minsky, 1986; Lake et al., 2017), and it helps humans learn language from a limited amount of data, and extend to unseen sentences.

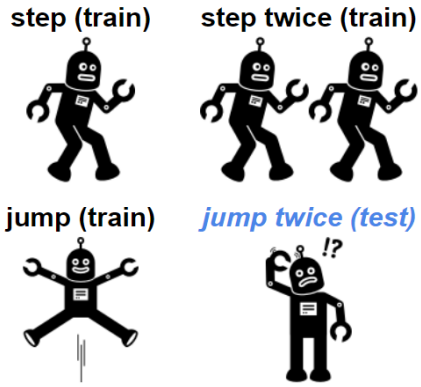

Figure 1: Problem illustration. If a person knows how to "step", "step twice" and "jump", then the person should know how to "jump twice". Although this is straightforward for humans, it remains an open problem to equip machines with such ability.

In recent years, deep neural networks have made many breakthroughs in various problems (LeCun et al., 2015; Krizhevsky et al., 2012; Yu and Deng, 2012; He et al., 2016; Wu and et al, 2016). However, there have been critiques that neural networks do not have compositional generalization ability (Fodor and Pylyshyn, 1988; Marcus, 1998; Fodor and Lepore, 2002; Marcus, 2003; Calvo and Symons, 2014).

Our observation is that conventional methods use a single representation for the input sentence, which makes it hard to apply prior knowledge of compositionality. In contrast, our approach leverages such knowledge with two representations, one generating attention maps, and the other mapping attended input words to output symbols. We reduce each of their entropies to improve generalization. This mechanism equips the proposed approach with the ability to understand and produce novel combinations of known words and to achieve compositional generalization.

In this paper, we focus on compositinal gener-

jump	JUMP
run after run left	LTURN RUN RUN
look left twice and look opposite right	LTURN LOOK LTURN LOOK RTURN RTURN LOOK
jump twice after look	LOOK JUMP JUMP
turn left after **jump** twice	JUMP JUMP LTURN
jump right twice after **jump** left twice	LTURN JUMP LTURN JUMP RTURN JUMP RTURN JUMP

(a) Jump task. In training, "jump" only appears as a single command. In test, it appears with other words.

turn left	LTURN
run thrice and jump right	RUN RUN RUN RTURN JUMP
look left thrice after run left twice	LTURN RUN LTURN RUN LTURN LOOK LTURN LOOK LTURN LOOK
look twice and **turn left** twice	LOOK LOOK LTURN LTURN
turn left thrice and **turn left**	LTURN LTURN LTURN LTURN
turn left twice after look opposite right twice	RTURN RTURN LOOK RTURN RTURN LOOK LTURN LTURN

(b) TurnLeft task. In training, "turn left" only appears as a single command. In test, it appears with other words.

Table 1: Examples of SCAN input commands (left) and output action sequences (right). Upper section is for training, and lower section is for testing. These tasks are difficult because "jump" (or "turn left") does not appear with other words in training.

alization for primitive substitutions. We use Primitive tasks in the SCAN (Lake and Baroni, 2018) dataset—a set of command-action pairs—for illustrating how the proposed algorithm works. In a Primitive task, training data include a single primitive command, and other training commands do not contain the primitive. In test data, the primitive appears together with other words. A primitive can be "jump" (Jump, see Table 1a for examples) or "turn left" (TurnLeft, see Table 1b for examples). These tasks are difficult because "jump" (or "turn left") does not appear with other words in training. A model without compositionality handling will easily learn a wrong rule such as "any sentence with more than one word should not contain the 'jump' action". This rule fits the training data perfectly, and may reduce training loss quickly, but it does not work for test data. In contrast, our algorithm can process a sentence such as "jump twice after look" correctly by generating a sequence of three attention maps from function representation and then a sequence of actions "LOOK JUMP JUMP" by decoding the primitive representation from the attended command words (see the example in Figure 2).

Besides Primitive tasks, we experiment on more tasks in SCAN and other datasets for instruction learning and machine translation. We also introduce an extension of SCAN dataset, dubbed as SCAN-ADJ, which covers additional compositional challenges. Our experiments demonstrate that the proposed method achieves significant improvements over the conventional methods. In the SCAN domain, it boosts accuracies from 14.0% to 98.8% in Jump task, and from 92.0% to 99.7% in TurnLeft task. It also beats human performance on a few-shot learning task.

2 Approach

In compositional generalization tasks, we consider both input X and output Y have multiple components that are not labeled in data. Suppose input has two components X_1 and X_2, and output has two components Y_1 and Y_2, then we can define compositional generalization probabilistically as follows. In training,

$$P(X_1) > 0 \text{ and } P(X_2) > 0,$$
$$P(X_1, X_2) = 0,$$
$$P(Y_1|X_1) \text{ and } P(Y_2|X_2) \text{ are high.}$$

In test,

$$P(X_1, X_2) > 0,$$
$$P(Y_1, Y_2|X_1, X_2) \text{ is predicted high.}$$

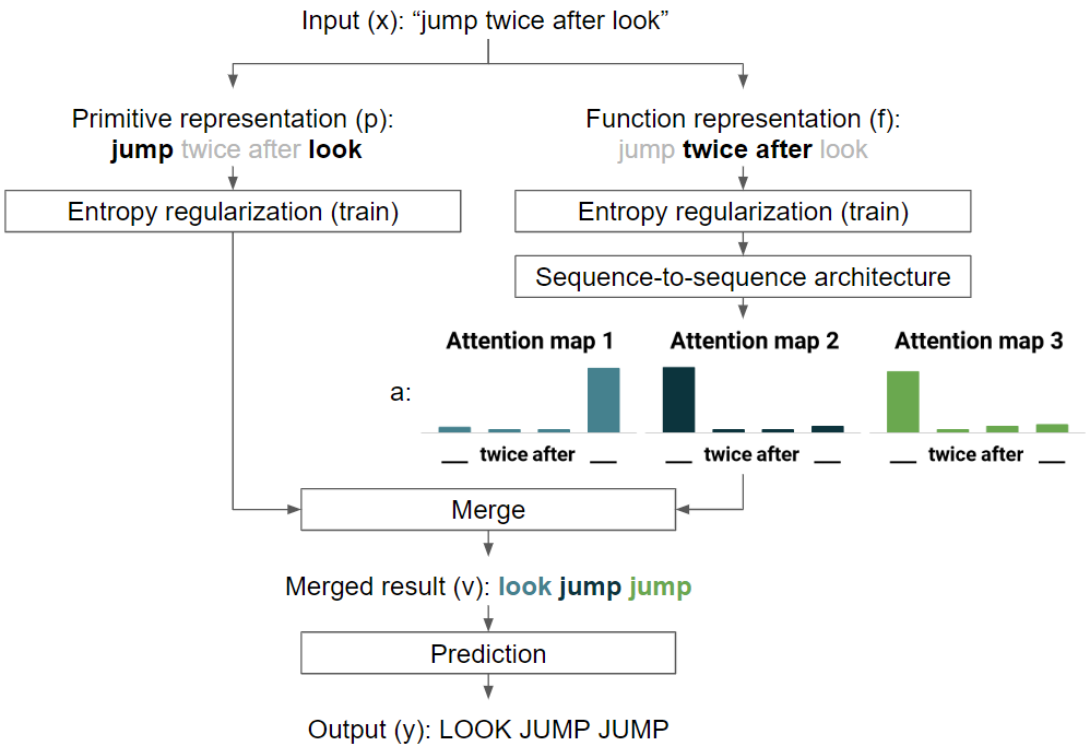

Figure 2: Illustration of network structure and flowchart for the proposed approach. Input is a sequence of words. Output is a sequence of actions. An input sentence is converted to primitive representation (left) and function representation (right). In training, we reduce entropy of two representations. Function representation is used to generate a sequence of attention maps. Each attention map is used to select an embedding from primitive representation to output an action.

We expect this is possible when we have prior knowledge that Y_1 depends only on X_1 and Y_2 depends only on X_2.

$$P(Y_1|X_1, X_2, Y_2) = P(Y_1|X_1),$$
$$P(Y_2|X_1, X_2, Y_1) = P(Y_2|X_2).$$

Therefore, with chain rule,

$$P(Y_1, Y_2|X_1, X_2) = P(Y_1|X_1)P(Y_2|X_2).$$

Since $P(Y_1|X_1)$ and $P(Y_2|X_2)$ are both high in training, if they generalize well, they should also be high in test, so that their product should be high in test. To make $P(Y_1|X_1)$ and $P(Y_2|X_2)$ generalize well at test time, we hope to remove unnecessary information from X_1 and X_2. In other words, we want X_1 (X_2) to be a *minimal sufficient statistic* for Y_1 (Y_2).

In this task, input X is a word sequence, and output Y is an action sequence. We consider X has two types of information: which actions are present (X_1), and how the actions should be ordered (X_2). Y is constructed by the output action types (Y_1), and output action order (Y_2). Y_1 depends only on X_1, and Y_2 depends only on X_2.

Based on these arguments, we design the algorithm with the following objectives:

(i) Learn two representations for input.

(ii) Reduce entropy in each representation.

(iii) Make output action type depend only on one representation, and output action order depend only on the other.

Figure 2 shows an illustration of flowchart for the algorithm design (see Algorithm 1 for details). We describe it further here.

2.1 Input and Output

Input x contains a sequence of n words, where each input word is from an input vocabulary of size U. Output y contains a sequence of m action symbols, where each output symbol is from an output vocabulary of size V. Both vocabularies contain an end-of-sentence symbol which appears at the end of x and y, respectively. The model output $\hat{y}$ is a prediction for y. Both input words and

Algorithm 1 Proposed approach. Decoder in Seq2seq architecture is autoregressive model here.

Require: V: output vocabulary size
k_p, k_f: embedding sizes
α: 1 for training, 0 for inference
Seq2seq: seq2seq architecture
Input: x: sequence of one-hot representations
Output: $\hat{y}$: sequence of distributions

for $i = 1, \ldots, n$ **do**
  $p_i = \text{Emb}_p(x_i) \in \mathbb{R}^{k_p}$
  $f_i = \text{Emb}_f(x_i) \in \mathbb{R}^{k_f}$
end for
$p' = p + \alpha\epsilon_p \in \mathbb{R}^{n \times k_p}, \epsilon_p \sim \mathcal{N}(0, I)$
$f' = f + \alpha\epsilon_f \in \mathbb{R}^{n \times k_f}, \epsilon_f \sim \mathcal{N}(0, I)$
decoder = Seq2seq(f')
for $j = 1, \ldots,$ max length **do**
  $b_j = \text{decoder.next}() \in \mathbb{R}^n$
  $a_j = \text{Softmax}(b_j) \in \mathbb{R}^n$
  $v_j = a_j p' \in \mathbb{R}^{k_p}$
  $l_j = f_{\text{predict}}(v_j) \in \mathbb{R}^V$
  $\hat{y}_j = \text{Softmax}(l_j) \in (0, 1)^V$
  break if $\operatorname{argmax} \hat{y}_j$ is <EOS>
end for

output symbols are in one-hot representation, i.e.,

$$x = [x_1, \ldots, x_n] \in \{0, 1\}^{U \times n},$$
$$y = [y_1, \ldots, y_m] \in \{0, 1\}^{V \times m}.$$

2.2 Primitive Representation and Function Representation

To achieve objective (i), we use two representations for an input sentence. For each word, we use two word embeddings for primitive and functional information.

$$p_i = \text{Emb}_p(x_i) \in \mathbb{R}^{k_p},$$
$$f_i = \text{Emb}_f(x_i) \in \mathbb{R}^{k_f}.$$

We concatenate p_i and f_i to form the primitive representation and functional representation for the entire input sequence, i.e.,

$$p = [p_1, \ldots, p_n] \in \mathbb{R}^{k_p \times n},$$
$$f = [f_1, \ldots, f_n] \in \mathbb{R}^{k_f \times n}.$$

2.3 Entropy Regularization

To achieve objective (ii), we reduce the amount of information, or entropy of the representations. We do this by regularizing the L_2 norm of the representations, and then adding noise to them. This reduces channel capacities, and thus entropy for the representations.

$$p' = p + \alpha\epsilon_p \in \mathbb{R}^{k_p \times n}, \epsilon_p \sim \mathcal{N}(0, I),$$
$$f' = f + \alpha\epsilon_f \in \mathbb{R}^{k_f \times n}, \epsilon_f \sim \mathcal{N}(0, I),$$
$$\mathcal{L}_{\text{regularize}} = L_2(p) + L_2(f).$$

Here, α is the weight for noise. Noise is helpful in training, but is not necessary in inference. Therefore, we set α as a hyper-parameter for training and $\alpha = 0$ for inference.

2.4 Combine Representations and Generate Output

To achieve objective (iii), we want to make the output action types depend only on primitive representation, and the output action order depend only on function representation. Attention mechanism is a good fit for this purpose. We generate a sequence of attention maps from function representation, and use each attention map to get the weighted average of primitive representation to predict the corresponding action.

We use attention mechanism with sequence-to-sequence architectures to aggregate representations in the following ways: (1) Instead of outputting a sequence of logits on vocabulary, we emit a sequence of logits for attention maps on input positions (see Figure 2 for an example). (2) During decoding for autoregressive models, we do not use the previous output symbol as input for the next symbol prediction, because output symbols contain information for primitives. We still use the last decoder hidden state as input. Non-autoregressive models should not have this problem. (3) We end decoding when the last output is end-of-sentence symbol.

More specifically, we feed the function representation, f', to a sequence-to-sequence neural network for decoding. At each step j, we generate $b_j \in \mathbb{R}^n$ from the decoder, and use Softmax to obtain the attention map, a_j. With attention maps, we extract primitives and generate output symbols. To do that, we compute the weighted average, v_j, on noised primitive representations, p', with attention, a_j. Then we feed it to a one-layer fully connected network, f_{predict}. We use Softmax to compute the output distribution, $\hat{y}_j$. The decoding ends when

$\text{argmax}\, \hat{y}_j$ is end-of-sentence symbol.

$$
\begin{aligned}
a_j &= \text{Softmax}(b_j) \in \mathbb{R}^n, \\
v_j &= a_j p' \in \mathbb{R}^{k_p}, \\
l_j &= f_{\text{predict}}(v_j) \in \mathbb{R}^V, \\
\hat{y}_j &= \text{Softmax}(l_j) \in (0,1)^V.
\end{aligned}
$$

2.5 Loss

We use the cross entropy of y and $\hat{y}$ as the prediction loss, $\mathcal{L}_{\text{prediction}}$, and the final loss, $\mathcal{L}$, is the combination of prediction loss and entropy regularization loss (Section 2.3). λ is the regularization weight.

$$
\begin{aligned}
\mathcal{L}_{\text{prediction}} &= \sum_{j=1}^{m} \text{CrossEntropy}(y_j, \hat{y}_j), \\
\mathcal{L} &= \mathcal{L}_{\text{prediction}} + \lambda \mathcal{L}_{\text{regularize}}.
\end{aligned}
$$

3 Experiments

We ran experiments on instruction learning and machine translation tasks. Following Lake and Baroni (2018), we used sequence-level accuracy as the evaluation metric. A prediction is considered correct if and only if it perfectly matches the reference. We ran all experiments five times with different random seeds for the proposed approach, and report mean and standard deviation (note that their sum may exceed 100%). The Appendix contains details of models and experiments.

3.1 SCAN Primitive Tasks

We used the SCAN dataset (Lake and Baroni, 2018), and targeted the Jump and TurnLeft tasks. For the Jump and TurnLeft tasks, "jump" and "turn left" appear only as a single command in their respective training sets, but they appear with other words at test time (see Table 1a and Table 1b, respectively).

We used multiple state-of-the-art or representative methods as baselines. L&B methods are from Lake and Baroni (2018), RNN and GRU are best models for each task from Bastings et al. (2018). Ptr-Bahdanau and Ptr-Luong are best methods from Kliegl and Xu (2018).

We applied the same configuration for all tasks (see Appendix A for details). The result in Table 2 shows that the proposed method boosts accuracies from 14.0% to 98.8% in Jump task, and from 92.0% to 99.7% in TurnLeft task.

Method	Jump	TurnLeft
L&B best overall	0.1	90.0
L&B best	1.2	90.3
RNN +Attn -Dep	2.7 ± 1.7	92.0 ± 5.8
GRU +Attn	12.5 ± 6.6	59.1 ± 16.8
Ptr-Bahdanau	3.3 ± 0.7	91.7 ± 3.6
Ptr-Loung	14.0 ± 2.8	66.0 ± 5.6
Proposed	**98.8** ± **1.4**	**99.7** ± **0.4**

Table 2: Test accuracy (mean ± std %) for SCAN Primitive tasks. L&B is from Lake and Baroni (2018). RNN and GRU are best models for each task from Bastings et al. (2018). Ptr-Bahdanau and Ptr-Loung are from Kliegl and Xu (2018). The proposed method achieves significantly higher performance than baselines.

3.2 SCAN Template-matching

We also experimented with the SCAN template-matching task. The task and dataset descriptions can be found in Loula et al. (2018b). There are four tasks in this dataset: *jump around right*, *primitive right*, *primitive opposite right* and *primitive around right*. Each requires compositional generalization. Please see Appendix B for more details.

Table 3 summarizes the results on SCAN template-matching tasks. The baseline methods are from Loula et al. (2018b). The proposed method achieves significantly higher performance than baselines in all tasks. This experiment demonstrates that the proposed method has better compositional generalization related to template matching.

Condition	Baseline	Proposed
Jump around	98.4 ± 0.5	**100.0** ± **0.0**
Prim.	23.5 ± 8.1	**99.7** ± **0.5**
Prim. opposite	47.6 ± 17.7	**89.3** ± **5.5**
Prim. around	2.5 ± 2.7	**83.2** ± **13.2**

Table 3: Test accuracy (mean ± std %) for SCAN template-matching tasks. The baseline methods are from Loula et al. (2018b). The proposed method achieves significantly higher performance than baselines.

3.3 Primitive and Functional Information Exist in One Word

One limitation of SCAN dataset is that each word contains either primitive or functional information, but not both. For example, "jump" contains only primitive information, but no functional information. On the other hand, "twice" contains only

functional information, but no primitive information. However, in general cases, each word may contain both primitive and functional information. The functional information of a word usually appears as a word class, such as part of speech. For example, in translation, a sequence of part-of-speech tags determines the output sentence structure (functional), and primitive information of each input word determines the corresponding output word.

To explore whether the proposed method works when a word contains both primitive and functional information, we introduced an extension of SCAN dataset for this purpose. We designed a task SCAN-ADJ to identify adjectives in a sentence, and place them according to their word classes. The adjectives have three word classes: color, size, and material. The word classes appear in random order in input sentences, but they should be in a fixed order in the expected outputs. For example, an input sentence is "push blue metal small cube", and the expected output is "PUSH CUBE SMALL BLUE METAL". For another input "push small metal blue cube", the expected output is the same. Please see Table 9 in Appendix for more details. To evaluate compositional generalization, similarly to the SCAN setting, the material, rubber, appears only with other fixed words in training "push small yellow rubber sphere". However, it appears with other combinations of words at test time. To solve this compositionality problem, a model needs to capture functional information of adjectives to determine their word classes, and primitive information to determine the specific value of the word in its class.

The experiment results are shown in Table 4. The proposed method achieves 100.0% ($\pm$0.0%) accuracy, and as a comparison, a standard LSTM model can only achieves 2.1% ($\pm$2.2%) accuracy. Please refer to Appendix C for more details. This indicates that the proposed method can extend beyond simple structures in the SCAN dataset to flexibly adapt for words containing both primitive and functional information.

Method	Accuracy
Baseline	2.1 $\pm$ 2.2
Proposed	**100.0** $\pm$ **0.0**

Table 4: Test accuracy (mean $\pm$ std %) for SCAN-ADJ task.

3.4 Few-shot Learning Task

We also probed the few-shot learning ability of the proposed approach using the dataset from Lake et al. (2019). The dataset is shown in Appendix Figure 4. In the few-shot learning task, human participants learned to produce abstract outputs (colored circles) from instructions in pseudowords. Some pseudowords are primitive corresponding to a single output symbol, while others are function words that process items. A primitive ("zup") is presented only in isolation during training and evaluated with other words during test. Participants are expected to learn each function from limited number of examples, and to generalize in a compositional way.

We trained a model from all training samples and evaluate them on both Primitive test samples and all test samples. We used a similar configuration to SCAN task (Appendix D) to train the model, and compared the results with baselines of human performance and conventional sequence to sequence model (Lake et al., 2019). In the Primitive task, we used the average over sample accuracies to estimate the accuracy of human participants, and the upper bound accuracy of the sequence-to-sequence model.

Table 5 shows the results that the proposed method achieves high accuracy on both test sets. In the Primitive task, the proposed method beats human performance. This indicates that the proposed method is able to learn compositionality from only a few samples. To our best knowledge, this is the first time machines beat humans in a few-shot learning task, and it breaks the common sense that humans are better than machines in learning from few samples.

Method	Primitive	All
Human	82.8	84.3
Baseline	$\leq$ 3.1	2.5
Proposed	**95.0** $\pm$ **6.8**	76.0 $\pm$ 5.5

Table 5: Test accuracy (mean $\pm$ std %) for few-shot learning task. The baseline methods are from Lake et al. (2019). The proposed method achieves performance superior to humans in Primitive task.

3.5 Compositionality in Machine Translation

We also investigated whether the proposed approach is applicable to other sequence-to-sequence problems. As an example, we ran a proof-of-

concept machine translation experiment. We consider the English-French translation task from Lake and Baroni (2018). To evaluate compositional generalization, for a word "dax", the training data contains only one pattern of sentence pair ("I am daxy", "je suis daxiste"), but test data contains other patterns. Appendix E provides more details on dataset and model configuration.

Compared to the baseline method, the proposed method increases sentence accuracy from 12.5% to 62.5% (±0.0%). Further, we find that other predicted outputs are even correct translations though they are different from references (Table 10 in Appendix). If we count them as correct, the adjusted accuracy for the proposed approach is 100.0% (±0.0%). This experiment shows that the proposed approach has promise to be applied to real-world tasks.

Method	Accuracy
Baseline	12.5
Proposed	**62.5**

Table 6: Test accuracy (%) for machine translation task. The baseline method is from Lake and Baroni (2018).

4 Discussion

Our experiments show that the proposed approach results in significant improvements on many tasks. To better understand why the approach achieves these gains, we designed the experiments on SCAN domain to address the following questions: (1) Does the proposed model work in the expected way that humans do (i.e., visualization)? (2) What factors of the proposed model contribute to the high performance (i.e., ablation study)? (3) Does the proposed method influence other tasks?

4.1 Visualization of Attention Maps

To investigate whether the proposed method works in the expected way, we visualize the model's attention maps. These maps indicate whether the sequence-to-sequence model produces correct position sequences.

We visualized these activations for one sample from the Jump task and one from the TurnLeft task (Figure 3). In both figures, the horizontal dimension is the input sequence position, and the vertical dimension is the output position. Each figure is an $m \times n$ matrix, where m and n are output and input lengths, including end-of-sentence symbols. The rows correspond to m attention maps, where the ith row corresponds to the attention map for the ith output ($i = 1, ..., m$). The values in each row sum to 1.

We expect that each attention map attends on the corresponding primitive input word. For the output end-of-sentence symbol, we expect that the attention is on the input end-of-sentence symbol. The visualization in both figures align with our expectation. When the model should replicate some input word multiple times, it correctly attends on that word in a manner similar to human understanding. In the Jump example, "jump" appears twice in the input. As expected, the generated attentions are on the second instance for the early part of the output, and on the first instance for the later part of the output. Similarly, the attentions are correct in the TurnLeft example with two words of "left".

These visualizations demonstrate that the models work in the way we expected, correctly parsing the organization of complex sentences. We have successfully encoded our prior knowledge to the network, and enabled compositional generalization.

4.2 Ablation Study

We conducted an ablation study to find out what factors of the proposed approach contribute to its high performance. The main idea of the proposed approach is to use two representations and corresponding entropy regularization. Also, for autoregressive decoders, the approach does not use the last output rather than feeding it as input for decoding. Based on that, we designed the following ablation experiments.

(A) Use only one representation.

(B) Do not use primitive entropy regularization.

(C) Do not use function entropy regularization.

(D) Both B and C.

(E) Use the last output as input in decoding.

The results are summarized in Table 7. Experiment A shows that the accuracy drops in both tasks, indicating that two representations are important factor in the proposed approach. When there are two representations, we find the following from experiments B, C and D. For Jump task, the accuracy drops in these three experiments, indicating both primitive and function entropy regularization are necessary. For TurnLeft task, the accuracy drops only in D, but not in B or C, indicating at least one of entropy regularization is necessary. The dif-

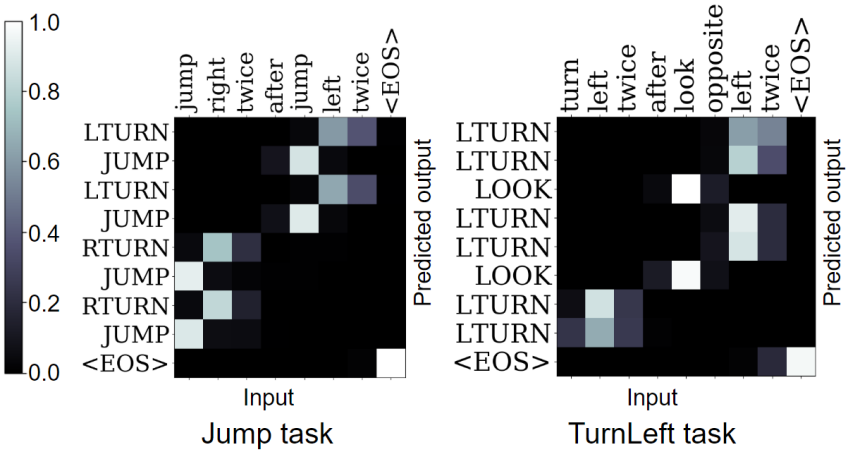

Figure 3: Visualization of attention maps. The figures show that the model solves the problem in a manner similar to humans, identifying the appropriate input to map to each output position. This indicates that the generalizable prior knowledge is successfully encoded in the network.

ference between Jump and TurnLeft tasks may be because TurnLeft is relatively easier than the Jump task. Both "turn" and "left" individually appear with other words in training data, but "jump" does not. Experiment E shows that we should not use last output as next input during decoding.

	Experiment	Jump	TurnLeft
A	one rep.	63.4 ± 36.3	55.7 ± 31.5
B	no prim reg.	79.8 ± 11.3	99.9 ± 0.1
C	no func reg.	29.5 ± 36.3	99.6 ± 1.0
D	both B and C	14.1 ± 23.2	64.0 ± 40.0
E	decoder input	68.8 ± 15.0	50.3 ± 48.8
	Proposed	98.8 ± 1.4	99.7 ± 0.4

Table 7: Ablation: Test accuracy (mean ± std %) for SCAN Primitive tasks.

4.3 Influence on Other Tasks

To find whether the proposed method affects other tasks, we conducted experiments on Simple and Length tasks in SCAN dataset. In Simple task, test data follows the same distribution as the training data. In Length task, test commands have longer action sequences than training. Simple task does not require compositional generalization, and Length task requires syntactic generalization, so that they are beyond the scope of this paper. However, we still hope to avoid big performance drop from previous methods. We used the same configuration (Appendix A) as SCAN Primitive tasks. The results in Table 8 confirms that the approach does not significantly reduce performance in other tasks.

Methods	Simple	Length
L&B best overall	99.7	13.8
L&B best	99.8	20.8
RNN +Attn -Dep	100.0 ± 0.0	11.7 ± 3.2
GRU +Attn	100.0 ± 0.0	18.1 ± 1.1
Ptr-Bahdanau	-	13.4 ± 0.8
Ptr-Loung	-	16.8 ± 0.9
Proposed	99.9 ± 0.0	20.3 ± 1.1

Table 8: Test accuracy (mean ± std %) for other SCAN tasks. L&B is from Lake and Baroni (2018). RNN and GRU are best models for each task from Bastings et al. (2018). Ptr-Bahdanau and Ptr-Loung are from Kliegl and Xu (2018). The proposed method does not significantly reduce performance.

5 Related Work

Human-level compositional learning has been an important open challenge (Yang et al., 2019), although there is a long history of studying compositionality in neural networks. Classic view (Fodor and Pylyshyn, 1988; Marcus, 1998; Fodor and Lepore, 2002) considers conventional neural networks lack systematic compositionality. With the breakthroughs in sequence to sequence neural networks for NLP and other tasks, such as RNN (Sutskever et al., 2014), Attention (Xu et al., 2015), Pointer Network (Vinyals et al., 2015), and Transformer (Vaswani et al., 2017), there are more contemporary attempts to encode compositionality in sequence to sequence neural networks.

There has been exploration on compositionality in neural networks for systematic behaviour (Wong and Wang, 2007; Brakel and Frank, 2009), count-

ing ability (Rodriguez and Wiles, 1998; Weiss et al., 2018) and sensitivity to hierarchical structure (Linzen et al., 2016). Recently, many related tasks (Lake and Baroni, 2018; Loula et al., 2018a; Liška et al., 2018; Bastings et al., 2018; Lake et al., 2019) and methods (Bastings et al., 2018; Loula et al., 2018a; Kliegl and Xu, 2018; Chang et al., 2018) using a variety of RNN models and attention mechanism have been proposed. These methods make successful generalization when the difference between training and test commands are small.

Our research further enhances the capability of neural networks for compositional generalization with two representations of a sentence and entropy regularization. The proposed approach has shown promising results in various tasks of instruction learning and machine translation.

Compositionality is also important and applicable in multimodal problems, including AI complete tasks like Image Captioning (Karpathy and Fei-Fei, 2015), Visual Question Answering (Antol et al., 2015), Embodied Question Answering (Das et al., 2018). These tasks requires compositional understanding of sequences (captions or questions), where our method could help. Compositional understanding could also help enable better transfer over time that could improve continual learning (Zenke et al., 2017; Aljundi et al., 2018; Chaudhry et al., 2019) ability of AI models.

6 Conclusions

This work is a fundamental research for encoding compositionality in neural networks. Our approach leverages prior knowledge of compositionality by using two representations, and by reducing entropy in each representation. The experiments demonstrate significant improvements over the conventional methods in five NLP tasks including instruction learning and machine translation. In the SCAN domain, it boosts accuracies from 14.0% to 98.8% in Jump task, and from 92.0% to 99.7% in TurnLeft task. It also beats human performance on a few-shot learning task. To our best knowledge, this is the first time machines beat humans in a few-shot learning task. This breaks the common sense that humans have advantage over machines in learning from few samples. We hope this work opens a path to encourage machines learn quickly and generalize widely like humans do, and to make machines more helpful in various tasks.

Abstract

Pronoun resolution is a major area of natural language understanding. However, large-scale training sets are still scarce, since manually labelling data is costly. In this work, we introduce WIKICREM (Wikipedia CoREferences Masked) a large-scale, yet accurate dataset of pronoun disambiguation instances. We use a language-model-based approach for pronoun resolution in combination with our WIKICREM dataset. We compare a series of models on a collection of diverse and challenging coreference resolution problems, where we match or outperform previous state-of-the-art approaches on 6 out of 7 datasets, such as GAP, DPR, WNLI, PDP, WINOBIAS, and WINOGENDER. We release our model to be used off-the-shelf for solving pronoun disambiguation.

1 Introduction

Pronoun resolution, also called coreference or anaphora resolution, is a natural language processing (NLP) task, which aims to link the pronouns with their referents. This task is of crucial importance in various other NLP tasks, such as information extraction (Nakayama, 2019) and machine translation (Guillou, 2012). Due to its importance, pronoun resolution has seen a series of different approaches, such as rule-based systems (Lee et al., 2013) and end-to-end-trained neural models (Lee et al., 2017; Liu et al., 2019). However, the recently released dataset GAP (Webster et al., 2018) shows that most of these solutions perform worse than naïve baselines when the answer cannot be deduced from the syntax. Addressing this drawback is difficult, partially due to the lack of large-scale challenging datasets needed to train the data-hungry neural models.

As observed by Trinh and Le (2018), language models are a natural approach to pronoun resolution, by selecting the replacement for a pronoun that forms the sentence with highest probability. Additionally, language models have the advantage of being pre-trained on a large collection of unstructured text and then fine-tuned on a specific task using much less training data. This procedure has obtained state-of-the-art results on a series of natural language understanding tasks (Devlin et al., 2018).

In this work, we address the lack of large training sets for pronoun disambiguation by introducing a large dataset that can be easily extended. To generate this dataset, we find passages of text where a personal name appears at least twice and mask one of its non-first occurrences. To make the disambiguation task more challenging, we also ensure that at least one other distinct personal name is present in the text in a position before the masked occurrence. We instantiate our method on English Wikipedia and generate the Wikipedia CoREferences Masked (WIKICREM) dataset with 2.4M examples, which we make publicly available for further usage[1]. We show its value by using it to fine-tune the BERT language model (Devlin et al., 2018) for pronoun resolution.

To show the usefulness of our dataset, we train several models that cover three real-world scenarios: (1) when the target data distribution is completely unknown, (2) when training data from the target distribution is available, and (3) the transductive scenario, where the unlabeled test data is available at the training time. We show that fine-tuning BERT with WIKICREM consistently improves the model in each of the three scenarios, when evaluated on a collection of 7 datasets. For example, we outperform the state-of-

[1]The code can be found at https://github.com/vid-koci/bert-commonsense.

the-art approaches on GAP (Webster et al., 2018), DPR (Rahman and Ng, 2012), and PDP (Davis et al., 2017) by 5.9%, 8.4%, and 12.7%, respectively. Additionally, models trained with WIKICREM show increased performance and reduced bias on the gender diagnostic datasets WINOGENDER (Rudinger et al., 2018) and WINOBIAS (Zhao et al., 2018).

2 Related Work

There are several large and commonly used benchmarks for coreference resolution, such as (Pradhan et al., 2012; Schäfer et al., 2012; Ghaddar and Langlais, 2016). However, Webster et al. (2018) argue that a high performance on these datasets does not correlate with a high accuracy in practice, because examples where the answer cannot be deduced from the syntax (we refer to them as *hard pronoun resolution*) are underrepresented. Therefore, several hard pronoun resolution datasets have been introduced (Webster et al., 2018; Rahman and Ng, 2012; Rudinger et al., 2018; Davis et al., 2017; Zhao et al., 2018; Emami et al., 2019). However, they are all relatively small, often created only as a test set.

Therefore, most of the pronoun resolution models that address hard pronoun resolution rely on little (Liu et al., 2019) or no training data, via unsupervised pre-training (Trinh and Le, 2018; Radford et al., 2019). Another approach involves using external knowledge bases (Emami et al., 2018; Fähndrich et al., 2018), however, the accuracy of these models still lags behind that of the aforementioned pre-trained models.

A similar approach to ours for unsupervised data generation and language-model-based evaluation has been recently presented in our previous work (Kocijan et al., 2019). We generated MASKEDWIKI, a large unsupervised dataset created by searching for repeated occurrences of nouns. However, training on MASKEDWIKI on its own is not always enough and sometimes makes a difference only in combination with additional training on the DPR dataset (called WSCR) (Rahman and Ng, 2012). In contrast, WIKICREM brings a much more consistent improvement over a wider range of datasets, strongly improving models' performance even when they are not fine-tuned on additional data. As opposed to our previous work (Kocijan et al., 2019), we evaluate models on a larger collection of test sets, showing the usefulness of WIKICREM beyond the Winograd Schema Challenge.

Moreover, a manual comparison of WIKICREM and MASKEDWIKI (Kocijan et al., 2019) shows a significant difference in the quality of the examples. We annotated 100 random examples from MASKEDWIKI and WIKICREM. In MASKEDWIKI, we looked for examples where masked nouns can be replaced with a pronoun, and only in 7 examples, we obtained a natural-sounding and grammatically correct sentence. In contrast, we estimated that 63% of the annotated examples in WIKICREM form a natural-sounding sentence when the appropriate pronoun is inserted, showing that WIKICREM consists of examples that are much closer to the target data. We highlight that pronouns are not actually inserted into the sentences and thus none of the examples sound unnatural. This analysis was performed to show that WIKICREM consists of examples with data distribution closer to the target tasks than MASKEDWIKI.

3 The WIKICREM Dataset

In this section, we describe how we obtained WIKICREM. Starting from English Wikipedia[2], we search for sentences and pairs of sentences with the following properties: at least two distinct personal names appear in the text, and one of them is repeated. We do not use pieces of text with more than two sentences to collect concise examples only. Personal names in the text are called "candidates". One non-first occurrence of the repeated candidate is masked, and the goal is to predict the masked name, given the correct and one incorrect candidate. In case of more than one incorrect candidate in the sentence, several datapoints are constructed, one for each incorrect candidate.

We ensure that the alternative candidate appears before the masked-out name in the text, in order to avoid trivial examples. Thus, the example is retained in the dataset if:

(a) the repeated name appears after both candidates, all in a single sentence; or

(b) both candidates appear in a single sentence, and the repeated name appears in a sentence directly following.

Examples where one of the candidates appears in the same sentence as the repeated name, while the

[2] https://dumps.wikimedia.org/enwiki/ dump id: enwiki-20181201

other candidate does not, are discarded, as they are often too trivial.

We illustrate the procedure with the following example:

*When asked about **Adams**' report, **Powell** found many of the statements to be inaccurate, including a claim that **Adams** first surveyed an area that was surveyed in 1857 by Joseph C.*

The second occurrence of "Adams" is masked. The goal is to determine which of the two candidates ("Adams","Powell") has been masked out. The masking process resembles replacing a name with a pronoun, but the pronoun is not inserted to keep the process fully unsupervised and error-free.

We used the Spacy Named Entity Recognition library[3] to find the occurrences of names in the text. The resulting dataset consists of $2,438,897$ samples. $10,000$ examples are held out to serve as the validation set. Two examples from our dataset can be found on Figure 1.

Gina arrives and she is furious with Denise for not protecting Jody from Kingsley, as `[MASK]` *was meant to be the parent.*
Candidates: Gina, **Denise**

When Ashley falls pregnant with Victor's child, Nikki is diagnosed with cancer, causing Victor to leave `[MASK]`*, who secretly has an abortion.*
Candidates: Ashley, Nikki

Figure 1: WIKICREM examples. Correct answers are given in bold.

We note that our dataset contains hard examples. To resolve the first example, one needs to understand that Denise was assigned a task and "meant to be the parent" thus refers to her. To resolve the second example, one needs to understand that having an abortion can only happen if one falls pregnant first. Since both candidates have feminine names, the answer cannot be deduced just on the common co-occurrence of female names and the word "abortion".

We highlight that our example generation method, while having the advantage of being unsupervised, also does not give incorrect signals, since we know the ground truth reference.

Even though WIKICREM and GAP both use text from English Wikipedia, they produce differing examples, because their generating processes differ. In GAP, passages with pronouns are collected and the pronouns are manually annotated, while WIKICREM is generated by masking names that appear in the text. Even if the same text is used, different masking process will result in different inputs and outputs, making the examples different under the transductive hypothesis.

WIKICREM statistics. We analyze our dataset for gender bias. We use the Gender guesser library[4] to determine the gender of the candidates. To mimic the analysis of pronoun genders performed in the related works (Webster et al., 2018; Rudinger et al., 2018; Zhao et al., 2018), we observe the gender of the correct candidates only. There were 0.8M "male" or "mostly_male" names and 0.42M "female" or "mostly_female" names, the rest were classified as "unknown". The ratio between female and male candidates is thus estimated around 0.53 in favour of male candidates. We will see that this gender imbalance does not have any negative impact on bias, as shown in Section 6.2.

However, our unsupervised generating procedure sometimes yields examples where the correct answer cannot be deduced given the available information, we refer to these as *unsolvable examples*. To estimate the percentage of unsolvable examples, we manually annotated 100 randomly selected examples from the WIKICREM dataset. In order to prevent guessing, the candidates were not visible to the annotators. For each example, we asked them to state whether it was solvable or not, and to answer the solvable examples. In 100 examples, we found 18 unsolvable examples and achieved 95.1% accuracy on the rest, showing that the annotation error rate is tolerable. These annotations can be found in Appendix A.

However, as shown in Section 6.2, training on WIKICREM alone does not match the performance of training on the data from the target distribution. The data distribution of WIKICREM differs from the data distribution of the datasets for evaluation. If we replace the `[MASK]` token with a pronoun instead of the correct candidate, the resulting sentence sometimes sounds unnatural and would not occur in a human-written text. On the annotated 100 examples, we estimated the percentage of natural-sounding sentences to be 63%. While the these sentences are not incorrect, the

[3] https://spacy.io/usage/linguistic-features#named-entities

[4] https://pypi.org/project/gender-guesser/

distribution of the training data differ from the target data.

4 Model

We use a simple language-model-based approach to anaphora resolution to show the value of the introduced dataset. In this section, we first introduce BERT (Devlin et al., 2018), a language model that we use throughout this work. In the second part, we describe the utilization of BERT and the fine-tuning procedures employed.

4.1 BERT

The Bidirectional Encoder Representations from Transformers (BERT) language model is based on the transformer architecture (Vaswani et al., 2017). We choose this model due to its strong language-modeling abilities and high performance on several NLU tasks (Devlin et al., 2018).

BERT is initially trained on two tasks: next sentence prediction and masked token prediction. In the next sentence prediction task, the model is given two sentences and is asked to predict whether the second sentence follows the first one. In the masked token prediction task, the model is given text with approximately 15% of the input tokens masked, and it is asked to predict these tokens. The details of the pre-training procedure can be found in Devlin et al. (2018).

In this work, we only focus on the masked token prediction. We use the PyTorch implementation of BERT[5] and the pre-trained weights for BERT-large released by Devlin et al. (2018).

4.2 Pronoun Resolution with BERT

This section introduces the procedure for pronoun resolution used throughout this work. Let S be the sentence with a pronoun that has to be resolved. Let $\mathbf{a}$ be a candidate for pronoun resolution. The pronoun in S is replaced with a `[MASK]` token and used as the input to the model to compute the log-probability $\log \mathbb{P}(\mathbf{a}|S)$. If $\mathbf{a}$ consists of more than one token, the same number of `[MASK]` tokens is inserted into S, and the log-probability $\log \mathbb{P}(\mathbf{a}|S)$ is computed as the average of log-probabilities of all tokens in $\mathbf{a}$.

The candidate-finding procedures are dataset-specific and are described in Section 6. Given a sentence S and several candidates $\mathbf{a}_1, \ldots, \mathbf{a}_n$, we select the candidate $\mathbf{a}_i$ with the largest $\log \mathbb{P}(\mathbf{a}_i|S)$.

4.3 Training

When training the model, the setup is similar to testing. We are given a sentence with a name or a pronoun masked out, together with two candidates. The goal is to determine which of the candidates is a better fit. Let $\mathbf{a}$ be the correct candidate, and $\mathbf{b}$ be an incorrect candidate. Following our previous work (Kocijan et al., 2019) we minimize the negative log-likelihood of the correct candidate, while additionally imposing a max-margin between the log-likelihood of the correct and incorrect terms. We observe that this combined loss consistently yields better results on validation sets of all experiments than negative log-likelihood or max-margin loss on their own.

$$\mathcal{L} = -\log \mathbb{P}(\mathbf{a}|S) + \\ +\alpha \cdot \max(0, \log \mathbb{P}(\mathbf{b}|S) - \log \mathbb{P}(\mathbf{a}|S) + \beta), \quad (1)$$

where α and β are hyperparameters controlling the influence of the max-margin loss term and the margin between the log-likelihood of the correct and incorrect candidates, respectively.

The hyperparameter settings for fine-tuning BERT on WIKICREM were the same as by Devlin et al. (2018), except for the learning rate and introduced constants α and β. For our hyperparameter search, we used learning rate $lr \in \{3 \cdot 10^{-5}, 1 \cdot 10^{-5}, 5 \cdot 10^{-6}, 3 \cdot 10^{-6}\}$ and hyperparameters $\alpha \in \{5, 10, 20\}$, $\beta \in \{0.1, 0.2, 0.4\}$ with grid search. The hyperparameter search is performed on a subset of WIKICREM with 10^5 datapoints to reduce the searching time. We compare the influence of hyperparameters on the validation set of WIKICREM dataset. The best validation score was achieved with $lr = 1 \cdot 10^{-5}$, $\alpha = 10$, and $\beta = 0.2$. We used batches of size 64.

Since WIKICREM is large and one epoch takes around two days even when parallelized on 8 Tesla P100 GPUs, we only fine-tune BERT on WIKICREM for a single epoch. We note that better results may be achieved with further fine-tuning and improved hyperparameter search.

Fine-tuning on other datasets is performed in the same way as training except for two differences. Firstly, in fine-tuning, the model is trained for 30 epochs due to the smaller size of datasets. Secondly, we do not sub-sample the training set for hyperparameter search. We validate the model

[5] https://github.com/huggingface/pytorch-pretrained-BERT

after every epoch, retaining the model that performs best on the WIKICREM validation set.

5 Evaluation Datasets

We now introduce the 7 datasets that were used to evaluate the models. We decide not to use the CONLL2012 and WINOCOREF (Pradhan et al., 2012; Peng et al., 2015) datasets, because they contain more general coreference examples than just pronouns. We did not evaluate on the KNOWREF dataset (Emami et al., 2019), since it was not yet publicly available at the time of writing.

GAP. GAP (Webster et al., 2018) is a collection of $4,454$ passages from Wikipedia containing ambiguous pronouns. It focuses on the resolution of personal pronouns referring to human names and has a $1:1$ ratio between masculine and feminine pronouns. In addition to the overall performance on the dataset, each model is evaluated also on its performance on the masculine subset (F_1^M), feminine subset (F_1^F), and its gender bias ($\frac{F_1^F}{F_1^M}$). The best performance was exhibited by the Referential Reader (Liu et al., 2019), a GRU-based model with additional external memory cells.

For each example, two candidates are given with the goal of determining whether they are the referent. In approximately 10% of the training examples, none of the candidates are correct. When training on the GAP dataset, we discard such examples from the training set. We do not discard any examples from the validation or test set.

When testing the model, we use the Spacy NER library to find all candidates in the sentence. Since the GAP dataset mainly contains examples with human names, we only retain named entities with the tag PERSON. We observe that in 18.5% of the test samples, the Spacy NER library fails to extract the candidate in question, making the answer for that candidate "FALSE" by default, putting our models at disadvantage. Because of this, 7.25% of answers are always false negatives, and 11.25% are always true negatives, regardless of the model. Taking this into account, we compute that the maximal F_1-score achievable by our models is capped at 91.1%.

We highlight that, when evaluating our models, we are stricter than previous approaches (Liu et al., 2019; Webster et al., 2018). While they count the answer as "correct" if the model returns a substring of the correct answer, we only accept the full answer. The aforementioned models return the exact location of the correct candidate in the input sentence, while our approach does not. This strictness is necessary, because a substring of a correct answer could be a substring of several answers at once, making it ambiguous.

WSC. The Winograd Schema Challenge (Levesque et al., 2011) is a hard pronoun resolution challenge inspired by the example from Winograd (1972):

The city councilmen refused the demonstrators a permit because ***they*** *[feared/advocated] violence.*
Question: Who [feared/advocated] violence?
Answer: the city councilmen / the demonstrators

A change of a single word in the sentence changes the referent of the pronoun, making it very hard to resolve. An example of a Winograd Schema must meet the following criteria (Levesque et al., 2011):

1. Two entities appear in the text.
2. A pronoun or a possessive adjective appears in the sentence and refers to one of the entities. It would be grammatically correct if it referred to the other entity.
3. The goal is to find the referent of the pronoun or possessive adjective.
4. The text contains a "special word". When switched for the "alternative word", the sentence remains grammatically correct, but the referent of the pronoun changes.

The Winograd Schema Challenge is specifically made up from challenging examples that require commonsense reasoning for resolution and should not be solvable with statistical analysis of co-occurence and association.

We evaluate the models on the collection of 273 problems used for the 2016 Winograd Schema Challenge (Davis et al., 2017), also known as WSC273. The best known approach to this problem uses the BERT language model, fine-tuned on the DPR dataset (Kocijan et al., 2019).

DPR. The Definite Pronoun Resolution (DPR) corpus (Rahman and Ng, 2012) is a collection of problems that resemble the Winograd Schema Challenge. The criteria for this dataset have been relaxed, and it contains examples that might not require commonsense reasoning or examples where the "special word" is actually a whole phrase. We remove 6 examples in the DPR training set that overlap with the WSC dataset. The

dataset was constructed manually and consists of 1316 training and 564 test samples after we removed the overlapping examples. The best result on the dataset was reported by Peng et al. (2015) using external knowledge sources and integer linear programming.

PDP. The Pronoun Disambiguation Problem (PDP) is a small collection of 60 problems that was used as the first round of the Winograd Schema Challenge in 2016 (Davis et al., 2017). Unlike WSC, the examples do not contain a "special word", however, they do require commonsense reasoning to be answered. The examples were manually collected from books. Despite its small size, there have been several attempts at solving this challenge (Fähndrich et al., 2018; Trinh and Le, 2018), the best result being held by the Marker Passing algorithm (Fähndrich et al., 2018).

WNLI. The Winograd Natural Language Inference (WNLI) is an inference task inspired by the Winograd Schema Challenge and is one of the 9 tasks on the GLUE benchmark (Wang et al., 2019). WNLI examples are obtained by rephrasing Winograd Schemas. The Winograd Schema is given as the "premise". A "hypothesis" is constructed by repeating the part of the premise with the pronoun and replacing the pronoun with one of the candidates. The goal is to classify whether the hypothesis follows from the premise.

A WNLI example obtained by rephrasing one of the WSC examples looks like this:

Premise: *The city councilmen refused the demonstrators a permit because they feared violence.*
Hypothesis: *The demonstrators feared violence.*
Answer: true / **false**

The WNLI dataset is constructed manually. Since the WNLI training and validation sets overlap with WSC, we use the WNLI test set only. The test set of WNLI comes from a separate source and does not overlap with any other dataset.

The currently best approach transforms examples back into the Winograd Schemas and solves them as a coreference problem (Kocijan et al., 2019). Following our previous work (Kocijan et al., 2019), we reverse the process of example generation in the same way. We automatically detect which part of the premise has been copied to construct the hypothesis. This locates the pronoun that has to be resolved, and the candidate in question. All other nouns in the premise are treated as alternative candidates. We find nouns in the premise with the Stanford POS tagger (Manning et al., 2014).

WINOGENDER. WINOGENDER (Rudinger et al., 2018) is a dataset that follows the WSC format and is aimed to measure gender bias. One of the candidates is always an occupation, while the other is a participant, both selected to be gender neutral. Examples intentionally contain occupations with strong imbalance in the gender ratio. Participant can be replaced with the neutral "someone", and three different pronouns (he/she/they) can be used. The aim of this dataset is to measure how the change of the pronoun gender affects the accuracy of the model.

Our models mask the pronoun and are thus not affected by the pronoun gender. They exhibit no bias on this dataset by design. We mainly use this dataset to measure the accuracy of different models on the entire dataset. According to Rudinger et al. (2018), the best performance is exhibited by Durrett and Klein (2013) when used on the male subset of the dataset. We use this result as the baseline.

WINOBIAS. Similarly to the WINOGENDER dataset, WINOBIAS (Zhao et al., 2018) is a WSC-inspired dataset that measures gender bias in the coreference resolution algorithms. Similarly to WINOGENDER, it contains instances of occupations with high gender imbalance. It contains 3,160 examples of Winograd Schemas, equally split into validation and test set. The test set examples are split into 2 types, where examples of type 1 are "harder" and should not be solvable using the analysis of co-occurrence, and examples of type 2 are easier. Additionally, each of these subsets is split into anti-stereotypical and pro-stereotypical subsets, depending on whether the gender of the pronoun matches the most common gender in the occupation. The difference in performance between pro- and anti-stereotypical examples shows how biased the model is. The best performance is exhibited by Lee et al. (2017) and Durrett and Klein (2013), as reported by Zhao et al. (2018).

6 Evaluation

We quantify the impact of WIKICREM on the introduced datasets.

6.1 Experiments

We train several different models to evaluate the contribution of the WIKICREM dataset in different real-world scenarios. In **Scenario A**, no information of the target distribution is available. In **Scenario B**, the distribution of the target data is known and a sample of training data from the target distribution is available. Finally, **Scenario C** is the transductive scenario where the unlabeled test samples are known in advance. All evaluations on the GAP test-set are considered to be Scenario C, because BERT has been pre-trained on the English Wikipedia and has thus seen the text in the GAP dataset at the pre-training time.

We describe the evaluated models below.

BERT. This model, pretrained by Devlin et al. (2018), is the starting point for all models and serves as the soft baseline for Scenario A.

BERT_WIKIRAND. This model serves as an additional baseline for Scenario A and aims to eliminate external factors that might have worked against the performance of BERT. To eliminate the effect of sentence lengths, loss function, and the percentage of masked tokens during the training time, we generate the RANDOMWIKI dataset. It consists of random passages from Wikipedia and has the same sentence-length distribution and number of datapoints as WIKICREM. However, the masked-out word from the sentence is selected randomly, while the alternative candidate is selected randomly from the vocabulary. BERT is then trained on this dataset in the same way as BERT_WIKICREM, as described in Section 4.3.

BERT_WIKICREM. BERT, additionally trained on WIKICREM. Its evaluation on non-GAP datasets serves as the evaluation of WIKICREM under Scenario A.

BERT_DPR. BERT, fine-tuned on DPR. We hold out 10% of the DPR train set (131 examples) to use them as the validation set. All datasets, other than GAP, were inspired by the Winograd Schema Challenge and come from a similar distribution. We use this model as the baseline for Scenario B.

BERT_WIKICREM_DPR. This model is obtained by fine-tuning BERT_WIKICREM on DPR using the same split as for BERT_DPR. It serves as the evaluation of WIKICREM under Scenario B.

BERT_GAP_DPR. This model serves as an additional comparison to the BERT_WIKICREM_DPR model. It is obtained by fine-tuning BERT_GAP on the DPR dataset.

BERT_GAP. This model is obtained by fine-tuning BERT on the GAP dataset. It serves as the baseline for Scenario C, as explained at the beginning of Section 6.1.

BERT_WIKICREM_GAP. This model serves as the evaluation of WIKICREM for Scenario C and is obtained by fine-tuning BERT_WIKICREM on GAP.

BERT_ALL. This model is obtained by fine-tuning BERT on all the available data from the target datasets at once. Combined GAP-train and DPR-train data are used for training. The model is validated on the GAP-validation set and the WINOBIAS-validation set separately. Scores on both sets are then averaged to obtain the validation performance. Since both training sets and both validation sets have roughly the same size, both tasks are represented equally.

BERT_WIKICREM_ALL. This model is obtained in the same way as the BERT_ALL model, but starting from BERT_WIKICREM instead.

6.2 Results

The results of the evaluation of the models on the test sets are shown in Table 1. We notice that additional training on WIKICREM consistently improves the performance of the models in all scenarios and on most tests. Due to the small size of some test sets, some of the results are subject to deviation. This especially applies to PDP (60 test samples) and WNLI (145 test samples).

We observe that BERT_WIKIRAND generally performs worse than BERT, with GAP and PDP being notable exceptions. This shows that BERT is a strong baseline and that improved performance of BERT_WIKICREM is not a consequence of training on shorter sentences or with different loss function. BERT_WIKICREM consistently outperforms both baselines on all tests, showing that WIKICREM can be used as a standalone dataset.

We observe that training on the data from the target distribution improves the performance the most. Models trained on GAP-train usually show more than a 20% increase in their F_1-score on GAP-test. Still, BERT_WIKICREM_GAP shows

	Transductive scenario							
	GAP F_1	GAP F_1^F	GAP F_1^M	Bias $\frac{F_1^F}{F_1^M}$	DPR	WSC	WNLI

Table 1: Evaluation of trained models on all test sets. GAP and WINOBIAS (abbreviated WB) are additionally split into subsets, as introduced in Section 5. Double lines in the table separate results from three different scenarios: when no training data is available, when additional training data exists, and the transductive scenario. The table is further split into sections separated with single horizontal lines. Each section contains a model that has been trained on WIKICREM and models that have not been. The best result in each section is in bold. The best overall result is underlined. Scores on GAP are measured as F_1-scores, while the performance on other datasets is given in accuracy. The source of each SOTA is listed in Section 5.

a consistent improvement over BERT_GAP on all subsets of the GAP test set. This confirms that WIKICREM works not just as a standalone dataset, but also as an additional pre-training in the transductive scenario.

Similarly, BERT_WIKICREM_DPR outperforms BERT_DPR on the majority of tasks, showing the applicability of WIKICREM to the scenario where additional training data is available. However, good results of BERT_GAP_DPR show that additional training on a manually constructed dataset, such as GAP, can yield similar results as additional training on WIKICREM. The reason behind this difference is the impact of the data distribution. GAP, DPR, and WIKICREM contain data that follows different distributions which strongly impacts the trained models. This can be seen when we fine-tune BERT_GAP on DPR to obtain BERT_GAP_DPR, as the model's performance on GAP-test drops by 8.2%. WIKICREM's data distribution strongly differs from the test sets' as described in Section 3.

However, the best results are achieved when all available data is combined, as shown by the models BERT_ALL and BERT_WIKICREM_ALL. BERT_WIKICREM_ALL achieves the highest performance on GAP, DPR, WNLI, and WINOBIAS among the models, and sets the new state-of-the-art result on GAP, DPR, and WINOBIAS. The new state-of-the-art result on the WINOGENDER dataset is achieved by the BERT_WIKICREM_DPR model, while BERT_WIKICREM_ALL and BERT_GAP_DPR set the new state-of-the-art on the PDP dataset.

7 Conclusions and Future Work

In this work, we introduced WIKICREM, a large dataset of training instances for pronoun resolution. We use our dataset to fine-tune the BERT language model. Our results match or outperform state-of-the-art models on 6 out of 7 evaluated datasets.

The employed data-generating procedure can be further applied to other large sources of text to generate more training sets for pronoun resolution. In addition, both variety and size of the generated datasets can be increased if we do not restrict ourselves to personal names. We hope that the community will make use of our released WIKICREM dataset to further improve the pronoun resolution task.

Identifying and Explaining Discriminative Attributes

Armins Stepanjans and **André Freitas**

andre.freitas@manchester.ac.uk

Abstract

Identifying what is at the center of the meaning of a word and what discriminates it from other words is a fundamental natural language inference task. This paper describes an explicit word vector representation model (WVM) to support the identification of discriminative attributes. A core contribution of the paper is a quantitative and qualitative comparative analysis of different types of data sources and Knowledge Bases in the construction of explainable and explicit WVMs: (i) *knowledge graphs built from dictionary definitions*, (ii) *entity-attribute-relationships graphs derived from images* and (iii) *commonsense knowledge graphs*. Using a detailed quantitative and qualitative analysis, we demonstrate that these data sources have complementary semantic aspects, supporting the creation of explicit semantic vector spaces. The explicit vector spaces are evaluated using the task of discriminative attribute identification, showing comparable performance to the state-of-the-art systems in the task (F1-score = 0.69), while delivering full model transparency and explainability.

1 Introduction

Word-vector/embedding models (WVM) have emerged as first-class representations in contemporary Natural Language Processing (NLP) tasks due to their ability to capture semantic similarity and relatedness in an unsupervised and comprehensive manner (Turney and Pantel, 2010), (Freitas, 2015). Additionally, the simplicity entailed by the vector space abstraction makes it an engineering-friendly representation, also explaining its widespread adoption and use (Freitas, 2015). However, the latent features (dense vectors) at the center of most of the best-performing models have limited their application to two main uses: (i) computing semantic similarity and relatedness measures and (ii) performing vocabulary generalization as an input layer on Machine Learning (ML) models.

The identification of discriminative attributes (IDA), recently introduced by Krebs et al. (2018), can motivate the development of word vector models which can support types of operations with finer semantics, going beyond the computation of semantic similarity and relatedness scores, with potential applications in fine-grained semantic inference tasks.

Concretely, using the example provided by (Krebs et al., 2018), given a pair of target terms *apple* and *banana*, the IDA task seeks to answer if the term *red* is a discriminative attribute for apple in comparison to banana. According to Krebs et al. *semantic difference* is a ternary relation between two concepts (*apple*, *banana*) and a discriminative feature (*red*) that characterizes the former concept but not the latter.

This paper focuses on proposing an explicit (sparse) WVM for detecting and explaining discriminative attributes. The proposed explicit WVM provides a dimension of *explainability* while keeping the simplicity of the vector space representation model. This addition allows the model to provide a *justification* while addressing tasks such as the computation of discriminative attributes (Figure 1). The explicit nature of the model and its ability to compute the difference between the term pairs is the core proposed contribution (instead of the improvement of the F1-score for the task). Models with the ability to compute discriminative attributes can provide a representation paradigm which can support more fine-grained semantic inference tasks.

Another core contribution of this paper is a comprehensive quantitative and qualitative comparative analysis on how different types of data sources and Knowledge Bases (KBs) affect the

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4313–4322,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

construction of explainable and explicit WVMs. The IDA task requires a granular representation of the necessary and sufficient conditions associated with the definition of a target concept, many of these transcending lexicographic and encyclopaedic representations. In order to address this problem, we analyse three types of data sources: (i) *knowledge graphs built from dictionary definitions*, (ii) *entity-attribute-relationship graphs derived from images* and (iii) *commonsense knowledge graphs*. The goal behind using these models is twofold: (i) to provide an explainable, fine-grained word-vector model and (ii) to support the capture of lexical-semantic relations not captured in a representative fashion in regular corpora used in existing distributional models (which in most cases combine news, encyclopedic and literary discourse).

In summary, this paper focuses on the following contributions: **(i)** *The creation of a novel interpretable word vector model based on the combination of structured definitions and visual features for the IDA task* and **(ii)** *a detailed comparative, quantitative and qualitative evaluation of the semantic contribution of different types of data sources for explicit semantics*.

2 Related Work

In this section we group related work into two major categories: (i) approaches for the identification of discriminative attributes (IDA) and (ii) definition-based word vector space models.

Existing approaches have explored combinations of linguistic and data resources (WordNet, ConceptNet, Wikipedia), linguistic features (syntactic dependencies), sparse word vector models (JoBimText), dense word-vector (DWV) models (W2V, GloVe) and supervised/ unsupervised machine learning approaches (SVM, MLP, Ensemble Methods).

With regard to interpretability and explainability we can classify IDA approaches into three categories. *Frequency-based models over text-based features*, heavily relying on textual features and frequency-based methods (Gamallo, 2018; González et al., 2018) ; *ML over Textual features* (Dumitru et al., 2018; Sommerauer et al., 2018; King et al., 2018; Mao et al., 2018) and *ML over dense vectors and textual features* (Brychcín et al., 2018; Attia et al., 2018; Wu et al., 2018; Dumitru et al., 2018; Arroyo-Fernández et al., 2018; Speer and Lowry-Duda, 2018; Santus et al., 2018; Grishin, 2018; Zhou et al., 2018; Vinayan et al., 2018; Kulmizev et al., 2018; Zhang and Carpuat, 2018; Shiue et al., 2018). While the first category concentrates on models with higher interpretability, none of these models provide explanations.

Comparatively, this work focuses on the creation of an explicit word vector space model (EWVM), with an associated explanation, evaluating the performance of different types of lexico-semantic resources in the context of the task of identification of discriminative attributes (IDA).

3 Identifying and Explaining Discriminative Attributes

3.1 Problem Definition

This paper provides an explainable word vector space model (EWVM) for detecting whether a given term is a discriminative attribute or not with regard to a pair of reference terms as defined by Krebs et al. (2018). Given a triple $< t_p, t_c, t_f >$, t_f (*feature*) is considered discriminative if it is related to the first term t_p (*pivot*) to a significantly higher extent than it is related to the second term t_c (*comparison*), i.e. $t_f \in p(t_p) \wedge t_f \notin p(t_c)$, where the function $p(t)$ returns a set of properties associated with term t.

Additionally, beyond the identification of the discriminative attribute (i.e. assigning a value of true or false to the target term triple), this paper explores different notions of an explanation e assigned to the inference, which can be both human and machine interpretable.

3.2 Types of Discriminative Attributes

The nature of the semantic relationships expressed in the task of identifying discriminative attributes can guide the selection of the supporting target corpora. In this section, we propose a classification of *term-discriminative attribute relationships* into three dual categories: **Essential vs. Incidental**, **Sensory vs. Logical** and **Relative vs. Absolute**.

Essential vs. Incidental: p is an *essential* property of an object o just in case it is necessary that o has p, whereas p is an *incidental* property of an object o just in case o has p but it is possible that o lacks p. Example: `(cognac, whiskey, french)` is *essential* and `(nose, throat, perfume)` is *incidental*. The notion of Essential v. Incidental is similar to the logical notion of

Necessary and Sufficient Conditions, but rooted in the philosophical notion of essential and accidental properties, particularly, as defined by Robertson and Atkins (2018).

Sensory vs. Logical: p is a *sensory* property of an object o, in case p can be identified as a property of o exclusively through sensory information, whereas p is a *logical* property of an object o otherwise. Example: `(cheek, brow, red)` is *sensory* and `(grapes, wine, fruit)` is *logical*. The Sensory vs. Logical dual category is inspired by Hayes' Second Naïve Physics Manifesto, particularly, the distinction of 'three ways in which tokens can be attached to their denotations', where our notion of Sensory attribute corresponds to the second way ('some of the tokens can be attached to sensory and motor systems'), whereas our notion of Logical attribute corresponds to the remaining two ('tokens could be attached to the world through language' and 'token is a metatheory of some internal part of the theory') (Hayes, 1995).

Relative vs. Absolute: p is a *relative* property of an object o_a in relation to o_b just in case there exists an object o_c with the property p where p is not an attribute of o_a in relation to o_c. Whereas p is an *absolute* property of an object o_a in case there does not exist an object o_b with the property p where p is not an attribute of o_a when compared to o_b. Example: `(giraffe, ostrich, tall)` is *relative* and `(bat, butterfly, fur)` is *absolute*. The Relative vs. Absolute dual category follows Hayes' idea of 'intrinsic qualities (absolute) versus the distance between such qualities (relative)' (Hayes, 1995).

The classification scheme will guide the creation of the discriminative word vector model described in the next section.

4 Building Explicit Word Vector Space Models (EWVM)

Based on the dual categories identified in the previous section, a composition of three word vector space models is used to define *explicit word vector spaces* (EWVM), using three different types of corpora:

Definition-Based Model (DBM): Consists of a dictionary-style definition corpus. In the context of this work, WordNet and Wiktionary *natural language definitions* are used as data sources.

Visual Feature Model (VFM): Built using lexical graph descriptors for images, containing entities, attributes and relations, grounded on image bounding boxes.

Commonsense Knowledge Graph (CKG): Consists on the use of lexico-semantic knowledge graphs such as ConceptNet.

The following sections describe the construction of the EWVM.

4.1 Definition-Based Models (DBMs)

DBMs are built out of natural language term definitions (glosses) found either in dictionaries or filtered out of larger corpora (for example, Wikipedia contains many definitional sentences which can be isolated using lexico-syntactic patterns). The intuition behind the use of natural language definitions is twofold: first they are succinct descriptions of the necessary attributes associated to a concept and secondly they are abundant across domains and languages as dictionaries or definitions embedded within discourse. The latter point makes DBMs potentially transportable across languages and domains.

4.1.1 Model Construction

The representation behind the definition-based model is built by segmenting and categorizing natural language definitions into a set of semantic roles, a model which was introduced by (2016), (2018b), (2017). These roles aim to transform natural definitions into definition knowledge graphs, in order to facilitate natural language inference tasks (Silva et al., 2018b), (Silva et al., 2018a). The set of semantic roles includes: *supertype, differentia quality, differentia event, event location, purpose, accessory determiner, origin location*. Figure 1 (DBM) depicts an example of a classified definition.

The semantic roles are assigned by building a recurrent neural network (RNN) Definition Role Labeling (DRL) classifier using POS-tags, and pre-trained word vectors as features using the configuration of Silva et al. (2016). After the semantic roles are assigned, they are used as an input to build the supporting word vector space. For each definition segment, all tokens are lemmatized and stop-words removed. Afterwards, an inverse document frequency (idf) weighting scheme is applied, in order to support the computation of semantic similarity and relatedness scores within the model (despite not being the target use of the model). Ad-

ditionally, for each target term, we take into account its upward taxonomic chain, i.e. it inherits the definition attributes from the parent terms linked by the detected supertypes at the definition.

An inverted index is used to materialize the vector space. A workflow of the proposed model is depicted in Figure 1.

Algorithm 1 EDAM: Identifying discriminative attributes

D: Set of definitions d, containing predicates p^D and terms t
I: Set of images i, containing features with predicates $p^{[O,R,A]}$ and terms t
Query: $< t_p, t_c, t_a >$
Output: discriminative, explanation
if $(t_a, t_p) \in D \wedge (t_a, t_c) \notin D$ **then**
  discriminative $\leftarrow$ **true**
  explanation $\leftarrow$ template(t_p, t_c, t_a, d)
  return
end if
if $(t_a, t_p) \in I \wedge (t_a, t_c) \notin I$ **then**
  discriminative $\leftarrow$ **true**
  explanation $\leftarrow$ template(t_p, t_c, t_a, i)
  return
end if
discriminative $\leftarrow$ **false**

4.2 Visual Feature Model

Natural language definition corpora by design focus on *essential*, *logical* and *absolute* discriminative attribute types. However, discriminative attributes can also occur as *incidental*, *sensorial* or *relative* instances. Most distributional semantic models available today are built over journalistic, encyclopedic or narrative types of discourse. While incidental attributes can be captured as a second-order distributional phenomena, these corpora do not reflect explicit commonsense knowledge, in particular with regard to extra-linguistic phenomena.

Recent datasets introduced for the purpose of supporting image classification tasks, such as VisualGenome (Krishna et al., 2017) have provided multi-modal resources connecting sub-symbolic visual data types to symbolic-level categories. These datasets explore both modalities of visual and textual data.

VisualGenome is a dataset consisting of scenes (108,077 images) segmented into bounding boxes (5.4M) and annotated with a set of objects (3.8M), attributes (2.8M) and relationships (2.3M). Each image has an associated lexical-semantic model represented as a labeled graph. VisualGenome concentrates on the description of a large spectrum of commonsense scenes (not focusing on specific named entities). Common terms are: *man, person, tree, window, grass, table* (objects), *white, black, blueish, metallic, round* (attributes) and *along, inside, almost, above, ride* (relationships). Essentially, VisualGenome expresses facts about objects in commonsense scenes.

The commonsense nature of VisualGenome scenes and the *object-attribute* relations provide a foundation for covering visual attribute sets, potentially covering part of the *sensorial* attributes. Additionally, VisualGenome can be used to cover *incidental* attributes. VisualGenome can provide some level of support for identifying relative discriminative attributes, by focusing on features which are mediated by visual interpretation such as size (e.g. large, small). However, this work does not focus on a representation which can support the identification of relative attributes mediated by visual features.

4.2.1 Model Construction

The Visual Feature Model (VFM) also uses a sparse explicit semantic vector space representation as its basis. The representation targets the identification of sensorial and incidental discriminative attributes, with a supporting explanatory model.

The model is based on the construction of two vector spaces: one for indexing objects and attributes, *object-attribute* (OA) space associated with bounding boxes and the other for indexing relationships, i.e. the *scene-object-relationship* (SOR) space. The OA space supports the identification of the set of attributes directly associated with objects while the SOR space supports the capture of association relations between objects (*objectA* can inherit an attribute from *objectB*).

4.3 Commonsense Knowledge Graph

Dictionary definitions have a limited ability to express incidental relations among concepts due to their conciseness. For example, relations which express affordances (e.g. 'can be used for') are not typically expressed in dictionaries. Labeled visual datasets are limited in their domain coverage. We use commonsense knowledge graphs as a third data source aiming to fill this gap. For ex-

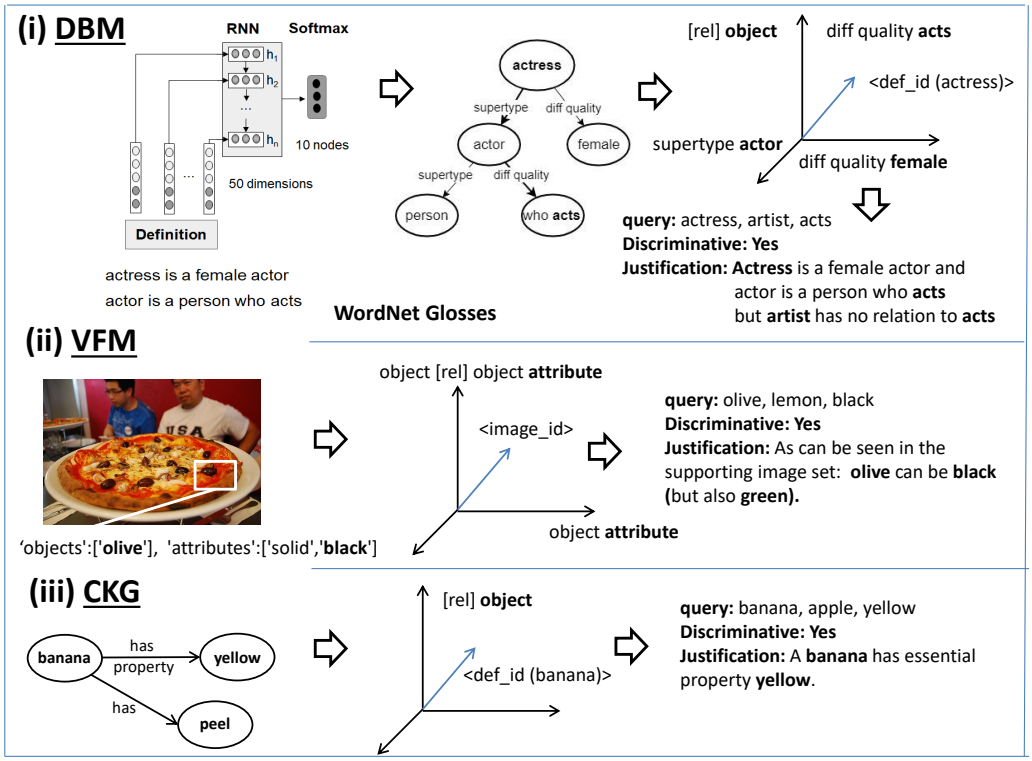

Figure 1: Sparse vector space representation and explanation of each model component.

ample Visual Genome contains 5.4 million region descriptions, whereas ConceptNet 5 contains 28 million relationships, captured using 39 relationship types.

4.3.1 Model Construction

The Commonsense Knowledge Graph is mapped into a sparse explicit semantic vector space. The model targets essential and logical attributes. The model is constructed by indexing each relationship using an idf weighting scheme, while ignoring negation (prefixed by Not).

4.4 Combined Model: Explainable Discriminative Attribute Model (EDAM)

The goal of the EDAM model is twofold: to maximize the quality of the discriminative attribute identification (IDA) and to maximize the underlying interpretability of the model. The EDAM model combines all three models by composing them into an interpretability hierarchy.

Each component of the EDAM model provides a different type of explanation, described below:
DBM/CKG: Consists of an attribute path between the natural language definitions, using the structure defined by the graphs. It provides an explanatory model at the intensional level.

VFM: Consists of the description of the attribute-pairs incidence and the supporting ground image-set. It provides an explanatory model at an extensional level.

The explanations are generated using a template-based approach as described in Algorithm 1. Details on the construction of the models and on the formalization of the explanations can be found online[1].

5 Evaluation

The proposed EDAM model was evaluated using the Semeval2018 Task 10 gold-standard on identifying discriminative attributes (Krebs et al., 2018). The dataset consists of 2340 triples (pivot, comparison and attribute) terms, classified as either discriminative (if the attribute is a discriminative feature of pivot) or not (otherwise). The evaluation aimed at answering the following questions:
Q1: Can the combination of the Definition-Based Model (DBM), the Visual Feature Model (VFM), and the Commonsense Knowledge Graphs (CKG) support the task of discriminative attribute identification?
Q2: What is the contribution of each component

[1] https://github.com/ab-10/Hawk

for each type of attribute category?

In the experiment, DBM was instantiated using WordNet 3.0 (only glosses structured into its semantic roles), VFM used VisualGenome 1.4 and CKG used ConceptNet 5. Table 2 depicts the outcome of the evaluation of the combined model.

In order to answer Q1, we compared our model to a set of reference systems in the task of discriminative attribute identification (see table 1. While EDAM performs lower than the state-of-the-art (F1-Score 0.76 vs 0.69), from existing approaches EDAM provides the only explainable model. Compared to EDAM, all the top performing models used distributional methods derived from large-scale corpora, while EDAM uses the combination of definition, visual features and commonsense structured KBs.

In order to answer Q2, we evaluated the performance of each component of the model for the six dual-categories. The goal is to provide a quantitative basis to understand the contribution of each component in addressing the task.

In order to perform the evaluation, we selected a stratified random subset of 230 triples and manually classified each triple with the dual categories. A triple can contain one or more categories associated with it. The annotation was performed by two independent annotators, which reached an inter-annotator agreement of 81%. For the final annotated dataset, triples which were not consensual were eliminated (i.e. the final dataset has a 100% inter-annotator agreement). The F1-score of the combined EDAM model and of each component for each category are shown in Table 2.

The list below summarizes the best component performance for each category:

- **Sensory:** DBM significantly outperforms the CKG and VFM model (75% over the second best).
- **Logical:** CKG significantly outperforms the other components (outperforms the second best component by 52%).
- **Relative:** DBM significantly outperforms the other components (100% over the second best).
- **Absolute:** CKG outperforms the second best component by 7%.
- **Essential:** CKG significantly outperforms DBM and VFM (100% over the second best).
- **Incidental:** DBM outperforms VFM by 154% and CKG by 48%.

The analysis shows the complementary nature of the models, where *DBM* contributes more for the identification of the sensory and incidental categories, while *CKG* contributes to the logical and essential categories. Additionally, *VFM* provides contributions across all categories and has smaller overlaps with other models. It is important to emphasize that the models are complementary at each dimension: the combined model (EDAM) significantly outperforms the best individual models at each dimension (as it can be observed at the gain row on Table 2).

In order to observe the proportion on which each model contributes (and conversely, the amount of redundancy for each model), we analyze for each individual model, the pairwise overlap, in terms of true positives and false positives (Table 3). The average redundancy between the individual models is low (average 11%), showing that all models contribute significantly to the performance of the combined model.

Table 4 further breaks down the true positives for each dimension, where we can analyse the pairwise contribution of each model for each attribute category. *The analysis shows that the overall redundancy between the three models is low for all categories*. Excluding the relative category (in which all models perform poorly), there is little variance in the overlap between the pairwise models (where the intersection between DBM and VFM is the largest for each category).

The quantitative analysis shows that the main limitation of the model is in the identification of *relative attributes*. While DBMs are able to correctly identify a small set of triples with relative features such as `(skyscraper, apartment, tall)` as discriminative, interpretation of relative relations requires two types of features which are not targeted by the models, namely: *(i)* the extraction of precise numerical reference points at scale (dealing with variations of dimensional units) and *(ii)* the ability to extrapolate the relations for unobserved lexemes by an explicit mechanism of comparative/transitive reasoning. As a consequence, the current model is able to identify "skyscraper" as being taller than an "apartment", but fails to identify neither as taller than a "giraffe".

DBM forms a significant (49% each) contribu-

tion to *sensory* attribute detection. CKG provides a significant (58%) contribution to *essential*. Additionally, CKG provides a significant (50%) contribution to *logical* attribute detection.

5.1 Error Analysis

Definition Based Models: False negatives comprise the majority (83%) of all model errors. The cause is that the pivot's definition does not include the discriminative attribute. False

negatives most commonly occurs with incidental features (e.g. `(potatoes, butter, mashed) - true:false` and `(nose, throat, perfume) - true:false`). False positives occur when the attribute applies to both pivot and comparison, however the comparison's definition does not include the feature. This is most prevalent with incidental attributes (e.g. `(banana,onions,peel) - false:true` and `(torah, bible, read) - false:true`).

Common Sense Knowledge Graphs: False negatives comprise the majority (80%) of the model's errors and are mainly caused by incidental attributes (e.g. `(trays,employee,wooden) - true:false`) and relative attributes (e.g. `(stool,tray,tall) - true:false`).

Visual Feature Models: Similarly as with DBMs and CKGs, false negatives comprise the majority (94%) of all false classifications. Most of the errors occur either with logical attributes (e.g. `(wife, lady, married) - true:false`, since these attributes are not likely to be expressed in a visual corpus or relative attributes (e.g. `(torah, bible, short) - true:false`. False positives occur due to domain incompleteness. This can be caused by a lack of domain coverage of the Visual Genome dataset (e.g. in `(cat, lion, whiskers) - false:true`; `(meal, supper, food) - false:true`).

Combined EDAM: *The decrease in the proportion of false negatives as compared to the individual models, illustrates the advantages of the model composition*. False negatives comprise 47% of model's total errors. False positives, on the contrary, illustrate the limitations of the model, since they occur when at least one of the model components incorrectly classifies a triple as discriminative: e.g. `(banana, onions, peel) - false:true` false positive of DBM and `(cat, lion, whiskers) - false:true` false positive of VFM.

5.2 Qualitative Analysis

In addition to correctly labeling common discriminative triples such as `(soup, meal, liquid)` and `(walnut, spinach, brown)` the technical specificity of definitions present at dictionaries supports the identification of discriminative triples such as `(brandy, whiskey, wine)`. Other noteworthy examples of discriminative attribute detection include labeling triples `(stomach, bladder, food)` and `(nightclub, bar, dancing)` as discriminative.

For the DBM, the structure induced by the extractor (e.g. the hypernym hierarchy) can support the transference of discriminative attributes across the taxonomic hierarchy. For the triple `(planet, moon, body)` using immediate definitions of pivot and comparison incorrectly suggests that the triple `(planet, moon, body)` is discriminative. However, after expanding using super-type definitions, the model correctly identifies `body` as a property of both `planet` and `moon`.

6 Conclusion

This paper described an explicit word vector model targeting the identification of discriminative attributes using the composition of definitions, visual features and commonsense knowledge graphs. The proposed model, which is built from structured representations from different types of data sources is able to achieve a state-of-the-art level F1-score (0.69) while producing, human interpretable explanations. The paper also provided an in-depth comparative quantitative and qualitative analysis on the contributions of different types of data sources for the generation of explicit semantic vector spaces (WordNet glosses, ConceptNet and Visual Genome), demonstrating the complementarity aspect of these resources. Future work will concentrate on extending the model to cope with relative attributes, the inclusion of additional data sources to increase model coverage, such as large-scale definition sets.

Acknowledgments

The authors would like to thank Viktor Schlegel for the initial supporting machine learning baselines (not included here) and related work discussions in the beginning of the project.

Patient Knowledge Distillation for BERT Model Compression

Abstract

Pre-trained language models such as BERT have proven to be highly effective for natural language processing (NLP) tasks. However, the high demand for computing resources in training such models hinders their application in practice. In order to alleviate this resource hunger in large-scale model training, we propose a Patient Knowledge Distillation approach to compress an original large model (teacher) into an equally-effective lightweight shallow network (student). Different from previous knowledge distillation methods, which only use the output from the last layer of the teacher network for distillation, our student model *patiently* learns from multiple intermediate layers of the teacher model for incremental knowledge extraction, following two strategies: (i) PKD-Last: learning from the last k layers; and (ii) PKD-Skip: learning from every k layers. These two patient distillation schemes enable the exploitation of rich information in the teacher's hidden layers, and encourage the student model to *patiently* learn from and imitate the teacher through a multi-layer distillation process. Empirically, this translates into improved results on multiple NLP tasks with significant gain in training efficiency, without sacrificing model accuracy.[1]

1 Introduction

Language model pre-training has proven to be highly effective in learning universal language representations from large-scale unlabeled data. ELMo (Peters et al., 2018), GPT (Radford et al., 2018) and BERT (Devlin et al., 2018) have achieved great success in many NLP tasks, such as sentiment classification (Socher et al., 2013), natural language inference (Williams et al., 2017), and question answering (Lai et al., 2017).

Despite its empirical success, BERT's computational efficiency is a widely recognized issue because of its large number of parameters. For example, the original BERT-Base model has 12 layers and 110 million parameters. Training from scratch typically takes four days on 4 to 16 Cloud TPUs. Even fine-tuning the pre-trained model with task-specific dataset may take several hours to finish one epoch. Thus, reducing computational costs for such models is crucial for their application in practice, where computational resources are limited.

Motivated by this, we investigate the redundancy issue of learned parameters in large-scale pre-trained models, and propose a new model compression approach, *Patient Knowledge Distillation* (Patient-KD), to compress original teacher (e.g., BERT) into a lightweight student model without performance sacrifice. In our approach, the teacher model outputs probability logits and predicts labels for the training samples (extendable to additional unannotated samples), and the student model learns from the teacher network to mimic the teacher's prediction.

Different from previous knowledge distillation methods (Hinton et al., 2015; Sau and Balasubramanian, 2016; Lu et al., 2017), we adopt a *patient* learning mechanism: instead of learning parameters from only the last layer of the teacher, we encourage the student model to extract knowledge also from previous layers of the teacher network. We call this 'Patient Knowledge Distillation'. This patient learner has the advantage of distilling rich information through the deep structure of the teacher network for multi-layer knowledge distillation.

We also propose two different strategies for the distillation process: (i) PKD-Last: the student learns from the last k layers of the teacher, under the assumption that the top layers of the original network contain the most informative knowledge

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4323–4332, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

to teach the student; and (ii) PKD-Skip: the student learns from every k layers of the teacher, suggesting that the lower layers of the teacher network also contain important information and should be passed along for incremental distillation.

We evaluate the proposed approach on several NLP tasks, including Sentiment Classification, Paraphrase Similarity Matching, Natural Language Inference, and Machine Reading Comprehension. Experiments on seven datasets across these four tasks demonstrate that the proposed Patient-KD approach achieves superior performance and better generalization than standard knowledge distillation methods (Hinton et al., 2015), with significant gain in training efficiency and storage reduction while maintaining comparable model accuracy to original large models. To the authors' best knowledge, this is the first known effort for BERT model compression.

2 Related Work

Language Model Pre-training Pre-training has been widely applied to universal language representation learning. Previous work can be divided into two main categories: (i) feature-based approach; (ii) fine-tuning approach.

Feature-based methods mainly focus on learning: (i) context-independent word representation (e.g., word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), FastText (Bojanowski et al., 2017)); (ii) sentence-level representation (e.g., Kiros et al. (2015); Conneau et al. (2017); Logeswaran and Lee (2018)); and (iii) contextualized word representation (e.g., Cove (McCann et al., 2017), ELMo (Peters et al., 2018)). Specifically, ELMo (Peters et al., 2018) learns high-quality, deep contextualized word representation using bidirectional language model, which can be directly plugged into standard NLU models for performance boosting.

On the other hand, fine-tuning approaches mainly pre-train a language model (e.g., GPT (Radford et al., 2018), BERT (Devlin et al., 2018)) on a large corpus with an unsupervised objective, and then fine-tune the model with in-domain labeled data for downstream applications (Dai and Le, 2015; Howard and Ruder, 2018). Specifically, BERT is a large-scale language model consisting of multiple layers of Transformer blocks (Vaswani et al., 2017). BERT-Base has 12 layers of Transformer and 110 million parameters, while BERT-Large has 24 layers of Transformer and 330 million parameters. By pre-training via masked language modeling and next sentence prediction, BERT has achieved state-of-the-art performance on a wide-range of NLU tasks, such as the GLUE benchmark (Wang et al., 2018) and SQuAD (Rajpurkar et al., 2016).

However, these modern pre-trained language models contain millions of parameters, which hinders their application in practice where computational resource is limited. In this paper, we aim at addressing this critical and challenging problem, taking BERT as an example, *i.e.,* how to compress a large BERT model into a shallower one without sacrificing performance. Besides, the proposed approach can also be applied to other large-scale pre-trained language models, such as recently proposed XLNet (Yang et al., 2019) and RoBERTa (Liu et al., 2019b).

Model Compression & Knowledge Distillation Our focus is model compression, *i.e.,* making deep neural networks more compact (Han et al., 2016; Cheng et al., 2015). A similar line of work has focused on accelerating deep network inference at test time (Vetrov et al., 2017) and reducing model training time (Huang et al., 2016).

A conventional understanding is that a large number of connections (weights) is necessary for training deep networks (Denil et al., 2013; Zhai et al., 2016). However, once the network has been trained, there will be a high degree of parameter redundancy. Network pruning (Han et al., 2015; He et al., 2017), in which network connections are reduced or sparsified, is one common strategy for model compression. Another direction is weight quantization (Gong et al., 2014; Polino et al., 2018), in which connection weights are constrained to a set of discrete values, allowing weights to be represented by fewer bits. However, most of these pruning and quantization approaches perform on convolutional networks. Only a few work are designed for rich structural information such as deep language models (Changpinyo et al., 2017).

Knowledge distillation (Hinton et al., 2015) aims to compress a network with a large set of parameters into a compact and fast-to-execute model. This can be achieved by training a compact model to imitate the soft output of a larger model. Romero et al. (2015) further demonstrated that intermediate representations learned by the

large model can serve as hints to improve the training process and the final performance of the compact model. Chen et al. (2015) introduced techniques for efficiently transferring knowledge from an existing network to a deeper or wider network. More recently, Liu et al. (2019a) used knowledge from ensemble models to improve single model performance on NLU tasks. Tan et al. (2019) tried knowledge distillation for multilingual translation. Different from the above efforts, we investigate the problem of compressing large-scale language models, and propose a novel *patient knowledge distillation* approach to effectively transferring knowledge from a teacher to a student model.

3 Patient Knowledge Distillation

In this section, we first introduce a vanilla knowledge distillation method for BERT compression (Section 3.1), then present the proposed Patient Knowledge Distillation (Section 3.2) in details.

Problem Definition The original large teacher network is represented by a function $f(\mathbf{x};\theta)$, where $\mathbf{x}$ is the input to the network, and θ denotes the model parameters. The goal of knowledge distillation is to learn a new set of parameters θ' for a shallower student network $g(\mathbf{x};\theta')$, such that the student network achieves similar performance to the teacher, with much lower computational cost. Our strategy is to force the student model to imitate outputs from the teacher model on the training dataset with a defined objective L_{KD}.

3.1 Distillation Objective

In our setting, the teacher $f(\mathbf{x};\theta)$ is defined as a deep bidirectional encoder, e.g., BERT, and the student $g(\mathbf{x};\theta')$ is a lightweight model with fewer layers. For simplicity, we use BERT_k to denote a model with k layers of Transformers. Following the original BERT paper (Devlin et al., 2018), we also use BERT-Base and BERT-Large to denote BERT_{12} and BERT_{24}, respectively.

Assume $\{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^{N}$ are N training samples, where $\mathbf{x}_i$ is the i-th input instance for BERT, and $\mathbf{y}_i$ is the corresponding ground-truth label. BERT first computes a contextualized embedding $\mathbf{h}_i = \text{BERT}(\mathbf{x}_i) \in \mathbb{R}^d$. Then, a softmax layer $\hat{\mathbf{y}}_i = P(\mathbf{y}_i|\mathbf{x}_i) = softmax(\mathbf{W}\mathbf{h}_i)$ for classification is applied to the embedding of BERT output, where $\mathbf{W}$ is a weight matrix to be learned.

To apply knowledge distillation, first we need to train a teacher network. For example, to train a 12-layer BERT-Base as the teacher model, the learned parameters are denoted as:

$$\hat{\theta}^t = \arg\min_{\theta} \sum_{i\in[N]} L_{CE}^t(\mathbf{x}_i, \mathbf{y}_i; [\theta_{\text{BERT}_{12}}, \mathbf{W}]) \tag{1}$$

where the superscript t denotes parameters in the teacher model, $[N]$ denotes set $\{1, 2, \ldots, N\}$, L_{CE}^t denotes the cross-entropy loss for the teacher training, and $\theta_{\text{BERT}_{12}}$ denotes parameters of BERT_{12}.

The output probability for any given input $\mathbf{x}_i$ can be formulated as:

$$\begin{aligned}\hat{\mathbf{y}}_i = P^t(\mathbf{y}_i|\mathbf{x}_i) &= softmax\Big(\frac{\mathbf{W}\mathbf{h}_i}{T}\Big) \\ &= softmax\Big(\frac{\mathbf{W}\cdot \text{BERT}_{12}(\mathbf{x}_i;\hat{\theta}^t)}{T}\Big)\end{aligned} \tag{2}$$

where $P^t(\cdot|\cdot)$ denotes the probability output from the teacher. $\hat{\mathbf{y}}_i$ is fixed as soft labels, and T is the temperature used in KD, which controls how much to rely on the teacher's soft predictions. A higher temperature produces a more diverse probability distribution over classes (Hinton et al., 2015). Similarly, let θ^s denote parameters to be learned for the student model, and $P^s(\cdot|\cdot)$ denote the corresponding probability output from the student model. Thus, the distance between the teacher's prediction and the student's prediction can be defined as:

$$\begin{aligned}L_{DS} = -\sum_{i\in[N]}\sum_{c\in C}\Big[&P^t(\mathbf{y}_i = c|\mathbf{x}_i;\hat{\theta}^t)\cdot \\ &\log P^s(\mathbf{y}_i = c|\mathbf{x}_i;\theta^s)\Big]\end{aligned} \tag{3}$$

where c is a class label and C denotes the set of class labels.

Besides encouraging the student model to imitate the teacher's behavior, we can also fine-tune the student model on target tasks, where task-specific cross-entropy loss is included for model training:

$$\begin{aligned}L_{CE}^s = -\sum_{i\in[N]}\sum_{c\in C}\Big[&\mathbb{1}[\mathbf{y}_i = c]\cdot \\ &\log P^s(\mathbf{y}_i = c|\mathbf{x}_i;\theta^s)\Big]\end{aligned} \tag{4}$$

Thus, the final objective function for knowledge distillation can be formulated as:

$$L_{KD} = (1-\alpha)L_{CE}^s + \alpha L_{DS} \tag{5}$$

where α is the hyper-parameter that balances the importance of the cross-entropy loss and the distillation loss.

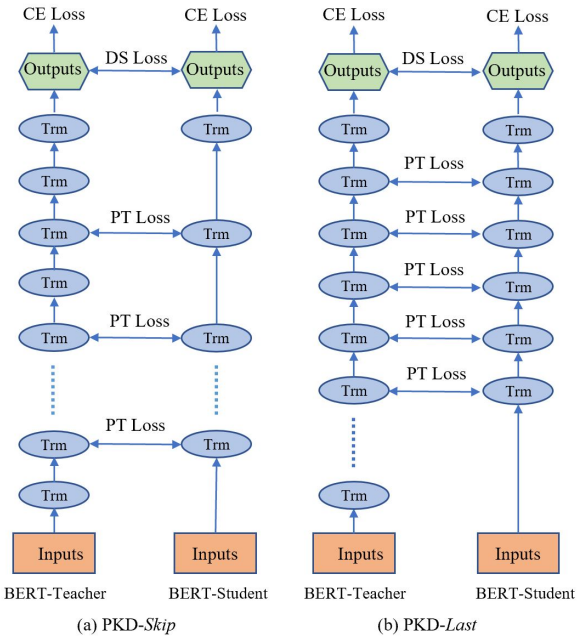

Figure 1: Model architecture of the proposed Patient Knowledge Distillation approach to BERT model compression. (Left) PKD-Skip: the student network learns the teacher's outputs in every 2 layers. (Right) PKD-Last: the student learns the teacher's outputs from the last 6 layers. Trm: Transformer.

3.2 Patient Teacher for Model Compression

Using a weighted combination of ground-truth labels and soft predictions from the last layer of the teacher network, the student network can achieve comparable performance to the teacher model on the training set. However, with the number of epochs increasing, the student model learned with this vanilla KD framework quickly reaches saturation on the test set (see Figure 2 in Section 4).

One hypothesis is that overfitting during knowledge distillation may lead to poor generalization. To mitigate this issue, instead of forcing the student to learn only from the logits of the last layer, we propose a "*patient*" teacher-student mechanism to distill knowledge from the teacher's intermediate layers as well. Specifically, we investigate two patient distillation strategies: (i) PKD-Skip: the student learns from every k layers of the teacher (Figure 1: Left); and (ii) PKD-Last: the student learns from the *last* k layers of the teacher (Figure 1: Right).

Learning from the hidden states of all the tokens is computationally expensive, and may introduce noise. In the original BERT implementation (Devlin et al., 2018), prediction is performed by only using the output from the last layer's `[CLS]` token. In some variants of BERT, like SDNet (Zhu et al., 2018), a weighted average of all layers' `[CLS]` embeddings is applied. In general, the final logit can be computed based on $\mathbf{h}_{\text{final}} = \sum_{j\in[k]} w_j \mathbf{h}_j$, where w_j could be either learned parameters or a pre-defined hyper-parameter, $\mathbf{h}_j$ is the embedding of `[CLS]` from the hidden layer j, and k is the number of hidden layers. Derived from this, if the compressed model can learn from the representation of `[CLS]` in the teacher's intermediate layers for any given input, it has the potential of gaining a generalization ability similar to the teacher model.

Motivated by this, in our Patient-KD framework, the student is cultivated to imitate the representations only for the `[CLS]` token in the intermediate layers, following the intuition aforementioned that the `[CLS]` token is important in predicting the final labels. For an input $\mathbf{x}_i$, the outputs of the `[CLS]` tokens for all the layers are denoted as:

$$\mathbf{h}_i = [\mathbf{h}_{i,1}, \mathbf{h}_{i,2}, \ldots, \mathbf{h}_{i,k}] = \text{BERT}_k(\mathbf{x}_i) \in \mathbb{R}^{k\times d} \tag{6}$$

We denote the set of intermediate layers to distill knowledge from as I_{pt}. Take distilling from BERT_{12} to BERT_6 as an example. For the PKD-Skip strategy, $I_{pt} = \{2, 4, 6, 8, 10\}$; and for the PKD-Last strategy, $I_{pt} = \{7, 8, 9, 10, 11\}$. Note that $k = 5$ for both cases, because the output from the last layer (e.g., Layer 12 for BERT-Base) is omitted since its hidden states are connected to the softmax layer, which is already included in the KD loss defined in Eqn. (5). In general, for BERT student with n layers, k always equals to $n - 1$.

The additional training loss introduced by the patient teacher is defined as the mean-square loss between the normalized hidden states:

$$L_{PT} = \sum_{i=1}^{N}\sum_{j=1}^{M}\left|\left|\frac{\mathbf{h}_{i,j}^{s}}{||\mathbf{h}_{i,j}^{s}||_2} - \frac{\mathbf{h}_{i,I_{pt}(j)}^{t}}{||\mathbf{h}_{i,I_{pt}(j)}^{t}||_2}\right|\right|_2^2 \tag{7}$$

where M denotes the number of layers in the student network, N is the number of training samples, and the superscripts s and t in $\mathbf{h}$ indicate the student and the teacher model, respectively. Combined with the KD loss introduced in Section 3.1, the final objective function can be formulated as:

$$L_{PKD} = (1-\alpha)L_{CE}^{s} + \alpha L_{DS} + \beta L_{PT} \tag{8}$$

where β is another hyper-parameter that weights the importance of the features for distillation in the intermediate layers.

4 Experiments

In this section, we describe our experiments on applying the proposed Patient-KD approach to four different NLP tasks. Details on the datasets and experimental results are provided in the following sub-sections.

4.1 Datasets

We evaluate our proposed approach on Sentiment Classification, Paraphrase Similarity Matching, Natural Language Inference, and Machine Reading Comprehension tasks. For Sentiment Classification, we test on Stanford Sentiment Treebank (SST-2) (Socher et al., 2013). For Paraphrase Similarity Matching, we use Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005) and Quora Question Pairs (QQP)[2] datasets. For Natural Language Inference, we evaluate on Multi-Genre Natural Language Inference (MNLI) (Williams et al., 2017), QNLI[3] (Rajpurkar et al., 2016), and Recognizing Textual Entailment (RTE).

More specifically, SST-2 is a movie review dataset with binary annotations, where the binary label indicates positive and negative reviews. MRPC contains pairs of sentences and corresponding labels, which indicate the semantic equivalence relationship between each pair. QQP is designed to predict whether a pair of questions is duplicate or not, provided by a popular online question-answering website Quora. MNLI is a multi-domain NLI task for predicting whether a given premise-hypothesis pair is entailment, contradiction or neural. Its test and development datasets are further divided into in-domain (MNLI-m) and cross-domain (MNLI-mm) splits to evaluate the generality of tested models. QNLI is a task for predicting whether a question-answer pair is entailment or not. Finally, RTE is based on a series of textual entailment challenges, created by General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018).

For the Machine Reading Comprehension task, we evaluate on RACE (Lai et al., 2017), a large-scale dataset collected from English exams, containing 25,137 passages and 87,866 questions. For each question, four candidate answers are provided, only one of which is correct. The dataset is further divided into RACE-M and RACE-H, containing exam questions for middle school and high school students.

4.2 Baselines and Training Details

For experiments on the GLUE benchmark, since all the tasks can be considered as sentence (or sentence-pair) classification, we use the same architecture in the original BERT (Devlin et al., 2018), and fine-tune each task independently.

For experiments on RACE, we denote the input passage as P, the question as q, and the four answers as $a_1, \ldots, a_4$. We first concatenate the tokens in q and each a_i, and arrange the input of BERT as `[CLS]` P `[SEP]` $q+a_i$ `[SEP]` for each input pair $(P, q + a_i)$, where `[CLS]` and `[SEP]` are the special tokens used in the original BERT. In this way, we can obtain a single logit value for each a_i. At last, a softmax layer is placed on top of these four logits to obtain the normalized probability of each answer a_i being correct, which is then used to compute the cross-entropy loss for modeling training.

We fine-tune BERT-Base (denoted as BERT_{12}) as the teacher model to compute soft labels for each task independently, where the pretrained model weights are obtained from Google's official BERT's repo[4], and use 3 and 6 layers of Transformers as the student models (BERT_3 and BERT_6), respectively. We initialize BERT_k with the first k layers of parameters from pre-trained BERT-Base, where $k \in \{3, 6\}$. To validate the effectiveness of our proposed approach, we first conduct direct fine-tuning on each task without using any soft labels. In order to reduce the hyper-parameter search space, we fix the number of hidden units in the final softmax layer as 768, the batch size as 32, and the number of epochs as 4 for all the experiments, with a learning rate from {5e-5, 2e-5, 1e-5}. The model with the best validation accuracy is selected for each setting.

Besides direct fine-tuning, we further implement a vanilla KD method on all the tasks by optimizing the objective function in Eqn. (5). We set the temperature T as {5, 10, 20}, $\alpha = \{0.2, 0.5, 0.7\}$, and perform grid search over T, α and learning rate, to select the model with the best validation accuracy. For our proposed Patient-KD approach, we conduct additional search over β

Table 1: Results from the GLUE test server. The best results for 3-layer and 6-layer models are in-bold. Google's submission results are obtained from official GLUE leaderboard. $BERT_{12}$ (Teacher) is our own implementation of the BERT teacher model. FT represents direct fine-tuning on each dataset without using knowledge distillation. KD represents using a vanilla knowledge distillation method. And PKD represents our proposed Patient-KD-Skip approach. Results show that PKD-Skip outperforms the baselines on almost all the datasets except for MRPC. The numbers under each dataset indicate the corresponding number of training samples.

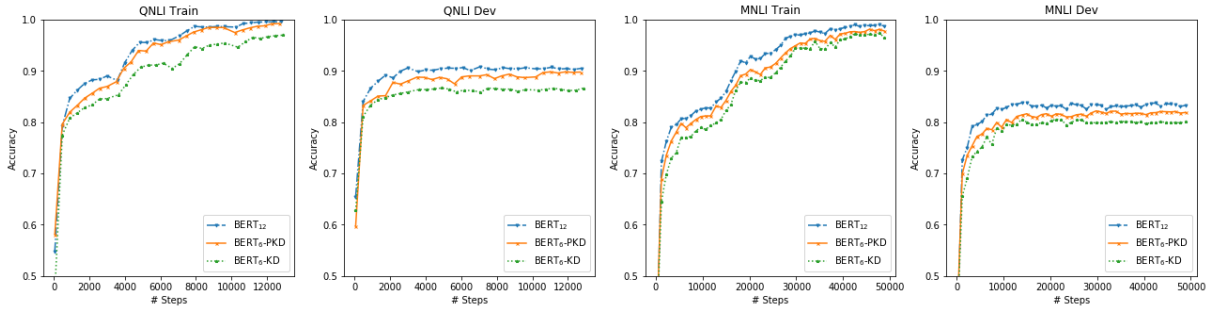

Figure 2: Accuracy on the training and dev sets of QNLI and MNLI datasets, by directly applying vanilla knowledge distillation (KD) and the proposed Patient-KD-Skip. The teacher and the student networks are $BERT_{12}$ and $BERT_6$, respectively. The student network learned with vanilla KD quickly saturates on the dev set, while the proposed Patient-KD starts to plateau only in a later stage.

from $\{10, 100, 500, 1000\}$ on all the tasks. Since there are so many hyper-parameters to learn for Patient KD, we fix α and T to the values used in the model with the best performance from the vanilla KD experiments, and only search over β and learning rate.

4.3 Experimental Results

We submitted our model predictions to the official GLUE evaluation server to obtain results on the test data. Results are summarized in Table 1. Compared to direct fine-tuning and vanilla KD, our Patient-KD models with $BERT_3$ and $BERT_6$ students perform the best on almost all the tasks except MRPC. For MNLI-m and MNLI-mm, our 6-layer model improves 1.1% and 1.3% over fine-tune (FT) baselines; for QNLI and QQP, even though the gap between $BERT_6$-KD and $BERT_{12}$ teacher is relatively small, our approach still succeeded in improving over both FT and KD baselines and further closing the gap between the student and the teacher models.

Furthermore, in 5 tasks out of 7 (SST-2 (-2.3% compared to BERT-Base teacher), QQP (-0.1%), MNLI-m (-2.2%), MNLI-mm (-1.8%), and QNLI (-1.4%)), the proposed 6-layer student coached by the patient teacher achieved similar performance to the original BERT-Base, demonstrating the effectiveness of our approach. Interestingly, all those 5 tasks have more than 60k training samples, which indicates that our method tends to perform better when there is a large amount of training data.

For the QQP task, we can further reduce the model size to 3 layers, where $BERT_3$-PKD can still have a similar performance to the teacher model. The learning curves on the QNLI and MNLI datasets are provided in Figure 2. The student model learned with vanilla KD quickly saturated on the dev set, while the proposed Patient-

Model	SST-2	MRPC	QQP	MNLI-m	MNLI-mm	QNLI	RTE
$BERT_6$ (PKD-Last)	91.9	**85.1**/79.5	70.5/**88.9**	80.9	**81.0**	88.2	65.0
$BERT_6$ (PKD-Skip)	**92.0**	85.0/**79.9**	**70.7/88.9**	**81.5**	**81.0**	**89.0**	**65.5**

Table 2: Performance comparison between PKD-Last and PKD-Skip on GLUE benchmark.

KD keeps learning from the teacher and improving accuracy, only starting to plateau in a later stage.

For the MRPC dataset, one hypothesis for the reason on vanilla KD outperforming our model is that the lack of enough training samples may lead to overfitting on the dev set. To further investigate, we repeat the experiments three times and compute the average accuracy on the dev set. We observe that fine-tuning and vanilla KD have a mean dev accuracy of 82.23% and 82.84%, respectively. Our proposed method has a higher mean dev accuracy of 83.46%, hence indicating that our Patient-KD method slightly overfitted to the dev set of MRPC due to the small amount of training data. This can also be observed on the performance gap between teacher and student on RTE in Table 5, which also has a small training set.

We further investigate the performance gain from two different patient teacher designs: PKD-Last vs. PKD-Skip. Results of both PKD variants on the GLUE benchmark (with $BERT_6$ as the student) are summarized in Table 2. Although both strategies achieved improvement over the vanilla KD baseline (see Table 1), PKD-Skip performs slightly better than PKD-Last. Presumably, this might be due to the fact that distilling information across every k layers captures more diverse representations of richer semantics from low-level to high-level, while focusing on the last k layers tends to capture relatively homogeneous semantic information.

Results on RACE are reported in Table 3, which shows that the Vanilla KD method outperforms direct fine-tuning by 4.42%, and our proposed patient teacher achieves further 1.6% performance lift, which again demonstrates the effectiveness of Patient-KD.

4.4 Analysis of Model Efficiency

We have demonstrated that the proposed Patient-KD method can effectively compress $BERT_{12}$ into $BERT_6$ models without performance sacrifice. In this section, we further investigate the efficiency of Patient-KD on storage saving and inference-time speedup. Parameter statistics and inference time

Model	RACE	RACE-M	RACE-H
$BERT_{12}$ (Leaderboard)	65.00	71.70	62.30
$BERT_{12}$ (Teacher)	65.30	71.17	62.89
$BERT_6$-FT	54.32	61.07	51.54
$BERT_6$-KD	58.74	64.69	56.29
$BERT_6$-PKD-Skip	**60.34**	**66.57**	**57.78**

Table 3: Results on RACE test set. $BERT_{12}$ (Leaderboard) denotes results extracted from the official leaderboard (http://www.qizhexie.com/data/RACE_leaderboard). $BERT_{12}$ (Teacher) is our own implementation. Results of $BERT_3$ are not included due to the large gap between the teacher and the $BERT_3$ student.

are summarized in Table 4. All the models share the same embedding layer with 24 millon parameters that map a 30k-word vocabulary to a 768-dimensional vector, which leads to 1.64 and 2.4 times of machine memory saving from $BERT_6$ and $BERT_3$, respectively.

To test the inference speed, we ran experiments on 105k samples from QNLI training set (Rajpurkar et al., 2016). Inference is performed on a single Titan RTX GPU with batch size set to 128, maximum sequence length set to 128, and FP16 activated. The inference time for the embedding layer is negligible compared to the Transformer layers. Results in Table 4 show that the proposed Patient-KD approach achieves an almost linear speedup, 1.94 and 3.73 times for $BERT_6$ and $BERT_3$, respectively.

4.5 Does a Better Teacher Help?

To evaluate the effectiveness of the teacher model in our Patient-KD framework, we conduct additional experiments to measure the difference between BERT-Base teacher and BERT-Large teacher for model compression.

Each Transformer layer in BERT-Large has 12.6 million parameters, which is much larger than the Transformer layer used in BERT-Base. For a compressed BERT model with 6 layers, $BERT_6$ with BERT-Base Transformer (denoted as $BERT_6$[Base]) has only 67.0 million parameters,

# Layers	# Param (Emb)	# Params (Trm)	Total Params	Inference Time (s)
3	23.8M	21.3M	45.7M (2.40×)	27.35 (3.73×)
6	23.8M	42.5M	67.0M (1.64×)	52.51 (1.94×)
12	23.8M	85.1M	109M (1×)	101.89 (1×)

Table 4: The number of parameters and inference time for BERT_3, BERT_6 and BERT_{12}. Parameters in Transformers (Trm) grow linearly with the increase of layers. Note that the summation of # Param (Emb) and # Param (Trm) does not exactly equal to Total Params, because there is another softmax layer with 0.6M parameters.

Setting	Teacher	Student	SST-2	MRPC	QQP	MNLI-m	MNLI-mm	QNLI	RTE
N/A	N/A	BERT_{12} (Teacher)	94.3	89.2/85.2	70.9/89.0	83.7	82.8	90.4	69.1
N/A	N/A	BERT_{24} (Teacher)	94.3	88.2/84.3	71.9/89.4	85.7	84.8	92.2	72.8
#1	BERT_{12}	BERT_6[Base]-KD	91.5	86.2/80.6	70.1/88.8	79.7	79.1	88.3	64.7
#2	BERT_{24}	BERT_6[Base]-KD	91.2	86.1/80.7	69.4/88.6	80.2	79.7	87.5	65.7
#3	BERT_{24}	BERT_6[Large]-KD	89.6	79.0/70.0	65.0/86.7	75.3	74.6	83.4	53.7
#4	BERT_{24}	BERT_6[Large]-PKD	89.8	77.8/68.3	67.1/87.9	77.2	76.7	83.8	53.2

Table 5: Performance comparison with different teacher and student models. BERT_6[Base]/[Large] denotes a BERT_6 model with a BERT-Base/Large Transformer in each layer. For PKD, we use the PKD-Skip architecture.

while BERT_6 with BERT-Large Transformer (denoted as BERT_6[Large]) has 108.4 million parameters. Since the size of the `[CLS]` token embedding is different between BERT-Large and BERT-Base, we cannot directly compute the patient teacher loss (7) for BERT_6[Base] when BERT-Large is used as teacher. Hence, in the case where the teacher is BERT-Large and the student is BERT_6[Base], we only conduct experiments in the vanilla KD setting.

Results are summarized in Table 5. When the teacher changes from BERT_{12} to BERT_{24} (*i.e.*, Setting #1 vs. #2), there is not much difference between the students' performance. Specifically, BERT_{12} teacher performs better on SST-2, QQP and QNLI, while BERT_{24} performs better on MNLI-m, MNLI-mm and RTE. Presumably, distilling knowledge from a larger teacher requires a larger training dataset, thus better results are observed on MNLI-m and MNLI-mm.

We also report results on using BERT-Large as the teacher and BERT_6[Large] as the student. Interestingly, when comparing Setting #1 with #3, BERT_6[Large] performs much worse than BERT_6[Base] even though a better teacher is used in the former case. The BERT_6[Large] student also has 1.6 times more parameters than BERT_6[Base]. One intuition behind this is that the compression ratio for the BERT_6[Large] model is 4:1 (24:6), which is larger than the ratio used for the BERT_6[Base] model (2:1 (12:6)). The higher compression ratio renders it more challenging for the student model to absorb important weights.

When comparing Setting # 2 and #3, we observe that even when the same large teacher is used, BERT_6[Large] still performs worse than BERT_6[Base]. Presumably, this may be due to initialization mismatch. Ideally, we should pre-train BERT_6[Large] and BERT_6[Base] from scratch, and use the weights learned from the pre-training step for weight initialization in KD training. However, due to computational limits of training BERT_6 from scratch, we only initialize the student model with the first six layers of BERT_{12} or BERT_{24}. Therefore, the first six layers of BERT_{24} may not be able to capture high-level features, leading to worse KD performance.

Finally, when comparing Setting #3 vs. #4, where for setting #4 we use Patient-KD-Skip instead of vanilla KD, we observe a performance gain on almost all the tasks, which indicates Patient-KD is a generic approach independent of the selection of the teacher model (BERT_{12} or BERT_{24}).

5 Conclusion

In this paper, we propose a novel approach to compressing a large BERT model into a shallow one via Patient Knowledge Distillation. To fully utilize the rich information in deep structure of the teacher network, our Patient-KD approach encourages the student model to patiently learn from the teacher through a multi-layer distillation process. Extensive experiments over four NLP tasks demonstrate the effectiveness of our proposed model.

For future work, we plan to pre-train BERT from scratch to address the initialization mismatch

issue, and potentially modify the proposed method such that it could also help during pre-training. Designing more sophisticated distance metrics for loss functions is another exploration direction. We will also investigate Patient-KD in more complex settings such as multi-task learning and meta learning.

Abstract

Variational language models seek to estimate the posterior of latent variables with an approximated variational posterior. The model often assumes the variational posterior to be factorized even when the true posterior is not. The learned variational posterior under this assumption does not capture the dependency relationships over latent variables. We argue that this would cause a typical training problem called posterior collapse observed in all other variational language models. We propose Gaussian Copula Variational Autoencoder (VAE) to avert this problem. Copula is widely used to model correlation and dependencies of high-dimensional random variables, and therefore it is helpful to maintain the dependency relationships that are lost in VAE. The empirical results show that by modeling the correlation of latent variables explicitly using a neural parametric copula, we can avert this training difficulty while getting competitive results among all other VAE approaches. [1]

1 Introduction

Variational Inference (VI) (Wainwright et al., 2008; Hoffman et al., 2013) methods are inspired by *calculus of variation* (Gelfand et al., 2000). It can be dated back to the 18th century when it was mainly used to study the problem of the change of *functional*, which is defined as the mapping from functions to real space and can be understood as the function of functions. **VI** takes a distribution as a *functional* and then studies the problem of matching this distribution to a target distribution using *calculus of variation*. After the rise of *deep learning* (Krizhevsky et al., 2012), a deep generative model called **Variational Autoencoder** (Kingma and Welling, 2014; Hoffman et al., 2013) is proposed based on the theory of **VI** and achieves great success over a huge number of tasks, such as transfer learning (Shen et al., 2017), unsupervised learning (Jang et al., 2017), image generation (Gregor et al., 2015), semi-supervised classification (Jang et al., 2017), and dialogue generation (Zhao et al., 2017). VAE is able to learn a continuous space of latent random variables which are useful for a lot of classification and generation tasks.

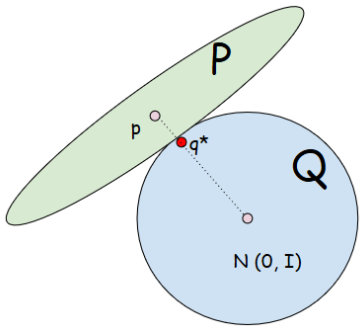

Figure 1: Intuitive illustration of **VI**: The elliptic P is a distribution family containing the true posterior $p \in P$, and the circle Q is a Mean-field variational family containing a standard normal prior $\mathcal{N}$. The optimal solution q^* is the one in Q that has the smallest $KL(q||p)$. In reality these two families may not overlap.

Recent studies (Bowman et al., 2015; Yang et al., 2017; Xiao et al., 2018; Xu and Durrett, 2018) show that when it comes to text generation and language modeling, VAE does not perform well and often generates random texts without making good use of the learned latent codes. This phenomenon is called **Posterior Collapse**, where the Kullback-Leibler (KL) divergence between the posterior and the prior (*often assumed to be a standard Gaussian*) vanishes. It makes the latent codes completely useless because any text input will be mapped to a standard Gaussian variable. Many recent studies (Yang et al., 2017; Xu and Durrett, 2018; Xiao et al., 2018; Miao et al.,

2016; He et al., 2018) try to address this issue by providing new model architectures or by changing the objective functions. Our research lies in this second direction. **We review the theory of VAE, and we argue that one of the most widely used assumptions in VAE, the Mean-field assumption, is problematic**. It assumes that all approximated solutions in a family of variational distributions should be factorized or dimensional-wise independent for tractability. We argue that it leads to the posterior collapse problem since any variational posterior learned in this way does not maintain the correlation among latent codes and will never match the true posterior which is unlikely factorized.

We avert this problem by proposing a **Neural Gaussian Copula (Copula-VAE)** model to train VAE on text data. Copula (Nelsen, 2007) can model dependencies of high-dimensional random variables and is very successful in risk management (Kole et al., 2007; McNeil et al., 2005), financial management (Wang and Hua, 2014), and other tasks that require the modeling of dependencies. We provide a reparameterization trick (Kingma and Welling, 2014) to incorporate it with VAE for language modeling. We argue that by maintaining the dependency relationships over latent codes, we can dramatically improve the performance of variational language modeling and avoid posterior collapse. Our major contributions can be summarized as the following:

- We propose Neural parameterized Gaussian Copula to get a better estimation of the posterior for latent codes.
- We provide a reparameterization technique for Gaussian Copula VAE. The experiments show that our method achieves competitive results among all other variational language modeling approaches.
- We perform a thorough analysis of the original VAE and copula VAE. The results and analysis reveal the salient drawbacks of VAE and explain how introducing a copula model could help avert the posterior collapse problem.

Copula: Before the rise of Deep Learning Copula (Nelsen, 2007) is a multivariate distribution whose marginals are all uniformly distributed. Over the years, it is widely used to extract correlation within high-dimensional random variables, and achieves great success in many subjects such as risk management (Kole et al., 2007; McNeil et al., 2005), finance (Wang and Hua, 2014), civil engineering(Chen et al., 2012; Zhang and Singh, 2006), and visual description generation (Wang and Wen, 2015). In the past, copula is often estimated by Maximum Likelihood method (Choroś et al., 2010; Jaworski et al., 2010) via parametric or semi-parametric approaches (Tsukahara, 2005; Choroś et al., 2010). One major difficulty when estimating the copula and extracting dependencies is the dimensionality of random variables. To overcome the curse of dimensionality, a graphical model called *vine copula* (Joe and Kurowicka, 2011; Czado, 2010; Bedford et al., 2002) is proposed to estimate a high-dimensional copula density by breaking it into a set of bivariate conditional copula densities. However, this approach is often hand-designed which requires human experts to define the form of each bivariate copula, and hence often results in overfitting. Therefore, Gaussian copula (Xue-Kun Song, 2000; Frey et al., 2001) is often used since its multivariate expression has a simple form and hence does not suffer from the curse of dimensionality.

VAE for Text Bowman et al. (2015) proposed to use VAE for text generation by using LSTM as encoder-decoder. The encoder maps the hidden states to a set of latent variables, which are further used to generate sentences. While achieving relatively low sample perplexity and being able to generate easy-to-read texts, the LSTM VAE often results in posterior collapse, where the learned latent codes become useless for text generation.

Recently, many studies are focusing on how to avert this training problem. They either propose a new model architecture or modify the VAE objective. Yang et al. (2017) seeks to replace the LSTM (Hochreiter and Schmidhuber, 1997) decoder with a CNN decoder to control model expressiveness, as they suspect that the over-expressive LSTM is one reason that makes KL vanish. Xiao et al. (2018) introduces a topic variable and pre-trains a *Latent Dirichlet Allocation* (Blei et al., 2003) model to get a prior distribution over the topic information. Xu and Durrett (2018) believes the *bubble soup effect* of high-dimensional Gaussian distribution is the main reason that causes KL vanishing, and therefore learns

a hyper-spherical posterior over the latent codes.

3 Variational Inference

The problem of inference in probabilistic modeling is to estimate the posterior density $p(\mathbf{z}|\mathbf{x})$ of latent variable $\mathbf{z}$ given input samples $\{x_i\}_{i=1}^{D}$. The direct computation of the posterior is intractable in most cases since the normalizing constant $\int p(\mathbf{z}, \mathbf{x})d\mathbf{z}$ lacks an analytic form. To get an approximation of the posterior, many approaches use sampling methods such as Markov chain Monte Carlo (MCMC) (Gilks et al., 1995) and Gibbs sampling (George and McCulloch, 1993). The downside of sampling methods is that they are inefficient, and it is hard to tell how close the approximation is from the true posterior. The other popular inference approach, **variational inference (VI)** (Wainwright et al., 2008; Hoffman et al., 2013), does not have this shortcoming as it provides a distance metric to measure the fitness of an approximated solution.

In **VI**, we assume a variational family of distributions $\mathcal{Q}$ to approximate the true posterior. The *Kullback-Leibler* (**KL**) divergence is used to measure how close $q \in Q$ is to the true $p(\mathbf{z}|\mathbf{x})$. The optimal variational posterior $q* \in Q$ is then the one that minimizes the KL divergence

$$KL(q||p) = \sum q(\mathbf{z}|\mathbf{x}) log \frac{q(\mathbf{z}|\mathbf{x})}{p(\mathbf{z}|\mathbf{x})}$$

Based on this, *variational autoencoder* (**VAE**) (Kingma and Welling, 2014) is proposed as a latent generative model that seeks to learn a posterior of the latent codes by minimizing the KL divergence between the true joint density $p_\theta(\mathbf{x}, \mathbf{z})$ the variational joint density $q_\phi(\mathbf{z}, \mathbf{x})$. This is equivalent to maximizing the following *evidence lower bound* **ELBO**,

$$\begin{aligned}\mathcal{L}(\theta; \phi; \mathbf{x}) &= -KL(q_\phi(\mathbf{z}, \mathbf{x})||p_\theta(\mathbf{x}, \mathbf{z})) \\ &= \mathbb{E}_{q(\mathbf{x})}[\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] \\ &\quad - KL(q_\phi(\mathbf{z}|\mathbf{x})||p(\mathbf{z}))]\end{aligned}$$

In this case, Mean-field (Kingma and Welling, 2014) assumption is often used for simplicity. That is, we assume that the members of variational family Q are dimensional-wise independent, meaning that the posterior q can be written as $q(\mathbf{z}|\mathbf{x}) = \prod_{i=1}^{D} q(z_i|\mathbf{x})$. The simplicity of this form makes the estimation of ELBO very easy. However, it also leads to a particular training difficulty called posterior collapse, where the KL divergence term becomes zero and the factorized variational posterior collapses to the prior. The latent codes $\mathbf{z}$ would then become useless since the generative model $p(\mathbf{x}|\mathbf{z})$ no longer depends on it.

We believe the problem comes from the nature of variational family itself and hence we propose our **Copula-VAE** which makes use of the dependency modeling ability of copula model to guide the variational posterior to match the true posterior. We will provide more details in the following sections.

We hypothesize that the Mean-field assumption is problematic itself as the q under this assumption can never recover the true structure of p. On the other hand, **Copula-VAE** makes use of the dependency relationships maintained by a copula model to guide the variational posterior to match the true posterior. Our approach differs from *Gaussian Copula-VAE* (Suh and Choi, 2016) in that we use copula to estimate the joint density $p(\mathbf{z})$ rather than the empirical data density $p(\mathbf{x})$.

4 Our Approach: Neural Gaussian Copula

4.1 Gaussian Copula

In this section, we review the basic concepts of Gaussian copula. Copula is defined as a probability distribution over a high-dimensional unit cube $[0, 1]^d$ whose univariate marginal distributions are uniform on $[0, 1]$. Formally, given a set of uniformaly distributed random variables $U_1, U_2, ..., U_n$, a copula is a joint distribution defined as

$$C(u_1, u_2, ..., u_n) = P(U_1 \leq u_1, ..., U_n \leq u_n)$$

What makes a copula model above so useful is the famous **Sklar's Theorem**. It states that for any joint cumulative distribution function **(CDF)** with a set of random variables $\{x_i\}_1^d$ and marginal CDF $F_i(x_i) = P(X_i \leq x)$, there exists one unique copula function such that the joint CDF is

$$F(x_1, ..., x_d) = C(F_1(x_1), ..., F_d(x_d))$$

By *probability integral transform*, each marginal CDF is a uniform random variable on $[0, 1]$. Hence, the above copula is a valid one. Since for each joint CDF, there is one unique copula function associated with it given a set of marginals, we can easily construct any joint distribution whose marginal univariate distributions are

the ones $F_i(x_i)$ that are given. And, for a given joint distribution, we can also find the corresponding copula which is the CDF function of the given marginals.

A useful representation we can get by **Sklar's Theorem** for a continuous copula is,

$$C(u_1, ...u_d) = F(F_1^-(u_1), ..., F_d^-(u_d))$$

If we further restrict the marginals to be Gaussian, then we can get an expression for Gaussian copula, that is,

$$C_\Sigma(u_1, ..., u_d) = \Phi(\Phi_1^-(u_1), ..., \Phi_d^-(u_d); 0, \Sigma)$$

where $\Phi(\cdot; \Sigma)$ is the CDF of a multivariate Gaussian Distribution $\mathcal{N}(0, \Sigma)$, and $\{\Phi_i^-\}$ is the inverse of a set of marginal Gaussian CDF.

To calculate the joint density of a copula function, we take the derivative with respect to random variables u and get

$$\begin{aligned} c_\Sigma(u_1, ..., u_d) &= \frac{\partial C_\Sigma(u_1, ..., u_d)}{\partial u_1 \cdots u_d} \\ &= \frac{\partial C_\Sigma(u_1, ..., u_d)}{\partial q_1 \cdots q_d} \prod_{i=1}^{d} \frac{\partial q_i}{\partial u_i} \\ &= (\prod_{i=1}^{d} \sigma_i)|\Sigma^{-1/2}|exp(-\frac{1}{2} q^T M q) \end{aligned}$$

where $M = \Sigma^- - diag(\Sigma)^-$, and $q_i = \Phi_i^-(u_i)$.

Then, if the joint density $p(x_1, ..., x_d)$ has a Gaussian form, it can be expressed by a copula density and its marginal densities, that is,

$$\begin{aligned} p(x_1, ..., x_d) &= \frac{\partial F(\cdot)}{\partial x_1 \cdots x_d} \\ &= \frac{\partial C_\Sigma(\cdot)}{\partial u_1 \cdots u_d} \prod \frac{\partial u_i}{\partial x_i} \\ &= c_\Sigma(u_1, ..., u_d) \prod_i p(x_i) \end{aligned}$$

Therefore, we can decompose the problem of estimating the joint density into two smaller subproblems: one is the estimation for the marginals; the other is the estimation for the copula density function c_Σ. In many cases, we assume independence over random variables due to the intractability of the joint density. For example, in the case of variational inference, we apply Mean-Field assumption which requires the variational distribution family to have factorized form so that we can get a closed-form KL divergence with respect to the prior. This assumption, however, sacrifices the useful dependency relationships over the latent random variables and often leads to training difficulties such as the posterior collapse problem. If we assume the joint posterior of latent variables to be Gaussian, then the above Gaussian copula model can be used to recover the correlation among latent variables which helps obtain a better estimation of the joint posterior density. In the VAE setting, we can already model the marginal independent posterior of latent variables, so the only problem left is how to efficiently estimate the copula density function c_Σ. In the next section, we introduce a neural parameterized Gaussian copula model, and we provide a way to incorporate it with the reparameterization technique used in VAE.

4.2 Neural Gaussian Copula for VI

By Mean-field assumption, we construct a variational family $\mathcal{Q}$ assuming that each member $q \in \mathcal{Q}$ can be factorized,

$$q(\mathbf{z}) = \prod_i^d q(z_i)$$

This assumption, however, loses dependencies over latent codes and hence does not consider the non-factorized form of the true posterior. In this case, as pictured by Figure 2, when we search the optimal q*, it will never reach to the true posterior p. If we relieve the assumption, the variational family may overlap with the posterior family. However, this is intractable as the Monto Carlo estimator with respect to the objective often has very high variance (Kingma and Welling, 2014). Hence, we need to find a way to make it possible to match the variational posterior with the true posterior while having a simple and tractable objective function so that the gradient estimator of the expectation is simple and precise.

This is where Gaussian Copula comes into the story. Given a factorized posterior, we can construct a Gaussian copula for the joint posterior,

$$q_\phi(\mathbf{z}|x) = c_\Sigma(\Phi_1(z_1), ...\Phi(z_d)) \prod_i^d q_\phi(z_i|x)$$

where c_Σ is the Gaussian copula density. If we take the log on both sides, then we have,

$$\log q_\phi(\mathbf{z}|x) = \log c_\Sigma(u_1, ..., u_d) + \sum_i^d \log q_\phi(z_i|x)$$

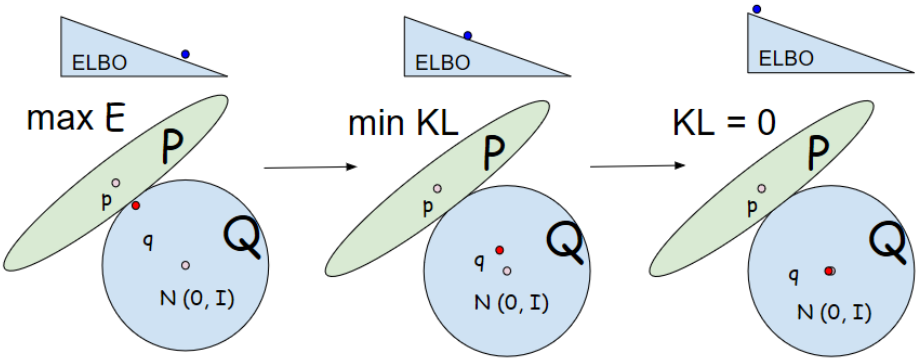

Figure 2: Training stage of VAE. Initially, the model tries to maximize ELBO by maximizing $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$. Once $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$ is maximized, the model maximizes ELBO by minimizing KL. During this stage, the posterior starts to move closer to the prior. In the final stage, the posterior collapses to the prior. But, the ELBO and $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$ are already maximized, which means the model keeps constraining KL and there are not enough gradients to move the posterior away from the prior anymore.

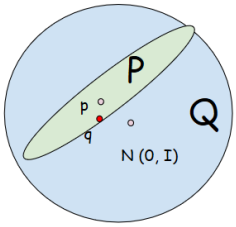

Figure 3: **Ideal** final stage of Copula-VAE. The family of distributions that contains the true posterior is now a subset of the variational family.

Note that the second term on the right hand side is just the factorized log posterior we have in the original VAE model. By reparameterization trick (Kingma and Welling, 2014), latent codes sampled from the posterior are parameterized as a deterministic function of μ and σ^2, that is, $\mathbf{z} = \mu + \sigma \cdot \epsilon, \epsilon \sim \mathcal{N}(0, I)$, where μ, σ^2 are parameterized by two neural networks whose inputs are the final hidden states of the LSTM encoder. Since $\prod_i q_\phi(z_i|x) = \mathcal{N}(\mu, \sigma^2 I)$, we can compute the sum of log density of posterior by,

$$\sum_i^d \log q_\phi(z_i|x) = -\sum_i^d \log|\sigma_i| - \sum_i^d \frac{(z_i - \mu_i)^2}{2\sigma_i^2} - \frac{d}{2}\log 2\pi$$

Now, to estimate the log copula density $\log c_\Sigma(\cdot)$, we provide a reparameterization method for the copula samples $q \sim C_\Sigma(\Phi_1(q_1), ...\Phi(q_d))$. As suggested by Kingma and Welling (2014); Hoffman et al. (2013), reparameterization is needed as it gives a differentiable, low-variance estimator of the objective function. Here, we parameterize the copula samples with a deterministic function with respect to the Cholesky factor L of its covariance matrix Σ. We use the fact that for any multivariate Gaussian random variables, a linear transformation of them is also a multivariate Gaussian random variable. Formally, if $X \sim \mathcal{N}(\mu, \Sigma)$, and $Y = AX$, then we must have $Y \sim \mathcal{N}(A\mu, A\Sigma A^T)$. Hence, for a Gaussian copula with the form $c_\Sigma = \mathcal{N}(0, \Sigma)$, we can reparameterize its samples q by,

$$\epsilon \sim \mathcal{N}(0, I)$$
$$q = L \cdot \epsilon$$

It is easy to see that $q = L \cdot \epsilon \sim \mathcal{N}(0, LI^-L^T = \Sigma)$ is indeed a sample from the Gaussian copula model. This is the standard way of sampling from Gaussian distribution with covariance matrix LL^T. To ensure **numerical stability** of the above reparameterization and to ensure that the covariance $\Sigma = LL^T$ is positive definite, we provide the following algorithm to parameterize L.

Algorithm 1: Neural reparameterization of Copula: Cholesky approach

h = LSTM(x)
w = ReLU($W_1 \cdot h + b_1$)
a = Tanh($W_2 \cdot h + b_2$)
$\Sigma = w \cdot I + aa^T$
L = CholeskyFactorization(Σ)

In Algorithm 1, we first parameterize the covariance matrix and then perform a Cholesky factor-

Table 1: Qualitative comparison between VAE and our proposed approach. First row: PTB samples generated from prior $p(\mathbf{z})$ by VAE (*upper half*) and copula-VAE (*lower half*). Second row: Yelp samples generated from prior $p(\mathbf{z})$ by VAE (*upper half*) and copula-VAE (*lower half*).

ization (Chen et al., 2008) to get the Cholesky factor L. The covariance matrix $\Sigma = w \cdot I + aa^T$ formed in this way is guaranteed to be positive definite. It is worth noting that we do not sample the latent codes from Gaussian copula. In fact, $\mathbf{z}$ still comes from the independent Gaussian distribution. Rather, we get sample q from Gaussian copula C_Σ so that we can compute the log copula density term in the following, which will then be used as a regularization term during training, in order to force the learned $\mathbf{z}$ to respect the dependencies among individual dimensions.

Now, to calculate the log copula density, we only need to do,

$$\log c_\Sigma = \sum_i^d \log \sigma_i - 1/2 \log |\Sigma| + 1/2 q^T M q$$

where $M = diag(\Sigma^-) - \Sigma^-$.

To make sure that our model maintains the dependency structure of the latent codes, we seek to maximize both the ELBO and the joint log posterior likelihood $\log q(\mathbf{z}|\mathbf{x})$ during the training. In other words, we maximize the following modified ELBO,

$$\mathcal{L}' = \mathcal{L} + \lambda(\log c_\Sigma(\cdot) + \sum_i^d \log q_\phi(z_i|\mathbf{x}))$$

where $\mathcal{L}$ is the original ELBO. λ is the weight of log density of the joint posterior. It controls how good the model is at maintaining the dependency relationships of latent codes. The reparameterization tricks both for $\mathbf{z}$ and q makes the above objective fully differentiable with respect to μ, σ^2, Σ. Maximizing $\mathcal{L}'$ will then maximize the log input likelihood $\log p(\mathbf{x})$ and the joint posterior log-likelihood $\log q(\mathbf{z}|\mathbf{x})$. If the posterior collapses to the prior and has a factorized form, then the joint posterior likelihood will not be maximized since the joint posterior is unlikely factorized. Therefore, maximizing the joint posterior log-likelihood along with ELBO forces the model to generate readable texts while also considering the dependency structure of the true posterior distribution, which is never factorized.

4.3 Evidence Lower Bound

Another interpretation can be seen by taking a look at the prior. If we compose the copula density with the prior, then, like the non-factorized posterior, we can get the non-factorized prior,

$$\log p_\theta(\mathbf{z}) = \log c_\Sigma(u_1, ..., u_d) + \sum_i^d \log p_\theta(z_i)$$

And the corresponding ELBO is,

$$\begin{aligned}\mathcal{L}(\theta; \phi; \mathbf{x}) &= \mathbb{E}_{q(\mathbf{x})}[\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] \\ &\quad - KL(q_\phi(\mathbf{z}|\mathbf{x})||p_\theta(\mathbf{z}))] \\ &= \mathbb{E}_{q(\mathbf{x})}[\mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log p_\theta(\mathbf{x}|\mathbf{z})] \\ &\quad - \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log q_\phi(\mathbf{z}|\mathbf{x}) - \log p(\mathbf{z})] \\ &\quad + \mathbb{E}_{q_\phi(\mathbf{z}|\mathbf{x})}[\log c_\Sigma(u_1, ..., u_d)]]\end{aligned}$$

Like Normalizing flow (Rezende and Mohamed, 2015), maximizing the log copula density will then learns a more flexible prior other than a standard Gaussian. The dependency among each z_i is

then restored since the KL term will push the posterior to this more complex prior.

We argue that relieving the Mean-field assumption by maintaining the dependency structure can avert the posterior collapse problem. As shown in Figure 2, during the training stage of original VAE, if kl-annealing (Bowman et al., 2015) is used, the model first seeks to maximize the expectation $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$. Then, since $q(\mathbf{z}|\mathbf{x})$ can never reach to the true $p(\mathbf{z}|\mathbf{x})$, q will reach to a boundary and then the expectation can no longer increase. During this stage, the model starts to maximize the ELBO by minimizing the KL divergence. Since the expectation is maximized and can no longer leverage KL, the posterior will collapse to the prior and there is not sufficient gradient to move it away since ELBO is already maximized. On the other hand, if we introduce a copula model to help maintain the dependency structure of the true posterior by maximizing the joint posterior likelihood, then, in the ideal case, the variational family can approximate distributions of any forms since it is now not restricted to be factorized, and therefore it is more likely for q in Figure 3 to be closer to the true posterior p. In this case, the $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$ can be higher since now we have latent codes sampled from a more accurate posterior, and then this expectation will be able to leverage the decrease of KL even in the final training stage.

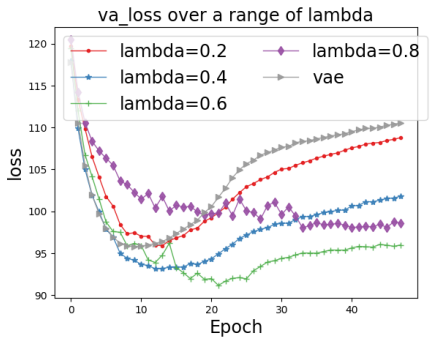
5.2 Experimental Setup



We set up a similar experimental condition as in (Bowman et al., 2015; Xiao et al., 2018; Yang et al., 2017; Xu and Durrett, 2018). We use LSTM as our encoder-decoder model, where the number of hidden units for each hidden state is set to 512. The word embedding size is 512. And, the number of dimension for latent codes is set to 32. For both encoder and decoder, we use a *dropout* layer for the initial input, whose dropout rate is $\alpha = 0.5$. Then, for inference, we pass the final hidden state to a linear layer following a *Batch Normalizing* (Ioffe and Szegedy, 2015) layer to get reparameterized samples from $\prod_i q(z_i|x)$ and from Gaussian copula C_Σ. For the training stage, the maximum vocabulary size for all inputs are set to 20000, and the maximum sequence length is set to 200. Batch size is set to 32, and we train for 30 epochs for each dataset, where we use the *Adam stochastic optimization* (Kingma and Ba, 2014) whose learning rate is $r = 10^{-3}$.

We use *kl annealing* (Bowman et al., 2015) during training. We also observe that the weight of *log copula* density is the most important factor which determines whether our model avoids the posterior collapse problem. We hyper tuned this parameter in order to find the optimal one.

Figure 4: Training and Validation KL divergence and sequential loss for PTB using Cholesky Neural Copula with different copula density weights λ. It is obvious that the optimal λ plays a huge role in alleviating the posterior collapse problem and does not result in overfitting as VAE does. Models are trained using 1-layer LSTM with 200 hidden units for Encoder/Decoder, in which the embedding size is 200 and the latent dimension is 32.

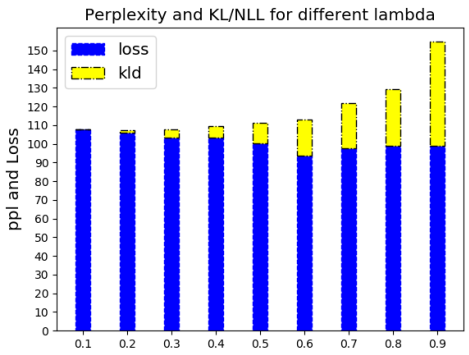

Figure 5: Reconstruction loss, KL divergence, and PPL (sum of loss and KL) on PTB. When we gradually increase λ, the KL divergence increases and the test reconstruction will decrease.

5.3 Language Modeling Comparison

5.3.1 Comparison with other Variational models

We compare the variational language modeling results over three datasets. We show the results for Negative log-likelihood (NLL), KL divergence, and sample perplexity (PPL) for each model on these datasets. NLL is approximated by the *evidence lower bound*.

First, we observe that kl-annealing does not help alleviate the posterior collapse problem when it comes to larger datasets such as Yelp, but the problem is solved if we can maintain the latent code's dependencies by maximizing the copula likelihood when we maximize the ELBO. We also observe that the weight λ of log copula density affects results dramatically. All λ produce competitive results compared with other methods. Here, we provide the numbers for those weights λ that produce the lowest PPL. For PTB, copula-VAE achieves the lowest sample perplexity, best NLL approximation, and do not result in posterior collapse when $\lambda = 0.4$. For Yelp, the lowest sample perplexity is achieved when $\lambda = 0.5$.

We also compare with VAE models trained with normalizing flows (Rezende and Mohamed, 2015). We observed that our model is superior to VAE based on flows. It is worth noting that Wasserstein Autoencoder trained with Normalizing flow (Wang and Wang, 2019) achieves the lowest PPL 66 on PTB, and 41 on Yelp. However, the

problem of designing flexible normalizing flow is orthogonal to our research.

5.3.2 Generation

Table 1 presents the results of text generation task. We first randomly sample $\mathbf{z}$ from $p(\mathbf{z})$, and then feed it into the decoder $p(\mathbf{x}|\mathbf{z})$ to generate text using greedy decoding. We can tell whether a model suffers from posterior collapse by examining the diversity of the generated sentences. The original VAE tends to generate the same type of sequences for different $\mathbf{z}$. This is very obvious in PTB where the posterior of the original VAE collapse to the prior completely. Copula-VAE, however, does not have this kind of issue and can always generate a diverse set of texts.

5.4 Hyperparameter-Tuning: Copula weights play a huge role in the training of VAE

In this section, we investigate the influence of log copula weight λ over training. From Figure 5, we observe that our model performance is very sensitive to the value of λ. We can see that when λ is small, the log copula density contributes a small part to the objective, and therefore does not help to maintain dependencies over latent codes. In this case, the model performs like the original VAE, where the KL divergence becomes zero at the end. When we increase λ, test KL becomes larger and test reconstruction loss becomes smaller.

This phenomenon is also observed in validation datasets, as shown in Figure 4. The training PPL is monotonically decreasing in general. However, when λ is small and the dependency relationships over latent codes are lost, the model quickly overfits, as the KL divergence quickly becomes zero and the validation loss starts to increase. This further confirms what we showed in Figure 2. For original VAE models, the model first maximizes $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$ which results in the decrease of both train and validation loss. Then, as $q(\mathbf{z}|\mathbf{x})$ can never match to the true posterior, $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$ reaches to its ceiling which then results in the decrease of KL as it is needed to maximize the ELBO. During this stage, the LSTM decoder starts to learn how to generate texts with standard Gaussian latent variables which then causes the increase of validation loss. On the other hand, if we gradually increase the contribution of copula density by increasing the λ, the model is able to maintain the dependencies of latent codes and hence the structure of the true posterior. In this case, $\mathbb{E}_{q(\mathbf{z}|\mathbf{x})}[p(\mathbf{x}|\mathbf{z})]$ will be much higher and will leverage the decrease of KL. In this case, the decoder is forced to generate texts from non-standard Gaussian latent codes. Therefore, the validation loss also decreases monotonically in general.

One major drawback of our model is the amount of training time, which is 5 times longer than the original VAE method. In terms of performance, copula-VAE achieves the lowest reconstruction loss when $\lambda = 0.6$. It is clear that from Figure 5 that increasing λ will result in larger KL divergence.

6 Conclusion

In this paper, we introduce **Copula-VAE** with Cholesky reparameterization method for Gaussian Copula. This approach averts **Posterior Collapse** by using Gaussian copula to maintain the dependency structure of the true posterior. Our results show that Copula-VAE significantly improves the language modeling results of other VAEs.

Abstract

Transformer is a powerful architecture that achieves superior performance on various sequence learning tasks, including neural machine translation, language understanding, and sequence prediction. At the core of the Transformer is the attention mechanism, which concurrently processes all inputs in the streams. In this paper, we present a new formulation of attention via the lens of the kernel. To be more precise, we realize that the attention can be seen as applying kernel smoother over the inputs with the kernel scores being the similarities between inputs. This new formulation gives us a better way to understand individual components of the Transformer's attention, such as the better way to integrate the positional embedding. Another important advantage of our kernel-based formulation is that it paves the way to a larger space of composing Transformer's attention. As an example, we propose a new variant of Transformer's attention which models the input as a product of symmetric kernels. This approach achieves competitive performance to the current state of the art model with less computation. In our experiments, we empirically study different kernel construction strategies on two widely used tasks: neural machine translation and sequence prediction.

1 Introduction

Transformer (Vaswani et al., 2017) is a relative new architecture which outperforms traditional deep learning models such as Recurrent Neural Networks (RNNs) (Sutskever et al., 2014) and Temporal Convolutional Networks (TCNs) (Bai et al., 2018) for sequence modeling tasks across neural machine translations (Vaswani et al., 2017), language understanding (Devlin et al., 2018), sequence prediction (Dai et al., 2019), image generation (Child et al., 2019), video activity classification (Wang et al., 2018), music generation (Huang et al., 2018a), and multimodal sentiment analysis (Tsai et al., 2019a). Instead of performing recurrence (e.g., RNN) or convolution (e.g., TCN) over the sequences, Transformer is a feed-forward model that concurrently processes the entire sequence. At the core of the Transformer is its attention mechanism, which is proposed to integrate the dependencies between the inputs. There are up to three types of attention within the full Transformer model as exemplified with neural machine translation application (Vaswani et al., 2017): 1) Encoder self-attention considers the source sentence as input, generating a sequence of encoded representations, where each encoded token has a global dependency with other tokens in the input sequence. 2) Decoder self-attention considers the target sentence (e.g., predicted target sequence for translation) as input, generating a sequence of decoded representations[1], where each decoded token depends on previous decoded tokens. 3) Decoder-encoder attention considers both encoded and decoded sequences, generating a sequence with the same length as the decoded sequence. It should be noted that some applications has only the decoder self-attention such as sequence prediction (Dai et al., 2019). In all cases, the Transformer's attentions follow the same general mechanism.

At the high level, the attention can be seen as a weighted combination of the input sequence, where the weights are determined by the similarities between elements of the input sequence. We note that this operation is order-agnostic to the permutation in the input sequence (order is encoded with extra positional embedding (Vaswani et al., 2017; Shaw et al., 2018; Dai et al., 2019)). The

[1]The generated sequence can be regarded as a translated sequence (i.e., translating from the encoded sequence), where each generated token depends on all tokens in the encoded sequence.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4344–4353,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

above observation inspires us to connect Transformer's attention to kernel learning (Scholkopf and Smola, 2001): they both concurrently and order-agnostically process all inputs by calculating the similarity between the inputs. Therefore, in the paper, we present a new formulation for Transformer's attention via the lens of kernel. To be more precise, the new formulation can be interpreted as a kernel smoother (Wasserman, 2006) over the inputs in a sequence, where the kernel measures how similar two different inputs are. The main advantage of connecting attention to kernel is that it opens up a new family of attention mechanisms that can relate to the well-established literature in kernel learning (Scholkopf and Smola, 2001). As a result, we develop a new variant of attention which simply considers a product of symmetric kernels when modeling non-positional and positional embedding.

Furthermore, our proposed formulation highlights naturally the main components of Transformer's attention, enabling a better understanding of this mechanism: recent variants of Transformers (Shaw et al., 2018; Huang et al., 2018b; Dai et al., 2019; Child et al., 2019; Lee et al., 2018; Wang et al., 2018; Tsai et al., 2019a) can be expressed through these individual components. Among all the components, we argue that the most important one is the construction of the kernel function. We empirically study multiple kernel forms and the ways to integrate positional embedding in neural machine translation (NMT) using IWSLT'14 German-English (De-En) dataset (Edunov et al., 2017) and sequence prediction (SP) using WikiText-103 dataset (Merity et al., 2016).

2 Attention

This section aims at providing an understanding of attention in Transformer via the lens of kernel. The inspiration for connecting the kernel (Scholkopf and Smola, 2001) and attention instantiates from the observation: both operations concurrently processes all inputs and calculate the similarity between the inputs. We first introduce the background (i.e., the original formulation) of attention and then provide a new reformulation within the class of kernel smoothers (Wasserman, 2006). Next, we show that this new formulation allows us to explore new family of attention while at the same time offering a framework to categorize previous attention variants (Vaswani et al., 2017; Shaw et al., 2018; Huang et al., 2018b; Dai et al., 2019; Child et al., 2019; Lee et al., 2018; Wang et al., 2018; Tsai et al., 2019a). Last, we present a new form of attention, which requires fewer parameters and empirically reaches competitive performance as the state-of-the-art models.

For notation, we use lowercase representing a vector (e.g., x), bold lowercase representing a matrix (e.g., $\mathbf{x}$), calligraphy letter denoting a space (e.g., $\mathcal{X}$), and S denoting a set. To relate the notations in sequence to sequence learning (Vaswani et al., 2017), x represents a specific element of a sequence, $\mathbf{x} = [x_1, x_2, \cdots, x_T]$ denotes a sequence of features, $S_{\mathbf{x}} = \{x_{\text{exp}}, x_2, \cdots, x_T\}$ represents the set with its elements being the features in sequence $\mathbf{x}$, and we refer the space of set $S_{\mathbf{x}}$ as $\mathcal{S}$.

2.1 Technical Background

Unlike recurrent computation (Sutskever et al., 2014) (i.e., RNNs) and temporal convolutional computation (Bai et al., 2018) (i.e., TCNs), Transformer's attention is an *order-agnostic* operation given the order in the inputs (Vaswani et al., 2017). Hence, in the presentation of the paper, we consider the inputs as a set instead of a sequence. When viewing sequence as a set, we lose the temporal (positional) information in inputs which is often crucial for sequence modeling (Sutskever et al., 2014). As a result, Transformer (Vaswani et al., 2017) introduced positional embedding to indicate the positional relation for the inputs. Formally, a sequence $\mathbf{x} = [x_1, x_2, \cdots, x_T]$ defines each element as $x_i = (f_i, t_i)$ with $f_i \in \mathcal{F}$ being the non-temporal feature at time i and $t_i \in \mathcal{T}$ as an temporal feature (or we called it positional embedding). Note that f_i can be the word representation (in neural machine translation (Vaswani et al., 2017)), a pixel in a frame (in video activity recognition (Wang et al., 2018)), or a music unit (in music generation (Huang et al., 2018b)). t_i can be a mixture of sine and cosine functions (Vaswani et al., 2017) or parameters that can be learned during back-propagation (Dai et al., 2019; Ott et al., 2019). The feature vector are defined over a joint space $\mathcal{X} := (\mathcal{F} \times \mathcal{T})$. The resulting permutation-invariant set is: $S_{\mathbf{x}} = \{x_1, x_2, \cdots, x_T\} = \{(f_1, t_1), (f_2, t_2), \cdots, (f_T, t_T)\}$.

Followed the definition by Vaswani et al. (2017), we use queries(q)/keys(k)/values(v) to represent the inputs for the attention. To be

more precise, $x_{\{q/k/v\}}$ is used for denoting a query/key/value data in the query/key/value sequence $\mathbf{x}_{\{q/k/v\}}$ ($x_{\{q/k/v\}} \in S_{\mathbf{x}_{\{q/k/v\}}}$) with $S_{\mathbf{x}_{\{q/k/v\}}}$ being its set representation. We note that the input sequences are the same ($\mathbf{x}_q = \mathbf{x}_k$) for self-attention and are different ($\mathbf{x}_q$ from decoder and $\mathbf{x}_k$ from encoder) for encoder-decoder attention.

Given the introduced notation, the attention mechanism in original Transformer (Vaswani et al., 2017) can be presented as:

$$\begin{aligned}&\text{Attention}(x_q\ ;\ S_{\mathbf{x}_k})\\ &=\text{softmax}\left(\frac{x_q W_q (\mathbf{x}_k W_k)^\top}{\sqrt{d_k}}\right)\mathbf{x}_k W_v\end{aligned} \tag{1}$$

with $x_q = f_q + t_q$, $\mathbf{x}_k = \mathbf{f}_k + \mathbf{t}_k$, $W_{q/k/v}$ being the weight, and d_k being the feature dimension of $\mathbf{x}_k W_k$. Decoder self-attention further introduces a mask to block the visibility of elements in $S_{\mathbf{x}_k}$ to x_q. Particularly, decoder self-attention considers the decoded sequence as inputs ($\mathbf{x}_k = \mathbf{x}_q$), where the decoded token at time t is not allowed to access the future decoded tokens (i.e., tokens decoded at time greater than t). On the contrary, encoder self-attention and decoder-encoder attention consider no additional mask to Eq. (1).

Recent work (Shaw et al., 2018; Dai et al., 2019; Huang et al., 2018b; Child et al., 2019; Lee et al., 2018; Parmar et al., 2018; Tsai et al., 2019a) proposed modifications to the Transformer for the purpose of better modeling inputs positional relation (Shaw et al., 2018; Huang et al., 2018b; Dai et al., 2019), appending additional keys in $S_{\mathbf{x}_k}$ (Dai et al., 2019), modifying the mask applied to Eq. (1) (Child et al., 2019), or applying to distinct feature types (Lee et al., 2018; Parmar et al., 2018; Tsai et al., 2019a). These works adopt different designs of attention as comparing to the original form (Eq. (1)). In our paper, we aim at providing an unified view via the lens of kernel.

2.2 Reformulation via the Lens of Kernel

We now provide the intuition to reformulate Eq. (1) via the lens of kernel. First, the softmax function can be realized as a probability function for x_q observing the keys $\{x_k\}$s in $S_{\mathbf{x}_k}$ ($S_{\mathbf{x}_k}$ is the set representation of sequence $\mathbf{x}_k$). The probability is determined by the dot product between x_q and x_k with additional mappings W_q/W_k and scaling by d_k, which we note the dot-product operation is an instance of kernel function. We also introduce a set filtering function $M(x_q, S_{\mathbf{x}_k}) : \mathcal{X} \times \mathcal{S} \to \mathcal{S}$ which returns a set with its elements that operate with (or are connected/visible to) x_q. The filtering function $M(\cdot,\cdot)$ plays as the role of the mask in decoder self-attention (Vaswani et al., 2017). Putting these altogether, we re-represent Eq. (1) into the following definition.

Definition 1. *Given a non-negative kernel function $k(\cdot,\cdot) : \mathcal{X} \times \mathcal{X} \to \mathbb{R}^+$, a set filtering function $M(\cdot,\cdot) : \mathcal{X} \times \mathcal{S} \to \mathcal{S}$, and a value function $v(\cdot) : \mathcal{X} \to \mathcal{Y}$, the Attention function taking the input of a query feature $x_q \in \mathcal{X}$ is defined as*

$$\begin{aligned}&\text{Attention}\Big(x_q\ ;\ M(x_q, S_{\mathbf{x}_k})\Big)\\ &=\sum_{x_k \in M(x_q, S_{\mathbf{x}_k})} \frac{k(x_q, x_k)}{\sum_{x_k{}' \in M(x_q, S_{\mathbf{x}_k})} k(x_q, x_k{}')} v(x_k).\end{aligned} \tag{2}$$

The Definition 1 is a class of linear smoothers (Wasserman, 2006) with kernel smoothing:

$$\begin{aligned}&\sum_{x_k \in M(x_q, S_{\mathbf{x}_k})} \frac{k(x_q, x_k)}{\sum_{x_k{}' \in M(x_q, S_{\mathbf{x}_k})} k(x_q, x_k{}')} v(x_k)\\ &= \mathbb{E}_{p(x_k|x_q)}\big[v(x_k)\big],\end{aligned}$$

where $v(x_k)$ outputs the "values" and $p(x_k|x_q) = \frac{k(x_q,x_k)}{\sum_{x_k{}' \in M(x_q, S_{\mathbf{x}_k})} k(x_q,x_k{}')}$ is a probability function depends on k and N when $k(\cdot,\cdot)$ is always positive. In the prior work (Vaswani et al., 2017), $k(x_q, x_k) = \exp\left(\langle x_q W_q, x_k W_k\rangle / \sqrt{d_k}\right)$ and $v(x_k) = x_k W_v$. Note that the kernel form $k(x_q, x_k)$ in the original Transformer (Vaswani et al., 2017) is a asymmetric exponential kernel with additional mapping W_q and W_k (Wilson et al., 2016; Li et al., 2017)[2].

The new formulation defines a larger space for composing attention by manipulating its individual components, and at the same time it is able to categorize different variants of attention in prior work (Shaw et al., 2018; Huang et al., 2018b; Dai et al., 2019; Child et al., 2019; Lee et al., 2018; Wang et al., 2018; Tsai et al., 2019a). In the following, we study these components by dissecting Eq. (2) into: 1) kernel feature space $\mathcal{X}$, 2)

[2]We note that rigorous definition of kernel function (Scholkopf and Smola, 2001) requires the kernel to be semi-positive definite and symmetric. While in the paper, the discussion on kernel allows it to be non-semi-positive definite and asymmetric. In Section 3, we will examine the kernels which are semi-positive and symmetric.

kernel construction $k(\cdot,\cdot)$, 3) value function $v(\cdot)$, and 4) set filtering function $M(\cdot,\cdot)$.

2.2.1 Kernel Feature Space $\mathcal{X}$

In Eq. (2), to construct a kernel on $\mathcal{X}$, the first thing is to identify the kernel feature space $\mathcal{X}$. In addition to modeling sequences like word sentences (Vaswani et al., 2017) or music signals (Huang et al., 2018b), the Transformer can also be applied to images (Parmar et al., 2018), sets (Lee et al., 2018), and multimodal sequences (Tsai et al., 2019a). Due to distinct data types, these applications admit various kernel feature space:

(i) Sequence Transformer (Vaswani et al., 2017; Dai et al., 2019):

$$\mathcal{X} := (\mathcal{F} \times \mathcal{T})$$

with $\mathcal{F}$ being non-positional feature space and $\mathcal{T}$ being the positional embedding space of the position in the sequence.

(ii) Image Transformer (Parmar et al., 2018):

$$\mathcal{X} := (\mathcal{F} \times \mathcal{H} \times \mathcal{W})$$

with $\mathcal{F}$ being non-positional feature space, $\mathcal{H}$ being the positional space of the height in an image, and $\mathcal{W}$ being the positional space of the width in an image.

(iii) Set Transformer (Lee et al., 2018) and Non-Local Neural Networks (Wang et al., 2018):

$$\mathcal{X} := (\mathcal{F})$$

with no any positional information present.

(iv) Multimodal Transformer (Tsai et al., 2019a):

$$\mathcal{X} := (\mathcal{F}^{\ell} \times \mathcal{F}^{v} \times \mathcal{F}^{a} \times \mathcal{T})$$

with $\mathcal{F}^{\ell}$ representing the language feature space, $\mathcal{F}^{v}$ representing the vision feature space, $\mathcal{F}^{a}$ representing the audio feature space, and $\mathcal{T}$ representing the temporal indicator space.

For the rest of the paper, we will focus on the setting for sequence Transformer $\mathcal{X} = (\mathcal{F} \times \mathcal{T})$ and discuss the kernel construction on it.

2.2.2 Kernel Construction and the Role of Positional Embedding $k(\cdot,\cdot)$

The kernel construction on $\mathcal{X} = (\mathcal{F} \times \mathcal{T})$ has distinct design in variants of Transformers (Vaswani et al., 2017; Dai et al., 2019; Huang et al., 2018b; Shaw et al., 2018; Child et al., 2019). Since now the kernel feature space considers a joint space, we will first discuss the kernel construction on $\mathcal{F}$ (the non-positional feature space) and then discuss how different variants integrate the positional embedding (with the positional feature space $\mathcal{T}$) into the kernel.

Kernel construction on $\mathcal{F}$. All the work considered the scaled asymmetric exponential kernel with the mapping W_q and W_k (Wilson et al., 2016; Li et al., 2017) for non-positional features f_q and f_k:

$$k_{\exp}(f_q, f_k) = \exp\left(\frac{\langle f_q W_q, f_k W_k\rangle}{\sqrt{d_k}}\right). \quad (3)$$

Note that the usage of asymmetric kernel is also commonly used in various machine learning tasks (Yilmaz, 2007; Tsuda, 1999; Kulis et al., 2011), where they observed the kernel form can be flexible and even non-valid (i.e., a kernel that is not symmetric and positive semi-definite). In Section 3, we show that symmetric design of the kernel has similar performance for various sequence learning tasks, and we also examine different kernel choices (i.e., linear, polynomial, and rbf kernel).

Kernel construction on $\mathcal{X} = (\mathcal{F} \times \mathcal{T})$. The designs for integrating the positional embedding t_q and t_k are listed in the following.

(i) Absolute Positional Embedding (Vaswani et al., 2017; Dai et al., 2019; Ott et al., 2019): For the original Transformer (Vaswani et al., 2017), each t_i is represented by a vector with each dimension being sine or cosine functions. For learned positional embedding (Dai et al., 2019; Ott et al., 2019), each t_i is a learned parameter and is fixed for the same position for different sequences. These works defines the feature space as the direct sum of its temporal and non-temporal space: $\mathcal{X} = \mathcal{F} \oplus \mathcal{T}$. Via the lens of kernel, the kernel similarity is defined as

$$k\Big(x_q, x_k\Big) := k_{\exp}\Big(f_q + t_q, f_k + t_k\Big). \quad (4)$$

(ii) Relative Positional Embedding in Transformer-XL (Dai et al., 2019): t represents the indicator of the position in the sequence, and the kernel is chosen to be asymmetric of mixing sine and cosine functions:

$$k\Big(x_q, x_k\Big) := k_{\exp}\Big(f_q, f_k\Big) \cdot k_{f_q}\Big(t_q, t_k\Big) \quad (5)$$

with $k_{f_q}\Big(t_q, t_k\Big)$ being an asymmetric kernel with coefficients inferred by f_q: $\log k_{f_q}\Big(t_q, t_k\Big) = \sum_{p=0}^{\lfloor d_k/2 \rfloor - 1} c_{2p} \sin(\frac{t_q - t_k}{10000^{\frac{2p}{512}}}) + c_{2p+1} \cos(\frac{t_q - t_k}{10000^{\frac{2p}{512}}})$ with $[c_0, \cdots, c_{d_k-1}] = f_q W_q W_R$ where W_R is an learned weight matrix. We refer readers to Dai et al. (2019) for more details.

(iii) Relative Positional Embedding of Shaw et al. (2018) and Music Transformer (Huang et al., 2018b): $t.$ represents the indicator of the position in the sequence, and the kernel is modified to be indexed by a look-up table:

$$k\Big(x_q, x_k\Big) := L_{t_q - t_k, f_q} \cdot k_{\exp}\Big(f_q, f_k\Big), \quad (6)$$

where $L_{t_q - t_k, f_q} = \exp(f_q W_q a_{t_q - t_k})$ with $a.$ being a learnable matrix having matrix width to be the length of the sequence. We refer readers to Shaw et al. (2018) for more details.

Dai et al. (2019) showed that the way to integrate positional embedding is better through Eq. (5) than through Eq. (6) and is better through Eq. (6) than through Eq. (4). We argue the reason is that if viewing f_i and t_i as two distinct spaces $\Big(\mathcal{X} := (\mathcal{F} \times \mathcal{T})\Big)$, the direct sum $x_i = f_i + t_i$ may not be optimal when considering the kernel score between x_q and x_k. In contrast, Eq. (5) represents the kernel as a product of two kernels (one for f_i and another for t_i), which is able to capture the similarities for both temporal and non-temporal components.

2.2.3 Value Function $v(\cdot)$

The current Transformers consider two different value function construction:

(i) Original Transformer (Vaswani et al., 2017) and Sparse Transformer (Child et al., 2019):

$$v(x_k) = v((f_k, t_k)) := (f_k + t_k) W_v. \quad (7)$$

(ii) Transformer-XL (Dai et al., 2019), Music Transformer (Huang et al., 2018b), Self-Attention with Relative Positional Embedding (Shaw et al., 2018):

$$v(x_k) = v((f_k, t_k)) := f_k W_v. \quad (8)$$

Compared Eq. (7) to Eq. (8), Eq. (7) takes the positional embedding into account for constructing the value function. In Section 3, we empirically observe that constructing value function with Eq. (8) constantly outperforms the construction with Eq. (7), which suggests that we do not need positional embedding for value function.

2.2.4 Set Filtering Function $M(\cdot, \cdot)$

In Eq. (2), the returned set by the set filtering function $M(x_q, S_{\mathbf{x}_k})$ defines how many keys and which keys are operating with x_q. In the following, we itemize the corresponding designs for the variants in Transformers:

(i) Encoder Self-Attention in original Transformer (Vaswani et al., 2017): For each query x_q in the encoded sequence, $M(x_q, S_{\mathbf{x}_k}) = S_{\mathbf{x}_k}$ contains the keys being all the tokens in the encoded sequence. Note that encoder self-attention considers $\mathbf{x}_q = \mathbf{x}_k$ with $\mathbf{x}_q$ being the encoded sequence.

(ii) Encoder-Decoder Attention in original Transformer (Vaswani et al., 2017): For each query x_q in decoded sequence, $M(x_q, S_{\mathbf{x}_k}) = S_{\mathbf{x}_k}$ contains the keys being all the tokens in the encoded sequence. Note that encode-decoder attention considers $\mathbf{x}_q \neq \mathbf{x}_k$ with $\mathbf{x}_q$ being the decoded sequence and $\mathbf{x}_k$ being the encoded sequence.

(iii) Decoder Self-Attention in original Transformer (Vaswani et al., 2017): For each query x_q in the decoded sequence, $M(x_q, S_{\mathbf{x}_k})$ returns a subset of $S_{\mathbf{x}_k}$ ($M(x_q, S_{\mathbf{x}_k}) \subset S_{\mathbf{x}_k}$). Note that decoder self-attention considers $\mathbf{x}_q = \mathbf{x}_k$ with $\mathbf{x}_q$ being the decoded sequence. Since the decoded sequence is the output for previous timestep, the query at position i can only observe the keys being the tokens that are decoded with position $< i$. For convenience, let us define S_1 as the set returned by original Transformer (Vaswani et al., 2017) from $M(x_q, S_{\mathbf{x}_k})$, which we will use it later.

(iv) Decoder Self-Attention in Transformer-XL (Dai et al., 2019): For each query x_q in the decoded sequence, $M(x_q, S_{\mathbf{x}_k})$ returns a set containing S_1 and additional memories ($M(x_q, S_{\mathbf{x}_k}) = S_1 + S_{mem}, M(x_q, S_{\mathbf{x}_k}) \supset S_1$). S_{mem} refers to additional memories.

(v) Decoder Self-Attention in Sparse Transformer (Child et al., 2019): For each query x_q in the decoded sentence, $M(x_q, S_{\mathbf{x}_k})$ returns a subset of S_1 ($M(x_q, S_{\mathbf{x}_k}) \subset S_1$).

To compare the differences for various designs, we see the computation time is inversely proportional to the number of elements in $M(x_q, S_{\mathbf{x}_k})$. For performance-wise comparisons, Transformer-XL (Dai et al., 2019) showed that, the additional memories in $M(x_q, S_{\mathbf{x}_k})$ are able to capture longer-term dependency than the original Transformer (Vaswani et al., 2017) and hence results in better performance. Sparse Transformer (Child

et al., 2019) showed that although having much fewer elements in $M(x_q, S_{\mathbf{x}_k})$, if the elements are carefully chosen, the attention can still reach the same performance as Transformer-XL (Dai et al., 2019).

2.3 Exploring the Design of Attention

So far, we see how Eq. (2) connects to the variants of Transformers. By changing the kernel construction in Section 2.2.2, we can define a larger space for composing attention. In this paper, we present a new form of attention with a kernel that is 1) valid (i.e., a kernel that is symmetric and positive semi-definite) and 2) delicate in the sense of constructing a kernel on a joint space (i.e., $\mathcal{X} = (\mathcal{F} \times \mathcal{T})$):

$$
\begin{aligned}
& k(x_q, x_k) := k_F\Big(f_q, f_k\Big) \cdot k_T\Big(t_q, t_k\Big) \\
& \text{with } k_F(f_q, f_k) = \exp\Big(\frac{\langle f_q W_F, f_k W_F \rangle}{\sqrt{d_k}}\Big) \\
& \text{and } \ k_T(t_q, t_k) = \exp\Big(\frac{\langle t_q W_T, t_k W_T \rangle}{\sqrt{d_k}}\Big),
\end{aligned}
\tag{9}
$$

where W_F and W_T are weight matrices. The new form considers product of kernels with the first kernel measuring similarity between non-temporal features and the second kernel measuring similarity between temporal features. Both kernels are symmetric exponential kernel. Note that t_i here is chosen as the mixture of sine and cosine functions as in the prior work (Vaswani et al., 2017; Ott et al., 2019). In our experiment, we find it reaching competitive performance as comparing to the current state-of-the-art designs (Eq. (5) by Dai et al. (2019)). We fix the size of the weight matrices $W_\cdot$ in Eq. (9) and Eq. (5) which means we save 33% of the parameters in attention from Eq. (9) to Eq. (5) (Eq. (5) has weights $W_Q/W_K/W_R$ and Eq. (9) has weights W_F/W_T).

3 Experiments

By viewing the attention mechanism with Eq. (2), we aims at answering the following questions regarding the Transformer's designs:

Q1. What is the suggested way for incorporating positional embedding in the kernel function?

Q2. What forms of kernel are recommended to choose in the attention mechanism? Can we replace the asymmetric kernel with the symmetric version?

Q3. Is there any exception that the attention mechanism is not order-agnostic with respect to inputs? If so, can we downplay the role of positional embedding?

Q4. Is positional embedding required in value function?

We conduct experiments on neural machine translation (NMT) and sequence prediction (SP) tasks since these two tasks are commonly chosen for studying Transformers (Vaswani et al., 2017; Dai et al., 2019). Note that NMT has three different types of attentions (e.g., encoder self-attention, decoder-encoder attention, decoder self-attention) and SP has only one type of attention (e.g., decoder self-attention). For the choice of datasets, we pick IWSLT'14 German-English (De-En) dataset (Edunov et al., 2017) for NMT and WikiText-103 dataset (Merity et al., 2016) for SP as suggested by Edunov *et al.* (Edunov et al., 2017) and Dai *et al.* (Dai et al., 2019). For fairness of comparisons, we train five random initializations and report test accuracy with the highest validation score. We fix the position-wise operations in Transformer[3] and only change the attention mechanism. Similar to prior work (Vaswani et al., 2017; Dai et al., 2019), we report BLEU score for NMT and perplexity for SP.

3.1 Incorporating Positional Embedding

In order to find the best way to integrate positional embedding (PE), we study different PE incorporation in the kernel function $k(\cdot, \cdot)$ in Eq. (2). Referring to Sections 2.2.2 and 2.3, we consider four cases: 1) PE as direct sum in the feature space (see Eq. (4)), 2) PE as a look-up table (see Eq. (6)), 3) PE in product kernel with asymmetric kernel (see Eq. (5)), and 4) PE in product kernel with symmetric kernel (see Eq. (9)). We present the results in Table 1.

First, we see that by having PE as a look-up table, it outperforms the case with having PE as direct-sum in feature space, especially for SP task. Note that the look-up table is indexed by the relative position (i.e., $t_q - t_k$) instead of absolute position. Second, we see that PE in the product kernel proposed by Dai *et al.* (Dai et al., 2019) may not

[3]The computation of Transformer can be categorized into position-wise and inter-positions (i.e., the attention mechanism) operations. Position-wise operations include layer normalization, residual connection, and feed-forward mapping. We refer the readers to Vaswani *et al.* (Vaswani et al., 2017) for more details.

Table 1: Incorporating Positional Embedding (PE). NMT stands for neural machine translation on IWSLT'14 De-En dataset (Edunov et al., 2017) and SP stands for sequence prediction on WikiText-103 dataset (Merity et al., 2016). ↑ means the upper the better and ↓ means the lower the better.

Approach	PE Incorporation	Kernel Form	NMT (BLEU↑)	SP (Perplexity↓)
Vaswani et al. (2017) (Eq. (4))	Direct-Sum	$k_{\exp}\Big(f_q + t_q, f_k + t_k\Big)$	33.98	30.97
Shaw et al. (2018) (Eq. (6))	Look-up Table	$L_{t_q - t_k, f_q} \cdot k_{\exp}\Big(f_q, f_k\Big)$	34.12	27.56
Dai et al. (2019) (Eq. (5))	Product Kernel	$k_{\exp}\Big(f_q, f_k\Big) \cdot k_{f_q}\Big(t_q, t_k\Big)$	33.62	**24.10**
Ours (Eq. (9))	Product Kernel	$k_F\Big(f_q, f_k\Big) \cdot k_T\Big(t_q, t_k\Big)$	**34.71**	24.28

Table 2: Kernel Types. Other than manipulating the kernel choice of the non-positional features, we fix the configuration by Vaswani et al. (2017) for NMT and the configuration by Dai et al. (2019) for SP.

Type	Kernel Form	NMT (BLEU↑)		SP (Perplexity↓)	
		Asym. ($W_q \neq W_k$)	Sym. ($W_q = W_k$)	Asym. ($W_q \neq W_k$)	Sym. ($W_q = W_k$)
Linear	$\langle f_a W_q, f_b W_k \rangle$	not converge	not converge	not converge	not converge
Polynomial	$\Big(\langle f_a W_q, f_b W_k \rangle\Big)^2$	32.72	32.43	25.91	26.25
Exponential	$\exp\Big(\frac{\langle f_a W_q, f_b W_k \rangle}{\sqrt{d_k}}\Big)$	33.98	33.78	24.10	**24.01**
RBF	$\exp\Big(-\frac{\|f_a W_q - f_b W_k\|^2}{\sqrt{d_k}}\Big)$	**34.26**	34.14	24.13	24.21

constantly outperform the other integration types (it has lower BLEU score for NMT). Our proposed product kernel reaches the best result in NMT and is competitive to the best result in SP.

3.2 Kernel Types

To find the best kernel form in the attention mechanism, in addition to the exponential kernel (see Eq. (3)), we compare different kernel forms (i.e., linear, polynomial, and rbf kernel) for the non-positional features. We also provide the results for changing asymmetric to the symmetric kernel, when forcing $W_q = W_k$, so that the resulting kernel is a valid kernel (Scholkopf and Smola, 2001). The numbers are shown in Table 2. Note that, for fairness, other than manipulating the kernel choice of the non-positional features, we fix the configuration by Vaswani *et al.* (Vaswani et al., 2017) for NMT and the configuration by Dai *et al.* (Dai et al., 2019) for SP.

We first observe that the linear kernel does not converge for both NMT and SP. We argue the reason is that the linear kernel may have negative value and thus it violates the assumption in kernel smoother that the kernel score must be positive (Wasserman, 2006). Next, we observe the kernel with infinite feature space (i.e., exponential and rbf kernel) outperforms the kernel with finite feature space (i.e., polynomial kernel). And we see rbf kernel performs the best for NMT and exponential kernel performs the best for SP. We conclude that the choice of kernel matters for the design of attention in Transformer. Also, we see no much performance difference when comparing asymmetric to symmetric kernel. In the experiment, we fix the size of $W_\cdot$ in the kernel, and thus adopting the symmetric kernel benefits us from saving parameters.

3.3 Order-Invariance in Attention

The need of the positional embedding (PE) in the attention mechanism is based on the argument that the attention mechanism is an order-agnostic (or, permutation equivariant) operation (Vaswani et al., 2017; Shaw et al., 2018; Huang et al., 2018b; Dai et al., 2019; Child et al., 2019). However, we show that, for decoder self-attention, the operation is not order-agnostic. For clarification, we are not attacking the claim made by the prior work (Vaswani et al., 2017; Shaw et al., 2018; Huang et al., 2018b; Dai et al., 2019; Child et al., 2019), but we aim at providing a new look at the order-invariance problem when considering the attention mechanism with masks (masks refer to the set filtering function in our kernel formulation). In other words, previous work did not consider the

Table 3: Order-Invariance in Attention. To save the space, we denote Encoder Self-Attention / Encoder-Decoder Attention / Decoder Self-Attention as A/B/C. Note that SP only has decoder self-attention.

Approach	Positional Embedding	NMT (BLEU↑)

Ours (Eq. (9))	34.60	**34.71**	24.42	24.28

mask between queries and keys when discussing the order-invariance problem (Pérez et al., 2019).

To put it formally, we first present the definition by Lee et al. (2018) for a permutation equivariance function:

Definition 2. *Denote* Π *as the set of all permutations over* $[n] = \{1, \cdots, n\}$. *A function* $func : \mathcal{X}^n \rightarrow \mathcal{Y}^n$ *is permutation equivariant iff for any permutation* $\pi \in \Pi$, $func(\pi x) = \pi func(x)$.

Lee et al. (2018) showed that the standard attention (encoder self-attention (Vaswani et al., 2017; Dai et al., 2019)) is permutation equivariant. Here, we present the non-permutation-equivariant problem on the decoder self-attention:

Proposition 1. *Decoder self-attention (Vaswani et al., 2017; Dai et al., 2019) is not permutation equivariant.*

To proceed the proof, we need the following definition and propositions.

Definition 3. *Denote* Π *as the set of all permutations over* $[n] = \{1, \cdots, n\}$ *and* $S^{\pi}_{\mathbf{x}_k}$ *as performing permutation* π *over* $S_{\mathbf{x}_k}$. $\text{Attention}(x_q; S_{\mathbf{x}_k})$ *is said to be permutation equivariant w.r.t.* $S_{\mathbf{x}_k}$ *if and only if for any* $\pi \in \Pi$, $\text{Attention}(x_q; S^{\pi}_{\mathbf{x}_k}) = \text{Attention}(x_q; S_{\mathbf{x}_k})$.

Proposition 2. *Attention with the set filtering function* $M(x_q, S_{\mathbf{x}_k}) = S_{\mathbf{x}_k}$ *is permutation equivariant w.r.t.* $S_{\mathbf{x}_k}$.

Proof. It is easy to show that if $M(x_q, S_{\mathbf{x}_k}) = S_{\mathbf{x}_k}$, Eq. (2) remains unchanged for any permutation π performed on $S_{\mathbf{x}_k}$. ■

Proposition 3. *Attention with the set difference* $S_{\mathbf{x}_k} \setminus M(x_q, S_{\mathbf{x}_k}) \neq \phi$ *is not permutation equivariant w.r.t.* $S_{\mathbf{x}_k}$.

Proof. First, suppose that $\hat{x} \in S_{\mathbf{x}_k} \setminus M(x_q, S_{\mathbf{x}_k})$. Then, we construct a permutation π such that $\hat{x} \in M(x_q, S^{\pi}_{\mathbf{x}_k})$. It is obvious that Eq. (2) changes after this permutation and thus $\text{Attention}\Big(x_q\ ;\ M(x_q, S_{\mathbf{x}_k})\Big)$ is not permutation equivariant w.r.t. $S_{\mathbf{x}_k}$. ■

Proof. [Proof for Proposition 1] First, we have $x_q \sim S_{\mathbf{x}_k}$. Hence, showing $\text{Attention}(x_q; S_{\mathbf{x}_k})$ not permutation equivariant w.r.t. $S_{\mathbf{x}_k}$ equals to showing Attention not permutation equivariant. Then, since the decoder self-attention considers masking (i.e., $M(x_q, S_{\mathbf{x}_k})$ returns a subset of $S_{\mathbf{x}_k}$), by Proposition 3, the decoder self-attention is not permutation equivariant. ■

In fact, not only being a permutation inequivariant process, the decoding process in the decoder self-attention already implies the order information from the data. To show this, take the decoded sequence $\mathbf{y} = [\text{init}, y_1, y_2, y_3, y_4]$ as an example. init stands for the initial token. When determining the output y_1 from init, the set filtering function is $M(\text{init}, S_{\mathbf{y}}) = \{\text{init}\}$. Similarly, we will have $M(y_1, S_{\mathbf{y}}), M(y_2, S_{\mathbf{y}}), M(y_3, S_{\mathbf{y}})$ to be $\{\text{init}, y_1\}, \{\text{init}, y_1, y_2\}, \{\text{init}, y_1, y_2, y_3\}$. Then, it raises a concern: do we require PE in decoder self-attention? By removing PE in decoder self-attention, we present the results in Table 3. From the table, we can see that, for NMT, removing PE

only in decoder self-attention results in slight performance drop (from 34.71 to 34.49). However, removing PE in the entire model greatly degrades the performance (from 34.71 to 14.47). On the other hand, for SP, removing PE from our proposed attention variant dramatically degrades the performance (from 24.28 to 30.92). Nonetheless, the performance is slightly better than considering PE from the original Transformer (Vaswani et al., 2017).

3.4 Positional Embedding in Value Function

To determine the need of positional embedding (PE) in value function, we conduct the experiments by adopting Eq. (7) or Eq. (8) in the attention mechanism. The results are presented in Table 4. From the table, we find that considering PE in value function (Eq. (7)) does not gain performance as compared to not considering PE in value function (Eq. (8)).

3.5 Take-Home Messages

Based on the results and discussions, we can now answer the questions given at the beginning of this section. The answers are summarized into the take-home messages in the following.

A1. We show that integrating the positional embedding in the form of product kernel (Eq. (5) or Eq. (9)) gives us best performance.

A2. The kernel form does matter. Adopting kernel form with infinite feature dimension (i.e., exponential kernel or rbf kernel) gives us best results. The symmetric design of the kernel may benefit us from saving parameters and barely sacrifice the performance as compared to the non-symmetric one.

A3. The decoder self-attention is not an order-agnostic operation with respect to the order of inputs. However, incorporating positional embedding into the attention mechanism may still improve performance.

A4. We find that there is no much performance difference by considering or not considering the positional embedding in value function.

4 Related Work

Other than relating Transformer's attention mechanism with kernel methods, the prior work (Wang et al., 2018; Shaw et al., 2018; Tsai et al., 2019b) related the attention mechanism with graph-structured learning. For example, Non-Local Neural Networks (Wang et al., 2018) made a connection between the attention and the non-local operation in image processing (Buades et al., 2005). Others (Shaw et al., 2018; Tsai et al., 2019b) linked the attention to the message passing in graphical models. In addition to the fundamental difference between graph-structured learning and kernel learning, the prior work (Wang et al., 2018; Shaw et al., 2018; Tsai et al., 2019b) focused on presenting Transformer for its particular application (e.g., video classification (Wang et al., 2018) and neural machine translation (Shaw et al., 2018)). Alternatively, our work focuses on presenting a new formulation of Transformer's attention mechanism that gains us the possibility for understanding the attention mechanism better.

5 Conclusions

In this paper, we presented a kernel formulation for the attention mechanism in Transformer, which allows us to define a larger space for designing attention. As an example, we proposed a new variant of attention which reaches competitive performance when compared to previous state-of-the-art models. Via the lens of the kernel, we were able to better understand the role of individual components in Transformer's attention and categorize previous attention variants in a unified formulation. Among these components, we found the construction of the kernel function acts the most important role, and we studied different kernel forms and the ways to integrate positional embedding on neural machine translation and sequence prediction. We hope our empirical study may potentially allow others to design better attention mechanisms given their particular applications.

Acknowledgments

We thank Zhilin Yang for helpful discussion on the positional encoding in Transformer's Attention. This work was supported in part by the DARPA grant FA875018C0150, Office of Naval Research grant N000141812861, AFRL CogDeCON, NSF Awards #1734868 #1722822, National Institutes of Health, JST PRESTO program JPMJPR165A, and Apple. We would also like to acknowledge NVIDIA's GPU support.

Abstract

Many tasks in natural language processing can be viewed as multi-label classification problems. However, most of the existing models are trained with the standard cross-entropy loss function and use a fixed prediction policy (e.g., a threshold of 0.5) for all the labels, which completely ignores the complexity and dependencies among different labels. In this paper, we propose a meta-learning method to capture these complex label dependencies. More specifically, our method utilizes a meta-learner to jointly learn the training policies and prediction policies for different labels. The training policies are then used to train the classifier with the cross-entropy loss function, and the prediction policies are further implemented for prediction. Experimental results on fine-grained entity typing and text classification demonstrate that our proposed method can obtain more accurate multi-label classification results.

1 Introduction

Multi-label classification aims at learning to make predictions on instances that are associated with multiple labels simultaneously, whereas in a classic multi-class classification setting, typically one instance has only one label. Multi-label classification is a common learning paradigm in a large amount of real-world natural language processing (NLP) applications, such as fine-grained entity typing (Ling and Weld, 2012; Shimaoka et al., 2017; Abhishek et al., 2017; Xin et al., 2018) and text classification (Nam et al., 2014; Liu et al., 2017; Chen et al., 2017; Wu et al., 2018).

Significant amounts of research studies have been dedicated to tackle the multi-label classification problem (Zhang and Zhou, 2014), from traditional statistical models (Zhang and Zhou, 2007; Zhou et al., 2012; Surdeanu et al., 2012) to neural network-based models (Nam et al., 2014; Shimaoka et al., 2017). These models have variable structures, but usually, share the standard cross-entropy loss function for training. After training, these models tend to use a single prediction policy for all the labels to generate the final predictions. Actually, the above process is based on the assumption that there is no dependency among the labels. However, as shown in Figure 1, this assumption is hard to be satisfied in real-world datasets, and the complex label dependencies receive little attention in multi-label classification (Dembszynski et al., 2010; Dembczyński et al., 2012). Owing to the impact of the label dependencies, although one object may have multiple labels simultaneously in the multi-label classification setting, the level of difficulty of prediction for different labels can vary a lot. Firstly, for those labels that are aligned with knowledge graphs, they usually indicate a hierarchical dependency struc-

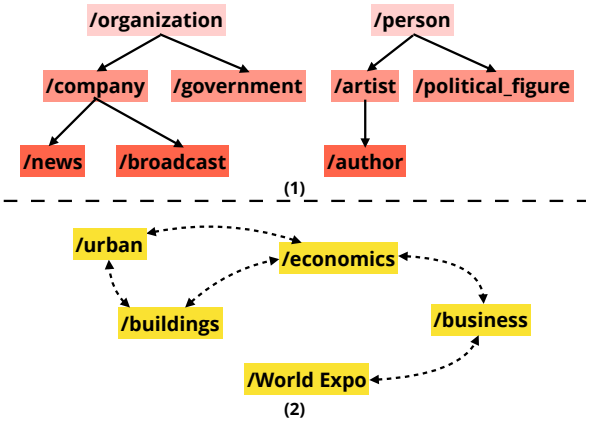

Figure 1: Illustration of complex label dependencies in multi-label classification. (1) Labels are aligned with some knowledge graphs. In this case, labels are organized in a hierarchical dependency structure. (2) Even if labels do not demonstrate explicit correlation, they can still have implicit semantic dependencies.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4354–4364,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ture (Ling and Weld, 2012; Ren et al., 2016; Ruder et al., 2016). It is intuitive that one trained classifier is easier to distinguish high-level parent labels, such as `/organization` and `/person`, but harder to distinguish low-level child labels, such as `/news` and `/broadcast`. Secondly, for those cases where labels do not demonstrate explicit correlation, the labels still contain implicit semantic dependencies, which is extremely common in the NLP field. For instance, the label `/urban` and `/economics` have obvious semantic correlation even if they are not organized in a hierarchical structure. Meanwhile, the labels with more implicit dependencies are easier to predict because they expose more semantic information during the training. These intuitions inspire our work on learning different training policies and prediction policies for different labels.

The training policies and prediction policies for all the labels can be viewed as a series of hyper-parameters. However, to learn high-quality policies, one needs to specify both explicit and implicit label dependencies, which is not manually realistic. To resolve both issues mentioned above, we propose a meta-learning framework to model these label dependencies and learn training and prediction policies automatically. Concretely, we introduce a joint learning formulation of the meta-learning method and multi-label classification. A gated recurrent unit (GRU)-based (Chung et al., 2014) meta-learner is implemented to capture the label dependencies and learn these hyper-parameters during the training process of a classifier. Empirically, we show our method outperforms previous related methods on fine-grained entity typing and text classification problems. In summary, our contributions are three-fold:

- We are the first to propose a joint formulation of "learning to learn" and "learning to predict" in a multi-label classification setting.
- Our learning method can learn a weight and a decision policy for each label, which can then be incorporated into training and prediction.
- We show that our method is model-agnostic and can apply to different models in multi-label classification and outperform baselines.

In Section 2, we outline related work in multi-label classification and meta-learning. We then describe our proposed method in Section 3. We show experimental results in Section 4. Finally, we conclude in Section 7.

2 Related Work

2.1 Multi-Label Classification

Multi-label classification assigns instances with multiple labels simultaneously (Tsoumakas et al., 2006). (Shore and Johnson, 1980; De Boer et al., 2005) introduce prediction policies that weight the training loss function with external knowledge. However, in real-world multi-label classification, it is hard to obtain knowledge to determine prediction policies. As for the prediction policies, Yang (2001) select the thresholds that achieve the best evaluation measure on a validation set, while Lewis et al. (2004) utilize a cross-validation method to determine the thresholds. Lipton et al. (2014) propose an optimal decision rule to maximize F1 measure with thresholds. However, most of the previous methods can be viewed as post-processing because the prediction policies are computed after training. Meanwhile, the ability of prediction policies to help train the classifier is less explored.

Compared to previous related methods, we propose a principled approach that learns a training policy and a prediction policy for each label automatically with modeling label dependencies implicitly. Furthermore, the prediction policies are learned during the training process instead of the post-processing, which can also help to train a better classifier.

2.2 Meta-learning

Meta-learning is a "learning to learn" method, in which a learner learns new tasks and another meta-learner learns to train the learner (Bengio et al., 1990; Runarsson and Jonsson, 2000; Thrun and Pratt, 2012). There are two types of meta-learning:

- learning a meta-policy to update model parameters (Andrychowicz et al., 2016; Mishra et al., 2018).
- learning a good parameter initialization for fast adaptation (Duan et al., 2016; Vinyals et al., 2016; Finn et al., 2017; Snell et al., 2017; Gu et al., 2018).

In this paper, we propose to extend meta-learning algorithm for multi-label classification based on the first category. Instead of only training the

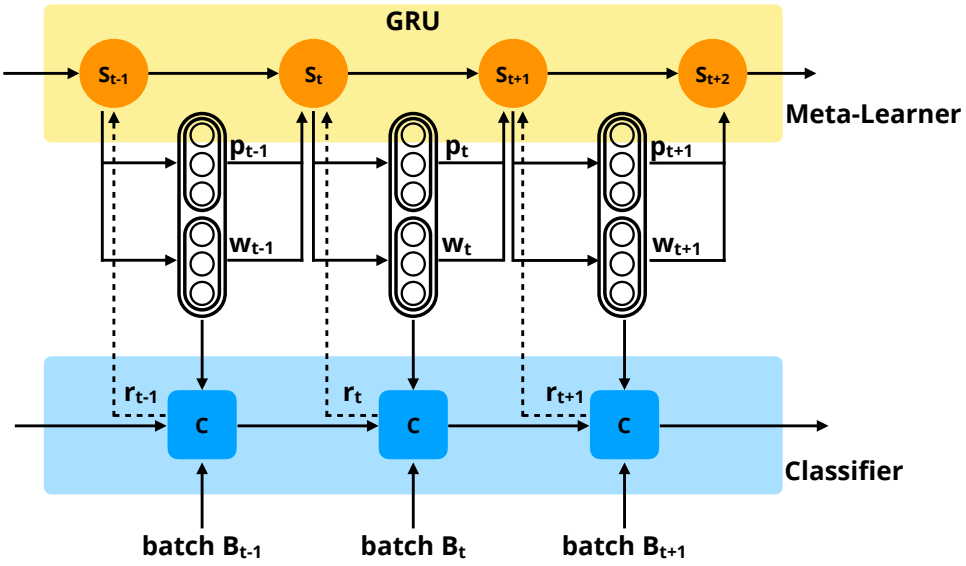

Figure 2: The meta-learning framework for multi-label classification.

model with meta-policy, we also consider prediction with meta-policy.

3 Method

In this section, we describe our meta-learning framework for learning and predicting multi-label classification in detail. In multi-label classification, the conventional methods usually learn classifiers with the standard cross-entropy loss function. After training, a single prediction policy (usually, a threshold of 0.5) is applied to all labels to generate the prediction. However, as mentioned in Figure 1, these methods ignore the explicit and implicit label dependencies among the labels. To improve the performance of multi-label classification, our main idea is to learn high-quality training policies and prediction policies by meta-learning, which can also model the label dependencies.

We view the training policies and prediction policies as a series of hyper-parameters, and then formulate the training of the classifier as a sequential process. At each iteration (time step t), the classifier updates its parameters with one sampled batch. The exploration of this classifier's hyper-parameters can be modeled by a meta-learner. We first briefly introduce the classifier model used in multi-label classification. Then we describe the meta-learner, and the interaction between the meta-learner and the classifier. Finally, we explain how to train the meta-learner in our unified framework.

3.1 Classifier Model

As mentioned in Section 1, many different model structures have already been explored in multi-label classification. Our framework is model-agnostic, which means different model structures are compatible if only they choose the cross-entropy loss function as the objective function. The classifier is represented as C. For a N- class multi-label classification, we represent the training policy as the vector $w = (w^{(1)}, w^{(2)}, \cdots, w^{(N)})$ and the prediction policy as the vector $p = (p^{(1)}, p^{(2)}, \cdots, p^{(N)})$, where $w^{(i)}$ and $p^{(i)}$ are the training weight and predicting threshold for the i-th class. w_t and p_t refer the weight vector and threshold vector at time step t. Then the goal of our framework is to learn a high-quality w and p for a certain classifier C.

To update the parameters of the classifier C, at each time step t, we sample a batch B_t from the training set U. We then set a weighted cross-entropy objective function to update the C, which is defined as:

$$L(\theta_t^C) = -\sum_{i}^{B_t}\sum_{j}^{N} w_t^{(j)} N\{y_i^{*(j)} \log y_i^{(j)} + (1 - y_i^{*(j)}) \log(1 - y_i^{(j)})\}, \quad (1)$$

where y_i^* indicates the ground truth prediction of the i-th sample from the B_t, and $y_i^{(j)}$ is the j-th entry of the corresponding output vector y_i. The

standard cross-entropy loss function is a special case when $w_t^{(j)} = \frac{1}{N}(j = 1, 2, \cdots, N)$.

3.2 Meta-Learner

Meta-learning is a widely used reinforcement learning method to learn the meta-information of a machine learning system (Bengio et al., 1990; Runarsson and Jonsson, 2000; Thrun and Pratt, 2012). The core of our proposed method is a meta-learner, which is trained to learn a training and a prediction policy for multi-label classification. At each time step t, the meta-learner observes the current state s_t, and then generate a training policy w_t and a prediction policy p_t. Based on the policies w_t and p_t, the parameters of classifier C can be update with the sampled batch B_t as described in Section 3.1. After training, the meta-learner receives a reward r_t. The goal of our meta-learner at each time step t is to choose the two policies w_t and p_t that can maximize the future reward

$$R_t = \sum_{t'=t}^{T} r_{t'}, \tag{2}$$

where a training episode terminates at time T.

3.2.1 State Representation

The state representation, in our framework, is designed to connect the policy generation and the environment. At each time step t, the training policy, and the prediction policy are generated based on the state s_t. A reward will be computed based on the change of the environment. In our case, the performance change of the classifier C. In order to successfully explore the policy space and generate high-quality policies, the meta-learner needs to remember what similar policies have already been tried and make further generation based on these memories.

Based on the above intuition, we formulate the meta-learner as a recurrent neural network (RNN)-based structure. To simplify our method, we use a GRU in our experiments. The state representation s_t is directly defined as the hidden state h_t of the GRU at time step t. The s_t is computed according to:

$$s_t = \text{GRU}(s_{t-1}, \begin{bmatrix} p_{t-1} \\ w_{t-1} \end{bmatrix}), \tag{3}$$

where the input of GRU at time step t is the concatenation of the prediction policy and training policy generated at time step $t-1$.

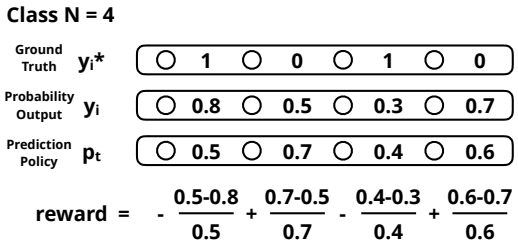

Figure 3: A example about the computation process of reward (one sample with class $N = 4$).

3.2.2 Policy Generation

At each time step t, the meta-learner can generate two policies, the training policy w_t and the prediction policy p_t. As mentioned in Section 3.1, both w_t and p_t are represented as a N-dimensional vector format.

To incorporate the training policy w_t into the cross-entropy objective function in Equation 1 and keep the training gradients of the classifier in the same magnitude during the whole training episode, the condition $\sum_i^N w_t^{(i)} = 1$ for w_t must be satisfied. Thus, at each time step t, the training policy is generated as:

$$w_t = \text{softmax}(W_w s_t + b_w). \tag{4}$$

As for the prediction policy, it is obvious that $p_t^{(i)} \in (0, 1)$ must be satisfied for $i = 1, 2, \cdots, N$. Then we define the prediction policy as:

$$p_t = \text{sigmoid}(W_p s_t + b_p). \tag{5}$$

The s_t is the state representation of the meta-learner at time step t. W_w, b_w, W_p and b_p all are learnable parameters.

3.2.3 Reward Function

The meta-leaner is trained to generate high-quality training and prediction policies jointly to improve the performance of the classifier C. To capture this performance change, we design a reward function based on the probability distributions of samples.

At each time step t, we first generate the training policy w_t and the prediction policy p_t according to Section 3.2.2. Then a batch B_t is sampled from the training set and used to update the classifier C based on Equation 1. We evaluate the output probability distribution of all the samples from B_t on the classifier C and compute the reward as:

$$r_t = \sum_{i}^{B_t} \sum_{j=1}^{N} (-1)^{y_i^{*(j)}} \frac{p_t^{(j)} - y_i^{(j)}}{p_t^{(j)}}, \tag{6}$$

where y_i is the output probability vector of the i-th sample from the batch B_t and y_i^* is the corresponding ground truth vector. The superscript (j) represents the j-th entry of a vector. A simple example about how the reward is computed is shown in Figure 3.

3.3 Training and Testing

The θ_{meta} is the set of all the parameters in the meta-learner, and the parameters can be trained by maximizing the total expect reward. The expected reward for an episode terminating at time step T is defined as:

$$J(\theta_{meta}) = \mathbb{E}_{\pi}[\sum_{t=1}^{T} r_t]. \quad (7)$$

$J(\theta_{meta})$ can be maximized by directly applying gradient-based optimization methods. We optimize it using policy gradient descent and implement a reward baseline to lower the variance during the training (Sutton, 1984). The details of the training process are shown in Algorithm 1. During the training, the reason why we use sample batches instead of the full training set at each time step is that we want to explore more policy space with diversity instead of iteratively fitting the whole training set.

At test time, we rerun the meta-learner and the classifier simultaneously for one episode. However, we use the whole training set as a batch at each time step. The generated policies w_T and p_T is chosen as the final policies. We then train a classifier with the w_T-weighted cross-entropy objective function and test it based on the prediction policy p_T.

Algorithm 1: The algorithm of our meta-learning framework.

Given a set of labeled training data U
Given a untrained classifier C
for *episode* $\leftarrow$ *1* **to** *M* **do**
  Initialize $w_0 \leftarrow (\frac{1}{N}, \frac{1}{N}, \cdots, \frac{1}{N}) \in \mathbb{R}^N$
  Initialize $p_0 \leftarrow (0.5, 0.5, \cdots, 0.5) \in \mathbb{R}^N$
  for *time step* $t \leftarrow$ *1* **to** T **do**
    $s_t \leftarrow \text{GRU}(s_{t-1}, \begin{bmatrix} p_{t-1} \\ w_{t-1} \end{bmatrix})$
    $w_t \leftarrow \text{softmax}(W_w s_t + b_w)$
    $p_t \leftarrow \text{sigmoid}(W_p s_t + b_p)$
    Sample a batch B_t from U
    Update C using B_t with w_t-based objective function in Equation 1
    Compute reward r_t with p_t in Equation 6
  Update θ_{meta} using $g \propto \nabla_\theta J(\theta_{meta})$

4 Experimental Setups

We evaluate our proposed method in following two settings: (1) **Fine-grained Entity Typing**, where the labels have explicit hierarchical dependencies; (2) **Text Classification**, where one needs to model the implicit label dependencies.

4.1 Baselines

Since our method is model-agnostic, we directly employ the state-of-the-art (SOTA) models for both two tasks. The details of SOTA models will be discussed in Section 5 and 6. We compare our method with multiple baselines:

- **Hierarchy-Aware Training Policy**: To explicitly add hierarchical information during the training, the labels are first given integer weights. For instance, the first-level (parent) labels are given weight 1 while the third-level labels are given 3. All the integer weights then are normalized to add into the cross-entropy loss function in Equation 1.

- **SCutFBR Prediction Policy**: The rank-based policy method RCut and proportion-based assignments PCut are jointly considered to set prediction policies for different labels after obtaining the trained classifier (Yang, 2001).

- **ODR Prediction Policy**: After training, an optimal decision rule is to implement to choose prediction policies based on maximizing micro F1 scores (Lipton et al., 2014).

- **Predictions-as-Features**: The model trains a classifier for each label, organize the classifiers in a partially ordered structure, and take predictions produced by the former classifiers as the latter classifiers' features (Li et al., 2015).

- **Subset Maximization**: The model views the multi-label prediction problem as classifier chains, and then replace classifier chains with recurrent neural networks (Nam et al., 2017).

5 Fine-grained Entity Typing

Entity type classification is the task for assigning semantic types to entity mentions based on their context. For instance, the system needs label the entity *"San Francisco Bay"* as `/location`, `/location/region` based on its context *"... the rest of San Francisco Bay, a spot ..."*.

In a fine-grained classification setting, entities are aligned with knowledge graphs (Ling and Weld, 2012), which typically makes labels be arranged in a hierarchical structure. We utilize our meta-learning framework to tackle this problem and evaluate our method.

Datasets We evaluate our method on three widely-used fine-grained entity typing datasets, FIGER, OntoNotes, and BBN, which are preprocessed by Ren et al. (2016). The statistics of these datasets are listed in Table 1.

FIGER: The training data is automatically generated by distant supervision, and then aligned with Freebase. The test data is collected from news reports and manually annotated by Ling and Weld (2012).

OntoNotes: The training sentences are collected from OntoNotes text corpus (Weischedel et al., 2013), and linked to Freebase. Gillick et al. (2014) releases a manually annotated test dataset.

BBN: The dataset consists of sentences from Wall Street Journal articles, which is entirely manually annotated (Weischedel and Brunstein, 2005).

Implementation Details We choose the SOTA model of fine-grained entity typing as the classifier C (Shimaoka et al., 2017; Abhishek et al., 2017). The overall model structure is shown in Figure 4. Given en entity and its context sentence, the words are initialized with word embeddings (Mikolov et al., 2013). The mention representation is simply computed by averaging the word embeddings of entity mention words. As for the context representation, a bidirectional LSTM and attention mechanism are used to encode left and right context representation separately. The attention operation is computed using a Multi-Layer Perceptron (MLP) as follows:

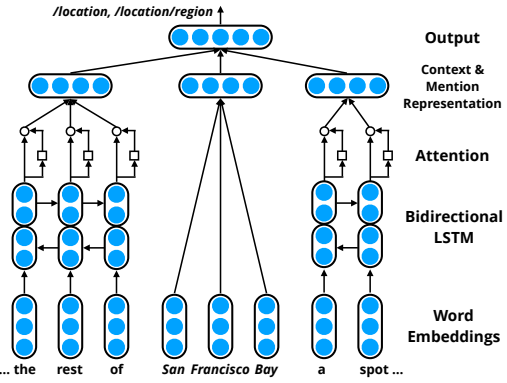

Figure 4: The SOTA model structure for fine-grained entity type classification (Shimaoka et al., 2017; Abhishek et al., 2017).

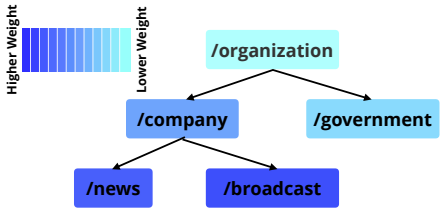

Figure 5: A case study about weights. See Section 5 for the detailed explanation.

$$a_i = \sigma\{W_1 \tanh(W_2 \begin{bmatrix} \overrightarrow{h}_i \\ \overleftarrow{h}_i \end{bmatrix})\}, \quad (8)$$

where W_1 and W_2 are parameter matrices of the MLP, and $\begin{bmatrix} \overrightarrow{h}_i \\ \overleftarrow{h}_i \end{bmatrix}$ is the hidden state of Bi-LSTM at the i-th position. Note that the parameters of MLP are shared by all the entities. The left, right context representations and mention representation are concatenated as the feature vector. A softmax layer is then implemented to perform final prediction. The standard cross-entropy loss function is used and the thresholds of all the labels are set as 0.5. To avoid overfitting, we employ dropout operation on entity mention representation.

Following the previous researches (Ling and Weld, 2012; Ren et al., 2016), we use strict accuracy, loose macro, and loose micro scores to evaluate the model performance.

Results The results of fine-grained entity typing are shown in Table 2. From the results, we observe that: (1) Our meta-learning method can outperform all the baselines in all three metrics, which

Table 2: The experimental results on fine-grained entity typing datasets. Acc.: Accuracy.

indicates the capability of our methods in improving the multi-label classification. (2) The SOTA model trained with learned training policy outperforms the one with hierarchy-aware training policy. It is because that our learned training policy can capture not only explicit hierarchical dependencies of labels, but also model other implicit label dependencies. (3) The three different prediction policies can improve the performance of the SOTA classifier. The results are consistent with previous researches that choosing a good prediction policy is an effective way to improve the performance (Fan and Lin, 2007; Lipton et al., 2014). (4) Compared with OntoNotes and BBN datasets, the FIGER show a relatively less improvement when applying these policies. The reason is that the test set of FIGER is not fine-grained enough (e.g., over 38% of entities are only annotated with `/person` and no more fine-grained labels) (Xin et al., 2018).

Algorithm Robustness Previous researches (Morimoto and Doya, 2005; Henderson et al., 2018) show that reinforcement learning-based methods usually lack robustness and are sensitive to the initialization, seeding datasets and pre-trained steps. Thus, we design an experiment to detect whether the trained meta-leaner is sensitive to the initialization. During the test time, instead of using the same initialization in Algorithm 1, we randomly initialize the w_0 and p_0 and learn 10 groups of policies w_T and p_T. For each group of policies, we train a classifier with w_T and evaluate it with p_T using the same metric. The results are shown in Table 3. The results demonstrate that our trained meta-learner is robust to different initialization, which indicates that the meta-learner in our method can generate high-quality and robust training and prediction policies to improve the multi-label classification.

Weight Analysis To analyze whether our meta-learner can really model the label dependencies, we perform a simple case study. In fine-grained entity classification, we choose 5 labels that are originally organized in a hierarchical structure from the OntoNotes dataset. The corresponding entries of the training policy vector w_T are extracted and expressed with colors. The case study is shown in Figure 5. From the results, we can observe that high-level (parent) labels tend to have less training weights than low-level (child) labels. The results are consistent with our intuition that the labels with more dependencies expose more semantic information during the training.

6 Text Classification

Text classification is a classic problem for NLP, where one needs to categorized documents into pre-defined classes (Nam et al., 2014; Liu et al., 2017; Chen et al., 2017). We choose the datasets

Table 6: The robustness analysis on the RCV1 dataset.

in which samples have multiple labels and evaluate our model on text classification problem.

Datasets Following the settings in (Nam et al., 2014), we choose two multi-label datasets, Reuters-21578 and RCV1-V2, to test our method. The statistics of two datasets are listed in Table 4.

Reuters-21578: The instances are collected Reuters news articles during the period 1987 to 1991. We use the same training/test split as previous work (Yang, 2001; Nam et al., 2014).

RCV1-V2: RCV1-V2 collects newswire stories from Reuters (Lewis et al., 2004). The training and test dataset originally consist of $23,149$ train and $781,265$ test instances, but we switch them to better training and evaluation (Nam et al., 2014).

Setup Many researches have proved convolutional neural networks (CNN) are effective in extracting information for text classification (LeCun et al., 1998; Kim, 2014; Zhang et al., 2015). Following the (Kim, 2014), we set a CNN model as the classifier C to evaluate our method. Concretely, we use CNN-non-static mentioned in Kim (2014), which means we initialize the word embeddings with pre-trained Word2Vec and update the word embeddings during the training. The standard cross-entropy loss function is implemented, and the thresholds of all the classes are set as 0.5.

We still use strict accuracy, loose macro, and loose micro scores to evaluate the model performance following the settings in (Lewis et al., 2004; Yang and Gopal, 2012; Nam et al., 2014).

Results The results of text classification are shown in Table 5. From the results, we can observe that: (1) Our meta-learning method can outperform all the baselines on two text classification tasks, which indicates that our approach is consistent with different tasks. (2) Compared with RCV1-V2, the classification results on Reuters-21578 show less improvement. The reason is that the number of average labels per instance in Reuters-21578 is 1.13, while the number is 3.24 for RCV1-V2 according to Table 4. That means the multi-label classification on Reuters is close to the multi-class classification. There are little potential label dependencies in Reuters-21578.

Algorithm Robustness Similar to Section 5, we evaluate whether our trained meta-learner is sensitive to the initialization. We follow the same steps mentioned in Section 5, and show the results in Table 6. The results indicate that the robustness of our meta-learner is consistent within different tasks and model structures, which again shows that the trained meta-learner can generate high-quality and robust policies.

7 Conclusion

In this paper, we propose a novel meta-learner to improve the multi-label classification. By modeling the explicit and implicit label dependencies automatically, the meta-learner in our model can learn to generate high-quality training and prediction policies to help both the training and testing process of multi-label classifiers in a principled way. We evaluate our models on two tasks, fine-grained entity typing and text classification. Experimental results show that our method outper-

forms other baselines.

Abstract

BERT-based architectures currently give state-of-the-art performance on many NLP tasks, but little is known about the exact mechanisms that contribute to its success. In the current work, we focus on the interpretation of self-attention, which is one of the fundamental underlying components of BERT. Using a subset of GLUE tasks and a set of handcrafted features-of-interest, we propose the methodology and carry out a qualitative and quantitative analysis of the information encoded by the individual BERT's heads. Our findings suggest that there is a limited set of attention patterns that are repeated across different heads, indicating the overall model overparametrization. While different heads consistently use the same attention patterns, they have varying impact on performance across different tasks. We show that manually disabling attention in certain heads leads to a performance improvement over the regular fine-tuned BERT models.

1 Introduction

Over the past year, models based on the Transformer architecture (Vaswani et al., 2017) have become the de-facto standard for state-of-the-art performance on many natural language processing (NLP) tasks (Radford et al., 2018; Devlin et al., 2018). Their key feature is the self-attention mechanism that provides an alternative to conventionally used recurrent neural networks (RNN).

One of the most popular Transformer-based models is BERT, which learns text representations using a bi-directional Transformer encoder pre-trained on the language modeling task (Devlin et al., 2018). BERT-based architectures have produced new state-of-the-art performance on a range of NLP tasks of different nature, domain, and complexity, including question answering, sequence tagging, sentiment analysis, and inference. State-of-the-art performance is usually obtained by fine-tuning the pre-trained model on the specific task. In particular, BERT-based models are currently dominating the leaderboards for SQuAD[1] (Rajpurkar et al., 2016) and GLUE benchmarks[2] (Wang et al., 2018).

However, the exact mechanisms that contribute to the BERT's outstanding performance still remain unclear. We address this problem through selecting a set of linguistic features of interest and conducting a series of experiments that aim to provide insights about how well these features are captured by BERT. This paper makes the following contributions:

- We propose a methodology and offer the first detailed analysis of BERT's capacity to capture different kinds of linguistic information by encoding it in its self-attention weights.
- We present evidence of BERT's overparametrization and suggest a counter-intuitive yet frustratingly simple way of improving its performance, showing absolute gains of up to 3.2%.

2 Related work

There have been several recent attempts to assess BERT's ability to capture structural properties of language. Goldberg (2019) demonstrated that BERT consistently assigns higher scores to the correct verb forms as opposed to the incorrect one in a masked language modeling task, suggesting some ability to model subject-verb agreement. Jawahar et al. (2019) extended this work to using multiple layers and tasks, supporting the claim that BERT's intermediate layers capture rich linguistic information. On the other hand, Tran et al. (2018) concluded that LSTMs generalize to longer

sequences better, and are more robust with respect to agreement distractors, compared to Transformers.

Liu et al. (2019) investigated the transferability of contextualized word representations to a number of probing tasks requiring linguistic knowledge. Their findings suggest that (a) the middle layers of Transformer-based architectures are the most transferable to other tasks, and (b) higher layers of Transformers are not as task specific as the ones of RNNs. Tang et al. (2018) argued that models using self-attention outperform CNN- and RNN-based models on a word sense disambiguation task due to their ability to extract semantic features from text. Voita et al. (2019) analyzed the original Transformer model on a translation task and found out that only a small subset of heads is important for the given task, but these heads have interpretable linguistic functions.

Our work contributes to the above discussion, but rather than examining representations extracted from different layers, we focus on the understanding of the self-attention mechanism itself, since it is the key feature of Transformer-based models.

Another research direction that is relevant to our work is neural network pruning. Frankle and Carbin (2018) showed that widely used complex architectures suffer from overparameterization, and can be significantly reduced in size without a loss in performance. Goldberg (2019) observed that the smaller version of BERT achieves better scores on a number of syntax-testing experiments than the larger one. Adhikari et al. (2019) questioned the necessity of computation-heavy neural networks, proving that a simple yet carefully tuned BiLSTM without attention achieves the best or at least competitive results compared to more complex architectures on the document classification task. Wu et al. (2019) presented more evidence of unnecessary complexity of the self-attention mechanism, and proposed a more lightweight and scalable dynamic convolution-based architecture that outperforms the self-attention baseline. Michel et al. (2019) demonstrated that some layers in Transformer can be reduced down to a single head without significant degradation of model performance. These studies suggest a potential direction for future research, and are in good accordance with our observations.

3 Methodology

We pose the following research questions:

1. What are the common attention patterns, how do they change during fine-tuning, and how does that impact the performance on a given task? (Sec. 4.1, 4.3)
2. What linguistic knowledge is encoded in self-attention weights of the fine-tuned models and what portion of it comes from the pre-trained BERT? (Sec. 4.2, 4.4, 4.5)
3. How different are the self-attention patterns of different heads, and how important are they for a given task? (Sec. 4.6)

The answers to these questions come from a series of experiments with the basic pre-trained or the fine-tuned BERT models, as will be discussed below. All the experiments with the pre-trained BERT were conducted using the model provided with the PyTorch implementation of BERT (bert-base-uncased, 12-layer, 768-hidden, 12-heads, 110M parameters)[3]. We chose this smaller version of BERT because it shows competitive, if not better, performance while having fewer layers and heads, which makes it more interpretable.

We use the following subset of GLUE tasks (Wang et al., 2018) for fine-tuning:

- *MRPC*: the Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005)
- *STS-B*: the Semantic Textual Similarity Benchmark (Cer et al., 2017)
- *SST-2*: the Stanford Sentiment Treebank, two-way classification (Socher et al., 2013)
- *QQP*: the Quora Question Pairs dataset
- *RTE*: the Recognizing Textual Entailment datasets
- *QNLI*: Question-answering NLI based on the Stanford Question Answering Dataset (Rajpurkar et al., 2016)
- *MNLI*: the Multi-Genre Natural Language Inference Corpus, matched section (Williams et al., 2018)

Please refer to the original GLUE paper for details on the QQP and RTE datasets (Wang et al., 2018). We excluded two tasks: CoLa and the Winograd Schema Challenge. The latter is excluded due to the small size of the dataset. As for CoLa (the task of predicting linguistic acceptability judgments), GLUE authors report that the hu-

[3] https://github.com/huggingface/pytorch-pretrained-BERT

man performance is only 66.4, which is explained by the problems with the underlying methodology (Schutze, 1996). Note also that CoLa is not included in the upcoming version of GLUE (Wang et al., 2019). All fine-tuning experiments follow the parameters reported in the original study (a batch size of 32 and 3 epochs, see Devlin et al. (2018)).

In all these experiments, for a given input, we extract self-attention weights for each head in every layer. This results in a 2D float array of shape $L \times L$, where L is the length of an input sequence. We will refer to such arrays as *self-attention maps*. Analysis of individual self-attention maps allows us to determine which target tokens are attended to the most as the input is processed token by token. We use these experiments to analyze how BERT processes different kinds of linguistic information, including the processing of different parts of speech (nouns, pronouns, and verbs), syntactic roles (objects, subjects), semantic relations, and negation tokens.

4 Experiments

In this section, we present the experiments conducted to address the above research questions.

4.1 BERT's self-attention patterns

Manual inspection of self-attention maps for both basic pre-trained and fine-tuned BERT models suggested that there is a limited set of self-attention map types that are repeatedly encoded across different heads. Consistently with previous observations[4], we identified five frequently occurring patterns, examples of which are shown in Figure 1:

- *Vertical*: mainly corresponds to attention to special BERT tokens *[CLS]* and *[SEP]* which serve as delimiters between individual chunks of BERT's inputs;
- *Diagonal*: formed by the attention to the previous/following tokens;
- *Vertical+Diagonal*: a mix of the previous two types,
- *Block*: intra-sentence attention for the tasks with two distinct sentences (such as, for example, RTE or MRPC),
- *Heterogeneous*: highly variable depending on the specific input and cannot be characterized by a distinct structure.

Note that, because the *Heterogeneous* category contains patterns not included in the other four categories, our constructed list of classes is exhaustive.

Whereas the attention to the special tokens is important for cross-sentence reasoning, and the attention to the previous/following token comes from language model pre-training, we hypothesize that the last of the listed types is more likely to capture interpretable linguistic features, necessary for language understanding.

To get a rough estimate of the percentage of attention heads that may capture linguistically interpretable information, we manually annotated around 400 sample self-attention maps as belonging to one of the five classes. The self-attention maps were obtained by feeding random input examples from selected tasks into the corresponding fine-tuned BERT model. This produced a somewhat unbalanced dataset, in which the "Vertical" class accounted for 30% of all samples. We then trained a convolutional neural network with 8 convolutional layers and ReLU activation functions to classify input maps into one of these classes. This model achieved the F1 score of 0.86 on the annotated dataset. We used this classifier to estimate the proportion of different self-attention patterns for the target GLUE tasks using up to 1000 examples (where available) from each validation set.

Results Figure 2 shows that the self-attention map types described above are consistently repeated across different heads and tasks. While a large portion of encoded information corresponds to attention to the previous/following token, to the special tokens, or a mixture of the two (the first three classes), the estimated upper bound on all heads in the "Heterogeneous" category (i.e. the ones that *could* be informative) varies from 32% (MRPC) to 61% (QQP) depending on the task.

We would like to emphasize that this only gives the upper bound on the percentage of attention heads that could potentially capture meaningful structural information beyond adjacency and separator tokens.

4.2 Relation-specific heads in BERT

In this experiment, our goal was to understand whether different syntactic and semantic relations are captured by self-attention patterns. While a

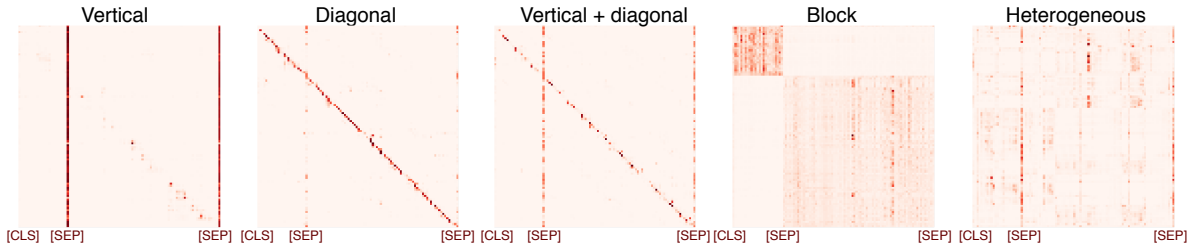

Figure 1: Typical self-attention classes used for training a neural network. Both axes on every image represent BERT tokens of an input example, and colors denote absolute attention weights (darker colors stand for greater weights). The first three types are most likely associated with language model pre-training, while the last two potentially encode semantic and syntactic information.

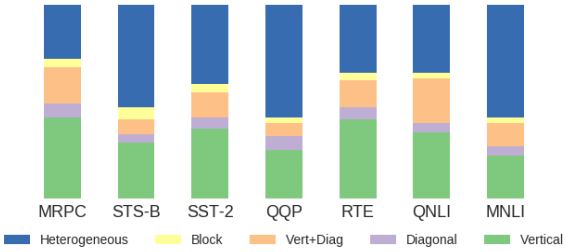

Figure 2: Estimated percentages of the identified self-attention classes for each of the selected GLUE tasks.

large number of such relations could be investigated, we chose to examine semantic role relations defined in frame semantics, since they can be viewed as being at the intersection of syntax and semantics. Specifically, we focused on whether BERT captures FrameNet's relations between frame-evoking lexical units (predicates) and core frame elements (Baker et al., 1998), and whether the links between them produce higher attention weights in certain specific heads. We used pre-trained BERT in these experiments.

The data for this experiment comes from FrameNet (Baker et al., 1998), a database that contains frame annotations for example sentences for different lexical units. Frame elements correspond to semantic roles for a given frame, for example, "buyer", "seller", and "goods" for the "Commercial_transaction" frame evoked by the words "sell" and "spend" or "topic" and "text" for the "Scrutiny" semantic frame evoked by the verb "address". Figure 4 shows an example of such annotation.

We extracted sample sentences for every lexical unit in the database and identified the corresponding core frame elements. Annotated elements in FrameNet may be rather long, so we considered only the sentences with frame elements of 3 tokens or less. Since each sentence is annotated only for one frame, semantic links from other frames can exist between unmarked elements. We therefore filter out all the sentences longer than 12 tokens, since shorter sentences are less likely to evoke multiple frames.

To establish whether BERT attention captures semantic relations that *do not* simply correspond to the previous/following token, we exclude sentences where the linked objects are less than two tokens apart. This leaves us with 473 annotated sentences.

For each of these sentences, we obtain pre-trained BERT's attention weights for each of the 144 heads. For every head, we return the maximum absolute attention weight among those token pairs that correspond to the annotated semantic link contained within a given sentence. We then average the derived scores over all the collected examples. This strategy allows us to identify the heads that prioritize the features correlated with frame-semantic relations within a sentence.

Results The heatmap of averaged attention scores over all collected examples (Figure 3) suggests that 2 out of 144 heads tend to attend to the parts of the sentence that FrameNet annotators identified as core elements of the same frame. The maximum attention weights averaged over all data examples for these identified heads account for 0.201 and 0.209, which are greater than a 99-th percentile of the distribution of values for all heads. Figure 3 shows an example of this attention pattern for these two heads. Both show high attention weight for "he" while processing "agitated" in the sentence "He was becoming agitated" (the frame "Emotion_directed").

We interpret these results as limited evidence that certain types of linguistic relations may be

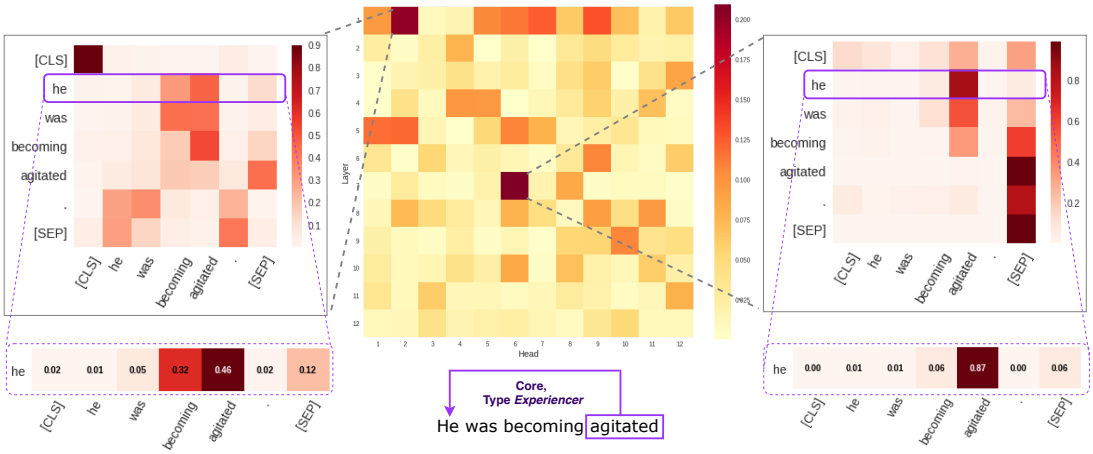

Figure 3: Detection of pre-trained BERT's heads that encode information correlated to semantic links in the input text. Two heads (middle) demonstrate their ability to capture semantic relations. Note that the heatmap in the middle is obtained through averaging of all the individual input example maps. For one random annotated FrameNet example (bottom) full attention maps with a zoom in the target token attention distribution are shown (leftmost and rightmost).

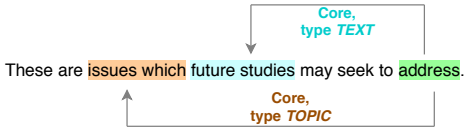

Figure 4: FrameNet annotation example for the "address" lexical unit with two core frame elements of different types annotated.

captured by self-attention patterns in specialized BERT heads. A wider range of relations remains to be investigated.

4.3 Change in self-attention patterns after fine-tuning

Fine-tuning has a huge effect on performance, and this section attempts to find out why. To study how attention per head changes on average for each of the target GLUE tasks, we calculate cosine similarity between pre-trained and fine-tuned BERT's flattened arrays of attention weights. We average the derived similarities over all the development set examples[5]. To evaluate contribution of pre-trained BERT to overall performance on the tasks, we consider two configurations of weights initialization, namely, pre-trained BERT weights and weights randomly sampled from normal distribution.

[5]If the number of development data examples for a given task exceeded 1000 (QQP, QNLI, MNLI, STS-B), we randomly sampled 1000 examples.

Results Figure 5 shows that for all the tasks except QQP, it is the last two layers that undergo the largest changes compared to the pre-trained BERT model. At the same time, Table 1 shows that fine-tuned BERT outperforms pre-trained BERT by a significant margin on all the tasks (with an average of 35.9 points of absolute difference). This leads us to conclude that the last two layers encode task-specific features that are attributed to the gain of scores, while earlier layers capture more fundamental and low-level information used in fine-tuned models. BERT with weights initialized from normal distribution and further fine-tuned for a given task consistently produces lower scores than the ones achieved with pre-trained BERT. In fact, for some tasks (STS-B and QNLI), initialization with random weights yields worse performance than pre-trained BERT without fine-tuning.

This suggests that pre-trained BERT does indeed contain linguistic knowledge that is help-

Dataset	Pre-trained	Fine-tuned, initialized with normal distr.	Fine-tuned, initialized with pre-trained	Metric	Size

Table 1: GLUE task performance of BERT models with different initialization. We report the scores on the validation, rather than test data, so these results differ from the original BERT paper.

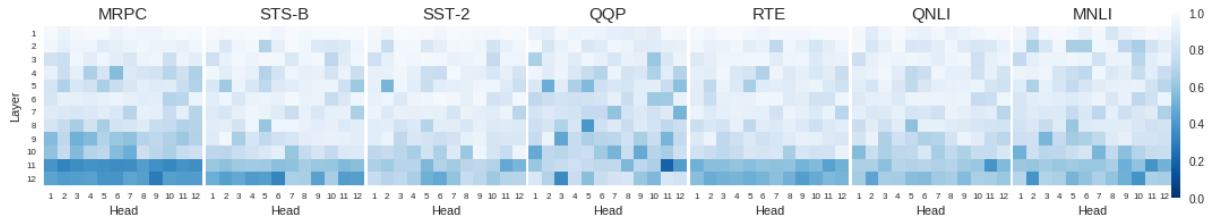

Figure 5: Per-head cosine similarity between pre-trained BERT's and fine-tuned BERT's self-attention maps for each of the selected GLUE tasks, averaged over validation dataset examples. Darker colors correspond to greater differences.

Figure 6: Per-task attention weights to the *[SEP]* (top row) and the *[CLS]* (bottom row) tokens averaged over input sequences' lengths and over dataset examples. Darker colors correspond to greater absolute weights.

ful for solving these GLUE tasks. These results are consistent with similar studies, e.g., Yosinski et al. (2014)'s results on fine-tuning a convolutional neural network pre-trained on ImageNet or Romanov and Shivade (2018)'s results on transfer learning for medical natural language inference.

4.4 Attention to linguistic features

In this experiment, we investigate whether fine-tuning BERT for a given task creates self-attention patterns which emphasize specific linguistic features. In this case, certain kinds of tokens may get high attention weights from all the other tokens in the sentence, producing vertical stripes on the corresponding attention maps (Figure 1).

To test this hypothesis we checked whether there are vertical stripe patterns corresponding to certain linguistically interpretable features, and to what extent such features are relevant for solving a given task. In particular, we investigated attention to nouns, verbs, pronouns, subjects, objects, and negation words[6], and special BERT tokens across the tasks.

For every head, we compute the sum of self-attention weights assigned to the token of interest from each input token. Since the weights depend on the number of tokens in the input sequence, this sum is normalized by sequence length. This allows us to aggregate the weights for this feature across different examples. If there are multiple tokens of the same type (e.g. several nouns or negations), we take the maximum value. We disregard input sentences that do not contain a given feature.

For each investigated feature, we calculate this aggregated attention score for each head in every layer and build a map in order to detect the heads potentially responsible for this feature. We then compare the obtained maps to the ones derived using the pre-trained BERT model. This comparison enables us to determine if a particular feature is important for a specific task and whether it contributes to some tasks more than to others.

Results Contrary to our initial hypothesis that the vertical attention pattern may be motivated by linguistically meaningful features, we found that it is associated predominantly, if not exclusively, with attention to *[CLS]* and *[SEP]* tokens (see

[6]Our manually constructed list of negation words consisted of the following words *neither, nor, not, never, none, don't, won't, didn't, hadn't, haven't, can't, isn't, wasn't, shouldn't, couldn't, nothing, nowhere.*

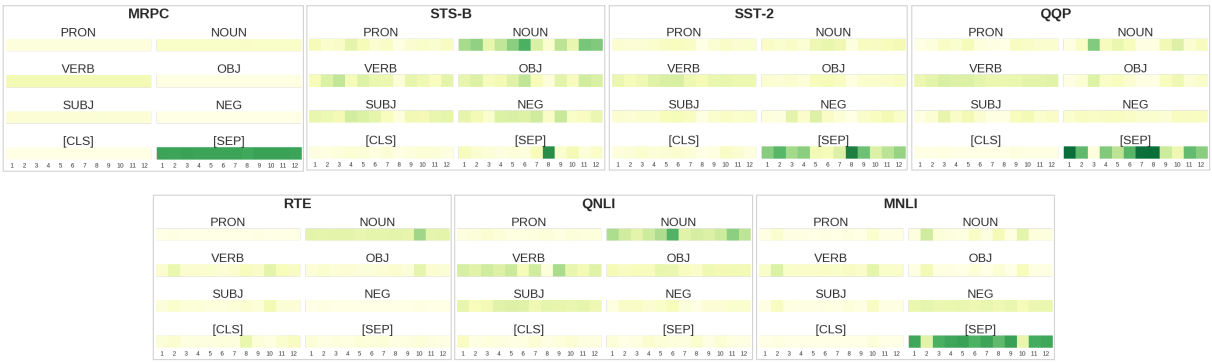

Figure 7: Per-task attention weights corresponding to the *[CLS]* token averaged over input sequences' lengths and over dataset examples, and extracted from the final layer. Darker colors correspond to greater absolute weights.

Figure 6. Note that the absolute *[SEP]* weights for the SST-2 sentiment analysis task are greater than for other tasks, which is explained by the fact that there is only one sentence in the model inputs, i.e. only one *[SEP]* token instead of two. There is also a clear tendency for earlier layers to pay attention to *[CLS]* and for later layers to *[SEP]*, and this trend is consistent across all the tasks. We did detect heads that paid increased (compared to the pre-trained BERT) attention to nouns and direct objects of the main predicates (on the MRPC, RTE and QQP tasks), and negation tokens (on the QNLI task), but the attention weights of such tokens were negligible compared to *[CLS]* and *[SEP]*. Therefore, we believe that the striped attention maps generally come from BERT pre-training tasks rather than from task-specific linguistic reasoning.

4.5 Token-to-token attention

To complement the experiments in Sec. 4.4 and 4.2, in this section, we investigate the attention patterns between tokens in the same sentence, i.e. whether any of the tokens are particularly important while a *given* token is being processed. We were interested specifically in the verb-subject relation and the noun-pronoun relation. Also, since BERT uses the representation of the *[CLS]* token in the last layer to make the prediction, we used the features from the experiment in Sec. 4.4 in order to check if they get higher attention weights while the model is processing the *[CLS]* token.

Results Our token-to-token attention experiments for detecting heads that prioritize noun-pronoun and verb-subject links resulted in a set of potential head candidates that coincided with diagonally structured attention maps. We believe that this happened due to the inherent property of English syntax where the dependent elements frequently appear close to each other, so it is difficult to distinguish such relations from the previous/following token attention coming from language model pre-training.

Our investigation of attention distribution for the *[CLS]* token in the output layer suggests that for most tasks, with the exception of STS-B, RTE and QNLI, the *[SEP]* gets attended the most, as shown in Figure 7. Based on manual inspection, for the mentioned remaining tasks, the greatest attention weights correspond to the punctuation tokens, which are in a sense similar to *[SEP]*.

4.6 Disabling self-attention heads

Since there does seem to be a certain degree of specialization for different heads, we investigated the effects of disabling different heads in BERT and the resulting effects on task performance. Since BERT relies heavily on the learned attention weights, we define disabling a head as modifying the attention values of a head to be constant $a = \frac{1}{L}$ for every token in the input sentence, where L is the length of the sentence. Thus, every token receives the same attention, effectively disabling the learned attention patterns while maintaining the information flow of the original model. Note that by using this framework, we can disable an arbitrary number of heads, ranging from a single head per model to the whole layer or multiple layers.

Results Our experiments suggest that certain heads have a detrimental effect on the overall performance of BERT, and this trend holds for all the chosen tasks. Unexpectedly, disabling some heads leads *not* to a drop in accuracy, as one would expect, but to an increase in performance. This is ef-

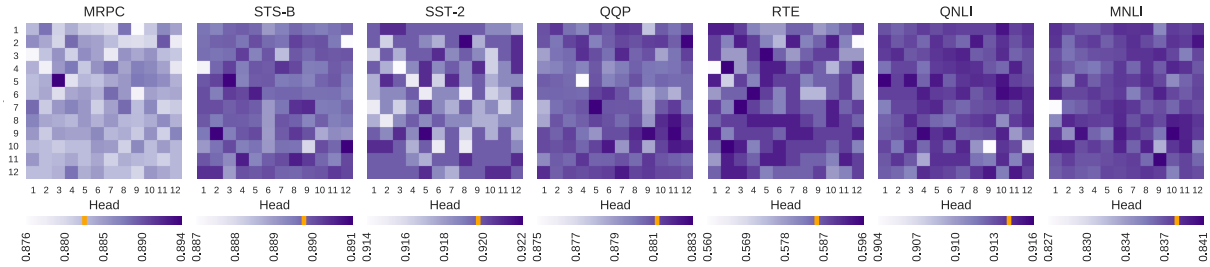

Figure 8: Performance of the model while disabling one head at a time. The orange line indicates the baseline performance with no disabled heads. Darker colors correspond to greater performance scores.

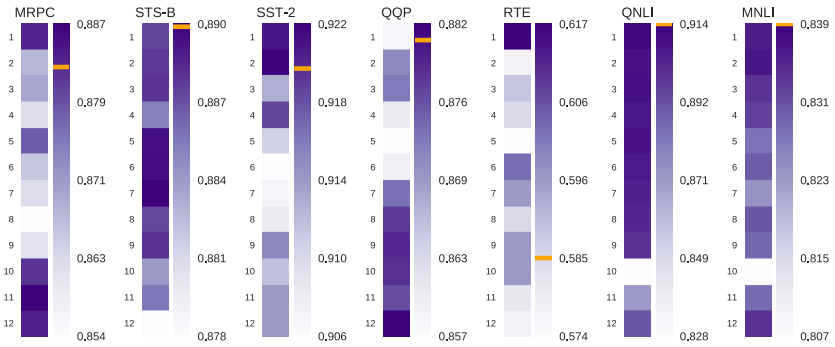

Figure 9: Performance of the model while disabling one layer (that is, all 12 heads in this layer) at a time. The orange line indicates the baseline performance with no disabled layers. Darker colors correspond to greater performance scores.

fect is different across tasks and datasets. While disabling some heads improves the results, disabling the others hurts the results. However, it is important to note that across all tasks and datasets, disabling some heads leads to an increase in performance. The gain from disabling a single head is different for different tasks, ranging from the minimum absolute gain of 0.1% for STS-B, to the maximum of 1.2% for MRPC (see Figure 8). In fact, for some tasks, such as MRPC and RTE, disabling a *random* head gives, on average, *an increase* in performance. Furthermore, disabling a whole layer, that is, all 12 heads in a given layer, also improves the results. Figure 9 shows the resulting model performance on the target GLUE tasks when different layers are disabled. Notably, disabling the first layer in the RTE task gives a significant boost, resulting in an absolute performance gain of 3.2%. However, effects of this operation vary across tasks, and for QNLI and MNLI, it produces a performance drop of up to -0.2%.

5 Discussion

In general, our results suggest that even the smaller base BERT model is significantly overparametrized. This is supported by the discovery of repeated self-attention patterns in different heads, as well as the fact that disabling both single and multiple heads is not detrimental to model performance and in some cases even improves it.

We found no evidence that attention patterns that are mappable onto core frame-semantic relations actually improve BERT's performance. 2 out of 144 heads that seem to be "responsible" for these relations (see Section 4.2) do not appear to be important in any of the GLUE tasks: disabling of either one does not lead to a drop of accuracy. This implies that fine-tuned BERT does not rely on this piece of semantic information and prioritizes other features instead.

For instance, we noticed that both STS-B and RTE fine-tuned models rely on attention in the same pair of heads (head 1 in the fourth layer, and head 12 in the second layer), as shown in Figure 8. We manually checked the attention maps in those heads for a set of random inputs, and established that both of them have high weights for words that appear in both sentences of the input examples. This most likely means that word-by-word comparison of the two sentences provides a solid strategy of making a classification prediction for STS-B and RTE. We were not able to find a conceptu-

ally similar interpretation of heads important for other tasks.

6 Conclusion

In this work, we proposed a set of methods for analyzing self-attention mechanisms of BERT, comparing attention patterns for the pre-trained and fine-tuned versions of BERT.

Our most surprising finding is that, although attention is the key BERT's underlying mechanism, the model can benefit from attention "disabling". Moreover, we demonstrated that there is redundancy in the information encoded by different heads and the same patterns get consistently repeated regardless of the target task. We believe that these two findings together suggest a further direction for research on BERT interpretation, namely, model pruning and finding an optimal sub-architecture reducing data repetition.

One of the directions for future research would be to study self-attention patterns in different languages, especially verb-final langauges and those with free word order. It is possible that English has relatively lower variety of self-attention patterns, as the subject-predicate relation happens to coincide with the following-previous token pattern.

Abstract

Neural machine translation, which achieves near human-level performance in some languages, strongly relies on the large amounts of parallel sentences, which hinders its applicability to low-resource language pairs. Recent works explore the possibility of unsupervised machine translation with monolingual data only, leading to much lower accuracy compared with the supervised one. Observing that weakly paired bilingual documents are much easier to collect than bilingual sentences, e.g., from Wikipedia, news websites or books, in this paper, we investigate training translation models with weakly paired bilingual documents. Our approach contains two components. 1) We provide a simple approach to mine implicitly bilingual sentence pairs from document pairs which can then be used as supervised training signals. 2) We leverage the topic consistency of two weakly paired documents and learn the sentence translation model by constraining the word distribution-level alignments. We evaluate our method on weakly paired documents from Wikipedia on six tasks, the widely used WMT16 German↔English, WMT13 Spanish↔English and WMT16 Romanian↔English translation tasks. We obtain 24.1/30.3, 28.1/27.6 and 30.1/27.6 BLEU points separately, outperforming previous results by more than 5 BLEU points in each direction and reducing the gap between unsupervised translation and supervised translation up to 50%.

1 Introduction

Neural machine translation (NMT) is a great success of deep learning for natural language processing (Koehn et al., 2003; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Jean et al., 2015; Vaswani et al., 2017; Gehring et al., 2017). It has significantly outperformed statistical machine translation and reached near human-level performance for several language pairs (Wu et al., 2016; Hassan et al., 2018). Such breakthroughs heavily depend on the availability of large scale bilingual sentence pairs. Taking WMT14 English→French task as an example, NMT uses 38 million parallel sentence pairs for training (Vaswani et al., 2017). As such bilingual sentence pairs are costly to collect, the success of NMT is not fully realized on the vast majority of language pairs, especially for low-resource languages. Recently, Artetxe et al. (2017); Lample et al. (2017) tackle this challenge by training NMT models using only monolingual data, which achieves considerably good accuracy but still far away from that of the state-of-the-art supervised models.

While it is costly to collect bilingual sentence pairs by human translation, we notice that there exists many weakly paired bilingual documents on the Web. For example, for the entity "machine learning", Wikipedia has multiple articles in different languages (e.g., the English and German articles). Though the two articles have very similar content, they are not sentence-by-sentence translations since they may be independently created by different people. Similarly, an English news in BBC and a Chinese news in China Daily talk about the same event but may have differences in details. Furthermore, a popular novel in different languages is usually liberal translation instead of literal translation. We call such weakly aligned documents *weakly paired bilingual documents*. In this paper, we explore learning NMT models from such weakly paired documents, which has several advantages. First, weakly paired documents are much easier to obtain than bilingual sentence pairs. We can obtain bilingual document pairs from Wikipedia pages, aligned news articles on internet, or even from books. Second, such weakly paired documents have great coverage of different

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4375–4384,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

languages. For example, Wikipedia covers more than 178 languages and most of them have paired pages to English. This means that learning translation models from paired bilingual documents are possible for many language pairs.

Weakly aligned document pairs can be utilized for NMT training from two aspects. First, although such two documents are not exactly sentence-by-sentence translations, it is possible that one specific sentence in one document is the translation of one sentence in the other document. Such a sentence pair can be used as bilingual signals for training. For example in Wikipedia, although the web structure and paragraphs are generally different for entity "Beijing" in English and "Pekin" in French, we find the first sentences of the pages are quite semantically similar, in which both of them define Beijing as the capital of China (*English: Beijing, formerly romanized as Peking, is the capital of the People's Republic of China. French: Pekin, galement appele Beijing, est la capitale de la Rpublique populaire de Chine.*) The challenge is how to mine such sentence pairs from those document pairs. Second, although the sentences in two weakly paired documents are not aligned, the topics of the documents are well aligned. Such topic alignment is a strong signal that can be used to train NMT models.

In this paper, we propose a method to train NMT models by leveraging weakly paired bilingual documents from Wikipedia. The key idea contains two aspects: a) Mining implicitly aligned sentence pairs. We provide a simple and efficient method to mine bilingual sentence pairs from weakly aligned document pairs. With the cross-lingual word embeddings trained from two monolingual corpora (one for each language) using MUSE (Conneau et al., 2017), we use weighted average of word embeddings in a sentence as the sentence embedding. We then select the sentence pairs using the sentence embeddings with large cosine similarity as bilingual sentence pairs to train NMT models. b) Leveraging topic alignment as regularization. Many previous works suggest that the word distribution can be usecd to well characterize the topic of the document (Petterson et al., 2010; Du et al., 2015; Funatsu et al., 2014; Pedrosa et al., 2016; Chemudugunta et al., 2007). To leverage the topic consistency between weakly paired documents, we minimize the KL-divergence of the word distributions between the ground-truth document and the model-generated document.

Taking Wikipedia corpus as the training data, we test our method on the widely used WMT16 German↔English, WMT13 Spanish↔English and WMT16 Romanian↔English translation tasks. Our method achieves 24.1/30.3 BLEU points for WMT16 German↔English translations, 28.1/27.6 BLEU points for WMT13 Spanish↔English translations and 30.1/27.6 BLEU scores for WMT16 Romanian↔English translations, outperforming the previous strong unsupervised method by more than 5 BLEU points and reduce the gap between unsupervised translation and supervised translation up to 50%.

2 Our method

We contribute two ways to leverage weakly paired documents: mining implicitly aligned sentence pairs from the document pairs and aligning the topic distributions of two documents in a weakly aligned pair. Before diving into details, we first introduce some notations.

Denote $D = \{(d_i^X, d_i^Y)\}, i \in \{1, 2, ..., M\}$ as the set of weakly paired documents, in which document d_i^X is aligned to d_i^Y. For example, d_i^X and d_i^Y are two cross-lingual linked Wikipedia pages. Denote n_i^X and n_i^Y as the number of sentences in document d_i^X and d_i^Y respectively. Note that usually $n_i^X \neq n_i^Y$.

Without any confusions, we denote x as a sentence in language X and y as a sentence in language Y. We denote *enc* as the encoder for language X and Y, which maps a sentence x or y into a sequence of real vectors using parameter θ_{enc}. We use *dec* with parameter θ_{dec} as the decoder, which takes the encoded vectors and target language tag (X or Y) as inputs and outputs a probability distribution over sentences in the target language. Let θ denote all the parameters of the translation model. Similar to (Artetxe et al., 2017; Lample et al., 2017), such a model can handle both $X \to Y$ and $Y \to X$ translations.

2.1 Mining implicitly aligned sentence pairs

Different language versions of Wikipedia pages about the same entity/event are usually created by different people speaking different native languages, and therefore most sentences in two weakly aligned documents are not aligned. Even though, there is still a small chance that some bilingual sentences are aligned, and we try to

mine such implicitly aligned sentence pairs and use them as supervision for NMT model training.

Many works rely on aligned sentences or bilingual dictionaries to mine the sentence pairs (Adafre and De Rijke, 2006; Yasuda and Sumita, 2008; Fung and Cheung, 2004). For example, Imankulova et al. (2017) extract bilingual sentence pairs from Wikipedia using a well-trained translation model learned from supervised sentence pairs. This method does not work for us since we are under unsupervised scenario and we do not have any aligned bilingual sentence pairs. Instead, our idea is to compute the similarity of two sentences using their cross-lingual sentence embeddings and choose the pairs with large similarity as aligned bilingual sentence pairs.

Sentence embedding is widely used to measure textual similarity in text classification tasks (Arora et al., 2017; Le and Mikolov, 2014; Wieting et al., 2015). (Arora et al., 2017) compute the weighted average of the word embedding in one sentence where the weight depends on word frequency and then project away the weighted average sentence embeddings from their first principal component. This method achieves good performance on a range of monolingual textual similarity task. We extend their method from monolingual sentence embedding to cross-lingual sentence embedding, given the cross-lingual word embeddings are pretrained using MUSE (Conneau et al., 2017). The detailed method is described as follows.

For each word w, we denote e_w as the word embedding trained from MUSE (Conneau et al., 2017), $p(w)$ as the estimated frequency from another document and a as a predefined parameter to calculate the weight of word embedding. We denote $\hat{e}_s$ as the weighted average sentence embedding of sentence s and E as the embedding matrix of all the sentences over the monolingual corpus. Then we remove the first principal components u_1 of E for every weighted average sentence embedding $\hat{e}_s$. Removing the first principal component from the sentence embeddings make them more diverse and expressive in the embedding space, and thus the resulted embeddings are more effective. We use the resulting embedding e_s as the final sentence embedding, i.e.,

$$\begin{aligned} \hat{e}_s &= \sum_{w \in s} \frac{a}{a + p(w)} e_w, \\ u_1 &\leftarrow PCA(E), \\ e_s &= \hat{e}_s - u_1 u_1^T \hat{e}_s. \end{aligned}$$

Based on the sentence embedding, we estimate the similarity between two sentences in different languages by their cosine similarity $\text{sim}(s^X, s^Y) = \frac{<e_{s^X}, e_{s^Y}>}{\|e_{s^X}\| \|e_{s^Y}\|}$. For each weakly aligned document pair (d_i^X, d_i^Y), we have $n_i^X \times n_i^Y$ pairs of sentences and form a bipartite graph between sentences in two documents where the weight of an edge between two cross-lingual sentences is their cosine similarity score. The goal is to find the most confident edges (sentence pairs) from this weighted bipartite graph. We adopt a greedy selection approach with two constraints: The first constraint is that the weight of a selected edge must be larger than threshold c_1, which is to ensure that the two sentences are similar enough. The second constraint is that the weight of a selected edge must be larger than the weights of all other edges connected to these two nodes (sentences) by threshold c_2. This ensures that the pair we selected is unique enough. Denote $S = \{(s_j^X, s_j^Y)\}$ as the set of selected sentence pairs. We use those pairs as supervision for model training, i.e., minimizing the negative log-likelihood as below.

$$\begin{aligned} L_p(S;\theta) = &-\frac{1}{|S|} \sum_{(s^X, s^Y) \in S} \log P_{X \to Y}(s^Y | s^X; \theta) \\ &-\frac{1}{|S|} \sum_{(s^X, s^Y) \in S} \log P_{Y \to X}(s^X | s^Y; \theta). \end{aligned}$$

2.2 Aligning Topic Distribution

Although cross-lingual linked Wikipedia pages are not aligned in sentences, they are usually aligned in topic distribution because they talk about the same event or entity. For example, the English topical words "politician", "United States" and "president" will appear in the English page for "Donald Trump", and similar topical words in French will appear in the corresponding French page. That is, if we translate an article from English to French sentence-by-sentence, the word distribution of the translated article should be generally similar to the word distribution of the corresponding article in French. Here we leverage the document-level word-distribution alignment to enhance and regularize the training of a translation model.

Given an NMT model, we first translate a document d_i^X by sentence translation and obtain a document $\bar{d}_i^Y$. Then we evaluate the word distributions between the generated document $\bar{d}_i^Y$ and the ground-truth document d_i^Y, and use such signal to optimize the model. However, straight-forward

loss design, e.g., KL-divergence or Wasserstein distance between the word distributions of $\bar{d}_i^Y$ and d_i^Y is not differentiable w.r.t. the NMT model, due to the non-differentiable operation (greedy search or beam search) while generating $\bar{d}_i^Y$.

To address this challenge, we need to design some loss function that is smooth with respect to the model parameters. Our proposal is assuming each generated sentence $\hat{s}_{i,k}^Y \in \bar{d}_i^Y$ is fixed and "refeeding" the pair $(s_{i,k}^X, \hat{s}_{i,k}^Y)$ to the model to get the probability distribution over all the words at each position. We calculate the word distribution by averaging word probability distributions over all sentences and positions of the generated document. Mathematically, we have

$$P(w_{i,k,t}^Y | s_{i,k}^X, \hat{s}_{i,k,<t}^Y) \sim P_{X\to Y}(w_t^Y | s_{i,k}^X, \hat{s}_{i,k,<t}^Y; \theta),$$
$$P(w^Y; d_i^X, \theta) \propto \sum_{i,k,t} P(w_t | \hat{s}_{i,k,<t}^Y),$$

where $P(w^Y; d_i^X, \theta)$ "acts" as the model-generated word distribution for document d_i^X. Note that this averaged distribution is differentiable to model parameters. The word distribution of the ground-truth document d_i^Y is $P(w^Y; d_i^Y) = \frac{\#w \text{ in } d_i^Y}{\#token \text{ in } d_i^Y}$. We simply use KL-divergence loss as the objective. Then the document alignment loss for $X \to Y$ translation is defined as

$$L_d(D; \theta, X \to Y) = \frac{1}{|D|} \sum_{(d_i^X, d_i^Y) \in D} KL(P(w^Y; d_i^Y) || P(w^Y; d_i^X, \theta)).$$

The corresponding document loss for $Y \to X$ translation can be defined in the same way. The final loss is as follows, which can be optimized using backpropagation thanks to its smoothness.

$$L_d(D; \theta) = L_d(D; \theta, X \to Y) + L_d(D; \theta, Y \to X).$$

2.3 Overall algorithm

In addition to the above two ways of using Wikipedia data, the sentences in the weakly paired documents can be used as monolingual data to optimize the losses of the unsupervised machine translation. Therefore, our proposed losses can be combined with the loss functions of unsupervised machine translation. Here we first recap unsupervised machine translation (Lample et al., 2017), and then present our algorithm in Algorithm 1.

The unsupervised machine translation considers two loss functions. Given a monolingual sentence s in language X/Y, the denoising auto-encoder loss is defined as $L_{dae} = -\mathbb{E}_{s\sim X}[\log P(s|c(s);\theta)] - \mathbb{E}_{s\sim Y}[\log P(s|c(s);\theta)]$, where $c(.)$ is to drop and swap words in sentence s. As for the reconstruction loss, given s in language X/Y and the translated sentence s' in Y/X by model $P_{X\to Y}/P_{Y\to X}$, the reconstruction loss is defined as $L_{rec} = -\mathbb{E}_{s\sim X}[\log P_{Y\to X}(s|s';\theta)] - \mathbb{E}_{s\sim Y}[\log P_{X\to Y}(s|s';\theta)]$.

Denote the combination of the monolingual data in language X and Y as M. We define the overall loss on monolingual data M as $L_m(M;\theta) = L_{dae} + L_{rec}$. Finally, the overall training objective of our algorithm is to minimize the following loss function with hyperparameters α and β:

$$L = L_m(M;\theta) + \alpha L_p(S;\theta) + \beta L_d(D;\theta).$$

Algorithm 1 Training Algorithm

Require: Initial translation model with parameter θ; monolingual dataset M, implicitly aligned sentence pairs dataset S, weakly paired documents dataset D; optimizer *Opt*

1: **while** not converged **do**
2: Randomly sample a mini-batch monolingual sentences from M, implicitly aligned sentence pairs from S and weakly paired documents from D
3: Calculate loss L_m, L_p and L_d
4: Update θ by minimizing the overall objective L using optimizer *Opt*
5: **end while**

3 Experiments

We test our method on several benchmark translation tasks. We first describe the data preparation and experimental design, and then present the main results, followed by some deep studies.

3.1 Data preparation

Wikimedia offers free copies of all available contents on Wikipedia for multiple languages. We download the language specific Wikipedia contents[1], and use WikiExtractor[2] to extract and clean

[1] For example, we download German Wikipedia contents from https://dumps.wikimedia.org/dewiki/.

[2] https://github.com/attardi/wikiextractor

Language	#Wiki Documents
English	5,684,240
German	2,201,782
Spanish	1,389,469
Romanian	387,627
Task	**#Document Pairs**
English-German	948,631
English-Spanish	836,564
English-Romanian	87,289

Table 1: Statistics of Wikipedia data, including numbers of documents and weakly paired documents.

the texts. The numbers of Wikipedia documents are listed in Table 1. We then use the sentence tokenizer from toolkit NLTK to generate segmented sentences from Wikipedia documents.

Many Wikipedia pages contain external links to the pages that describe the same entity but in different languages. We extract weakly paired documents using these external links. We filter out a document pair if any document in the pair contains less than 5 sentences. We also remove the sentences longer than 100 words. We conduct experiments on three language pairs: English-German (En-De), English-Spanish (En-Es) and English-Romanian (En-Ro) translations. The former two language pairs are indeed high-resource language pairs while the last is a low-resource language pair. Statistics of the processed Wikipedia documents are provided in Table 1.

We use the monolingual data as in Lample et al. (2017, 2018) together with Wikipedia document pairs to train NMT models. For the En-De task, we use all available sentences from the WMT monolingual News Crawl datasets from year 2007 to 2017 containing about 50 million sentences for each language. For Romanian, it has more than 2 million sentences. For En-Es, we use News Crawl datasets from year 2007 to 2012 containing about 10 million sentences. The translation models are evaluated on *newstest 2016* dataset for En-De and En-Ro, and *newstest 2013* dataset for En-Es which are widely used (Koehn and Knowles, 2017).

3.2 Experimental Design

To mine implicitly aligned sentences from weakly paired documents, we use the open-sourced word embeddings trained by Fasttext (Joulin et al., 2016) and use MUSE[3] to build cross-lingual word embeddings. We then generate sentence embeddings with the weighted average of cross-lingual word embeddings and further remove the top-1 principal components of sentence embedding matrix as introduced in Section 2.1. We set the two thresholds $c_1 = 0.7$ and $c_2 = 0.1$ respectively when selecting sentence pairs, and the parameter a to calculate the weight of word embedding is 0.001. To translate a document d_i^X for topic alignment, we use greedy search.

For the training of translation models, the monolingual datasets, Wikipedia document pairs and mined sentence pairs are jointly processed by BPE (Sennrich et al., 2016b) with $60,000$ codes. For model initialization, we follow (Lample et al., 2018), which uses cross-lingual BPE embeddings to initialize the shared lookup tables, and the cross-lingual BPE embeddings are trained by fastText with embedding dimension 512, a context windows of size 5 and 10 negative samples. We adopt the Transformer (Vaswani et al., 2017) architecture in our experiments. We stack 6 layers in both the encoder and the decoder. Following (Lample et al., 2018), we share the lookup tables between the encoder and the encoder, and between the source and target languages. The dimension of the hidden state is 512. The weights α and β of the loss functions are set to be 1 and 0.05. For training, we use Adam optimizer (Kingma and Ba, 2014) and the same learning rate scheduler as used in (Vaswani et al., 2017). For decoding, we use beam search with beam width 4 and length penalty 0.6, and report the case-sensitive BLEU[4] score.

3.3 Main Results

Our method is compared with several previous works (Lample et al., 2018, 2017; Yang et al., 2018) in Table 2. We also consider some simple and heuristic ways of using the weakly paired documents as baselines. One baseline, referred as "NMT + First Wikipedia Sentence", is to directly use the first sentence of the aligned documents as an aligned sentence pair to train NMT model. The motivation behind it is that usually the first sentence of a Wikipedia document summarizes the main content of the document, which is more likely to be similar across languages. The second baseline, referred as "NMT + Document Translation", is to treat the weakly aligned doc-

Table 2: BLEU scores compared with previous approaches.

uments as two long sentences and use them as a bilingual sentence pair to train NMT models.

From Table 2, our approach achieves BLEU score of 24.1 and 30.3 on En→De and De→En translations respectively. The previous best performance is achieved by (Lample et al., 2018): combining phrase-based approach and neural machine translation together, they achieve 20.2 and 25.2 BLEU scores on En→De and De→En translation with monolingual data only. Our approach outperforms their method by more than 4 and 5 BLEU points on En→De and De→En respectively, with limited weakly paired sentences and documents. For the En-Es, we achieve 28.1 and 27.6 BLEU scores on En→Es and Es→En respectively, with more than 8 and 7 points improvement over unsupervised Transformer baseline models. Similarly, for the En-Ro low-resource task, we achieve 30.1 and 27.6 BLEU scores for En→Ro and Ro→En respectively, which has more than 5 and 4 points improvement compared with previously reported results. One interesting point is that there are only nearly $6k$ aligned sentence pairs mined by our approach for En-Ro[5], but we can still achieve a large BLEU improvement. This result can well demonstrate the effectiveness of our method in real low-resource settings and the sentences mined by our approach are in high quality.

For the two heuristic baselines, we find that they hurt the performance of NMT models with more than 2 points decrease in terms of the BLEU score. The results indicate that the careful utilization of Wikipedia data is important, which can also be verified by the superior performance of our approach.

Furthermore, we report the supervised result in the last row of Table 2. The supervised setting is conducted on the full training set on WMT16 En-De translation with 4.5 million parallel sentences, and WMT13 En-Es translation with 3.8 million parallel sentences. As shown in the table, our approach takes a big step towards the supervised result, and reduce the gap between unsupervised translation and supervised translation up to 50%.

3.4 Discussions

To make a clear comparison on sentence pair extraction, we work similarly to existing works in our unsupervised scenario.

As introduced before, previous works usually leverage bilingual pairs to train a model or a classifier, or use a bilingual dictionary to mine sentence pairs. In our unsupervised scenario, the most related initial model for selecting pairs is the unsupervised NMT model. Therefore, we first train an unsupervised NMT model followed Lample et al. (2018) and use this model to mine the sentence pairs. Specifically, we conduct following experiments: a). Similarly to Adafre and De Rijke (2006); Yasuda and Sumita (2008), for each x, we generate the translation using the unsupervised NMT model, and select the most similar sentence to the translation (w.r.t. BLEU) as paired data. b). We use the model outputted translation probability $p(y|x)$ as the scoring function, as used in Smith et al. (2010); Munteanu and Marcu (2005), and select sentence pairs with larger probabilities. As the unsupervised NMT model is not good enough, we found the selected sentence pairs were in poor quality and using such poor data does not work well. On De→En task, the BLEU score of the model trained in a) and b) can only reach 23.4 and 19.8 (dropped) respectively. Both show that the trained unsupervised NMT models are not good

[5]Compared with nearly $200k$ aligned sentences pairs for En-De, which can be found in Section 3.5.

Our Method	En→De	De→En
with L_p and L_d	24.2	30.3
without L_d	22.9	28.7
without L_p	18.5	23.3

Table 3: Ablation study of our approach.

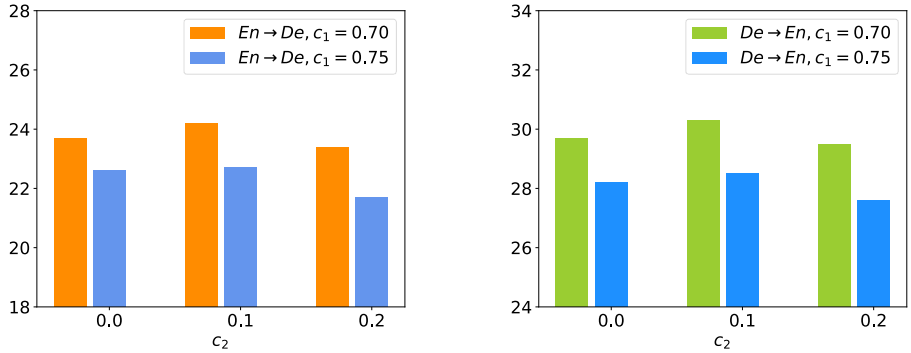
as expected.

Besides, we build a bilingual dictionary based on the titles from cross-lingual Wikipedia pages which we want to use to mine sentence pairs like Fung and Cheung (2004) and evaluate the quality using tool from MUSE. However, the top 1 accuracy of the word translation is poor ($< 20\%$), which makes it unable to select trustable sentence pairs using such a weak lexicon. In contrast, by leveraging our cross-lingual word embedding and unsupervised sentence representation, the selected sentences are much better (see more in Section 3.5). We believe our findings are important to the field of unsupervised machine translation.

3.5 Further Studies

In this subsection, we provide an ablation study to our method, check the performance variance with respect to the thresholds for mining implicit sentence pairs, and finally present several cases of mined sentence pairs. The studies are conducted on the En-De translation pair.



Ablation Study Our method leverages weakly paired documents in two ways. To better understand the importance of the two ways, we report results from an ablation study in Table 3. From the table, we can see that removing the topic alignment, the accuracy drops with more than 1 BLEU points. Without the implicitly aligned sentence pairs, the accuracy decreases with about 6 BLEU points. These findings clearly demonstrate that both the two ways are important, and both contribute to the improvement of translation accuracy.

Impact of Sentence Quality As introduced before, to control the data quality of mined sentence pairs, we set two constraints with threshold c_1 and c_2. We present the paired sentence number and the BLEU scores with respect to these two thresholds in Table 4 and Figure 1. We vary the threshold c_1 in $\{0.70, 0.75\}$ and c_2 in $\{0.0, 0.1, 0.2\}$. For $c_1 \leq 0.70$, we observe that the sentence quality is poor, while for $c_1 \geq 0.75$, we can only extract few pairs. As shown in the table and the figure, with more strict constraint, we obtain fewer sentence pairs but with higher quality. We can see that there is a clear trade-off between the data quality and the data number. A good configuration is $c_1 = 0.7$ and $c_2 = 0.1$.

Case Study of Mined Sentence Pairs We present three cases of our selected sentence pairs in Table 5. We can see that our approach can mine high-quality pairs, such as the first case, in which one sentence is a good translation of the other one. Besides, our method can select interesting paired sentences with similar, if not the exactly same, semantics. As shown in the second case, the two sentences are almost semantically the same, while the German word *"gewählt"* (*"elected"* in English) is not included in the corresponding English sentence. Also in the last case, the detailed description *"15 Meter hoch"* (which means "15 meters high" in English) in the German sentence is missed in the English sentence. Although they are not exact translations, such sentence pairs are still very helpful for NMT model training, as demonstrated by the results of our method.

4 Related Work

Using monolingual data to boost the machine translation performance has attracted a lot of attention (Gulcehre et al., 2015; Sennrich et al., 2016a; Zhang and Zong, 2016; Wu et al., 2018; He et al., 2016; Wu et al., 2017), especially when the bilingual supervision is limited. Sennrich et al. (2016a) propose the back-translation approach which is an effective way to augment the training sentence pairs with ctarget-side monolingual data. He et al. (2016) leverage both source-side and target-side monolingual data in a dual learning framework. However, these methods still require a relatively large amount of labeled bilingual data. Recently, Lample et al. (2017) and Artetxe et al. (2017) make an initial study of unsupervised machine translation, in which the model is trained by the monolingual data only. Lample et al. (2017) leverage two key components to learn unsupervised translation models: 1) suitable initial-

(a) En→De BLEU performance. (b) De→En BLEU performance.

ization of the translation model by cross-lingual word embeddings, 2) denoising auto-encoder as language model and reconstruction loss based on translation-back-translation. Both works only leverage monolingual sentences without quite rich weakly paired documents from Web.

We study how to leverage document pairs for training without supervised bilingual sentence pairs from Wikipedia. Leveraging the free online Wikipedia database as an additional source to improve the natural language processing tasks has attracted interest in recent years. For example, Conneau et al. (2017) show that word translation can be effectively learned based on the embedding trained from Wikipedia corpora. This embedding further becomes one of the key components for unsupervised machine translation. Different from using Wikipedia to train warm-start word embeddings, we aim to leverage more and stronger signals from such weakly paired documents to train translation model. Hálek et al. (2011) use the category information in Wikipedia corpus to improve the translation of named entities. Drexler et al. (2014) incorporate language models from target language documents that are comparable to the source documents in Wikipedia pages to improve the document translation.

There are several works aim at extracting potential sentence pairs from comparable corpus, but most of them rely on a set of bilingual sentence pairs to train a model or obtain a bilingual lexicon and use this model/lexicon to select sentence pairs. For example, Adafre and De Rijke (2006) and Yasuda and Sumita (2008) use a strong machine translation system to obtain a rough translation of a given page in one language into another, and then calculate word overlap or BLEU score between sentences as measure. Smith et al. (2010) and Munteanu and Marcu (2005) develop a ranking model/binary classifier to learn how likely a sentence in target language is a translation of the source language using parallel corpora. (Fung and Cheung, 2004) use a small set of parallel corpora to initialize their EM lexical learning and further use this lexicon to iteratively mine sentence pairs. However, in our unsupervised scenario, we have no bilingual sentence pairs to train such a model or lexicon to further select new sentence pairs.

Our work is also related to document translation (Tu et al., 2018) but with different goals and settings. The goal of document translation is to enhance sentence translation with stronger signals beyond sentences by using richer inputs (e.g., the topic information from the documen-

t that contains this sentence). During training, it takes one sentence as well as the cross-sentence (document-level) information as input and predicts the ground-truth translation sentence in other languages. Therefore, training a document translation model requires bilingual sentence pairs and their surrounding contexts. In our scenario, our goal is to learn a sentence translation model with weaker signals than sentence pairs. We target to extract useful information from weakly paired documents to train a translation model without human-labeled bilingual data.

5 Conclusion and Future Work

In this work, we propose a general method to train machine translation models using weakly paired bilingual documents from Web, e.g., Wikipedia. Our approach contains two key components: mining implicitly aligned sentence pairs and aligning topic distributions. Experiments on public benchmarks verify the effectiveness of our method.

For future work, we will apply our method to more other language pairs. Besides, we will study using weakly paired documents from other data resources, such as news websites. Furthermore, we will investigate better ways to utilize such weakly paired documents, going beyond mining sentence pairs and aligning topic distributions.

Abstract

Emergent multi-agent communication protocols are very different from natural language and not easily interpretable by humans. We find that agents that were initially pretrained to produce natural language can also experience detrimental *language drift*: when a non-linguistic reward is used in a goal-based task, e.g. some scalar success metric, the communication protocol may easily and radically diverge from natural language. We recast translation as a multi-agent communication game and examine auxiliary training constraints for their effectiveness in mitigating language drift. We show that a combination of syntactic (language model likelihood) and semantic (visual grounding) constraints gives the best communication performance, allowing pre-trained agents to retain English syntax while learning to accurately convey the intended meaning.

1 Introduction

A long-standing goal of artificial intelligence research is to develop agents that can cooperate with other agents, including humans, to solve tasks. As Gauthier and Mordatch (2016) propose, one way to get closer to this goal is to develop agents that can flexibly use human language to coordinate with themselves and with humans.

Recently, there has been a renewed interest in multi-agent communication (Foerster et al., 2016; Lazaridou et al., 2016). While agents can be very effective in solving the tasks that they were trained on, their multi-agent communication protocols bear little resemblance to human languages. A major open question revolves around training multi-agent systems such that their communication protocols can be interpreted by humans.

One option is to pre-train in a supervised fashion with human language, but even then it is found that the protocols diverge quickly when the agents are fine-tuned on an external reward, as Lewis et al. (2017) showed on a negotiation task. Indeed, language drift is to be expected if we are optimizing for an external non-linguistic reward, such as a reward based on whether or not two agents successfully accomplish a negotiation.

Intended message:	*2 elephants and 1 lion*
No constraints	*floopy globber*
Syntactic	*democracy is a political system*
Syntactic+Semantic	*a pair of elephants and a large feline*

Table 1: Examples of valid messages under different constraints. Without constraints, agents may invent an arbitrary protocol to communicate the intended message. Syntactic constraints enforce "Englishness" but not semantic correspondence. Semantic constraints, e.g. with visual grounding, can enforce the communication channel to retain the meaning of the message.

Language drift might be avoided by imposing a "naturalness" constraint, e.g. by factoring language model likelihood into the reward function. However, such a constraint only acts on the *syntax* of the generated language, ignoring its *semantics*. See Table 1 for an illustration of different constraints. As has been advocated by multi-modal semantics (Baroni, 2016; Kiela, 2017), we investigate if appropriate semantic constraints can be imposed on the generated language through (in this case visually) *grounding* its meaning in a different modality.

In order to carefully study this problem, we require a task where drift can be accurately measured. Inspired by Lee et al. (2018), we use a multi-modal machine translation (MMT) dataset (Multi30k; Elliott et al., 2016) to construct a new communication game: Two machine translation agents—i.e., encoder-decoder models with attention—are tasked with successfully translating source language se-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4385–4395,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

quences to the target language using a third pivot language as an intermediary. The first agent's decoder output is fed into the second agent's encoder as input. We employ policy gradient methods to train the first agent with the target language log-likelihood as reward. Thus, we effectively fine-tune two pre-trained machine translation agents via a pivot language, facilitating the study of its drift.

Contrary to alternative two-agent communication tasks such as navigation, game-playing or dialogue—which either don't have clearly defined metrics or easily available natural language data—this pivot-based translation allows us to check exactly whether the communicated sequence corresponds to the intended meaning, as well as to the gold standard sequence. In addition, every single utterance has very clear and well-known metrics such as BLEU and log-likelihood, allowing us to measure performance at every single step.

In what follows, we show that language drift happens, and quite dramatically so, when fine-tuning using policy gradients. Next, we investigate imposing syntactic conformity (i.e., "Englishness") via language model constraints, and show that this does somewhat mitigate drift, but does not lead to semantic correspondence. We then show that additionally imposing semantic constraints via (visual) grounding leads to the best retention of original syntax and intended semantics, and minimizes drift while improving performance. We conduct a token frequency analysis, which corroborates our hypothesis, and show that grounding causes the model to better preserve the token frequency distribution of the pivot language (English), while fine-tuning with language model constraints alone leads to a frequency distribution different from the original natural language.

The ability to keep drift in check opens up exciting possibilities for natural language processing research: we could maximize reward while *retaining* the "Englishness" of the decoder, with obvious benefits for interpretability and interaction with humans. One general use case would be fine-tuning a language model pre-trained on large amounts of data for a given generation task with limited data, which is especially interesting given the recent interest in pre-trained language models (Radford et al., 2019). For instance when training chit-chat dialogue agents, we often want to optimize for some very high-level reward, such as engagingness or consistency, with hardly enough data to learn simple English grammar. The ability to fine-tune a pre-trained independent "language module", without drift, is an exciting prospect. With this work, we aim to take a step in that direction, and show that semantic constraints in the form of grounding play an important role.

2 Prior Work

Our work is inspired by recent work in protocols or languages that emerge from multi-agent interaction (Lazaridou et al., 2017; Lee et al., 2018; Andreas et al., 2017; Evtimova et al., 2018; Kottur et al., 2017; Havrylov and Titov, 2017; Mordatch and Abbeel, 2017). Work on the emergence of language in multi-agent settings goes back a long way (Steels, 1997; Nowak and Krakauer, 1999; Kirby, 2001; Briscoe, 2002; Skyrms, 2010). In our case, we are specifically interested in *tabula inscripta* agents that are already pre-trained to generate natural language, and we are primarily concerned with keeping their generated language as natural as possible during further training.

Reinforcement Learning has been applied to fine-tuning models for various natural language generation tasks, including summarization (Ranzato et al., 2015; Paulus et al., 2017), information retrieval (Nogueira and Cho, 2017), MT (Gu et al., 2017; Bahdanau et al., 2016) and dialogue (Li et al., 2017). Our work can be viewed as fine-tuning MT systems using an intermediary pivot language. In MT, there is a long line of work of pivot-based approaches, most notably Muraki (1986) and more recently with neural approaches (Wang et al., 2017; Cheng et al., 2017; Chen et al., 2018). There has also been work on using visual pivots directly (Hitschler et al., 2016; Nakayama and Nishida, 2017; Lee et al., 2018). Grounded language learning in general has been shown to give significant practical improvements in various natural language understanding tasks (Gella et al., 2017; Elliott and Kádár, 2017; Chrupała et al., 2015; Kiela et al., 2017; Kádár et al., 2018).

3 Task and Models

3.1 Communication Task

We recast pivot-based translation as a communication game involving two MT agents: Fr→En and En→De. See Figure 1. Our dataset consists of N triples of aligned sentences $\{\text{Fr}_k, \text{En}_k, \text{De}_k\}_{k=1}^{N}$. Note that En_k is only used for evaluation and is not required for training. We first feed the

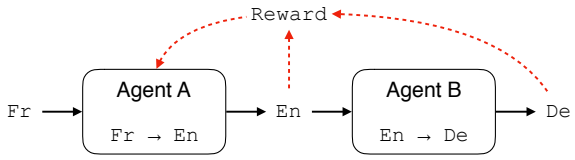

Figure 1: Diagram of our communication game.

French sentence Fr_k to Agent A, which generates an English message $\overline{\text{En}_k}$ as output. Agent B is then trained to maximize the log-likelihood of the ground truth German sentence given the English message, i.e. $\log p(\text{De}_k|\overline{\text{En}_k})$. Agent A is trained using REINFORCE (Williams, 1992) with reward $R = \log p_B(\text{De}_k|\overline{\text{En}_k})$.[1] This encourages Agent A to develop helpful communication policies for Agent B, and allows Agent B to adapt to Agent A's new policies. In other words: communication via the pivot language (English) is a success if we are able to translate the intended source sequence (French) into the desired target sequence (German).

Both agents are pre-trained on their respective tasks before communication, which means that the intermediate language starts off as English in the early stages of the communication game, where the goal is to translate French to German. This work examines what happens to the intermediate language as we fine-tune the system jointly for the given goal: will the agents keep communicating in English, or diverge? And if so, what can we do to prevent that from happening?

This particular task and setup directly addresses the problem of language drift, as the availability of ground truth references and well-understood metrics (e.g. BLEU) allows us to exactly measure the degree of language drift over time. The Fr→En→De BLEU score informs communication success, while (the relative change in) the Fr→En BLEU score captures the degree of language drift.

3.2 Constraints via Auxiliary Tasks

The action space of Agent A is $|V|^L$, where $|V|$ is the size of the vocabulary (approximately 20k) and L is the sequence length. We explore the two aforementioned constraints: a syntactic constraint via language modeling (LM) and a semantic constraint via grounding (G).

Language Model (LM) Given a language model pre-trained on a standard English corpus, the (sentence-level) log-likelihood of the English message informs its general "Englishness". We incorporate this into the reward for Agent A, so that it learns to send messages that are plausible English.[2] Reward for Agent A is:

$$R_k^{\text{LM}} = \log p_B(\text{De}_k|\overline{\text{En}_k}) + \beta_{LM} \log p_{LM}(\overline{\text{En}_k}).$$

Grounding Model (G) Let us assume we have access to a set of images $\{\text{Img}_k\}$ associated with each triple $\{\text{Fr}_k, \text{En}_k, \text{De}_k\}$. Given a pre-trained image-caption retrieval model, such as VSE++ (Faghri et al., 2018), the log-likelihood of the image given the English message (and vice versa) captures how much the English message is grounded in the original semantic content (Kiela et al., 2017). We incorporate the ranking loss into Agent A's reward.

$$R_k^{\text{G}} = \log p_B(\text{De}_k|\overline{\text{En}_k}) + \beta_G \log p_G(\text{Img}_k|\overline{\text{En}_k}).$$

β_{LM} and β_G are hyperparameters.

3.3 Training Objective

Let us denote the t-th token in the k-th English training example with En_k^t, the actual reward and the state-dependent baseline in the k-th training example as R_k and $\overline{R_k^t}$.

Policy Gradient Training At decoding timestep t, Agent A takes an action (outputs token $\overline{\text{En}_k^t}$) given an environment (previous hidden states and previous token $\overline{\text{En}_k^{t-1}}$). It receives reward R_k at the end of the sequence, from which we subtract a state-dependent baseline $\overline{R_k^t}$ to reduce variance. Therefore, we maximize $(R_k - \overline{R_k^t}) \log p(\overline{\text{En}_k^t}|\overline{\text{En}_k^{<t}}, \text{Fr}_k)$. In addition, we employ entropy regularization on Agent A's decoder to encourage exploration. Hence, Agent A's overall objective function is given as:

$$\begin{aligned}\mathbb{L}_A = \sum_{k=1}^{N} \Bigg\{ \sum_{t=1}^{T_k} \Big\{ & \alpha_{\text{entr}} H\left(p(\overline{\text{En}_k^t}|\overline{\text{En}_k^{<t}}, \text{Fr}_k)\right) \\ & - \alpha_{\text{b}} \text{MSE}(R_k, \overline{R_k^t}) \\ & + \alpha_{\text{pg}} \left(R_k - \overline{R_k^t}\right) \log p(\overline{\text{En}_k^t}|\overline{\text{En}_k^{<t}}, \text{Fr}_k) \Big\} \Bigg\},\end{aligned}$$

[1] We use subscript B to denote that the probability is computed with Agent B.

[2] We also experimented with a dense LM reward on the word-level, but found this to lead to worse performance. We hypothesize that the model might be focusing too much on the dense LM reward, ignoring the sparse reward for the communication task and leading to poor performance. We did not use BLEU as it is a corpus-level metric.

where H and MSE denote entropy and mean squared error losses. T_k is the maximum decoding timestep in the k-th training example.

Cross Entropy Training Agent B is trained using standard cross entropy loss, i.e.

$$\mathbb{L}_B = \sum_{k=1}^{N} \Big\{ \sum_{t=1}^{T_k} \log p(\mathrm{De}_k^t | \mathrm{De}_k^{<t}, \overline{\mathrm{En}_k}) \Big\}.$$

We jointly train both agents by maximizing $\mathbb{L} = \mathbb{L}_A + \mathbb{L}_B$.

4 Experimental Settings

In this section we provide the details of our experimental setup: a Fr→X→De translation task where the intermediate language X is initialized as English, and subsequently fine-tuned with policy gradient methods. The model is trained either with no constraints (**PG**), syntactic constraints via language modeling (**PG+LM**) or both syntactic and semantic constraints via language modeling and grounding (**PG+LM+G**).

Datasets Agents A and B are initially pre-trained on IWSLT Fr→En and En→De, respectively (Cettolo et al., 2012). Fine-tuning is performed on Multi30k Task 1 (Elliott et al., 2016). That is, importantly, there is no overlap in the pre-training data and the fine-tuning data. Multi30k Task 1 consists of 30k images and one caption per image in English, French, German and Czech (of which we only use the first three). To ensure our findings are robust, we compare four different language models, trained on WikiText103, MS COCO, Flickr30k and all of the above.

The grounding model is trained on Flickr30k (Young et al., 2014). Following Faghri et al. (2018), we randomly crop training images for data augmentation. We use 2048-dimensional features from a pretrained and fixed ResNet-152 (He et al., 2016).

Preprocessing The same tokenization and vocabulary are used across different tasks and datasets. We lowercase and tokenize our corpora with Moses (Koehn et al., 2007) and use subword tokenization with Byte Pair Encoding (BPE) (Sennrich et al., 2016) with 10k merge operations. This allows us to use the same vocabulary across different models seamlessly (translation, language model, image-caption ranker model).

Controling the English message length When fine-tuning the agents, we observe that the length of English messages becomes excessively long. As Agent A has no explicit incentive to output the end-of-sentence (EOS) symbol, it tends to keep transmitting the same token repeatedly. While redundancy might be beneficial for communication, excessively long messages obscure evaluation of the communication protocol. For instance, BLEU score quickly deteriorates as the message length becomes longer, as it is a precision metric. When the message length is fixed, a drop in BLEU score will by necessity mean that the intermediate language has drifted away more. For this reason, we constrain the length of English messages to be no longer than the length of their French source sentence, or shorter if the model outputs the EOS symbol early. Recall that Agent B is supervised to predict the EOS symbol at the right position, so does not suffer from this issue.

Model Architecture and Pretraining Our MT agents are standard sequence-to-sequence models with attention (Bahdanau et al., 2015) with a unidirectional, 1-layer GRU (Cho et al., 2014) with 256 hidden units and 256-dimensional embeddings. During initial pre-training on IWSLT, we early-stop on the validation BLEU score (tst2013). The best checkpoints give 34.05 BLEU and 21.94 BLEU on IWSLT Fr→En and En→De development sets with greedy decoding. For our policy gradient value function, we use a 2-layer MLP with ReLU activations.

The language model is a 1-layer recurrent language model with 512 LSTM hidden units. The image-caption retrieval model is a recently proposed VSE++ model (Faghri et al., 2018), with a unidirectional 1-layer GRU with 512 hidden units and a single fully connected layer from 2048-dimensional ResNet features to 512-dimensional GRU hidden states.

Training Details When fine-tuning our agents, we perform learning rate annealing and early stopping based on Fr→En→De BLEU (communication performance) on the Multi30k development set. We use Adam (Kingma and Ba, 2014) with an initial learning rate of 0.001 and dropout (Srivastava et al., 2014) rate of 0.1. We grid search over the learning rate schedule and the reward coefficients ($\alpha_{\text{pg}}, \alpha_{\text{entr}}, \alpha_{\text{b}}$) for agent A and ($\beta_{LM}, \beta_G$) for agent B, respectively (see previous section). For

our joint systems with policy gradient fine-tuning, we run every model three times with different random seeds and report averaged results.

Baseline and Upper Bound Our main quantitative experiment has three baselines:

- Pretrained models : models pretrained on IWSLT are used without finetuning.
- Ensembling : Given Fr, we let Agent A generate K En hypotheses with beam search. Then, we let Agent B generate the translation $\overline{\text{De}}$ using an ensemble of K source sentences (Firat et al., 2016; Zoph and Knight, 2016).
- Agent A fixed : We fix Agent A (Fr→En) and only fine-tune Agent B using $\mathbb{L}_B$. This shows the communication performance achievable when Agent A cannot drift.

Meanwhile, we also train an NMT model of the same architecture and size directly on the Fr→De task in Multi30k Task 1 (without English intermediary). This serves as an upper bound on the Fr→De performance achievable with available data.

5 Quantitative Results

In Table 2, the top three rows are the baselines described above. The pretrained-only baseline performs relatively poorly on Fr→De, conceivably because it was pretrained on a different corpus in a different domain (IWLST dataset is compiled from TED talks, while Multi30k dataset is a collection of image captions). Ensembling multiple English hypotheses for Agent B gives a negligible increase in Fr→De performance. When only Agent B is fine-tuned and Agent A is kept fixed, we observe an increase from 16.30 to 22.37 in Fr→De. Unsurprisingly, the upper bound NMT model directly trained end-to-end on Multi30k Fr→De (without any pivot, at the bottom of the table) performs best.

When the joint system is fine-tuned on German log-likelihood with policy gradients (PG), we observe a large, 8 BLEU increase in Fr→De (16.30→24.51) at the cost of a substantial, 15 BLEU drop in Fr→En (27.18→12.38). This clearly shows that optimizing for external reward may improve performance on that metric, but at the expense of a drastic language drift in the communication channel on which the reward is imposed.

When the system is fine-tuned only on staying grounded but without any language model constraint (PG+G), we obtain small performance improvements. This makes sense, since BLEU first and foremost focuses on the surface form. When the agent is trained with the language model constraint (PG+LM), we notice a significant improvement in Fr→En BLEU. When the LM is trained on WikiText103, a widely used language modeling dataset, we observe an improvement of 9 BLEU score over PG (12.38→21.63). When the training corpus is closer to the target domain, such as MS COCO or Flickr30k, we observe even bigger increases. Fr→De translation also improves by 2–3 BLEU (24.51→26.88-27.67).

We see the biggest improvements in performance when agents are trained using both visual grounding feedback and the language model constraint (PG+LM+G). This is particularly pronounced with the LM trained on WikiText103: introducing visual grounding leads to more than 2 BLEU score improvement in Fr→En (21.63→23.65), and 1 BLEU score improvement in Fr→De (26.88→27.87). We hypothesize that the "Englishness" constraint forces agents to communicate with correct syntax and fluency, while the grounding model restricts the search space of languages to ones that are grounded in visual semantics. To investigate the contribution of grounding, we train a much stronger LM on all three datasets combined, and find that there is still more drift even with access to much more language modeling data (23.60→24.75).

It is important to check that the improvement from grounding is actually significant, so we perform a bootstrapped Wilcoxon signed-rank test (Wilcoxon, 1945) on paired English hypotheses for each reference sentence between PG+LM and PG+LM+G, using the model instance that gives the median communication performance (Fr→En→De BLEU) out of three runs. We assess significance on a bootstrapped test set (repeatedly sampled with replacement) and average the statistic over bootstrap samples. With the threshold of $p < 0.02$, PG+LM+G is found to differ significantly for all the LM models, including the All model that had access to much more data. See Table 3.

Figure 2 shows the learning curves, as measured by Fr→De BLEU (left), Fr→En BLEU (middle) and English LM negative log-likelihood (NLL; right). All models improve in fine-tuned task performance (left plot). We observe that vanilla PG fine-tuning quickly leads to highly "un-English" communication, as can be seen from a distinct in-

	LM	Ranker	A: Fr→En	A&B: Fr→En→De

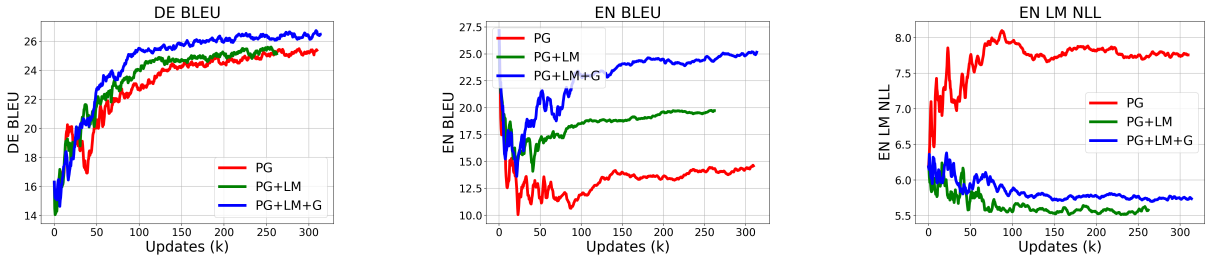
Table 2: Results in BLEU score on Multi30k Task 1. For our models using policy gradient fine-tuning, we report results averaged over three runs and provide standard deviations in brackets. **PG** (no constraint): trained with vanilla policy gradient fine-tuning. **PG+G** (semantic): trained with grounding only. **PG+LM** (syntactic): trained with "Englishness" constraint. For MS COCO and Flickr30k, the LM was trained directly on image captions. **PG+LM+G** (syntactic+semantic): trained with grounding loss as well as the LM loss. Fr→En: degree of intermediate language drift in agent A; lower indicates more drift. Fr→En→De: overall A&B communication performance; higher is better. For LM=All the LM was trained on all three LM datasets combined.

		PG+LM			
	No LM	WikiText103	MS COCO	Flickr30k	All
+G	✔	✔	✔	✔	✔

Table 3: Using the bootstrapped Wilcoxon signed-rank test (Wilcoxon, 1945), Fr→En results of PG+LM+G are found to be significantly different from its baselines in all cases considered (on all LM datasets) within the threshold of $p = 0.02$.



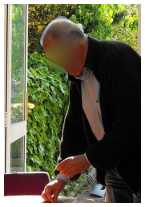


Figure 2: Test set performance over time. En LM NLL curves show the NLL of English messages, computed by a language model trained on WikiText103. Lower En BLEU and higher En LM NLL indicate more language drift.

crease in LM negative log-likelihood (right plot). While PG+LM achieves slightly lower LM NLL than PG+LM+G, its communication protocol drifts much more from English (middle plot). That is, for PG+LM, syntactic conformity is obtained at the expense of semantic preservation. Imposing both syntactic and semantic constraints makes models the least susceptible to drift, almost recovering to the original BLEU score (blue line, middle plot).

6 Analysis

A close investigation into the token statistics of each communication strategy reveals that PG fine-tuning causes the word frequency distribution to be flatter (see Figure 3). The PG model has negative frequency difference values for the most frequent tokens, indicating that PG downweighs frequent words severely, possibly because they are less discriminative. On the other hand, PG+LM gives highly positive frequency differences, meaning that language modeling alone disproportionately emphasizes frequent tokens. Using both the LM and grounding constraints keep the token frequencies closest to the pretrained regimes. Investigating the top 20 most frequent words shows that PG+LM disproportionately favors quotation marks, which are very common in many language modeling datasets but rare in Multi30k (see Table 5).

Table 6: Exact-match word recall by POS-tag on IWSLT development set: when the English reference contains a word of a certain POS tag, how often does the agent produce it.

Table 6 compares the degree of drift by part-of-speech, and shows that the PG model has very low recall on function words, such as periods and infinitives. Models trained with LM and grounding losses retain function words with much higher accuracy. PG fares relatively better with content words (nouns and verbs), but adding LM and grounding losses still outperform PG. Grounding leads to overall improvements in recall, particularly with content words. Conceivably, when optimizing Agent

A's policy on the communication task alone, it is most crucial to relay content information to Agent B, and this might cause agents to ignore syntactic conformity in the original intermediate language. Imposing both syntactic and semantic constraints reduces the space of the intermediate communication protocol to a more stable language space, as reflected in overall task performance.

Table 7 corroborates the finding that vanilla PG fine-tuning leads to flatter token frequency distributions, as the number of unique tokens used by PG is greater than that of the pretrained model. Despite using a more diverse set of tokens, PG uses the smallest number of unique symbols per sentence (/sent) and overall (/all). This implies that PG communication is redundant. PG+LM uses fewer tokens overall, and learns a sharper distribution using a smaller set of high-frequency tokens. Using

Table 8: Evidence of token flipping. The agents use the word "punk" to denote "child" or "baby", which is clearly not desirable.

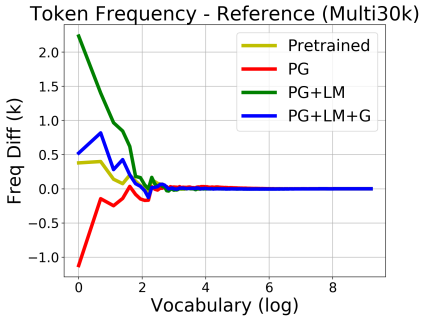

Figure 3: Token frequency analysis on three different models (PG, PG+LM, PG+LM+G) together with the pre-trained model before fine-tuning (Pretrained). We show word frequency curves for each model, after subtracting the reference English frequency statistics (both sorted in decreasing order). Positive y values indicate higher frequency values than the English reference, and negative y values indicate lower frequency values than English. The y-axis is the frequency difference in the thousands, and the x-axis shows the vocabulary index (sorted by frequency) in log scale.

both constraints yields a frequency distribution that most closely resembles the original one.

7 Qualitative Results

In the first example of Table 4 (previous page), it is clear that PG's communication messages have significantly diverged from English: the model is highly repetitive ("table table table table table") and misses some key content words such as "man". Agent B, however, correctly generates the German word "mann". This exemplifies a communication protocol that is successful in solving the task it was trained on, but not fully interpretable to humans. While the output from PG+LM is better, the grounded model's message (PG+LM+G) is distinctly the most fluent and semantically correct.

In the second example, observe that the PG Agent B misinterprets "talking talking a coach a coach" as "spricht mit einem spieler" (talking to a player). The PG+LM+G model again generates a flawless English sentence. Furthermore, its agents succeed in communicating both colors (red and white) to German while retaining the original English words, when the other models fail to do so.

Interestingly, we observe some instances of token flipping with the PG model and to a lesser extent with the PG+LM model. For example, one particular model uses "punk" to describe "child" (see Table 8). As no occurrence of "punk" in any training data is associated with "child", the agents must have acquired this new meaning assignment during fine-tuning. Among 35 examples in the Multi30k development set where the English reference contains "child", the model uses "punk" 15 times, indicating this is no random phenomenon. We did not observe such examples with the PG+LM+G model.

8 Conclusion

In this paper, we show that language drift happens when fine-tuning natural language agents with some external reward using policy gradients without constraints. We investigate what constraints to put on the communication channel in order to mitigate this. We find that imposing syntactic constraints (via adding language model log-likelihood to the reward) does somewhat mitigate drift, but does not preserve semantic correspondence. We then observe that additionally imposing semantic constraints, e.g. with a perceptual grounding loss, yields communication protocols that best retain the original syntax and intended semantics, while giving the overall best communication performance.

Further analysis into the learned communication protocols reveals that pure PG fine-tuning tends to learn flatter and repetitive token distributions, while encouraging naturalness under a language model disproportionately emphasizes frequent syntactic tokens, yielding a much sharper token distribution than a natural language. The grounded model best retains the original token frequencies.

We examined language drift within a translation game as this allows for direct measurements at each

step (input, intermediate, output), in a way where the semantics stays identical (i.e., the meaning is exactly the same for all languages and modalities) while the communication channel gets only an extrinsic reward (i.e., communication success). The findings in this work, however, are generally applicable to policy gradient fine-tuning of generative language models. We believe that our work shows an intuitive method for addressing language drift and hope that it opens up interesting directions for future work.

Abstract

We seek to understand how the representations of individual tokens and the structure of the learned feature space evolve between layers in deep neural networks under different learning objectives. We focus on the Transformers for our analysis as they have been shown effective on various tasks, including machine translation (MT), standard left-to-right language models (LM) and masked language modeling (MLM). Previous work used black-box probing tasks to show that the representations learned by the Transformer differ significantly depending on the objective. In this work, we use canonical correlation analysis and mutual information estimators to study how information flows across Transformer layers and how this process depends on the choice of learning objective. For example, as you go from bottom to top layers, information about the past in left-to-right language models gets vanished and predictions about the future get formed. In contrast, for MLM, representations initially acquire information about the context around the token, partially forgetting the token identity and producing a more generalized token representation. The token identity then gets recreated at the top MLM layers.

1 Introduction

Deep (i.e. multi-layered) neural networks have become the standard approach for many natural language processing (NLP) tasks, and their analysis has been an active topic of research. One popular approach for analyzing representations of neural models is to evaluate how informative they are for various linguistic tasks, so-called "probing tasks". Previous work has made some interesting observations regarding these representations; for example, Zhang and Bowman (2018) show that untrained LSTMs outperform trained ones on a word identity prediction task; and Blevins et al. (2018) show that up to a certain layer performance of representations obtained from a deep LM improves on a constituent labeling task, but then decreases, while with representations obtained from an MT encoder performance continues to improve up to the highest layer. These observations have, however, been somewhat anecdotal and an explanation of the process behind such behavior has been lacking.

In this paper, we attempt to explain more generally why such behavior is observed. Rather than measuring the quality of representations obtained from a particular model on some auxiliary task, we characterize how the learning objective determines the information flow in the model. In particular, we consider how the representations of individual tokens in the Transformer evolve between layers under different learning objectives.

We look at this task from the information bottleneck perspective on learning in neural networks. Tishby and Zaslavsky (2015) state that "the goal of any supervised learning is to capture and efficiently represent the relevant information in the input variable about the output-label variable" and hence the representations undergo transformations which aim to encode as much information about the output label as possible, while 'forgetting' irrelevant details about the input. As we study sequence encoders and look into representations of individual tokens rather than the entire input, our situation is more complex. In our model, the information preserved in a representation of a token is induced due to two roles it plays: (i) predicting the output label from a current token representation;[1] (ii) preserving information necessary to build representations of other tokens. For example, a language model constructs a representation which is not only useful for predicting an output label (in this case, the next token), but also informative for

[1]We will clarify how we define output labels for LM, MLM and MT objectives in Section 2.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4396–4406, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

producing representations of subsequent tokens in a sentence. This is different from the MT setting, where there is no single encoder state from which an output label is predicted. We hypothesize that the training procedure (or, in our notation, the **task**) defines

1. the nature of changes a token representation undergoes, from layer to layer;

2. the process of interactions and relationships between tokens;

3. the type of information which gets lost and acquired by a token representation in these interactions.

In this work, we study how the choice of objective affects the process by which information is encoded in token representations of the Transformer (Vaswani et al., 2017), as this architecture achieves state-of-the-art results on tasks with very different objectives such as machine translation (MT) (Bojar et al., 2018; Niehues et al., 2018), standard left-to-right language modeling (LM) (Radford et al., 2018) and masked language modeling (MLM) (Devlin et al., 2018). The Transformer encodes a sentence by iteratively updating representations associated with each token starting from a context-agnostic representation consisting of a positional and a token embedding. At each layer token representations exchange information among themselves via multi-head attention and then this information is propagated to the next layer via a feed-forward transformation. We investigate how this process depends on the choice of objective function (LM, MLM or MT) while keeping the data and model architecture fixed.

We start with illustrating the process of information loss and gain in representations of individual tokens by estimating the mutual information between token representations at each layer and the input token identity (i.e. the word type) or the output label (e.g., the next word for LM).

Then, we investigate behavior of token representations from two perspectives: how they influence and are influenced by other tokens. Using canonical correlation analysis, we evaluate the extent of change the representation undergoes and the degree of influence. We reveal differences in the patterns of this behavior for different tasks.

Finally, we study which type of information gets lost and gained in the interactions between tokens and to what extent a certain property is important for defining a token representation at each layer and for each task. As the properties, we consider token identities ('word type'), positions, identities of surrounding tokens and CCG supertags. In these analyses we rely on similarity computations.

We find, that (1) with the LM objective, as you go from bottom to top layers, information about the past gets lost and predictions about the future get formed; (2) for MLMs, representations initially acquire information about the context around the token, partially forgetting the token identity and producing a more generalized token representation; the token identity then gets recreated at the top layer; (3) for MT, though representations get refined with context, less processing is happening and most information about the word type does not get lost. This provides us with a hypothesis for why the MLM objective may be preferable in the pretraining context to LM. LMs may not be the best choice, because neither information about current token and its past nor future is represented well: the former since this information gets discarded, the latter since the model does not have access to the future.

Our key contributions are as follows:

- we propose to view the evolution of a token representation between layers from the compression/prediction trade-off perspective;

- we conduct a series of experiments supporting this view and showing that the two processes, losing information about input and accumulating information about output, take place in the evolution of representations (for MLM, these processes are clearly distinguished and can be viewed as two stages, 'context encoding' and 'token prediction');

- we relate to some findings from previous work, putting them in the proposed perspective, and provide insights into the internal workings of Transformer trained with different objectives;

- we propose an explanation for superior performance of the MLM objective over the LM one for pretraining.

All analysis is done in a model-agnostic manner by investigating properties of token represen-

tations at each layer, and can, in principle, be applied to other multi-layer deep models (e.g., multi-layer RNN encoders).

2 Tasks

In this section, we describe the tasks we consider. For each task, we define input X and output Y.

2.1 Machine translation

Given source sentence $X = (x_1, x_2, ..., x_S)$ and a target sentence $Y = (y_1, y_2, ..., y_T)$, NMT models predict words in the target sentence, word by word, i.e. provide estimates of the conditional distribution $p(y_i|X, y_{1,i-1}, \theta)$.

We train a standard Transformer for the translation task and then analyze its encoder. In contrast to the other two tasks we describe below, representations from the top layers are not directly used to predict output labels but to encode the information which is then used by the decoder.

2.2 Language modeling

LMs estimate the probability of a word given the previous words in a sentence $P(x_t|x_1, \ldots, x_{t-1}, \theta)$. More formally, the model is trained with inputs $X = (x_1, \ldots, x_{t-1})$ and outputs $Y = (x_t)$, where x_t is the output label predicted from the final (i.e. top-layer) representation of a token x_{t-1}. It is straightforward to apply the Transformer to this task (Radford et al., 2018; Lample and Conneau, 2019).

2.3 Masked language modeling

We also consider the MLM objective (Devlin et al., 2018), randomly sampling 15% of the tokens to be predicted. We replace the corresponding input token by [MASK] or a random token in 80% and 10% of the time, respectively, keeping it unchanged otherwise.

For a sentence $(x_1, x_2, ..., x_S)$, where token x_i is replaced with $\tilde{x_i}$, the model receives $X = (x_1, \ldots, x_{i-1}, \tilde{x_i}, x_{i+1}, \ldots, x_S)$ as input and needs to predict $Y = (x_i)$. The label x_i is predicted from the final representation of the token $\tilde{x_i}$.

3 Data and Setting

As described below, for a fair comparison, we use the same training data, model architecture and parameter initialization across all the tasks. In order to make sure that our findings are reliable, we also use multiple datasets and repeat experiments with different random initializations for each task.

We train all models on the data from the WMT news translation shared task. We conduct separate series of experiments using two language pairs: WMT 2017 English-German (5.8m sentence pairs) and WMT 2014 English-French (40.8m sentence pairs). For language modeling, we use only the source side of the parallel data. We remove randomly chosen 2.8m sentence pairs from the English-French dataset and use the source side for analysis. English-French models are trained on the remaining 38m sentence pairs. We consider different dataset sizes (2.5m and 5.8m for English-German, 2.5m, 5.8m and 38m for English-French). We find that our findings are true for all languages, dataset sizes and initializations. In the following, all the illustrations are provided for the models trained on the full English-German dataset (5.8m sentence pairs).

We follow the setup and training procedure of the Transformer base model (Vaswani et al., 2017). For details, see the appendix.

4 The Information-Bottleneck Viewpoint

In this section, we give an intuitive explanation of the Information Bottleneck (IB) principle (Tishby et al., 1999) and consider a direct application of this principle to our analysis.

4.1 Background

The IB method (Tishby et al., 1999) considers a joint distribution of input-output pairs $p(X, Y)$ and aims to extract a compressed representation $\tilde{X}$ for an input X such that $\tilde{X}$ retains as much as possible information about the output Y. More formally, the IB method maximizes the mutual information (MI) with the output $I(\tilde{X}; Y)$, while penalizing for MI with the input $I(\tilde{X}; X)$. The latter term in the objective ensures that the representation is indeed a compression. Intuitively, the choice of the output variable Y determines the split of X into irrelevant and relevant features. The relevant features need to be retained while irrelevant ones should be dropped.

Tishby and Zaslavsky (2015) argue that computation in a multi-layered neural model can be regarded as an evolution towards the theoretical optimum of the IB objective. A sequence of layers is viewed as a Markov chain, and the process of obtaining Y corresponds to compressing the representation as it flows across layers and retaining only information relevant to predicting Y. This implies that Y defines the information flow in the

model. Since Y is different for each model, we expect to see different patterns of information flow in models, and this is the focus of our study.

4.2 IB for token representations

In this work, we view every sequence model (MT, LM and MLM) as learning a function from input X to output Y. The input is a sequence of tokens $X = (x_1, x_2, \ldots, x_n)$ and the output Y is defined in Section 2. Recall that we focus on representations of individual tokens in every layer rather than the representation of the entire sequence.

We start off our analysis of divergences in the information flow for different objectives by estimating the amount of information about input or output tokens retained in the token representation at each layer.

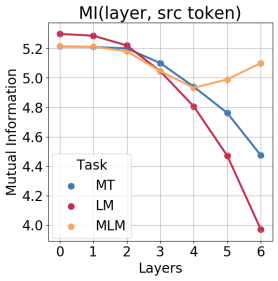
4.2.1 Estimating mutual information

Inspired by Tishby and Zaslavsky (2015), we estimate MI between token representations at a certain layer and an input token. To estimate MI, we need to consider token representations at a layer as samples from a discrete distribution. To get such distribution, in the original works (Shwartz-Ziv and Tishby, 2017), the authors binned the neuron's $\arctan$ activations. Using these discretized values for each neuron in a layer, they were able to treat a layer representation as a discrete variable. They considered neural networks with maximum 12 neurons at a layer, but in practical scenarios (e.g. we have 512 neurons in each layer) this approach is not feasible. Instead, similarly to Sajjadi et al. (2018), we discretize the representations by clustering them into a large number of clusters. Then we use cluster labels instead of the continuous representations in the MI estimator.

Specifically, we take only representations of the 1000 most frequent (sub)words. We gather representations for 5 million occurrences of these at each layer for each of the three models. We then cluster the representations into $N = 10000$ clusters using mini-batch k-means with $k = 100$. In the experiments studying the mutual information between a layer and source (or target) labels we further filter occurrences. Namely, we take only occurrences where the source and target labels are among the top 1000 most frequent (sub)words.

4.2.2 Results

First, we estimate the MI between an input token and a representation of this token at each layer. In this experiment, we form data for MLM as in the test regime; in other words, the input token is always the same as the output token. Results are shown in Figure 1. For LM, the amount of relevant information about the current input token decreases. This agrees with our expectations: some of the information about the history is intuitively not relevant for predicting the future. MT shows a similar behavior, but the decrease is much less sharp. This is again intuitive: the information about the exact identity is likely to be useful for the decoder. The most interesting and surprising graph is for MLM: first, similarly to other models, the information about the input token is getting lost but then, at two top layers, it gets recovered. We will refer to these phases in further discussion as context encoding and token reconstruction, respectively. Whereas such non-monotonic behavior is impossible when analyzing entire layers, as in Tishby and Zaslavsky (2015), in our case, it suggests that this extra information is obtained from other tokens in the context.



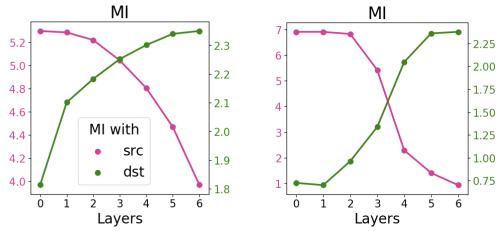


Figure 1: The mutual information between an input token and a representation of this token at each layer.

(a) LM (b) MLM

Figure 2: The mutual information of token representations at a layer and source (or target) tokens. For MLM, only tokens replaced at random are considered to get examples where input and output are different.

We perform the same analysis but now measuring MI with the output label for LM and MLM. In this experiment, we form data for MLM as in training, masking or replacing a fraction of tokens. We then take only tokens replaced with a random one to get examples where input and output tokens are different. Results are shown in Figure 2. We can see that, as expected, MI with input tokens

decreases while MI with output tokens increases. Both LM and MLM are trained to predict a token (next for LM and current for MLM) by encoding input and context information. While in Figure 1 we observed monotonic behavior of LM, when looking at the information with both input and output tokens, we can see the two processes, losing information about input and accumulating information about output, for both LM and MLM models. For MLM these processes are more distinct and can be thought of as the context encoding and token prediction (compression/prediction) stages. For MT, since nothing is predicted directly, we see only the encoding stage of this process. This observation relates also to the findings by Blevins et al. (2018). They show that up to a certain layer the performance of representations obtained from a deep multi-layer RNN LM improves on a constituent labeling task, but then decreases, while for representations obtained from an MT encoder performance continues to improve up to the highest layer. We further support this view with other experiments in Section 6.3.

Even though the information-theoretic view provides insights into processes shaping the representations, direct MI estimation from finite samples for densities on multi-dimensional spaces is challenging (Paninski, 2003). For this reason in the subsequent analysis we use more well-established frameworks such as canonical correlation analysis to provide new insights and also to corroborate findings we made in this section (e.g., the presence of two phases in MLM encoding). Even though we will be using different machinery, we will focus on the same two IB-inspired questions: (1) how does information flow across layers? and (2) what information does a layer represent?

5 Analyzing Changes and Influences

In this section, we analyze the flow of information. The questions we ask include: how much processing is happening in a given layer; which tokens influence other tokens most; which tokens gain most information from other tokens. As we will see, these questions can be reduced to a comparison between network representations. We start by describing the tool we use.

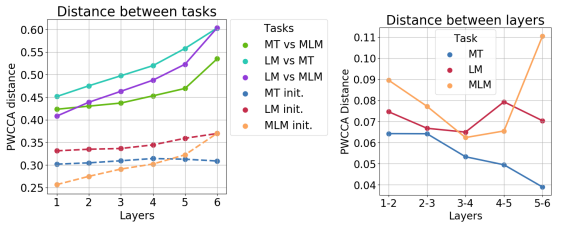
5.1 Canonical Correlation Analysis

We rely on recently introduced projection weighted Canonical Correlation Analysis (PWCCA) (Morcos et al., 2018), which is an improved version of SVCCA (Raghu et al., 2017). Both approaches are based on classic Canonical Correlation Analysis (CCA) (Hotelling, 1936).

CCA is a multivariate statistical method for relating two sets of observations arising from an underlying process. In our setting, the underlying process is a neural network trained on some task. The two sets of observations can be seen as 'two views' on the data. Intuitively, we look at the same data (tokens in a sentence) from two standpoints. For example, one view is one layer and another view is another layer. Alternatively, one view can be l-th layer in one model, whereas another view can be the same l-th layer in another model. CCA lets us measure similarity between pairs of views.

Formally, given a set of tokens $(x_1, x_2, \ldots, x_N)$ (with the sentences they occur in), we gather their representations produced by two models (m_1 and m_2) at layers l_1 and l_2, respectively. To achieve this, we encode the whole sentences and take representations of tokens we are interested in. We get two views of these tokens by the models: $v^{m_1,l_1} = (x_1^{m_1,l_1}, x_2^{m_1,l_1}, \ldots, x_N^{m_1,l_1})$ and $v^{m_2,l_2} = (x_1^{m_2,l_2}, x_2^{m_2,l_2}, \ldots, x_N^{m_2,l_2})$. The representations are gathered in two matrices $X_1 \in M_{a,N}$ and $X_2 \in M_{b,N}$, where a and b are the numbers of neurons in the models.[2] These matrices are then given to CCA (specifically, PWCCA). CCA identifies a linear relation maximizing the correlation between the matrices and computes the similarity. The values of PWCCA range from 0 to 1, with 1 indicating that the observations are linear transformations of each other, 0 indicating no correlation.

In the next sections, we vary two aspects of this process: tokens and the 'points of view'.



5.2 A coarse-grained view

We start with the analysis where we do not attempt to distinguish between different token types.

5.2.1 Distances between tasks

As the first step in our analysis, we measure the difference between representations learned for different tasks. In other words, we compare representations for $v^{m_1,l}$ and $v^{m_2,l}$ at different layers l. Here the data is all tokens of 5000 sentences. We also quantify differences between representations of models trained with the same objective but different random initializations. The results are pro-

[2] In our experiments, $N > 100000$.

(a) (b)

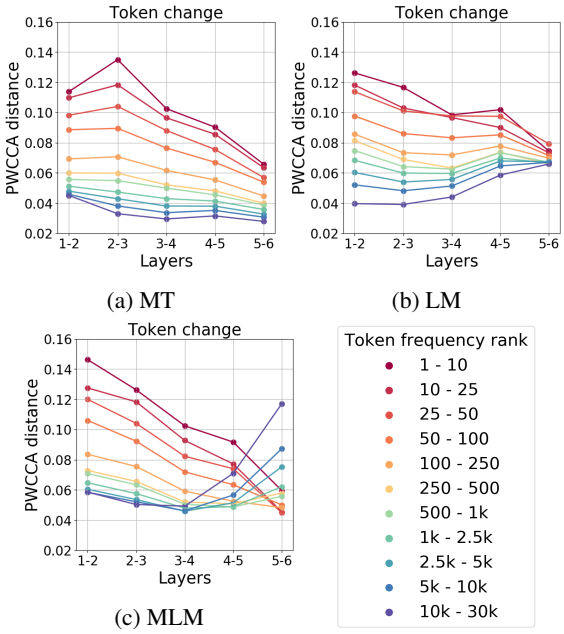
Figure 3: PWCCA distance (a) between representations of different models at each layer ("init." indicates different initializations), (b) between consecutive layers of the same model.

vided in Figure 3a.

First, differences due to training objective are much larger than the ones due to random initialization of a model. This indicates that PWCCA captures underlying differences in the types of information learned by a model rather than those due to randomness in the training process.

MT and MLM objectives produce representations that are closer to each other than to LM's representations. The reason for this might be twofold. First, for LM only preceding tokens are in the context, whereas for MT and MLM it is the entire sentence. Second, both MT and MLM focus on a given token, as it either needs to be reconstructed or translated. In contrast, LM produces a representation needed for predicting the next token.

5.2.2 Changes between layers



In a similar manner, we measure the difference between representations of consecutive layers in each model (Figure 3b). In this case we take views $v^{m,l}$ and $v^{m,l+1}$ and vary layers l and tasks m.

For MT, the extent of change monotonically decreases when going from the bottom to top layers, whereas there is no such monotonicity for LM and MLM. This mirrors our view of LM and especially MLM as undergoing phases of encoding and reconstruction (see Section 4.2), thus requiring a stage of dismissing information irrelevant to the output, which, in turn, is accompanied by large changes in the representations between layers.

5.3 Fine-grained analysis

In this section, we select tokens with some predefined property (e.g., frequency) and investigate how much the tokens are influenced by other tokens or how much they influence other tokens.

Amount of change. We measure the extent of change for a group of tokens as the PWCCA distance between the representations of these tokens

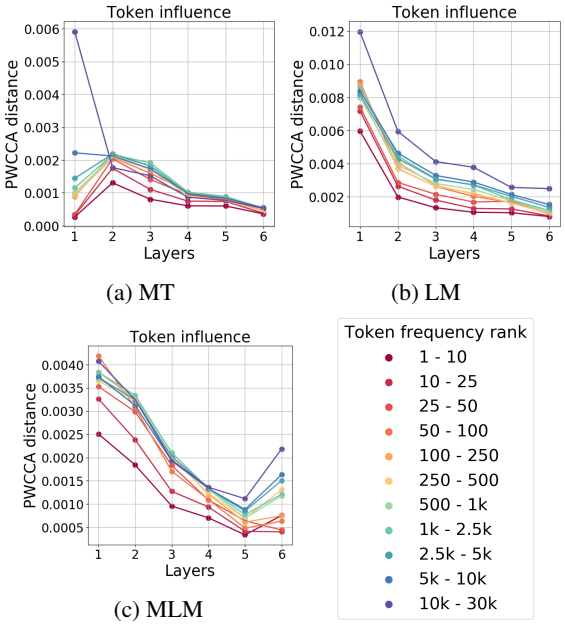
(a) MT (b) LM

(c) MLM

Figure 4: Token change vs its frequency.

for a pair of adjacent layers $(l, l+1)$. This quantifies the amount of information the tokens receive in this layer.

Influence. To measure the influence of a token at lth layer on other tokens, we measure PWCCA distance between two versions of representations of other tokens in a sentence: first after encoding as usual, second when encoding first $l-1$ layers as usual and masking out the influencing token at the lth layer.[3]

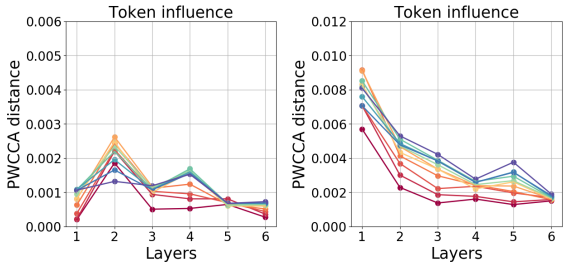


5.3.1 Varying token frequency

Figure 4 shows a clear dependence of the amount of change on token frequency. Frequent tokens change more than rare ones in all layers in both LM and MT. Interestingly, unlike MT, for LM this dependence dissipates as we move towards top layers. We can speculate that top layers focus on predicting the future rather than incorporating the past, and, at that stage, token frequency of the last observed token becomes less important.

The behavior for MLM is quite different. The two stages for MLMs could already be seen in Figures 1 and 3b. They are even more pronounced here. The transition from a generalized token representation, formed at the encoding stage, to recreating token identity apparently requires more changes for rare tokens.

When measuring influence, we find that rare tokens generally influence more than frequent ones (Figure 5). We notice an extreme influence of rare



[3] By masking out we mean that other tokens are forbidden to attend to the chosen one.

(a) MT (b) LM

(c) MLM

Figure 5: Token influence vs its frequency.

(a) MT (b) LM

Figure 6: Token influence vs its frequency for models trained with word dropout (in training, each input token is replaced with a random with the probability 10%).

tokens at the first MT layer and at all LM layers. In contrast, rare tokens are not the most influencing ones at the lower layers of MLM. We hypothesize that the training procedure of MLM, with masking out some tokens or replacing them with random ones, teaches the model not to over-rely on these tokens before their context is well understood. To test our hypothesis, we additionally trained MT and LM models with token dropout on the input side (Figure 6). As we expected, there is no extreme influence of rare tokens when using this regularization, supporting the above interpretation.

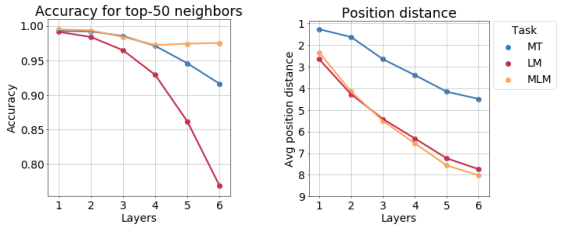
Interestingly, our earlier study of the MT Transformer (Voita et al., 2019) shows how this influence of rare tokens is implemented by the model. In that work, we observed that, for any considered language pair, there is one dedicated attention head in the first encoder layer which tends to point to the least frequent tokens in every sentence. The above analysis suggest that this phenomenon is likely due to overfitting.

We also analyzed the extent of change and influence splitting tokens according to their part of speech; see appendix for details.

6 What does a layer represent?

Whereas in the previous section we were interested in quantifying the amount of information exchanged between tokens, here we primarily want to understand what representation in each layer 'focuses' on. We evaluate to what extent a certain property is important for defining a token representation at each layer by (1) selecting a large number of token occurrences and taking their representations; (2) validating if a value of the property is the same for token occurrences corresponding to the closest representations. Though our approach is different from probing tasks, we choose the properties which will enable us to relate to other works reporting similar behaviour (Zhang and Bowman, 2018; Blevins et al., 2018; Tenney et al., 2019a). The properties we consider are token identity, position in a sentence, neighboring tokens and CCG supertags.

6.1 Methodology



For our analysis, we take 100 random word types from the top 5,000 in our vocabulary. For each word type, we gather 1,000 different occurrences along with the representations from all three models. For each representation, we take the closest neighbors among representations at each layer and evaluate the percentage of neighbors with the same value of the property.

6.2 Preserving token identity and position

In this section, we track the loss of information about token identity (i.e., word type) and position. Our motivation is three-fold. First, this will help us to confirm the results provided on Figure 1; second, to relate to the work reporting results for probing tasks predicting token identity. Finally, the Transformer starts encoding a sentence from a positional and a word embedding, thus it is natural to look at how this information is preserved.

6.2.1 Preserving token identity

We want to check to what extent a model confuses representations of different words. For each of the considered words we add 9000 representations of words which potentially could be confused with

(a) (b)

Figure 7: Preserving (a) token identity, (b) position

it.[4] For this extended set of representations, we follow the methodology described above.

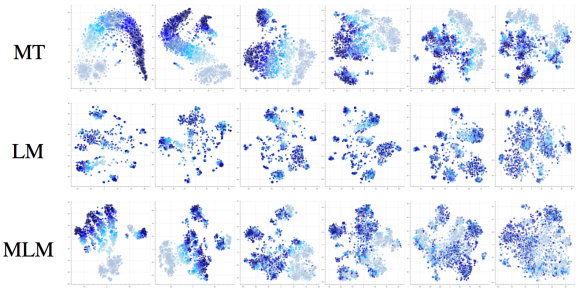
Results are presented in Figure 7a. Reassuringly, the plot is very similar to the one computed with MI estimators (Figure 1), further supporting the interpretations we gave previously (Section 4). Now, let us recall the findings by Zhang and Bowman (2018) regarding the superior performance of untrained LSTMs over trained ones on the task of token identity prediction. They mirror our view of the evolution of a token representation as going through compression and prediction stages, where the learning objective defines the process of forgetting information. If a network is not trained, it is not forced to forget input information.

Figure 8 shows how representations of different occurrences of the words "is", "are", "was", "were" get mixed in MT and LM layers and disambiguated for MLM. For MLM, 15% of tokens were masked as in training. In the first layer, these masked states form a cluster separate from the others, and then they get disambiguated as we move bottom-up across the layers.

6.2.2 Preserving token position

We evaluate the average distance of position of the current occurrence and the top 5 closest representations. The results are provided in Figure 7b. This

[4] See appendix for the details.



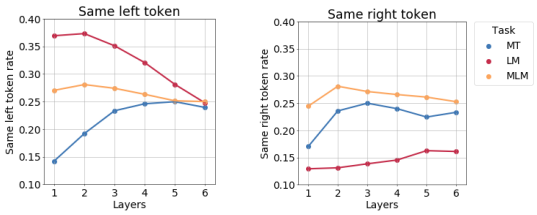


Figure 9: t-SNE of different occurrences of the token "it", position is in color (the larger the word index the darker its color). On the x-axis are layers.

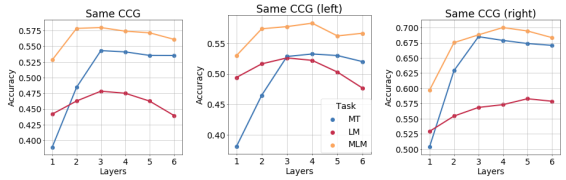
(a) left (b) right

Figure 10: Preserving immediate neighbors



illustrates how the information about input (in this case, position), potentially not so relevant to the output (e.g., next word for LM), gets gradually dismissed. As expected, encoding input positions is more important for MT, so this effect is more pronounced for LM and MLM. An illustration is in Figure 9. For MT, even on the last layer ordering by position is noticeable.

6.3 Lexical and syntactic context

In this section, we will look at the two properties: identities of immediate neighbors of a current token and CCG supertag of a current token. On the one hand, these properties represent a model's understanding of different types of context: lexical (neighboring tokens identity) and syntactic. On the other, they are especially useful for our analysis since they can be split into information about 'past' and 'future' by taking either left or right neighbor or part of a CCG tag.

6.3.1 The importance of neighboring tokens

Figure 10 supports our previous expectation that for LM the importance of a previous token decreases, while information about future token is being formed. For MLM, the importance of neighbors gets higher until the second layer and decreases after. This may reflect stages of context encoding and token reconstruction.

(a) (b) (c)

Figure 11: Preserving CCG supertag.

6.3.2 The importance of CCG tags

Results are provided in Figure 11a.[5] As in previous experiments, importance of CCG tag for MLM degrades at higher layers. This agrees with the work by Tenney et al. (2019a). The authors observe that for different tasks (e.g., part-of-speech, constituents, dependencies, semantic role labeling, coreference) the contribution[6] of a layer to a task increases up to a certain layer, but then decreases at the top layers. Our work gives insights into the underlying process defining this behavior.

For LM these results are not really informative since it does not have access to the future. We go further and measure importance of parts of a CCG tag corresponding to previous (Figure 11b) and next (Figure 11c) parts of a sentence. It can be clearly seen that LM first accumulates information about the left part of CCG, understanding the syntactic structure of the past. Then this information gets dismissed while forming information about future.

Figure 12 shows how representations of different occurrences of the token "is" get reordered in the space according to CCG tags (colors correspond to tags).

7 Additional related work

Previous work analyzed representations of MT and/or LM models by using probing tasks. Different levels of linguistic analysis have been considered including morphology (Belinkov et al., 2017a; Dalvi et al., 2017; Bisazza and Tump, 2018), syntax (Shi et al., 2016; Tenney et al., 2019b) and semantics (Hill et al., 2017; Belinkov et al., 2017b; Raganato and Tiedemann, 2018; Tenney et al., 2019b). Our work complements this line of research by analyzing how word representations evolve between layers and gives insights into how models trained on different tasks come to represent different information.

Canonical correlation analysis has been previously used to investigate learning dynamics of CNNs and RNNs, to measure the intrinsic dimensionality of layers in CNNs and compare representations of networks which memorize and generalize (Raghu et al., 2017; Morcos et al., 2018). Bau et al. (2019) used SVCCA as one of the methods used for identifying important individual neurons in NMT models. Saphra and Lopez (2019) used SVCCA to investigate how representations of linguistic structure are learned over time in LMs.

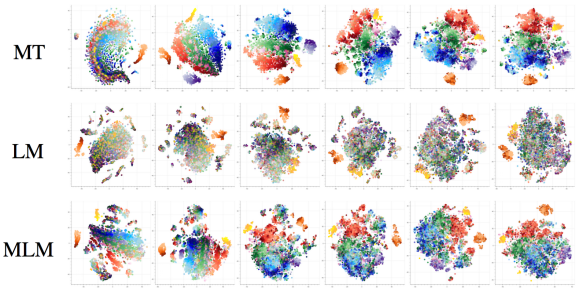


Figure 12: t-SNE of different occurrences of the token "is", CCG tag is in color (intensity of a color is a token position). On the x-axis are layers.

8 Conclusions

In this work, we analyze how the learning objective determines the information flow in the model. We propose to view the evolution of a token representation between layers from the compression/prediction trade-off perspective. We conduct a series of experiments supporting this view and propose a possible explanation for superior performance of MLM over LM for pretraining. We relate our findings to observations previously made in the context of probing tasks.

Do We Really Need Fully Unsupervised Cross-Lingual Embeddings?

Abstract

Recent efforts in cross-lingual word embedding (CLWE) learning have predominantly focused on *fully unsupervised* approaches that project monolingual embeddings into a shared cross-lingual space without any cross-lingual signal. The lack of any supervision makes such approaches conceptually attractive. Yet, their only core difference from (weakly) supervised projection-based CLWE methods is in the way they obtain a *seed dictionary* used to initialize an iterative *self-learning* procedure. The fully unsupervised methods have arguably become more robust, and their *primary use case* is CLWE induction for pairs of resource-poor and distant languages. In this paper, we question the ability of even the most robust unsupervised CLWE approaches to induce meaningful CLWEs in these more challenging settings. A series of bilingual lexicon induction (BLI) experiments with 15 diverse languages (210 language pairs) show that fully unsupervised CLWE methods still fail for a large number of language pairs (e.g., they yield zero BLI performance for 87/210 pairs). Even when they succeed, they never surpass the performance of weakly supervised methods (seeded with 500-1,000 translation pairs) using the same self-learning procedure in any BLI setup, and the gaps are often substantial. These findings call for revisiting the main motivations behind fully unsupervised CLWE methods.

1 Introduction and Motivation

The wide use and success of monolingual word embeddings in NLP tasks (Turian et al., 2010; Chen and Manning, 2014) has inspired further research focus on the induction of cross-lingual word embeddings (CLWEs). CLWE methods learn a *shared cross-lingual word vector space* where words with similar meanings obtain similar vectors regardless of their actual language. CLWEs benefit cross-lingual NLP, enabling multilingual modeling of meaning and supporting cross-lingual transfer for downstream tasks and resource-lean languages. CLWEs provide invaluable cross-lingual knowledge for, *inter alia*, bilingual lexicon induction (Gouws et al., 2015; Heyman et al., 2017), information retrieval (Vulić and Moens, 2015; Litschko et al., 2019), machine translation (Artetxe et al., 2018c; Lample et al., 2018b), document classification (Klementiev et al., 2012), cross-lingual plagiarism detection (Glavaš et al., 2018), domain adaptation (Ziser and Reichart, 2018), cross-lingual POS tagging (Gouws and Søgaard, 2015; Zhang et al., 2016), and cross-lingual dependency parsing (Guo et al., 2015; Søgaard et al., 2015).

The landscape of CLWE methods has recently been dominated by the so-called *projection-based* methods (Mikolov et al., 2013a; Ruder et al., 2019; Glavaš et al., 2019). They align two monolingual embedding spaces by learning a projection/mapping based on a training dictionary of translation pairs. Besides their simple conceptual design and competitive performance, their popularity originates from the fact that they rely on rather weak cross-lingual supervision. Originally, the seed dictionaries typically spanned several thousand word pairs (Mikolov et al., 2013a; Faruqui and Dyer, 2014; Xing et al., 2015), but more recent work has shown that CLWEs can be induced with even weaker supervision from small dictionaries spanning several hundred pairs (Vulić and Korhonen, 2016), identical strings (Smith et al., 2017), or even only shared numerals (Artetxe et al., 2017).

Taking the idea of reducing cross-lingual supervision to the extreme, the latest CLWE developments almost exclusively focus on *fully unsupervised approaches* (Conneau et al., 2018a; Artetxe et al., 2018b; Dou et al., 2018; Chen and Cardie, 2018; Alvarez-Melis and Jaakkola, 2018; Kim et al., 2018; Alaux et al., 2019; Mohiuddin and Joty, 2019, *inter alia*): they fully abandon any source of

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4407–4418, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

(even weak) supervision and extract the initial seed dictionary by exploiting topological similarities between pre-trained monolingual embedding spaces. Their *modus operandi* can roughly be described by three main components: **C1)** *unsupervised* extraction of a *seed dictionary*; **C2)** a *self-learning* procedure that iteratively refines the dictionary to learn projections of increasingly higher quality; and **C3)** a set of preprocessing and postprocessing steps (e.g., unit length normalization, mean centering, (de)whitening) (Artetxe et al., 2018a) that make the entire learning process more robust.

The induction of fully unsupervised CLWEs is an inherently interesting research topic *per se*. Nonetheless, the main practical motivation for developing such approaches in the first place is to facilitate the construction of multilingual NLP tools and widen the access to language technology for resource-poor languages and language pairs. However, the first attempts at fully unsupervised CLWE induction failed exactly for these use cases, as shown by Søgaard et al. (2018). Therefore, the follow-up work aimed to improve the robustness of unsupervised CLWE induction by introducing more robust self-learning procedures (Artetxe et al., 2018b; Kementchedjhieva et al., 2018). Besides increased robustness, recent work claims that fully unsupervised projection-based CLWEs can even match or surpass their supervised counterparts (Conneau et al., 2018a; Artetxe et al., 2018b; Alvarez-Melis and Jaakkola, 2018; Hoshen and Wolf, 2018; Heyman et al., 2019).

In this paper, we critically examine these claims on robustness and improved performance of unsupervised CLWEs by running a large-scale evaluation in the bilingual lexicon induction (BLI) task on 15 languages (i.e., 210 languages pairs, see Table 2 in §3). The languages were selected to represent different language families and morphological types, as we argue that fully unsupervised CLWEs have been designed to support exactly these setups. However, we show that even the most robust unsupervised CLWE method (Artetxe et al., 2018b) still fails for a large number of language pairs: 87/210 BLI setups are unsuccessful, yielding (near-)zero BLI performance. Further, even when the unsupervised method succeeds, it is because the components C2 (self-learning) and C3 (pre-/post-processing) can mitigate the undesired effects of noisy seed lexicon extraction. We then demonstrate that the combination of C2 and C3 with a small provided seed dictionary (e.g., 500 or 1K pairs) outscores the unsupervised method in *all* cases, often with a huge margin, and does not fail for *any* language pair. Furthermore, we show that the most robust unsupervised CLWE approach still fails completely when it relies on monolingual word vectors trained on domain-dissimilar corpora. We also empirically verify that unsupervised approaches cannot outperform weakly supervised approaches also for closely related languages (e.g., Swedish–Danish, Spanish–Catalan).

While the "no supervision at all" premise behind fully unsupervised CLWE methods is indeed seductive, our study strongly suggests that future research efforts should revisit the main motivation behind these methods and focus on designing even more robust solutions, given their current inability to support a wide spectrum of language pairs. In hope of boosting induction of CLWEs for more diverse and distant language pairs, we make all 210 training and test dictionaries used in this work publicly available at: `https://github.com/ivulic/panlex-bli`.

2 Methodology

We now dissect a general framework for unsupervised CLWE learning, and show that the "bag of tricks of the trade" used to increase their robustness (which often slips under the radar) can be equally applied to (weakly) supervised projection-based approaches, leading to their fair(er) comparison.

2.1 Projection-Based CLWE Approaches

In short, projection-based CLWE methods learn to (linearly) align independently trained monolingual spaces $\boldsymbol{X}$ and $\boldsymbol{Z}$, using a word translation dictionary D_0 to guide the alignment process. Let $\boldsymbol{X}_D \subset \boldsymbol{X}$ and $\boldsymbol{Z}_D \subset \boldsymbol{Z}$ be the row-aligned subsets of monolingual spaces containing vectors of aligned words from D_0. Alignment matrices $\boldsymbol{X}_D$ and $\boldsymbol{Z}_D$ are then used to learn orthogonal transformations $\boldsymbol{W}_x$ and $\boldsymbol{W}_z$ that define the joint bilingual space $\boldsymbol{Y} = \boldsymbol{X}\boldsymbol{W}_x \cup \boldsymbol{Z}\boldsymbol{W}_z$. While supervised projection-based CLWE models learn the mapping using a provided external (clean) dictionary D_0, their unsupervised counterparts automatically induce the seed dictionary in an unsupervised way (C1) and then refine it in an iterative fashion (C2).

Unsupervised CLWEs. These methods first induce a seed dictionary $D^{(1)}$ leveraging only two unaligned monolingual spaces (C1). While the

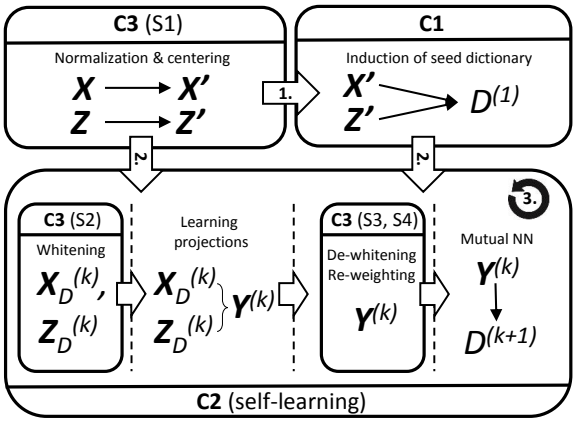

Figure 1: General unsupervised CLWE approach.

algorithms for unsupervised seed dictionary induction differ, they all strongly rely on the assumption of similar topological structure between the two pretrained monolingual spaces. Once the seed dictionary is obtained, the two-step iterative self-learning procedure (C2) takes place: 1) a dictionary $D^{(k)}$ is first used to learn the joint space $\boldsymbol{Y}^{(k)} = \boldsymbol{X}\boldsymbol{W}_x^{(k)} \cup \boldsymbol{Z}\boldsymbol{W}_z^{(k)}$; 2) the nearest neighbours in $\boldsymbol{Y}^{(k)}$ then form the new dictionary $D^{(k+1)}$. We illustrate the general structure in Figure 1.

A recent empirical survey paper (Glavaš et al., 2019) has compared a variety of latest unsupervised CLWE methods (Conneau et al., 2018a; Alvarez-Melis and Jaakkola, 2018; Hoshen and Wolf, 2018; Artetxe et al., 2018b) in several downstream tasks (e.g., BLI, cross-lingual information retrieval, document classification). The results of their study indicate that the VECMAP model of Artetxe et al. (2018b) is by far the most robust and best performing unsupervised CLWE model. For the actual results and analyses, we refer the interested reader to the original paper of Glavaš et al. (2019). Another recent evaluation paper (Doval et al., 2019) as well as our own preliminary BLI tests (not shown for brevity) have further verified their findings. We thus focus on VECMAP in our analyses, and base the following description of the components C1-C3 on that model.

2.2 Three Key Components

C1. Seed Lexicon Extraction. VECMAP induces the initial seed dictionary using the following heuristic: monolingual similarity distributions for words with similar meaning will be similar across languages.[1] The monolingual similarity distributions for the two languages are given as rows (or columns; the matrices are symmetric) of $\boldsymbol{M}_x = \boldsymbol{X}\boldsymbol{X}^T$ and $\boldsymbol{M}_z = \boldsymbol{Z}\boldsymbol{Z}^T$. For the distributions of similarity scores to be comparable, the values in each row of $\boldsymbol{M}_x$ and $\boldsymbol{M}_z$ are first sorted. The initial dictionary $D^{(1)}$ is finally obtained by searching for mutual nearest neighbours between the rows of $\sqrt{\boldsymbol{M}_x}$ and of $\sqrt{\boldsymbol{M}_z}$.

C2. Self-Learning. Not counting the preprocessing and postprocessing steps (component C3), self-learning then *iteratively* repeats two steps:

1) Let $\boldsymbol{D}^{(k)}$ be the binary matrix indicating the aligned words in the dictionary $D^{(k)}$.[2] The orthogonal transformation matrices are then obtained as $\boldsymbol{W}_x^{(k)} = \boldsymbol{U}$ and $\boldsymbol{W}_z^{(k)} = \boldsymbol{V}$, where $\boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$ is the singular value decomposition of the matrix $\boldsymbol{X}^T\boldsymbol{D}^{(k)}\boldsymbol{Z}$. The cross-lingual space of the k-th iteration is then $\boldsymbol{Y}^{(k)} = \boldsymbol{X}\boldsymbol{W}_x^{(k)} \cup \boldsymbol{Z}\boldsymbol{W}_z^{(k)}$.

2) The new dictionary $D^{(k+1)}$ is then built by identifying nearest neighbours in $\boldsymbol{Y}^{(k)}$. These can be easily extracted from the matrix $\boldsymbol{P} = \boldsymbol{X}\boldsymbol{W}_x^{(k)}(\boldsymbol{Z}\boldsymbol{W}_z^{(k)})^T$. *All* nearest neighbours can be used, or additional *symmetry* constraints can be imposed to extract only mutual nearest neighbours: all pairs of indices (i, j) for which $\boldsymbol{P}_{ij}$ is the largest value both in row i and column j.

The above procedure, however, often converges to poor local optima. To remedy for this, the second step (i.e., dictionary induction) is extended with techniques that make self-learning more robust. First, the vocabularies of $\boldsymbol{X}$ and $\boldsymbol{Z}$ are cut to the top k most frequent words.[3] Second, similarity scores in $\boldsymbol{P}$ are kept with probability p, and set to zero otherwise. This *dropout* allows for a wider exploration of possible word pairs in the dictionary and contributes to escaping poor local optima given the noisy seed lexicon in the first iterations.

C3. Preprocessing and Postprocessing Steps. While iteratively learning orthogonal transformations $\boldsymbol{W}_x$ and $\boldsymbol{W}_z$ for $\boldsymbol{X}$ and $\boldsymbol{Z}$ is the central step of unsupervised projection-based CLWE methods, preprocessing and postprocessing techniques are additionally applied before and after the transformation. While such techniques are often over-

[1] For instance, *zwei* and *two* will have similar distributions of similarities over their respective language vocabularies – *zwei* is expected to be roughly as (dis)similar to *drei* and *Katze* as *two* is to *three* and *cat*.

[2] I.e., $\boldsymbol{D}_{ij}^{(k)} = 1 \iff$ the i-th word of one language and the j-th word of the other are a translation pair in $D^{(k)}$.

[3] This is done to prevent spurious nearest neighbours consisting of infrequent words with unreliable vectors.

looked in model comparisons, they may have a great impact on the model's final performance, as we validate in §4. We briefly summarize two preprocessing (S1 and S2) and post-processing (S3 and S4) steps used in our evaluation, originating from the framework of Artetxe et al. (2018a).

S1) *Normalization and mean centering*. We first apply unit length normalization: all vectors in $\boldsymbol{X}$ and $\boldsymbol{Z}$ are normalized to have a unit Euclidean norm. Following that, $\boldsymbol{X}$ and $\boldsymbol{Z}$ are mean centered dimension-wise and then again length-normalized.

S2) *Whitening*. ZCA whitening (Bell and Sejnowski, 1997) is applied on (S1-processed) $\boldsymbol{X}$ and $\boldsymbol{Z}$: it transforms the matrices such that each dimension has unit variance and that the dimensions are uncorrelated. Intuitively, the vector spaces are easier to align along directions of high variance.

S3) *Dewhitening*. A transformation inverse to S2: for improved performance it is important to restore the variance information after the projection, if whitening was applied in S2 (Artetxe et al., 2018a).

S4) *Symmetric re-weighting*. This step attempts to further align the embeddings in the cross-lingual embedding space by measuring how well a dimension in the space correlates across languages for the current iteration dictionary $D^{(k)}$.[4] The best results are obtained when re-weighting is neutral to the projection direction, that is, when it is applied symmetrically in both languages.

In the actual implementation S1 is applied only once, before self-learning. S2, S3 and S4 are applied in each self-learning iteration.

Model Configurations. Note that C2 and C3 can be equally used on top of any (provided) seed lexicon (i.e., $D^{(1)}$:=D_0) to enable weakly supervised learning, as we propose here. In fact, the variations of the three key components, C1) seed lexicon, C2) self-learning, and C3) preprocessing and post-processing, construct various model configurations which can be analyzed to probe the importance of each component in the CLWE induction process. A selection of representative configurations evaluated later in §4 is summarized in Table 1.

3 Experimental Setup

Evaluation Task. Our task is *bilingual lexicon induction* (BLI). It has become the *de facto* standard evaluation for projection-based CLWEs (Ruder et al., 2019; Glavaš et al., 2019). In short, after a shared CLWE space has been induced, the task is to retrieve target language translations for a test set of source language words. Its lightweight nature allows us to conduct a comprehensive evaluation across a large number of language pairs.[5] Since BLI is cast as a ranking task, following Glavaš et al. (2019) we use mean average precision (MAP) as the main evaluation metric: in our BLI setup with only one correct translation for each "query" word, MAP is equal to mean reciprocal rank (MRR).[6]

(Selection of) Language Pairs. Our selection of test languages is guided by the following goals: **a)** following recent initiatives in other NLP research (e.g., for language modeling) (Cotterell et al., 2018; Gerz et al., 2018), we aim to ensure the coverage of different genealogical and typological language properties, and **b)** we aim to analyze a large set of language pairs and offer new evaluation data which extends and surpasses other work in the CLWE literature. These two properties will facilitate analyses between (dis)similar language pairs and offer a comprehensive set of evaluation setups that test the robustness and portability of fully unsupervised CLWEs. The final list of 15 diverse test languages is provided in Table 2, and includes samples from different languages types and families. We run BLI evaluations for all language pairs in both directions, for a total of 15×14=210 BLI setups.

Monolingual Embeddings. We use the 300-dim vectors of Grave et al. (2018) for all 15 languages, pretrained on Common Crawl and Wikipedia with fastText (Bojanowski et al., 2017).[7] We trim all

[4] More formally, assume that we are working with matrices $\boldsymbol{X}$ and $\boldsymbol{Z}$ that already underwent all transformations described in S1-S3. Another matrix $\boldsymbol{D}$ represents the current bilingual dictionary D: $D_{ij} = 1$ if the i^{th} source word is translated by the j^{th} target word and $D_{ij} = 0$ otherwise. Then, given the singular value decomposition $\boldsymbol{USV^T} = \boldsymbol{X^T DZ}$, the final re-weighted projection matrices are $\boldsymbol{W}_x = \boldsymbol{US}^{\frac{1}{2}}$ (and $\boldsymbol{W}_z = \boldsymbol{VS}^{\frac{1}{2}}$. We refer the reader to (Artetxe et al., 2018a) and (Artetxe et al., 2018b) for more details.

[5] While BLI is an intrinsic task, as discussed by Glavaš et al. (2019) it is a strong indicator of CLWE quality also for downstream tasks: relative performance in the BLI task correlates well with performance in cross-lingual information retrieval (Litschko et al., 2018) or natural language inference (Conneau et al., 2018b). More importantly, it also provides a means to analyze whether a CLWE method manages to learn anything meaningful at all, and can indicate "unsuccessful" CLWE induction (e.g., when BLI performance is similar to a random baseline): detecting such CLWEs is especially important when dealing with fully unsupervised models.

[6] MRR is more informative than the more common *Precision@1 (P@1)*; our main findings are also valid when P@1 is used; we do not report the results for brevity.

vocabularies to the 200K most frequent words.

Training and Test Dictionaries. They are derived from PanLex (Baldwin et al., 2010; Kamholz et al., 2014), which was used in prior work on cross-lingual word embeddings (Duong et al., 2016; Vulić et al., 2017). PanLex currently spans around 1,300 language varieties with over 12M expressions: it offers some support and supervision also for low-resource language pairs (Adams et al., 2017). For each source language (L_1), we automatically translate their vocabulary words (if they are present in PanLex) to all 14 target (L_2) languages. To ensure the reliability of the translation pairs, we retain only unigrams found in the vocabularies of the respective L_2 monolingual spaces which scored above a PanLex-predefined threshold.

As in prior work (Conneau et al., 2018a; Glavaš et al., 2019), we then reserve the 5K pairs created from the more frequent L_1 words for training, while the next 2K pairs are used for test. Smaller training dictionaries (1K and 500 pairs) are created by again selecting pairs comprising the most frequent L_1 words.

original fastText and skip-gram (Mikolov et al., 2013b) trained on Wikipedia show the same trends in the final results.

Training Setup. In all experiments, we set the hyper-parameters to values that were tuned in prior research. When extracting the UNSUPERVISED seed lexicon, the 4K most frequent words of each language are used; self-learning operates on the 20K most frequent words of each language; with dropout the keep probability p is 0.1; CSLS with $k = 10$ nearest neighbors (Artetxe et al., 2018b).

Again, Table 1 lists the main model configurations in our comparison. For the fully UNSUPERVISED model we always report the best performing configuration after probing different self-learning strategies (i.e., +SL, +SL+NOD, and +SL+SYM are tested). The results for UNSUPERVISED are always reported as averages over 5 restarts: this means that with UNSUPERVISED we count BLI setups as unsuccessful only if the results are close to zero in all 5/5 runs. ORTHG-SUPER is the standard supervised model with orthogonal projections from prior work (Smith et al., 2017; Glavaš et al., 2019).

4 Results and Discussion

Main BLI results averaged over each source language (L_1) are provided in Table 3 and Table 4. We now summarize and discuss the main findings across several dimensions of comparison.

Unsupervised vs. (Weakly) Supervised. First, when exactly the same components C2 and C3 are used, UNSUPERVISED is unable to outperform a (weakly) supervised FULL+SL+SYM variant, and the gap in final performance is often substantial. In fact, FULL+SL+SYM and FULL+SL+NOD outperform the best UNSUPERVISED for all 210/210 BLI setups: we observe the same phenomenon with varying dictionary sizes, that is, it equally holds when we seed self-learning with 5K, 1K, and 500 translation pairs, see also Figure 2. This also suggests that the main reason why UNSUPERVISED approaches were considered on-par with supervised approaches in prior work (Conneau et al., 2018a; Artetxe et al., 2018b) is because they were not compared under fair circumstances: while UNSUPER-

Table 3: BLI scores (MRR) for all model configurations. The scores are averaged over all experimental setups where each of the 15 languages is used as L_1: e.g., CA-* means that the translation direction is from Catalan (CA) as source (L_1) to each of the remaining 14 languages listed in Table 2 as targets (L_2), and we average over the corresponding 14 CA-* BLI setups. $5k$ and $1k$ denote the seed dictionary size for (weakly) supervised methods (D_0). *Unsuccessful setups* refer to the number of BLI experimental setups with the fully UNSUPERVISED model that yield an MRR score ≤ 0.01. The **Avg** column refers to the averaged MRR scores of each model configuration over all 15×14=210 BLI setups. The highest scores for two different seed dictionary sizes in each column are in bold, the second best are underlined. See Table 1 for the brief description of all model configurations in the comparison. Full results for each particular language pair are available in the supplemental material.

	$\lvert D_0\rvert = 5k$		$\lvert D_0\rvert = 1k$	
	Unsuc.	**Win**	**Unsuc.**	**Win**
UNSUPERVISED	87 (94)	0	87 (94)	0
ORTHG-SUPER	0 (2)	0	2 (82)	0
ORTHG+SL+SYM	0 (1)	0	1 (34)	0
FULL-SUPER	0 (0)	46	0 (41)	0
FULL+SL	0 (7)	0	0 (9)	0
FULL+SL+NOD	0 (1)	7	0 (3)	33
FULL+SL+SYM	0 (0)	157	0 (0)	177

Table 4: Summary statistics computed over all 15×14=210 BLI setups. **a) Unsuc.** denotes the total number of unsuccessful setups, where a setup is considered unsuccessful if MRR ≤ 0.01 or MRR ≤ 0.05 (in the parentheses); **b) Win** refers to the total number of "winning" setups, that is, for all language pairs it counts how many times each particular model yields the best overall MRR score. We compute separate statistics for two settings ($\lvert D_0\rvert = 1k$ and $\lvert D_0\rvert = 5k$).

VISED relied heavily on the components C2 and C3, these were omitted when running supervised baselines. Our unbiased comparison reveals that there is a huge gap even when supervised projection-based approaches consume only several hundred translation pairs to initiate self-learning.

Are Unsupervised CLWEs Robust? The results also indicate that, contrary to the beliefs established by very recent work (Artetxe et al., 2018b; Mohiuddin and Joty, 2019), fully UNSUPERVISED approaches are still prone to getting stuck in local optima, and still suffer from robustness issues when dealing with distant language pairs: 87 out of 210 BLI setups ($= 41.4\%$) result in (near-)zero BLI performance, see also Table 4. At the same time, weakly supervised methods with a seed lexicon of 1k or 500 pairs do not suffer from the robustness problem and always converge to a good solution,

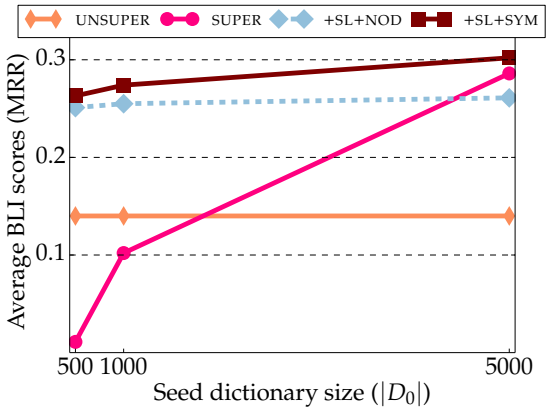

Figure 2: A comparison of average BLI scores with different seed dictionary sizes D_0 between a fully unsupervised method (UNSUPER), a supervised method without self-learning (SUPER), and two best performing weakly supervised methods with self learning (+SL+NOD and +SL+SYM). While SUPER without self-learning displays a steep drop in performance with smaller seed dictionaries, there is only a slight decrease when self-learning is used: e.g., 500 translation pairs are still sufficient to initialize robust self-learning.

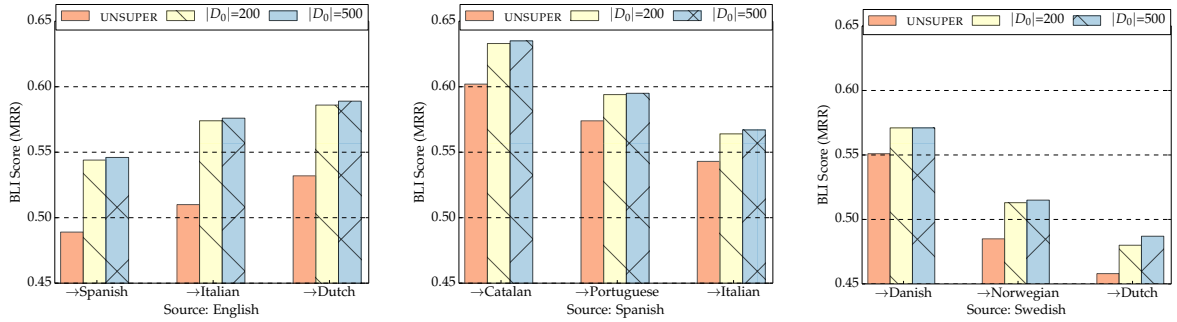
as also illustrated by the results reported in Table 5.

How Important are Preprocessing and Post-processing? The comparisons between ORTHG-SUPER (and ORTHG+SL+SYM) on the one hand, and FULL-SUPER (and FULL+SL+SYM) on the other hand clearly indicate that the component C3 plays a substantial role in effective CLWE learning. FULL-SUPER, which employs all steps S1-S4 (see §2), outperforms ORTHG-SUPER in 208/210 setups with $|D_0|$=*5k* and in 210/210 setups with $|D_0|$=*1k*. Similarly, FULL+SL+SYM is better than ORTHG+SL+SYM in 210/210 setups (both for $|D_0|$=*1k,5k*). The scores also indicate that dropout with self-learning is useful only when we work with noisy unsupervised seed lexicons: FULL+SL+NOD and FULL+SL+SYM without dropout consistently outperform FULL+SL across the board.

How Important is (Robust) Self-Learning? We note that the best self-learning method is often useful even when $|D_0| = 5k$ (i.e., FULL+SL+SYM is better than FULL-SUPER in 164/210 setups). However, the importance of robust self-learning gets more pronounced as we decrease the size of D_0: FULL+SL+SYM is better than FULL-SUPER in 210/210 setups when $|D_0| = 500$ or $|D_0| = 1,000$. The gap between the two models, as shown in Figure 2, increases dramatically in favor of FULL+SL+SYM as we decrease $|D_0|$.

Again, just comparing FULL-SUPER and UNSUPERVISED in Figure 2 might give a false impression that fully unsupervised CLWE methods can match their supervised counterparts, but the comparison to FULL+SL+SYM reveals the true extent of performance drop when we abandon even weak supervision. The scores also reveal that the choice of self-learning (C2) does matter: all best performing BLI runs with $|D_0| = 1k$ are obtained by two configs with self-learning, and FULL+SL+SYM is the best configuration for 177/210 setups (see Table 4).



Language Pairs. As suggested before by Søgaard et al. (2018) and further verified by Glavaš et al. (2019) and Doval et al. (2019), the language pair at hand can have a huge impact on CLWE induction: the adversarial method of Conneau et al. (2018a) often gets stuck in poor local optima and yields degenerate solutions for distant language pairs such as English-Finnish. More recent CLWE methods (Artetxe et al., 2018b; Mohiuddin and Joty, 2019) focus on mitigating this robustness issue. However, they still rely on one critical assumption which leads them to degraded performance for distant language pairs: they assume *approximate isomorphism* (Barone, 2016; Søgaard et al., 2018) between monolingual embedding spaces to learn the initial seed dictionary. In other words, they assume very similar geometric constellations between two monolingual spaces: due to the Zipfian phenomena in language (Zipf, 1949) such near-isomorphism can be satisfied only for *similar languages* and for *similar domains* used for training monolingual vectors. This property is reflected in the results reported in Table 3, the number of unsuccessful setups in Table 4, as well as later in Figure 4.

For instance, the largest number of unsuccessful BLI setups with the UNSUPERVISED model is reported for Korean, Thai (a tonal language), and Basque (a language isolate): their morphological and genealogical properties are furthest away from other languages in our comparison. A substantial number of unsuccessful setups is also observed with other two language outliers from our set (see Table 2 again), Georgian and Indonesian, as well as with morphologically-rich languages such as Estonian or Turkish.

One setting in which fully UNSUPERVISED methods did show impressive results in prior work are similar language pairs. However, even in these settings when the comparison to the weakly supervised FULL-SUPER+SYM is completely fair (i.e.,

	BG-EU	EU-TR	FI-KO	ID-ET	ID-TH	KA-FI	KA-ID	KO-TR	NO-EU	TR-TH

500:FULL+SL+SYM	0.245	0.189	0.192	0.195	0.188	0.285	0.138	0.264	0.266	0.109

Table 5: Results for a selection of BLI setups which were unsuccessful with the UNSUPERVIED CLWE method.

(a) English→ L_2 (b) Spanish→ L_2 (c) Swedish→ L_2

Figure 3: A comparison of BLI scores on "easy" (i.e., similar) language pairs between the fully UNSUPERVISED model and a weakly supervised model (seed dictionary size $|D_0| = 200$ or $|D_0| = 500$) which relies on the self-learning procedure with the symmetry constraint (FULL+SL+SYM).

(a) English→ Spanish (b) English → Finnish (c) English → Hungarian

Figure 4: BLI scores with the (most robust) fully UNSUPERVISED model for different language pairs when monolingual word embeddings are trained on dissimilar domains: parliamentary proceedings (EuroParl), Wikipedia (Wiki), and medical corpora (EMEA). Training and test data are the same as in (Søgaard et al., 2018).

the same components C2 and C3 are used for both), UNSUPERVISED still falls short of FULL-SUPER+SYM. These results for three source languages are summarized in Figure 3. What is more, one could argue that we do not need unsupervised CLWEs for similar languages in the first place: we can harvest cheap supervision here, e.g., cognates. The main motivation behind unsupervised approaches is to support dissimilar and resource-poor language pairs for which supervision cannot be guaranteed.

Domain Differences. Finally, we also verify that UNSUPERVISED CLWEs still cannot account for domain differences when training monolingual vectors. We rely on the probing test of Søgaard et al. (2018): 300-dim fastText vectors are trained on 1.1M sentences on three corpora: 1) EuroParl.v7 (Koehn, 2005) (parliamentary proceedings); 2) Wikipedia (Al-Rfou et al., 2013), and 3) EMEA (Tiedemann, 2009) (medical), and BLI evaluation for three language pairs is conducted on standard MUSE BLI test sets (Conneau et al., 2018a). The results, summarized in Figure 4, reveal that UNSUPERVISED methods are able to yield a good solution only when there is no domain mismatch and for the pair with two most similar languages (English-Spanish), again questioning their robustness and portability to truly low-resource and more challenging setups. Weakly supervised methods ($|D_0| = 500$ or D_0 seeded with identical strings), in contrast, yield good solutions for all setups.

5 Further Discussion and Conclusion

The superiority of weakly supervised methods (e.g., FULL+SL+SYM) over unsupervised methods is especially pronounced for distant and typologi-

cally heterogeneous language pairs. However, our study also indicates that even carefully engineered projection-based methods with some seed supervision yield lower absolute performance for such pairs. While we have witnessed the proliferation of fully unsupervised CLWE models recently, some fundamental questions still remain. For instance, the underlying assumption of all projection-based methods (both supervised and unsupervised) is the topological similarity between monolingual spaces, which is why standard simple linear projections result in lower absolute BLI scores for distant pairs (see Table 4 and results in the supplemental material). Unsupervised approaches even exploit the assumption *twice* as their seed extraction is fully based on the topological similarity.

Future work should move beyond the restrictive assumption by exploring new methods that can, e.g., 1) increase the isomorphism between monolingual spaces (Zhang et al., 2019) by distinguishing between language-specific and language-pair-invariant subspaces; 2) learn effective non-linear or multiple local projections between monolingual spaces similar to the preliminary work of Nakashole (2018); 3) similar to Vulić and Korhonen (2016) and Lubin et al. (2019) "denoisify" seed lexicons during the self-learning procedure. For instance, keeping only mutual/symmetric nearest neighbour as in FULL+SL+SYM can be seen as a form of rudimentary denoisifying: it is indicative to see that the best overall performance in this work is reported with that model configuration.

Further, the most important contributions of unsupervised CLWE models are, in fact, the improved and more robust self-learning procedures (component C2) and technical enhancements (component C3). In this work we have demonstrated that these components can be equally applied to weakly supervised approaches: starting from a set of only several hundred pairs, they can guarantee consistently improved performance across the board. As there is still no clear-cut use case scenario for unsupervised CLWEs,[8] instead of "going fully unsupervised", one pragmatic approach to widen the scope of CLWE learning and its application might invest more effort into extracting at least some seed supervision for a variety of language pairs (Artetxe et al., 2017). This finding aligns well with the ongoing initiatives of the PanLex project (Kamholz et al., 2014) and the ASJP database (Wichmann et al., 2018), which aim to collate at least some translation pairs in most of the world's languages.[9]

Finally, this paper demonstrates that, in order to enable fair comparisons, future work on CLWEs should focus on evaluating the CLWE methods' constituent components (e.g, components C1-C3 from this work) instead of full-blown composite systems directly. One goal of the paper is to acknowledge that the work on fully unsupervised CLWE methods has indeed advanced state-of-the-art in cross-lingual word representation learning by offering new solutions also to weakly supervised CLWE methods. However, the robustness problems are still prominent with fully unsupervised CLWEs, and future work should invest more time and effort into developing more robust and more effective methods, e.g., by reaching beyond projection-based methods towards joint approaches (Ruder et al., 2019; Ormazabal et al., 2019).

[8] E.g., unsupervised CLWEs are fully substitutable with the superior weakly supervised CLWEs in unsupervised NMT architectures (Artetxe et al., 2018c; Lample et al., 2018a,b), or in domain adaptation systems (Ziser and Reichart, 2018) and fully unsupervised cross-lingual IR (Litschko et al., 2018).

Weakly-Supervised Concept-based Adversarial Learning for Cross-lingual Word Embeddings

Abstract

Distributed representations of words which map each word to a continuous vector have proven useful in capturing important linguistic information not only in a single language but also across different languages. Current unsupervised adversarial approaches show that it is possible to build a mapping matrix that aligns two sets of monolingual word embeddings without high quality parallel data, such as a dictionary or a sentence-aligned corpus. However, without an additional step of refinement, the preliminary mapping learnt by these methods is unsatisfactory, leading to poor performance for typologically distant languages.

In this paper, we propose a weakly-supervised adversarial training method to overcome this limitation, based on the intuition that mapping across languages is better done at the concept level than at the word level. We propose a concept-based adversarial training method which improves the performance of previous unsupervised adversarial methods for most languages, and especially for typologically distant language pairs.

1 Introduction

Distributed representations of words which map each word to a continuous vector have proven useful in capturing important linguistic information. Vectors of words that are semantically or syntactically similar have been shown to be close to each other in the same space (Mikolov et al., 2013a,c; Pennington et al., 2014), making them widely useful in many natural language processing tasks such as machine translation and parsing (Bansal et al., 2014; Mi et al., 2016), both in a single language and across different languages.

Mikolov et al. (2013b) first observed that the geometric positions of similar words in different languages were related by a linear relation. Zou et al. (2013) showed that a cross-lingually shared word embedding space is more useful than a monolingual space in an end-to-end machine translation task. However, traditional methods for mapping two monolingual word embeddings require high quality aligned sentences or dictionaries (Faruqui and Dyer, 2014; Ammar et al., 2016b).

Reducing the need for parallel data, then, has become the main issue for cross-lingual word embedding mapping. Some recent work aiming at reducing resources has shown competitive cross-lingual mappings across similar languages, using a pseudo-dictionary, such as identical character strings between two languages (Smith et al., 2017), or a simple list of numerals (Artetxe et al., 2017).

In a more general method, Zhang et al. (2017) have shown that learning mappings across languages via adversarial training (Goodfellow et al., 2014) can avoid using bilingual evidence. This generality comes at the expense of performance. To overcome this limitation, Lample et al. (2018) refine the preliminary mapping matrix trained by generative adversarial networks (GANs) and obtain a model that is again comparable to supervised models for several language pairs. Despite these big improvements, the performance of these refined GAN models depends largely on the quality of the preliminary mappings. It is probably for this reason that these models still do not show satisfactory performance for typologically distant languages.

In this paper, we explore new augmented models of the adversarial framework that are based on the intuition that the right level of lexical alignment between languages, especially distant languages, is not the word but the concept. We also observe that some cross-lingual resources, such as document-aligned data, are not as expensive as high-quality dictionaries. For example, Wikipedia provides thousands of aligned articles in many lan-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4419–4430,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

guages. Combining these two observations, we develop a concept-based, weakly supervised adversarial method for learning cross-lingual word embedding mappings that rely on these readily available cross-lingual resources.

The main novelty of our method lies in the use of Wikipedia concept-aligned article pairs in the discriminator, which encourages the generator to align words from different languages which are used to describe the same concept. We leverage the power of the adversarial framework and its ability to align distributions by defining concepts as the distribution of words in their respective Wikipedia articles.

The results of our experiments on bilingual lexicon induction show that the preliminary mappings (without post-refinement) trained by our proposed multi-discriminator model are much better than unsupervised adversarial training methods. When we include the post-refinement of Lample et al. (2018), in most cases, our models are comparable or even better than our dictionary-based supervised baselines, and considerably improve the performance of the method of Lample et al. (2018), especially for distant language pairs, such as Chinese-English and Finnish-English.[1] Compared to the previous state-of-the-art, our method still shows competitive performance.

2 Models

The basic idea of mapping two sets of pre-trained monolingual word embeddings together was first proposed by Mikolov et al. (2013b). They use a small dictionary of n pairs of words $\{(w_{s_1}, w_{t_1}), ..., (w_{s_n}, w_{t_n})\}$ obtained from Google Translate to learn a transformation matrix W that projects the embeddings v_{s_i} of the source language words w_{s_i} onto the embeddings v_{t_i} of their translation words w_{t_i} in the target language, by optimizing the objective:

$$\min_{W} \sum_{i=1}^{n} \|W v_{s_i} - v_{t_i}\|^2 \tag{1}$$

The trained matrix W can then be used for detecting the translation for any source language word w_s by simply finding the word w_t whose embedding v_t is nearest to $W v_s$. Recent work by Smith et al. (2017) has shown that forcing the matrix W to be orthogonal can effectively improve the results of mapping.

2.1 GANs for cross-lingual word embeddings

Since the core of this linear mapping is derived from a dictionary, the quality and size of the dictionary can considerably affect the result. Recent attempts by Zhang et al. (2017) and Lample et al. (2018) have shown that, even without a dictionary or any other cross-lingual resource, training the transformation matrix W is still possible using the GAN framework (Goodfellow et al., 2014). The standard GAN framework plays a min-max game between two models: a generative model G and a discriminative model D. The generator G learns from the source data distribution and tries to generate new samples that appear drawn from the distribution of target data. The discriminator D discriminates the generated samples from the target data.

If we adapt the standard GAN framework to the goal of mapping cross-lingual word embeddings, the objective of the generator G is to learn the transformation matrix W that maps the source language embeddings to the target language embedding space, and the discriminator D_l, usually a neural network classifier, detects whether the input is from the target language, giving us the objective:

$$\begin{aligned} &\min_{G} \max_{D_l} \; \mathbb{E}_{v_t \sim p_{v_t}} \log D_l(v_t) \\ &+ \mathbb{E}_{v_s \sim p_{v_s}} \log(1 - D_l(G(v_s))) \end{aligned} \tag{2}$$

where $G(v_s) = W v_s$ and $D_l(v_t)$ denotes the probability that v_t came from the distribution p_{v_t} rather than the distribution p_{v_s}. The inputs of generator G are the embeddings sampled from the distribution of source language word embeddings, p_{v_s}, and the inputs of discriminator D_l are sampled from both the distribution p_{v_t} of real target language word embeddings and the distribution $p_{G(v_s)}$ of generated target language word embeddings. Both G and D_l are trained simultaneously by stochastic gradient descent. A good transformation matrix W can make $p_{G(v_s)}$ similar to p_{v_t}, so that D_l can no longer distinguish between them. However, this kind of similarity is at the distribution level. Good monolingual word embeddings are widely spread in the vector space. Consequently, without any post-processing, the cross-lingual mappings are usually inaccurate when we look at specific words (Lample et al., 2018).

[1] We provide our definition of *similar* and *distant* in section 5.

2.2 Concept-based GANs for cross-lingual word embeddings

Under the assumption that words in different languages are similar when they are used to describe the same topic or concept (Søgaard et al., 2015), it seems possible to use concept-aligned documents to improve the mapping performance and make the generated embeddings of the source language words closer to the embeddings of corresponding words in the target language. Unlike dictionaries and sentence-aligned corpora, cross-lingual concept-aligned documents are much more readily available. For example, Wikipedia contains more than 40-million articles in more than 200 languages.[2] Therefore, many articles of different languages can be linked together because they are about the same concept.

Given two monolingual word embeddings $V_s^j = \{v_{s_1}, ..., v_{s_j}\}$ and $V_t^k = \{v_{t_1}, , ..., v_{t_k}\}$, our work consists in using a set of Wikipedia concept-aligned article pairs, such that $(C_s^h, C_t^h) = \{(c_{s_1}, c_{t_1})..., (c_{s_h}, c_{t_h})\}$, to reshape the transformation matrix W, where $c_{s_i} \in C_s^h$ represents the article of concept c_i in the source language and $c_{t_i} \in C_t^h$ represents the article of the same concept in the target language.

As shown in Figure 1, the generator uses the transformation matrix W to map the input embeddings v_s from the source to the target language. Differently from the original GANs, the input of the generator and the input of the discriminator on concept D_{cl} are not sampled from the whole distribution of V_s^j or V_t^k, but from their sub-distribution conditioned on the concept c, denoted $p_{v_s|c}$ and $p_{v_t|c}$. v_c represents the embedding of the shared concept c. In this paper, we use the embedding of the title of c in the target language. For titles consisting of multiple words, we average the embeddings of its words.

The input of the discriminator on concept D_{cl} is the concatenation of the embedding of the shared concept v_c and the generated target embeddings $G(v_s)$ or the real target embeddings v_t. Instead of determining whether its input follows the whole target language distribution p_{v_t}, the objective of D_{cl} now becomes to judge whether its input follows the distribution $p_{v_t|c}$, and its loss function is given in equation (3).

$$\log D_{cl}(v_t, v_c) + log(1 - D_{cl}(G(v_s), v_c)) \quad (3)$$

[2] https://en.wikipedia.org/wiki/List_of_Wikipedias

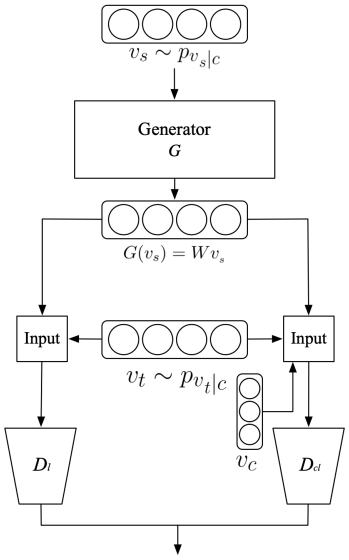

Figure 1: Architecture of our concept-based multi-discriminator model. D_l word-level discriminator, D_{cl} concept-level discriminator.

Because the sub-distribution conditioned on the concept $p_{v_t|c}$ is less spread than p_{v_t} and the proportion of similar words in $p_{v_t|c}$ is higher than in p_{v_t}, the embeddings of the input source words have a greater chance of being trained to align with the embeddings of their similar words in the target language.

Our multi-discriminator concept-based model does not completely remove the usual language discriminator D_l that determines whether its input follows the real target language distribution p_{v_t} or the generated target language distribution, $p_{G(v_s)}$. The simpler discriminator D_l is useful when the concept-based discriminator is not stable. The objective function of the multi-discriminator model, shown in equation (4), combines all these elements.

$$\begin{aligned} &\min_G \max_{D_l, D_{cl}} \mathbb{E}_{v_t \sim p_{v_t}} \log D_l(v_t) \\ &+ \mathbb{E}_{v_s \sim p_{v_s}} \log(1 - D_l(G(v_s))) \\ &+ \mathbb{E}_{v_t \sim p_{v_t|c}} \log D_{cl}(v_t, v_c) \\ &+ \mathbb{E}_{v_s \sim p_{v_s|c}} \log(1 - D_{cl}(G(v_s), v_c)) \end{aligned} \quad (4)$$

3 Shared Components

Both the GAN and the concept-based GAN models use a variety of further methods that have been shown to improve results.

3.1 Orthogonalization

Previous studies (Xing et al., 2015; Smith et al., 2017) show that enforcing the mapping matrix W to be orthogonal can improve the performance and

make the adversarial training more stable. In this work, we perform the same update step proposed by Cisse et al. (2017) to approximate setting W to an orthogonal matrix:

$$W \leftarrow (1+\beta)\,W - \beta\left(WW^{\top}\right)W \qquad (5)$$

According to Lample et al. (2018) and Chen and Cardie (2018), when setting β to less than 0.01, the orthogonalization usually performs well.

3.2 Post-refinement

Previous work has shown that the core cross-lingual mapping can be improved by refining it by bootstrapping from a dictionary extracted from the learned mapping itself (Lample et al., 2018). Since this refinement process is not the focus of this work, we perform the same refinement procedure as Lample et al. (2018). After the core mapping matrix is learned, we use it to translate the ten thousand most frequent source words $(s_1, s_2, ..., s_{10000})$ into the target language. We then take these ten thousand translations $(t_1, t_2, ..., t_{10000})$ and translate them back into the source language. We call these translation $(s'_1, s'_2, ..., s'_{10000})$. We then consider all the word pairs (s_i, t_i) where $s_i = s'_i$ as our seed dictionary and use this dictionary to update our preliminary mapping matrix using the objective in equation 1.

Moreover, following Xing et al. (2015) and Artetxe et al. (2016), we force the refined matrix W^* to be orthogonal by using singular value decomposition (SVD):

$$W^* = ZU^{\top}, U\Sigma Z^{\top} = SVD({V_s}^{\top}V_t) \qquad (6)$$

3.3 Cross-Domain Similarity Local Scaling

Previous work (Radovanović et al., 2010; Dinu et al., 2015) has shown that standard nearest neighbour techniques are not effective to retrieve target similar words in high-dimensional spaces. The work of Lample et al. (2018) showed that using cross-domain similarity local scaling (CSLS) to retrieve target similar words is more accurate than standard nearest neighbour techniques. Instead of just considering the similarity between the source word and its neighbours in the target language, CSLS also takes into account the similarity between the target word and its neighbours in the source language:

$$CSLS(Wv_s, v_t) = \\ 2\cos(Wv_s, v_t) - r_t(Wv_s) - r_s(v_t) \qquad (7)$$

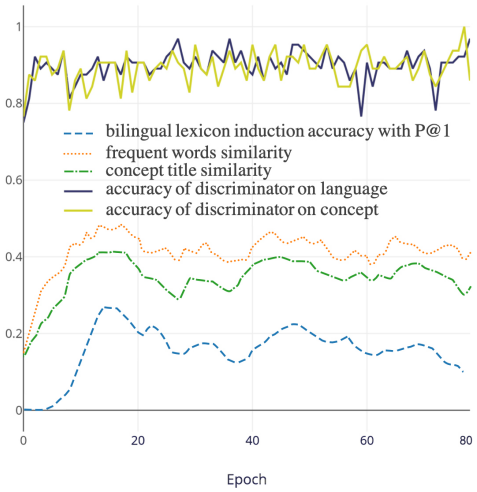

Figure 2: Model selection criteria

where $r_t(Wv_s)$ represents the mean similarity between a source embedding and its neighbours in the target language, and $r_s(v_t)$ represent the mean similarity between a target embedding and its neighbours in the source language. In this work, we use CSLS to build a dictionary for our post-refinement.

4 Training

In our weakly-supervised model, the sampling and model selection procedures are important.

Sampling Procedure As the statistics show in Table 1, even after filtering, the vocabulary of concept-aligned articles is still large. But it has been shown that the embeddings of frequent words are the most informative and useful (Luong et al., 2013; Lample et al., 2018), so we only keep the one-hundred thousand most frequent words for learning W.

For each training step, then, the input word s of our generator is randomly sampled from the vocabulary that is common both to the source monolingual word embedding S and the source Wikipedia concept-aligned articles. After the input source word s is sampled, we sample a concept c according to the frequency of s in each source article of the ensemble of concepts. Then we uniformly sample a target word t from the sub-vocabulary of the target article of concept c.[3]

Model Selection It is not as difficult to select the best model for weakly-supervised learning as it is

[3]We use uniform sampling for the target words because the distribution of the sampled sub-vocabulary is very small. Sampling t according to its local frequency in the target article would significantly increase the sampling probability of function words, which have less semantic information.

for unsupervised learning. In our task, the first selection criterion is the average of the cosine similarity between the embeddings of the concept title in the source and the target languages. Moreover, we find that another good indicator for selecting the best model is the average cosine similarity between the two sets of embeddings consisting of the average embeddings of the ten most frequent words in the source and in the target languages for each aligned article pair. As shown in Figure 2, both of these two criteria correlate well with the word translation evaluation task that we describe in section 5. In this paper, we use the average similarity of the cross-lingual title as the criterion for selecting the best model.

Other Details For our generator, the mapping matrix W is initialized with a random orthogonal matrix. Our two discriminators D_l and D_{cl} are two multi-layer perceptron classifiers with different hidden layer sizes (1024 for D_l and 2048 for D_{cl}), and a ReLU function as the activation function. In this paper, we set the number of hidden layers to 2 for both D_l and D_{cl}. In practice, one hidden layer also performs very well.

5 Experiments

We experimentally evaluate our proposal on the task of Bilingual Lexicon Induction (BLI). This task evaluates directly the bilingual mapping ability of a cross-lingual word embedding model. For each language pair, we retrieve the best translations for source words in the test data, and we report the accuracy.

More precisely, for a given source language word, we map its embedding onto the target language and retrieve the closest word. If this closest word is included in the correct translations in the evaluation dictionary, we consider that it is a correct case. In this paper, we report the results that use CSLS to retrieve translations.

Baselines As the objective of this work is to improve the performance of unsupervised GANs by using our weakly-supervised concept-based model, we choose the model of Lample et al. (2018) (called MUSE below), as our unsupervised baseline, since it is a typical standard GAN model. We evaluate the models both in a setting without refinement and a setting with refinement. The procedure of refinement is described in section 3.2 and 3.3. Moreover, it is important to evaluate whether our model is comparable to previous supervised models. We use two different dictionary-based systems, VecMap proposed by Artetxe et al. (2017) and Procrustes, provided by Lample et al. (2018), as our supervised baselines. Previous experiments have already shown that these two systems are strong baselines.

5.1 Data

Different previous pieces of work on bilingual lexicon induction use different datasets. We choose two from the publicly available ones, selected to have a comprehensive evaluation of our method.

BLI-1 The dataset provided by Lample et al. (2018) contains high quality dictionaries for more than 150 language pairs. For each language pair, it has a training dictionary of 5000 words and an evaluation dictionary of 1500 words. This dataset allows us to have a better understanding of the performance of our method on many different language pairs. We choose nine languages for testing and compare our method to our supervised and unsupervised baselines described in section 5: English (en), German (de), Finnish (fi), French (fr), Spanish (es), Italian (it), Russian (ru), Turkish (tr) and Chinese (zh). We classify *similar* and *distant* languages based on a combination of structural properties (directional dependency distance, as proposed and measured in Chen and Gerdes (2017)) and lexical properties, as measured by the clustering of current large-scale multilingual sentence embeddings.[4] We consider en ⇄ de, en ⇄ fr, en ⇄ es, en ⇄ it as similar language pairs and en ⇄ fi, en ⇄ ru, en ⇄ tr, en ⇄ zh as distant language pairs.

BLI-2 Unlike BLI-1, the dataset of Dinu et al. (2015) and its extensions provided by Artetxe et al. (2017, 2018b) only consists of dictionaries of 4 language pairs trained on a Europarl parallel cor-

pus. Each dictionary has a training set of 5000 entries and a test set of 1500 entries. Compared to BLI-1, this dataset is much noisier and the entries are selected from different frequency ranges. However, BLI-2 has been widely used for testing by previous methods (Faruqui and Dyer, 2014; Dinu et al., 2015; Xing et al., 2015; Artetxe et al., 2016; Zhang et al., 2016; Artetxe et al., 2017; Smith et al., 2017; Lample et al., 2018; Artetxe et al., 2018a,b).[5] Using BLI-2 allows us to have a direct comparison with the state-of-the-art.

Monolingual Word Embeddings The quality of monolingual word embeddings has a considerable impact on cross-lingual embeddings (Lample et al., 2018). Compared to CBOW and Skip-gram embeddings, FastText embeddings (Bojanowski et al., 2017) capture syntactic information better. The ideal situation would be to use FastText embeddings for both the BLI-1 and BLI-2 datasets. However, much previous work uses CBOW embeddings, so we use different monolingual word embeddings for BLI-1 and for BLI-2.

For BLI-1, we use FastText[6] to train our monolingual word embedding models with 300 dimensions for each language and default settings. The training corpus comes from a Wikipedia dump.[7] For European languages, words are lower-cased and tokenized by the scripts of Moses (Koehn et al., 2007).[8] For Chinese, we first use OpenCC[9] to convert traditional characters to simplified characters and then use Jieba[10] to perform tokenization. For each language, we only keep the words that appear more than five times.

For BLI-2, following the work of Artetxe et al. (2018a),[11] we use their pretrained CBOW embeddings of 300 dimensions. For English, Italian and German, the models are trained on the WacKy corpus. The Finnish model is trained from Common Crawl and the Spanish model is trained from WMT News Crawl.

Concept Aligned Data For concept-aligned articles, we use the Linguatools Wikipedia comparable corpus.[12] The statistics of our concept-aligned data are reported in Table 1.

5.2 Results and Discussion

Table 2 summarizes the results of bilingual lexicon induction on the BLI-1 dataset. We can see

[5] Most of these methods have been tested by Artetxe et al. (2018b) by using their own implementations.

[12] http://linguatools.org/tools/corpora/wikipedia-comparable-corpora/

that with post-refinement, our method achieves the best performance on eight language pairs. Table 3 illustrates the results of bilingual lexicon induction on the BLI-2 dataset. Although our method (with refinement) does not achieve the best results, the gap between our method and the best state-of-the-art (Artetxe et al., 2018a) is very small, and in most cases, our method is better than previous supervised methods.

Comparison with unsupervised GANs As we have mentioned before, the preliminary mappings trained by the method of Lample et al. (2018) perform well for some similar language pairs, such as Spanish to English and French to English. After refinement, their unsupervised GANs models can reach the same level as supervised models for these similar language pairs. However, the biggest drawback of standard GANs is that they exhibit poor performance for distant language pairs. The results from Table 2 clearly confirm this. For example, without refinement, the mapping trained by the unsupervised GAN method can only correctly predict 12% of the words from Turkish to English. Given that the quality of preliminary mappings can seriously affect the effect of refinement, the low-quality preliminary mappings for distant language pairs severely limits the improvements brought by post-refinement. Notice that the method of Lample et al. (2018) scores a null result for English to Finnish on both BLI-1 and BLI-2, indicating that totally unsupervised adversarial training can yields rather unpredictable results.

Compared to the method of Lample et al. (2018), the improvement brought by our method is apparent. Our concept-based GAN models perform better than their unsupervised models on almost every language pair for both datasets, BLI-1 and BLI-2. For those languages where no better results are achieved, the gaps from the best are very small. Figure 4 reports the error reduction rate brought by our method for bilingual lexicon induction on the BLI-1 dataset. It can be clearly seen that the improvement brought by our method is more pronounced on distant language pairs than on similar language pairs.

Comparison with supervised baselines Our two dictionary-based supervised baselines are strong. In most cases, the preliminary mappings trained by our concept-based model are not as good, but the gap is small. After post-refinement, our method becomes comparable with these supervised methods. For some language pairs, such as French-English and for English to Finnish, our method performs better.

Table 3: Results of bilingual lexicon induction (accuracy % P@1) on BLI-2 dataset, all the results of previous methods come from (Artetxe et al., 2018a).

Comparison with the state-of-the-art From the results shown in Table 3, we can see that in most cases, our method works better than previous supervised and unsupervised approaches. However, the performance of Artetxe et al. (2018a) is very strong and their method always works better than ours. Two potential reasons may cause this difference: First, their self-learning framework iteratively fine-tunes the transformation until convergence, while our refinement just runs for a certain number of iterations.[13] Second, their framework consists of many optimization steps, such as symmetric re-weighting of vectors, steps that we do not have.

Mapping examples Table 4 lists some examples of mapping, randomly selected from our experiment results on the dataset of BLI-1. From this table, we can see that for these selected English words, our model performs better than the unsupervised GANs model of Lample et al. (2018), but when we consider the top 3 translation candidates, both models are able to predict the correct translations well. Interestingly, the word "battery" is most commonly translated as Chinese "电池(dianchi)", correctly predicted by our model, and the top 3 translation candidates provided by

[13] As optimisation of the refinement is not the objective of this paper, we follow the work of Lample et al. (2018) and run only five iterations for post-refinement.

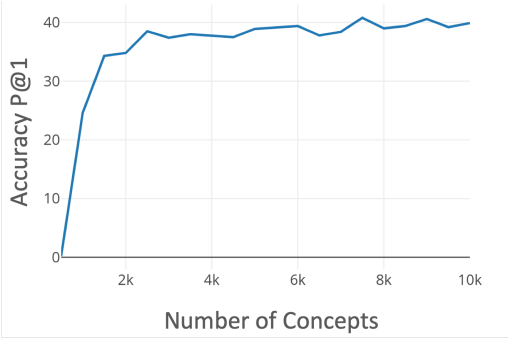

Figure 3: Accuracy of Chinese-English bilingual lexicon induction task for models trained from different concept numbers.

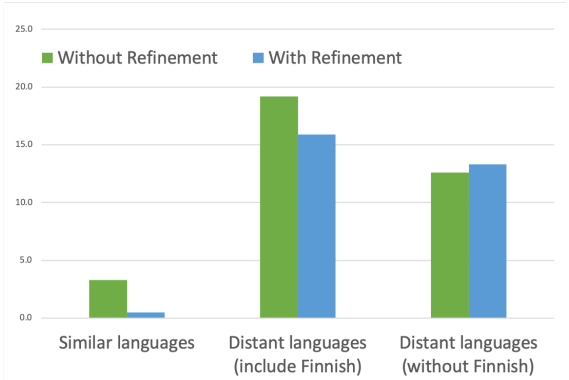

Figure 4: Average error reduction of our method compared to unsupervised adversarial method for bilingual lexicon induction on BLI-1 dataset (Lample et al., 2018). Since the Finnish-English pair is an outlier for the unsupervised method, we report both the average with and without this pair.

our model are all related to "electronic device". However, the translation candidates provided by MUSE are all related to "artillery", a different sense of the the word "battery" both in English and in Chinese, but not as common.

Impact of number of concepts To understand whether the number of aligned concepts affects our method, we trained our concept-based models on a range of Chinese-English concept-aligned article pairs, from 550 to 10'000. We test them on the BLI-1 dataset. Following the trend of performance change shown in Figure 3, we see that, when the number of shared concepts reaches 2500, the improvement in accuracy is already very close to the result of the model trained from the total number of concepts (reported in Table 1), thus indicating a direction for future optimization.

6 Related Work

Sharing a word embedding space across different languages has proven useful for many cross-lingual tasks, such as machine translation (Zou et al., 2013) and cross-lingual dependency parsing (Jiang et al., 2015, 2016; Ammar et al., 2016a). Generally, such spaces can be trained directly from bilingual sentence aligned or document aligned text (Hermann and Blunsom, 2014; Chandar A P et al., 2014; Søgaard et al., 2015; Vulić and Moens, 2013). However the performance of directly trained models is limited by their vocabulary size.

Initial work on the topic has shown that two monolingual spaces can be combined by applying a linear mapping matrix (Mikolov et al., 2013b). This simple approach has been improved upon in several ways: using canonical correlation analysis to map source and target embeddings (Faruqui and Dyer, 2014); or by forcing the mapping matrix to be orthogonal (Xing et al., 2015).

Recently, efforts have concentrated on how to limit or avoid reliance on dictionaries. Good results were achieved with some drastically minimal techniques. Zhang et al. (2016) achieved good results at bilingual POS tagging, but not bilingual lexicon induction, using only ten word pairs to build a coarse orthonormal mapping between source and target monolingual embeddings. The work of Smith et al. (2017) has shown that a singular value decomposition (SVD) method can produce a competitive cross-lingual mapping by using identical character strings across languages. Artetxe et al. (2017, 2018b) proposed a self-learning framework, which iteratively trains its cross-lingual mapping by using dictionaries trained in previous rounds. The initial dictionary of the self-learning can be reduced to 25 word pairs or even only a list of numerals and still have competitive performance. Furthermore, Artetxe et al. (2018a) extend their self-learning framework to unsupervised models, and build the state-of-the-art for bilingual lexicon induction. Instead of using a pre-build dictionary for initialization, they sort the value of the word vectors in both the source and the target distribution, treat two vectors that have similar permutations as possible translations and use them as the initialization dictionary. Additionally, their unsupervised framework also includes many optimization augmentations, such as stochastic dictionary induction and symmetric re-weighting, among others.

Theoretically, employing GANs for training cross-lingual word embedding is also a promising way to avoid the use of bilingual evidence. As far as we know, Miceli Barone (2016) was the first

Word translations are retrieved by using CSLS. Both MUSE and our model are after refinement. Bold face indicates the common translation of selected English words.

attempt at this approach, but the performance of their model is not competitive. Zhang et al. (2017) enforce the mapping matrix to be orthogonal during the adversarial training and achieve good performance on bilingual lexicon induction. The main drawback of their approach is that the vocabularies of their training data are small, and the performance of their models drops significantly when they use large training data. The recent model proposed by Lample et al. (2018) is so far the most successful, becoming competitive with previous supervised approaches through a strong CSLS-based refinement to the core mapping matrix trained by GANs. Even in this case, though, without refinement, the core mappings are not as good as hoped for some distant language pairs. More recently, Chen and Cardie (2018) extends the work of Lample et al. (2018) from the bilingual setting to the multi-lingual setting. Instead of training crosslingual word embeddings for only one language pair, their approach allows them to train crosslingual word embeddings for many language pairs at the same time. Another recent piece of work which is similar to Lample et al. (2018) comes from Xu et al. (2018). Their approach can be divided into 2 steps: first, using Wasserstein GAN (Arjovsky et al., 2017) to train a preliminary mapping between two monolingual distributions and then minimizing the Sinkhorn Distance across distributions. Although their method performs better than Lample et al. (2018) in several tasks, the improvement mainly comes from the second step, showing that the problem of how to train a better preliminary mapping has not been resolved.

7 Conclusions and Future Work

In this paper, we propose a weakly-supervised adversarial training method for cross-lingual word embedding mapping. Our approach is based on the intuition that mapping across distant languages is better done at the concept level than at the word level. We propose using the distributions of words in aligned Wikipedia articles as data for this concept mapping. The method improves the performance over previous unsupervised adversarial methods in almost all cases, especially for distant languages.

The monolingual word embeddings that we have used in this paper represent a word and not its different senses. These models do not handle polysemous words well. This also can have a negative impact on the performance of cross-lingual mapping. Recent work on contextualized word embeddings (Peters et al., 2018; Devlin et al., 2019) provides dynamic representations for words and has been shown to perform better at handling the problem of polysemy. Extending our concept-based cross-lingual mapping to contextualized word representations will be the focus of our future work.

Abstract

Multilingual knowledge graphs (KGs), such as YAGO and DBpedia, represent entities in different languages. The task of cross-lingual entity alignment is to match entities in a source language with their counterparts in target languages. In this work, we investigate embedding-based approaches to encode entities from multilingual KGs into the same vector space, where equivalent entities are close to each other. Specifically, we apply graph convolutional networks (GCNs) to combine multi-aspect information of entities, including topological connections, relations, and attributes of entities, to learn entity embeddings. To exploit the literal descriptions of entities expressed in different languages, we propose two uses of a pretrained multilingual BERT model to bridge cross-lingual gaps. We further propose two strategies to integrate GCN-based and BERT-based modules to boost performance. Extensive experiments on two benchmark datasets demonstrate that our method significantly outperforms existing systems.

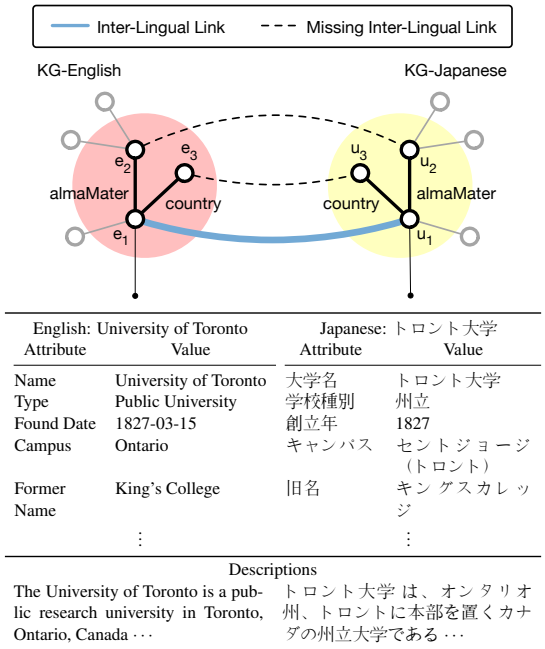

Figure 1: An example fragment of two KGs (in English and Japanese) connected by an inter-lingual link (ILL). In addition to the graph structures (top) consisting of entity nodes and typed relation edges, KGs also provide attributes and literal descriptions of entities (bottom).

1 Introduction

A growing number of multilingual knowledge graphs (KGs) have been built, such as DBpedia (Bizer et al., 2009), YAGO (Suchanek et al., 2008; Rebele et al., 2016), and BabelNet (Navigli and Ponzetto, 2012), which typically represent real-world knowledge as separately-structured monolingual KGs. Such KGs are connected via inter-lingual links (ILLs) that align entities with their counterparts in different languages, exemplified by Figure 1 (top). Highly-integrated multilingual KGs contain useful knowledge that can benefit many knowledge-driven cross-lingual NLP tasks, such as machine translation (Moussallem et al., 2018) and cross-lingual named entity recognition (Darwish, 2013). However, the coverage of ILLs among existing KGs is quite low (Chen et al., 2018): for example, less than 20% of the entities in DBpedia are covered by ILLs. The goal of cross-lingual entity alignment is to discover entities from different monolingual KGs that actually refer to the same real-world entities, i.e., discovering the missing ILLs.

Traditional methods for this task apply machine translation techniques to translate entity labels (Spohr et al., 2011). The quality of alignments in the cross-lingual scenario heavily depends on the quality of the adopted translation systems. In addition to entity labels, existing KGs also provide multi-aspect information of entities,

* Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4431–4441, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

including topological connections, relation types, attributes, and literal descriptions expressed in different languages (Bizer et al., 2009; Xie et al., 2016), as shown in Figure 1 (bottom). The key challenge of addressing such a task thus is how to better model and use provided multi-aspect information of entities to bridge cross-lingual gaps and find more equivalent entities (i.e., ILLs).

Recently, embedding-based solutions (Chen et al., 2017b; Sun et al., 2017; Zhu et al., 2017; Wang et al., 2018; Chen et al., 2018) have been proposed to unify multilingual KGs into the same low-dimensional vector space where equivalent entities are close to each other. Such methods only make use of one or two aspects of the aforementioned information. For example, Zhu et al. (2017) relied only on topological features while Sun et al. (2017) and Wang et al. (2018) exploited both topological and attribute features. Chen et al. (2018) proposed a co-training algorithm to combine topological features and literal descriptions of entities. However, combining these multi-aspect information of entities (i.e., topological connections, relations and attributes, as well as literal descriptions) remains under-explored.

In this work, we propose a novel approach to learn cross-lingual entity embeddings by using all aforementioned aspects of information in KGs. To be specific, we propose two variants of GCN-based models, namely MAN and HMAN, that incorporate multi-aspect features, including topological features, relation types, and attributes into cross-lingual entity embeddings. To capture semantic relatedness of literal descriptions, we fine-tune the pretrained multilingual BERT model (Devlin et al., 2019) to bridge cross-lingual gaps. We design two strategies to combine GCN-based and BERT-based modules to make alignment decisions. Experiments show that our method achieves new state-of-the-art results on two benchmark datasets. Source code for our models is publicly available at https://github.com/h324yang/HMAN.

2 Problem Definition

In a multilingual knowledge graph $\mathcal{G}$, we use $\mathcal{L}$ to denote the set of languages that $\mathcal{G}$ contains and $\mathcal{G}_i = \{E_i, R_i, A_i, V_i, D_i\}$ to represent the language-specific knowledge graph in language $L_i \in \mathcal{L}$. E_i, R_i, A_i, V_i and D_i are sets of entities, relations, attributes, values of attributes, and literal descriptions, each of which portrays one aspect of an entity. The graph $\mathcal{G}_i$ consists of relation triples $\langle h_i, r_i, t_i\rangle$ and attribute triples $\langle h_i, a_i, v_i\rangle$ such that $h_i, t_i \in E_i$, $r_i \in R_i$, $a_i \in A_i$ and $v_i \in V_i$. Each entity is accompanied by a literal description consisting of a sequence of words in language L_i, e.g., $\langle h_i, d_{h,i}\rangle$ and $\langle t_i, d_{t,i}\rangle$, $d_{h,i}, d_{t,i} \in D_i$.

Given two knowledge graphs $\mathcal{G}_1$ and $\mathcal{G}_2$ expressed in source language L_1 and target language L_2, respectively, there exists a set of pre-aligned ILLs $I(\mathcal{G}_1, \mathcal{G}_2) = \{(e, u) | e \in E_1, u \in E_2\}$ which can be considered training data. The task of cross-lingual entity alignment is to align entities in $\mathcal{G}_1$ with their cross-lingual counterparts in $\mathcal{G}_2$, i.e., discover missing ILLs.

3 Proposed Approach

In this section, we first introduce two GCN-based models, namely MAN and HMAN, that learn entity embeddings from the graph structures. Second, we discuss two uses of a multilingual pretrained BERT model to learn cross-lingual embeddings of entity descriptions: POINTWISEBERT and PAIRWISEBERT. Finally, we investigate two strategies to integrate the GCN-based and the BERT-based modules.

3.1 Cross-Lingual Graph Embeddings

Graph convolutional networks (GCNs) (Kipf and Welling, 2017) are variants of convolutional networks that have proven effective in capturing information from graph structures, such as dependency graphs (Guo et al., 2019b), abstract meaning representation graphs (Guo et al., 2019a), and knowledge graphs (Wang et al., 2018). In practice, multi-layer GCNs are stacked to collect evidence from multi-hop neighbors. Formally, the l-th GCN layer takes as input feature representations $H^{(l-1)}$ and outputs $H^{(l)}$:

$$H^{(l)} = \phi\left(\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}H^{(l-1)}W^{(l)}\right) \quad (1)$$

where $\tilde{A} = A + I$ is the adjacency matrix, I is the identity matrix, $\tilde{D}$ is the diagonal node degree matrix of $\tilde{A}$, $\phi(\cdot)$ is ReLU function, and $W^{(l)}$ represents learnable parameters in the l-th layer. $H^{(0)}$ is the initial input.

GCNs can iteratively update the representation of each entity node via a propagation mechanism through the graph. Inspired by previous studies (Zhang et al., 2018; Wang et al., 2018), we also

adopt GCNs in this work to collect evidence from multilingual KG structures and to learn cross-lingual embeddings of entities. The primary assumptions are: (1) equivalent entities tend to be neighbored by equivalent entities via the same types of relations; (2) equivalent entities tend to share similar or even the same attributes.

Multi-Aspect Entity Features. Existing KGs (Bizer et al., 2009; Suchanek et al., 2008; Rebele et al., 2016) provide multi-aspect information of entities. In this section, we mainly focus on the following three aspects: topological connections, relations, and attributes. The key challenge is how to utilize the provided features to learn better embeddings of entities. We discuss how we construct raw features for the three aspects, which are then fed as inputs to our model. We use X_t, X_r and X_a to denote the topological connection, relation, and attribute features, individually.

The topological features contain rich neighborhood proximity information of entities, which can be captured by multi-layer GCNs. As in Wang et al. (2018), we set the initial topological features to $X_t = I$, i.e., an identity matrix serving as index vectors (also known as the featureless setting), so that the GCN can learn the representations of corresponding entities.

In addition, we also consider the relation and attribute features. As shown in Figure 1, the connected relations and attributes of two equivalent entities, e.g., "*University of Toronto*" (English) and "トロント大学" (Japanese), have a lot of overlap, which can benefit cross-lingual entity alignment. Specifically, they share the same relation types, e.g., "country" and "almaMater", and some attributes, e.g., "foundDate" and "創立年". To capture relation information, Schlichtkrull et al. (2018) proposed RGCN with relation-wise parameters. However, with respect to this task, existing KGs typically contain thousands of relation types but few pre-aligned ILLs. Directly adopting RGCN may introduce too many parameters for the limited training data and thus cause overfitting. Wang et al. (2018) instead simply used the unlabeled GCNs (Kipf and Welling, 2017) with two proposed measures (i.e., functionality and inverse functionality) to encode the information of relations into the adjacency matrix. They also considered attributes as input features in their architecture. However, this approach may lose information about relation types. Therefore, we regard relations and attributes of entities as bag-of-words features to explicitly model these two aspects. Specifically, we construct count-based *N-hot* vectors X_r and X_a for these two aspects of features, respectively, where the (i, j) entry is the count of the j-th relation (attribute) for the corresponding entity e_i. Note that we only consider the top-F most frequent relations and attributes to avoid data sparsity issues. Thus, for each entity, both of its relation and attribute features are F-dimensional vectors.

MAN. Inspired by Wang et al. (2018), we propose the *Multi-Aspect Alignment Network* (MAN) to capture the three aspects of entity features. Specifically, three l-layer GCNs take as inputs the triple-aspect features (i.e., X_t, X_r, and X_a) and produce the representations $H_t^{(l)}$, $H_r^{(l)}$, and $H_a^{(l)}$ according to Equation 1, respectively. Finally, the multi-aspect entity embedding is:

$$H_m = [H_t^{(l)} \oplus H_a^{(l)} \oplus H_r^{(l)}] \quad (2)$$

where $\oplus$ denotes vector concatenation. H_m can then feed into alignment decisions.

Such fusion through concatenation is also known as *Scoring Level Fusion*, which has been proven simple but effective for capturing multi-modal semantics (Bruni et al., 2014; Kiela and Bottou, 2014; Collell et al., 2017). It is worth noting that the main differences between MAN and the work of Wang et al. (2018) are two fold: First, we use the same approach as in Kipf and Welling (2017) to construct the adjacency matrix, while Wang et al. (2018) designed a new connectivity matrix as the adjacency matrix for the GCNs. Second, MAN explicitly regards the relation type features as model input, while Wang et al. (2018) incorporated such relation information into the connectivity matrix.

HMAN. Note that MAN propagates relation and attribute information through the graph structure. However, for aligning a pair of entities, we observe that considering the relations and attributes of neighboring entities, besides their own ones, may introduce noise. Merely focusing on relation and attribute features of the current entity could be a better choice. Thus, we propose the *Hybrid Multi-Aspect Alignment Network* (HMAN) to better model such diverse features, shown in Figure 2. Similar to MAN, we still leverage the l-th layer of a GCN to obtain topological embeddings $H_t^{(l)}$, but exploit feedforward neural networks to obtain

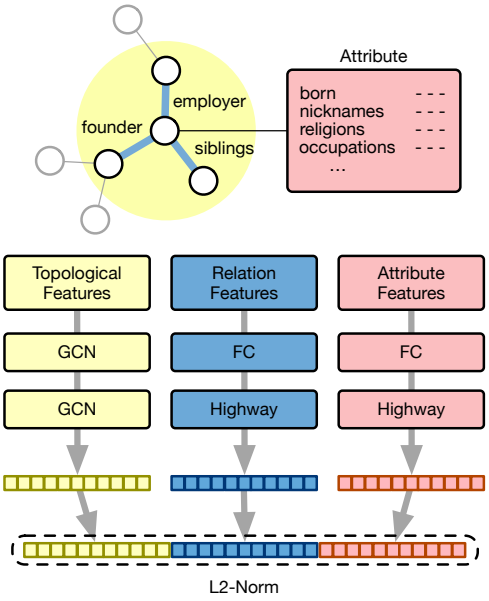

Figure 2: Architecture of HMAN.

the embeddings with respect to relations and attributes. The feedforward neural networks consist of one fully-connected (FC) layer and a highway network layer (Srivastava et al., 2015). The reason we use highway networks is consistent with the conclusions of Mudgal et al. (2018), who conducted a design space exploration of neural models for entity matching and found that highway networks are generally better than FC layers in convergence speed and effectiveness.

Formally, these feedforward neural networks are defined as:

$$\begin{aligned} S_f &= \phi(W_f^{(1)} X_f + b_f^{(1)}) \\ T_f &= \sigma(W_f^t S_f + b_f^t) \\ G_f &= \phi(W_f^{(2)} S_f + b_f^{(2)}) \cdot T_f + S_f \cdot (1 - T_f) \end{aligned} \tag{3}$$

where $f \in \{r, a\}$ and X_f refer to one specific aspect (i.e., relation or attribute) and the corresponding raw features, respectively, $W_f^{(1,2,t)}$ and $b_f^{(1,2,t)}$ are model parameters, $\phi(\cdot)$ is ReLU function, and $\sigma(\cdot)$ is sigmoid function. Accordingly, we obtain the hybrid multi-aspect entity embedding $H_y = [H_t^{(l)} \oplus G_r \oplus G_a]$, to which ℓ_2 normalization is further applied.

Model Objective. Given two knowledge graphs, $\mathcal{G}_1$ and $\mathcal{G}_2$, and a set of pre-aligned entity pairs $I\,(\mathcal{G}_1, \mathcal{G}_2)$ as training data, our model is trained in a supervised fashion. During the training phase, the goal is to embed cross-lingual entities into the same low-dimensional vector space where equivalent entities are close to each other. Following Wang et al. (2018), our margin-based ranking loss function is defined as:

$$\begin{aligned} J = \sum_{(e_1,e_2)\in I} \sum_{(e_1',e_2')\in I'} & [\rho(h_{e_1}, h_{e_2}) + \beta \\ & - \rho(h_{e_1'}, h_{e_2'})]_+ \end{aligned} \tag{4}$$

where $[x]_+ = \max\{0, x\}$, I' denotes the set of negative entity alignment pairs constructed by corrupting the gold pair $(e_1, e_2) \in I$. Specifically, we replace e_1 or e_2 with a randomly-chosen entity in E_1 or E_2. $\rho(x, y)$ is the ℓ_1 distance function, and $\beta > 0$ is the margin hyperparameter separating positive and negative pairs.

3.2 Cross-Lingual Textual Embeddings

Existing multilingual KGs (Bizer et al., 2009; Navigli and Ponzetto, 2012; Rebele et al., 2016) also provide literal descriptions of entities expressed in different languages and contain detailed semantic information about the entities. The key observation is that literal descriptions of equivalent entities are semantically close to each other. However, it is non-trivial to directly measure the semantic relatedness of two entities' descriptions, since they are expressed in different languages.

Recently, Bidirectional Encoder Representations from Transformer (BERT) (Devlin et al., 2019) has advanced the state-of-the-art in various NLP tasks by heavily exploiting pretraining based on language modeling. Of special interest is the multilingual variant, which was trained with Wikipedia dumps of 104 languages. The spirit of BERT in the multilingual scenario is to project words or sentences from different languages into the same semantic space. This aligns well with our objective—bridging gaps between descriptions written in different languages. Therefore, we propose two methods for applying multilingual BERT, POINTWISEBERT and PAIRWISEBERT, to help make alignment decisions.

POINTWISEBERT. A simple choice is to follow the basic design of BERT and formulate the entity alignment task as a text matching task. For two entities e_1 and e_2 from two KGs in L_1 and L_2, denoting source language and target language, respectively, their textual descriptions are d_1 and d_2, consisting of word sequences in two languages. The model takes as inputs [CLS] d_1 [SEP] d_2 [SEP], where [CLS] is the special classification token,

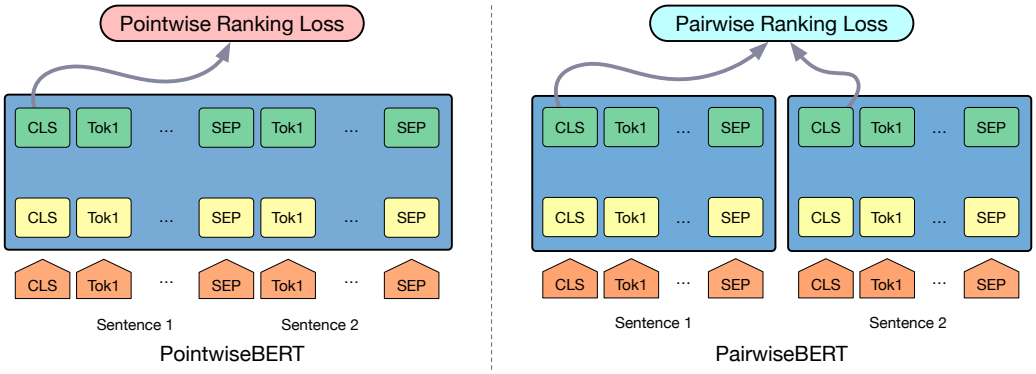

Figure 3: Architecture overview of POINTWISEBERT (left) and PAIRWISEBERT (right).

from which the final hidden state is used as the sequence representation, and [SEP] is the special token for separating token sequences, and produces the probability of classifying the pair as equivalent entities. The probability is then used to rank all candidate entity pairs, i.e., ranking score. We denote this model as POINTWISEBERT, shown in Figure 3 (left).

This approach is computationally expensive, since for each entity we need to consider all candidate entities in the target language. One solution, inspired by the work of Shi et al. (2019), is to reduce the search space for each entity with a *reranking strategy* (see Section 3.3).

PAIRWISEBERT. Due to the heavy computational cost of POINTWISEBERT, semantic matching between all entity pairs is very expensive. Instead of producing ranking scores for description pairs, we propose PAIRWISEBERT to encode the entity literal descriptions as cross-lingual textual embeddings, where distances between entity pairs can be directly measured using these embeddings.

The PAIRWISEBERT model consists of two components, each of which takes as input the description of one entity (from the source or target language), as depicted in Figure 3 (right). Specifically, the input is designed as [CLS] $d_1(d_2)$ [SEP], which is then fed into PAIRWISEBERT for contextual encoding. We select the hidden state of [CLS] as the textual embedding of the entity description for training and inference. To bring the textual embeddings of cross-lingual entity descriptions into the same vector space, a similar ranking loss function as in Equation 4 is used.

3.3 Integration Strategy

Sections 3.1 and 3.2 introduce two modules that separately collect evidence from knowledge graph structures and the literal descriptions of entities, namely graph and textual embeddings. In this section, we investigate two strategies to integrate these two modules to further boost performance.

Reranking. As mentioned in Section 3.2, the POINTWISEBERT model takes as input the concatenation of two descriptions for each candidate–entity pair, where conceptually we must process every possible pair in the training set. Such a setting would be cost prohibitive computationally.

One way to reduce the cost of POINTWISEBERT would be to ignore candidate pairs that are unlikely to be aligned. Rao et al. (2016) showed that uncertainty-based sampling can provide extra improvements in ranking. Following this idea, the GCN-based models (i.e., MAN and HMAN) are used to generate a candidate pool whose size is much smaller than the entire universe of entities. Specifically, GCN-based models provide top-q candidates of target entities for each source entity (where q is a hyperparameter). Then, the POINTWISEBERT model produces a ranking score for each candidate–entity pair in the pool to further rerank the candidates. However, the weakness of such a reranking strategy is that performance is bounded by the quality of (potentially limited) candidates produced by MAN or HMAN.

Weighted Concatenation. With the textual embeddings learned by PAIRWISEBERT denoted as H^B and graph embeddings denoted as H^G, a simple way to combine the two modules is by weighted concatenation:

$$H^C = \tau \cdot H^G \oplus (1 - \tau) \cdot H^B \quad (5)$$

where H^G is the graph embeddings learned by either MAN or HMAN, and τ is a factor to balance the contribution of each source (where τ is a hyperparameter).

3.4 Entity Alignment

After we obtain the embeddings of entities, we leverage ℓ_1 distance to measure the distance between candidate–entity pairs. A small distance reflects a high probability for an entity pair to be aligned as equivalent entities. To be specific, with respect to the reranking strategy, we select the target entities that have the smallest distances to a source entity in the vector space learned by MAN or HMAN as its candidates. For weighted concatenation, we employ the ℓ_1 distance of the representations of a pair derived from the concatenated embedding, i.e., H^C, as the ranking score.

4 Experiments

4.1 Datasets and Settings

We evaluate our methods over two benchmark datasets: DBP15K and DBP100K (Sun et al., 2017). Table 1 outlines the statistics of both datasets, which contain 15,000 and 100,000 ILLs, respectively. Both are divided into three subsets: Chinese-English (ZH-EN), Japanese-English (JA-EN), and French-English (FR-EN).

Following previous work (Sun et al., 2017; Wang et al., 2018), we adopt the same split settings in our experiments, where 30% of the ILLs are used as training and the remaining 70% for evaluation. *Hits@k* is used as the evaluation metric (Bordes et al., 2013; Sun et al., 2017; Wang et al., 2018), which measures the proportion of correctly aligned entities ranked in the top-k candidates, and results in both directions, e.g., ZH-EN and EN-ZH, are reported.

In all our experiments, we employ two-layer GCNs and the top 1000 (i.e., F=1000) most frequent relation types and attributes are included to build the N-hot feature vectors. For the MAN model, we set the dimensionality of topological, relation, and attribute embeddings to 200, 100, and 100, respectively. When training HMAN, the hyperparameters are dependent on the dataset sizes due to GPU memory limitations. For DBP15K, we set the dimensionality of topological embeddings, relation embeddings, and attribute embeddings to 200, 100, and 100, respectively. For DBP100K, the dimensionalities are set to 100, 50, and 50, respectively. We adopt SGD to update parameters and the numbers of epochs are set to 2,000 and 50,000 for MAN and HMAN, respectively. The margin β in the loss function is set to 3. The balance factor τ is determined by grid search, which shows that the best performance lies in the range from 0.8 to 0.7. For simplicity, τ is set to 0.8 in all associated experiments. Multilingual BERT-base models with 768 hidden units are used in POINTWISEBERT and PAIRWISEBERT. We additionally append one more FC layer to the representation of [CLS] and reduce the dimensionality to 300. Both BERT models are fine-tuned using the Adam optimizer.

4.2 Results on Graph Embeddings

We first compare MAN and HMAN against previous systems (Hao et al., 2016; Chen et al., 2017a; Sun et al., 2017; Wang et al., 2018). As shown in Table 2, MAN and HMAN consistently outperform all baselines in all scenarios, especially HMAN. It is worth noting that, in this case, MAN and HMAN use as much information as Wang et al. (2018), while Sun et al. (2017) require extra supervised information (relations and attributes of two KGs need to be aligned in advance). The performance improvements confirm that our model can better utilize topological, relational, and attribute information of entities provided by KGs.

To explain why HMAN achieves better results than MAN, recall that MAN collects relation and attribute information by the propagation mechanism in GCNs where such knowledge is exchanged through neighbors, while HMAN uses feedforward networks to capture expressive features directly from the input feature vectors without propagation. As we discussed before, it is not always the case that neighbors of equivalent entities share similar relations or attributes. Propagating such features through linked entities in GCNs may introduce noise and thus harm performance.

Table 2: Results of using graph information on DBP15K and DBP100K. @1, @10 and @50 refer to Hits@1, Hits@10 and Hits@50, respectively.

Moreover, we perform ablation studies on the two proposed models to investigate the effectiveness of each component. We alternatively remove each aspect of features (i.e., topological, relation, and attribute features) and the highway layer in HMAN, denoted as w/o TE (RE, AE, and HW). As reported in Table 2, we observe that after removing relation or attribute features, the performance of HMAN and MAN drops across all datasets. These figures prove that these two aspects of features are useful in making alignment decisions. On the other hand, compared to MAN, HMAN shows more significant performance drops, which also demonstrates that employing the feedforward networks can better categorize relation and attribute features than GCNs in this scenario. Interestingly, looking at the two variants MAN w/o TE and HMAN w/o TE, we can see the former achieves better results. Since MAN propagates relation and attribute features via graph structures, it can still implicitly capture topological knowledge of entities even after we remove the topological features. However, HMAN loses such structure knowledge when topological features are excluded, and thus its results are worse. From these experiments, we can conclude that the topological information is playing an indispensable role in making alignment decisions.

4.3 Results with Textual Embeddings

In this section, we discuss empirical results involving the addition of entity descriptions, shown in Table 3. Applying literal descriptions of entities to conduct cross-lingual entity alignment is relatively under-explored. The recent work of Chen et al. (2018) used entity descriptions in their model; however, we are unable to make comparisons with their work, as we do not have access to their code and data. Since we employ BERT to learn textual embeddings of descriptions, we consider systems that also use external resources, like Google Translate,[1] as our baselines. We directly

take results reported by Sun et al. (2017), denoted as "Translation" and "JAPE+Translation".

The POINTWISEBERT model is used with GCN-based models, which largely reduces the search space, as indicated by MAN (RERANK) and HMAN (RERANK), where the difference is that the candidate pools are given by MAN and HMAN, respectively. For DBP15K, we select top-200 candidate target entities as the candidate pool while for DBP100K, top-20 candidates are selected due to its larger size. The reranking method does lead to performance gains across all datasets, where the improvements are dependent on the quality of the candidate pools. HMAN (RERANK) generally performs better than MAN (RERANK) since HMAN recommends more promising candidate pools.

The PAIRWISEBERT model learns the textual embeddings that map cross-lingual descriptions into the same space, which can be directly used to align entities. The results are listed under PAIRWISEBERT in Table 3. We can see that it achieves good results on its own, which also shows the efficacy of using multilingual descriptions. Moreover, such textual embeddings can be combined with graph embeddings (learned by MAN or HMAN) by weighted concatenation, as discussed in Section 3.3. The results are reported as MAN (WEIGHTED) and HMAN (WEIGHTED), respectively. As we can see, this simple operation leads to significant improvements and gives excellent results across all datasets. However, it is not always the case that KGs provide descriptions for every entity. For those entities whose descriptions are not available, the graph embeddings would be the only source for making alignment decisions.

	English	Chinese
ILL pair	Casino_Royale_(2006_film) (3)	007大戰皇家賭場 (3)
Features	starring, starring, distributor	starring, starring, language
Neighbors	Daniel_Craig (1), Eva_Green (4), Columbia_Pictures (9)	丹尼爾·克雷格 (1), 伊娃·格蓮 (4), 英語 (832)

Table 4: Case study of the noise introduced by the propagation mechanism.

4.4 Case Study

In this section, we describe a case study to understand the performance gap between HMAN and MAN. The example in Table 4 provides insights potentially explaining this performance gap. We argue that MAN introduces unexpected noise from heterogeneous nodes during the GCN propagation process. We use the number in parentheses (*) after entity names to denote the number of relation features they have.

In this particular example, the two entities "*Casino_Royale_(2006_film)*" in the source language (English) and "*007*大戰皇家賭場" in the target language (Chinese) both have three relation features. We notice that the propagation mechanism introduces some neighbors which are unable to find cross-lingual counterparts from the other end, marked in red. Considering the entity "英語" (English), a neighbor of "*007*大戰皇家賭場", no counterparts can be found in the neighbors of "*Casino_Royale_(2006_film)*". We also observe that "英語" (English) is a pivot node in

the Chinese KG and has 832 relations, such as "語言" (Language), "官方語言" (Official Language), and "頻道語言" (Channel Language). In this case, propagating features from neighbors can harm performance. In fact, the feature sets of the ILL pair already convey information that captures their similarity (e.g., the "starring" marked in blue are shared twice). Therefore, by directly using feedforward networks, HMAN is able to effectively capture such knowledge.

5 Related Work

KG Alignment. Research on KG alignment can be categorized into two groups: monolingual and multilingual entity alignment. As for monolingual entity alignment, main approaches align two entities by computing string similarity of entity labels (Scharffe et al., 2009; Volz et al., 2009; Ngomo and Auer, 2011) or graph similarity (Raimond et al., 2008; Pershina et al., 2015; Azmy et al., 2019). Recently, Trsedya et al. (2019) proposed an embedding-based model that incorporates attribute values to learn the entity embeddings.

To match entities in different languages, Wang et al. (2012) leveraged only language-independent information to find possible links cross multilingual Wiki knowledge graphs. Recent studies learned cross-lingual embeddings of entities based on TransE (Bordes et al., 2013), which are then used to align entities across languages. Chen et al. (2018) designed a co-training algorithm to alternately learn multilingual entity and description embeddings. Wang et al. (2018) applied GCNs with the connectivity matrix defined on relations to embed entities from multilingual KGs into a unified low-dimensional space.

In this work, we also employ GCNs. However, in contrast to Wang et al. (2018), we regard relation features as input to our models. In addition, we investigate two different ways to capture relation and attribute features.

Multilingual Sentence Representations. Another line of research related to this work is aligning sentences in multiple languages. Recent works (Hermann and Blunsom, 2014; Conneau et al., 2018; Eriguchi et al., 2018) studied cross-lingual sentence classification via zero-shot learning. Johnson et al. (2017) proposed a sequence-to-sequence multilingual machine translation system where the encoder can be used to produce cross-lingual sentence embeddings (Artetxe and Schwenk, 2018). Recently, BERT (Devlin et al., 2019) has advanced the state-of-the-art on multiple natural language understanding tasks. Specifically, multilingual BERT enables learning representations of sentences under multilingual settings. We adopt BERT to produce cross-lingual representations of entity literal descriptions to capture their semantic relatedness, which benefits cross-lingual entity alignment.

6 Conclusion and Future Work

In this work, we focus on the task of cross-lingual entity alignment, which aims to discover mappings of equivalent entities in multilingual knowledge graphs. We proposed two GCN-based models and two uses of multilingual BERT to investigate how to better utilize multi-aspect information of entities provided by KGs, including topological connections, relations, attributes, and entity descriptions. Empirical results demonstrate that our best model consistently achieves state-of-the-art performance across all datasets. In the future, we would like to apply our methods to other multilingual datasets such as YAGO and BabelNet. Also, since literal descriptions of entities are not always available, we will investigate alternative ways to design graph-based models that can better capture structured knowledge for this task.

Abstract

We study cross-lingual stance detection, which aims to leverage labeled data in one language to identify the relative perspective (or stance) of a given document with respect to a claim in a different target language. In particular, we introduce a novel contrastive language adaptation approach applied to memory networks, which ensures accurate alignment of stances in the source and target languages, and can effectively deal with the challenge of limited labeled data in the target language. The evaluation results on public benchmark datasets and comparison against current state-of-the-art approaches demonstrate the effectiveness of our approach.

1 Introduction

The rise of social media has enabled the phenomenon of "fake news," which could target specific individuals and can be used for deceptive purposes (Lazer et al., 2018; Vosoughi et al., 2018). As manual fact-checking is a time-consuming and tedious process, computational approaches have been proposed as a possible alternative (Popat et al., 2017; Wang, 2017; Mihaylova et al., 2018, 2019), based on information sources such as social media (Ma et al., 2017), Wikipedia (Thorne et al., 2018), and knowledge bases (Huynh and Papotti, 2018). Fact-checking is a multi-step process (Vlachos and Riedel, 2014): (*i*) checking the reliability of media sources, (*ii*) retrieving potentially relevant documents from reliable sources as evidence for each target claim, (*iii*) predicting the stance of each document with respect to the target claim, and finally (*iv*) making a decision based on the stances from (*iii*) for all documents from (*ii*).

Here, we focus on stance detection which aims to identify the relative perspective of a document with respect to a claim, typically modeled using labels such as *agree*, *disagree*, *discuss*, and *unrelated*. Current approaches to stance detection (Bar-Haim et al., 2017; Dungs et al., 2018; Kochkina et al., 2018; Sobhani et al., 2017; Mohtarami et al., 2018) are well-studied in mono-lingual settings, in particular for English, but less attention has been paid to other languages and *cross-lingual* settings. This is partially due to domain differences and to the lack of training data in other languages.

We aim to bridge this gap by proposing a cross-lingual model for stance detection. Our model leverages resources of a source language (e.g., English) to train a model for a target language (e.g., Arabic). Furthermore, we propose a novel contrastive language adaptation approach that effectively aligns samples with similar or dissimilar stances across source and target languages using task-specific loss functions. We apply our language adaptation approach to memory networks (Sukhbaatar et al., 2015), which have been found effective for mono-lingual stance detection (Mohtarami et al., 2018).

Our model can explain its predictions about stances of documents against claims in a different/target language by extracting relevant text snippets from the documents of the target language as evidence. We use evidence extraction as a measure to evaluate the trasferability of our model. This is because more accurate evidence extraction indicates that the model can better learn semantic relations between claims and pieces of evidence, and consequently can better transfer knowledge to the target language.

The contributions of this paper are summarized as follows:

- We propose a novel language adaptation approach based on contrastive stance alignment that aligns the class labels between source and target languages for effective cross-lingual stance detection.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4442–4452, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- Our model is able to extract accurate text snippets as evidence to explain its predictions in the target language (results are in Section 4.2).
- To the best of our knowledge, this is the first work on cross-lingual stance detection.

We conducted our experiments on English (as source language) and Arabic (as target language). In particular, we used the Fake News Challenge dataset (Hanselowski et al., 2018) as source data and an Arabic benchmark dataset (Baly et al., 2018) as target data. The evaluation results have shown 2.7 and 4.0 absolute improvement in terms of macro-F1 and weighted accuracy for stance detection over the current state-of-the-art mono-lingual baseline, and 11.4, 14.9, 16.1, 12.9, and 13.1 points of absolute improvement in terms of precision at ranks 1–5 for extracting evidence snippets respectively. Furthermore, a key finding in our investigation is that, in contrast to other tasks (Devlin et al., 2019; Peters et al., 2018), pre-training with large amounts of source data is less effective for cross-lingual stance detection. We show that this is because pre-training can considerably bias the model toward the source language.

2 Method

Assume that we are given a training dataset for a source language, $\mathcal{D}_s$, which contains a set of triplets as follows: $\mathcal{D}_s = \left\{\left((c_i^s, d_i^s), y_i^s\right)\right\}_{i=1}^{N}$, where N is the number of source samples, (c_i^s, d_i^s) is a pair of claim c_i^s and document d_i^s, and $y_i^s \in Y$, $Y = \{agree, disagree, discuss, unrelated\}$, is the corresponding label indicating the stance of the document with respect to the claim. In addition, we are given a very small training dataset for the target language $\mathcal{D}_t = \left\{\left((c_i^t, d_i^t), y_i^t\right)\right\}_{i=1}^{M}$, where M ($M << N$) is the number of target samples, and (c_i^t, d_i^t) is a pair of claim and document in the target language with stance label $y_i^t \in Y$. In reality, (*i*) the size of the target dataset is very small, (*ii*) claims and documents in the source and target languages are from different domains, and (*iii*) the only commonality between the source and target datasets is in their stance labels, i.e., $y_i^s, y_i^t \in Y$.

We develop a language adaptation approach to effectively use the commonality between the source and the target datasets in their label space and to deal with the limited size of the target training data. We apply our language adaptation approach to end-to-end memory networks (Sukhbaatar et al., 2015) for cross-lingual stance detection.

We use memory networks as they have achieved state-of-the-art performance for mono-lingual stance detection (Mohtarami et al., 2018). However, our language adaptation approach can be applied to any other type of neural network. The architecture of our cross-lingual stance detection model is shown in Figure 1. It has two main components: (*i*) *Memory Networks* indicated with two dashed boxes for the source and the target languages, and (*ii*) *Contrastive Language Adaptation* component. In what follows, we first explain our memory network model for cross-lingual stance detection (Section 2.1) and then present our contrastive language adaptation approach (Section 2.2).

2.1 Memory Networks

Memory networks are designed to remember past information (Sukhbaatar et al., 2015) and have been successfully applied to NLP tasks ranging from dialog (Bordes et al., 2017) to question answering (Xiong et al., 2016) and mono-lingual stance detection (Mohtarami et al., 2018). They include components that can potentially use different learning models and inference strategies. Our source and target memory networks follow the same architecture as depicted in Figure 1:

A memory network consists of six components. The network takes as input a document d and a claim c and encodes them into the *input space* I. These representations are stored in the *memory* component M for future processing. The relevant parts of the input are identified in the *inference* component F, and used by the *generalization* component G to update the memory M. Finally, the *output* component O generates an output from the updated memory, and encodes it to a desired format in the *response* component R using a prediction function, e.g., `softmax` for classification tasks. We elaborate on these components below.

Input representation component I: It encodes documents and claims into corresponding representations. Each document d is divided into a sequence of paragraphs $X = (x_1, \ldots, x_l)$, where each x_j is encoded as $\mathbf{m}_j$ using an LSTM network, and as $\mathbf{n}_j$ using a CNN; these representations are stored in the memory component M. Note that while LSTMs are designed to capture and memorize their inputs (Tan et al., 2016), CNNs emphasize the local interaction between individual words in sequences, which is important for obtaining good representation (Kim, 2014).

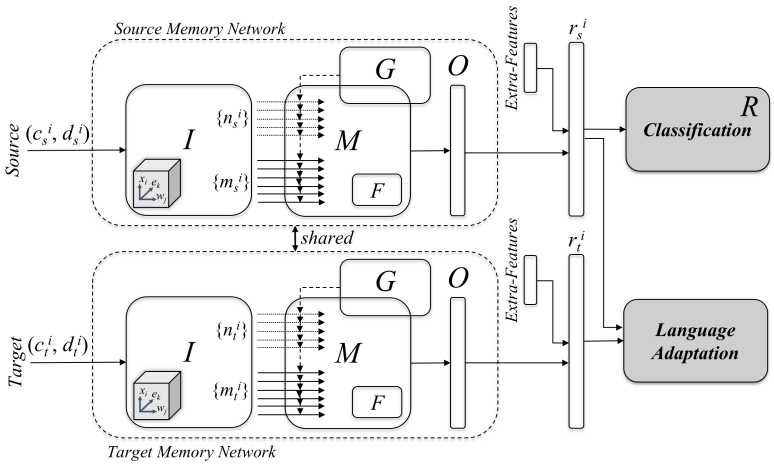

Figure 1: The architecture of our cross-lingual memory network for stance detection.

Thus, our I component uses both LSTM and CNN representations. It also uses separate LSTM and CNN with their own parameters to represent each input claim c as $\mathbf{c}_{lstm}$ and $\mathbf{c}_{cnn}$, respectively.

We consider each paragraph as a single piece of *evidence* because a paragraph usually represents a coherent argument, unified under one or more interrelated topics. We thus use the terms paragraph and evidence interchangeably.

Inference component F: Our inference component computes LSTM- and CNN-based similarity between each claim c and evidence x_j as follows:

$$P_j^{lstm} = \mathbf{c}_{lstm}{}^{\intercal} \times \mathbf{M} \times \mathbf{m}_j, \forall j$$
$$P_j^{cnn} = \mathbf{c}_{cnn}{}^{\intercal} \times \mathbf{M}' \times \mathbf{n}_j, \forall j$$

where $P_\cdot^{lstm}$ and $P_\cdot^{cnn}$ indicate claim-evidence similarity based on LSTM and CNN respectively, $\mathbf{c}_{lstm} \in \mathbb{R}^q$ and $\mathbf{m}_j \in \mathbb{R}^d$ are LSTM representations of c and x_j respectively, $\mathbf{c}_{cnn} \in \mathbb{R}^{q'}$ and $\mathbf{n}_j \in \mathbb{R}^{d'}$ are the corresponding CNN representations, and $\mathbf{M} \in \mathbb{R}^{q \times d}$ and $\mathbf{M}' \in \mathbb{R}^{q' \times d'}$ are similarity matrices trained to map claims and paragraphs into the same space with respect to their LSTM and CNN representations. The rationale behind using these similarity matrices is that, in the memory network, we seek a transformation of the input claim, i.e., $\mathbf{c}^{\intercal} \times \mathbf{M}$, in order to obtain the closest evidence to the claim.

Additionally, we compute another semantic similarity vector, P_j^{tfidf}, by applying a cosine similarity between the TF.IDF (Spärck Jones, 2004) representation of x_j and c. This is particularly useful for stance detection as it can help filtering out unrelated pieces of evidence.

Memory M and Generalization G components: Our memory component stores representations and the generalization component improves their quality by filtering out unrelated evidence. For example, the LSTM representations of paragraphs, $\mathbf{m}_j, \forall j$, are updated using the claim-evidence similarity P_j^{tfidf} as follows: $\mathbf{m}_j = \mathbf{m}_j \odot P_j^{tfidf}, \forall j$. This transformation will help filter out unrelated evidence with respect to claims. The updated $\mathbf{m}_j$ in conjunction with $\mathbf{c}_{lstm}$ are used by the inference component F to compute $P_j^{lstm}, \forall j$ as we explained above. Then, P_j^{lstm} are in turn used to update CNN representations in memory as follows: $\mathbf{n}_j = \mathbf{n}_j \odot P_j^{lstm}, \forall j$. Finally, the updated $\mathbf{n}_j$ and $\mathbf{c}_{cnn}$ are used to compute P_j^{cnn}.

Output representation component O: This component computes the output of the memory M by concatenating the average vector of the updated $\mathbf{n}_j$ with the *maximum* and *average* of claim-evidence similarity vectors P_j^{tfidf}, P_j^{lstm} and P_j^{cnn}. The maximum helps to identify parts of documents that are most similar to claims, while the average estimates the overall document-claim similarity.

Response generation component R: This component computes the final stance of a document with respect to a claim. For this, the output of component O is concatenated with $\mathbf{c}_{lstm}$ and $\mathbf{c}_{cnn}$ and fed into a `softmax` to predict the stance of the document with respect to the claim.

All the memory network parameters, including those of CNN and LSTM in the I component, the similarity matrices $\mathbf{M}$ and $\mathbf{M}'$ in F, and the classifier parameters in R, are jointly learned during the training process with our language adaptation.

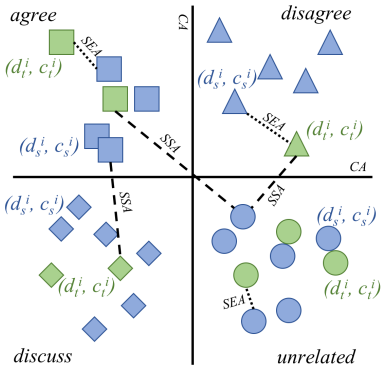

Figure 2: Illustration of stance equal alignment (SEA), stance separation alignment (SSA), and classification alignment (CA) constraints. Different shapes indicate different stance labels and colors specify source (*blue*) and target (*green*) languages.

2.2 Contrastive Language Adaptation

Memory networks are effective for stance detection in mono-lingual settings (Mohtarami et al., 2018) when there is sufficient training data. However, we show that these models have limited transferability to target languages with limited data. This could be due to discrepancy between the underlying data distributions in the source and target languages. We show that the performance of these networks can be trivially increased when the model, pre-trained on source data, is fine-tuned using small amounts of labeled target data. We further develop contrastive language adaptation that can exploit the labeled source data to perform well on target data.

Our contrastive adaptation approach:

- encourages pairs (d_i^s, c_i^s) from the source language and (d_i^t, c_i^t) from the target language with the same stance labels (i.e., $y_i^s = y_i^t$) to be nearby in the embedding space. We call this mapping *Stance Equal Alignment* (SEA), illustrated with dotted lines in Figure 2. Note that documents and claims in the two languages are often semantically different and are not corresponding translations of each other.
- encourages pairs (d_i^s, c_i^s) from the source language and (d_i^t, c_i^t) from the target language with different stance labels (i.e., $y_i^s \neq y_i^t$) to be far apart in the embedding space. We call this mapping *Stance Separation Alignment* (SSA), shown with dashed lines in Figure 2.
- encourages pairs (d_i^s, c_i^s) from the source language and (d_i^t, c_i^t) from the target language to be correctly classified as $(d_i^s, c_i^s) \rightarrow y_i^s$ and $(d_i^t, c_i^t) \rightarrow y_i^t$. We call this *Classification Alignment* (CA), solid lines in Figure 2.

Algorithm 1. Cross-Lingual Stance Detection Model

Inputs:

- $\{(d_i^s, c_i^s), y_i^s\}_1^{l^s}$: set of pairs of documents d_i^s and claims c_i^s in the source language, where $y_i^s \in Y$, $Y = \{agree, disagree, discuss, unrelated\}$
- $\{(d_i^t, c_i^t), y_i^t\}_1^{l^t}$: small set of pairs of documents d_i^t and claims c_i^t in the target language with $y_i^t \in Y$

Output:

- $\{(d_i^t, c_i^t) \rightarrow y_i^t\}_{l^t+1}^{M}$: assign stance labels $y_i^t \in Y$ to given unlabeled target pairs

Cross-Lingual model:

1 Create the sets $\{\big((d_i^s, c_i^s), (d_j^t, c_j^t)\big), (y_i^s, y_i')\}$ and $\{\big((d_j^t, c_j^t), (d_i^s, c_i^s)\big), (y_j^t, y_j')\}$, where $y' = 1$ if the source and the target have the same label, and $y' = 0$ otherwise.
2 **Loop for** e **epochs:**
3 pass (d_i^s, c_i^s) to the source memory network to create its representation r_i^s.
4 pass (d_j^t, c_j^t) to the target memory network to create its representation r_j^t.
5 pass (r_i^s, y_i^s) to the classification to compute its classification loss $L_{CA_i^s}$.
6 pass (r_i^s, r_i^t, y'^i) to the language adaptation to compute the stance alignment loss L_{CSA_i}.
7 compute total loss $L_i^s = (1-\alpha)L_{CA_i^s} + \alpha L_{CSA_i}$.
8 repeat steps 2-7 with a change in step 5 by passing the target sample (r_j^t, y_j^t) to the classification instead of the source sample, and compute its L_j^t in step 7.
9 jointly optimize all parameters of the model using the average loss $L = \text{mean}(\{L_i^s\} + \{L_j^t\})$.

Table 1: Cross-lingual stance detection model.

We make complete use of the stance labels in the cross-lingual setting by parameterizing our model according to the distance between the source and the target samples in the embedding space.

For stance equal alignment (SEA) constraint, the objective is to minimize the distance between pairs of source and target data with the same stance labels. We achieve this using the following loss:

$$L_{SEA} = \begin{cases} \mathtt{D}\big(\mathtt{g}(d_i^s, c_i^s) - \mathtt{g}(d_i^t, c_i^t)\big)^2, & y_i^s = y_i^t \\ 0, & \text{otherwise,} \end{cases} \quad (1)$$

where $\mathtt{g}$ maps its input pair to an embedding space using our memory network or any mono-lingual model, and $\mathtt{D}$ computes Euclidean distance.

For stance separation alignment (SSA), the goal is to maximize the distance between pairs with different stance labels. We use the following loss:

$$L_{SSA} = \begin{cases} \max\Big(0, m - \\ \qquad \mathtt{D}\big(\mathtt{g}(d_i^s, c_i^s) - \mathtt{g}(d_i^t, c_i^t)\big)^2\Big), & y_i^s \neq y_i^t \\ 0, & \text{otherwise,} \end{cases} \quad (2)$$

where we maximize the distance between pairs with different stance labels up to the margin m.

The margin parameter m specifies the extent of separability in the embedding space.

We can further use any classification loss to enforce classification alignment (CA). We use categorical cross-entropy and call it *Classification Alignment* loss L_{CA}.

We develop our overall language adaptation loss, named *Contrastive Stance Alignment* loss, L_{CSA}, by combining L_{SEA} and L_{SSA} as follows:

$$L_{CSA} = L_{SEA} + L_{SSA}. \quad (3)$$

Finally, the total loss of our cross-lingual stance detection model is defined as follows:

$$L = (1 - \alpha)L_{CA} + \alpha L_{CSA}, \quad (4)$$

where the α parameter controls the balance between classification and language adaptation losses, which we optimize on the validation dataset.

Information Flow: Our overall cross-lingual model for stance detection is shown in Figure 1, and a summary of the algorithm is presented in Table 1. As Figure 1 shows, each source and target pairs are passed to the source and to the target memory networks to obtain their corresponding representations (Lines 3-4 in Table 1). The source representation and its gold stance label are passed to the classifier to compute the classification loss (Line 5). In addition, the source and the target representations in conjunction with a binary parameter (y', which is 1 if the source and the target have the same stance label, and 0 otherwise) are passed to the language adaptation component to compute the contrastive stance alignment loss L_{CSA} (Line 6). Finally, the total loss is computed based on Equation (4) (Line 7).

The classifier also uses labeled target samples to create a shared embedding space and to fine-tune itself with respect to the target language. For this purpose, we repeat the above steps by switching the target and the source pipelines (Line 8). Finally, we compute the average of all losses and we use it to optimize the parameters of our model (Line 9).

Pre-training for Language Adaptation: Pre-training has been found effective in many language adaptation settings (Tzeng et al., 2017). To investigate the effect of pre-training, we first pre-train the source memory network and the classifier using $\mathcal{D}_s$ (only the top pipeline in Figure 1), and then we apply language adaptation with the full model.

3 Experiments

Data and Settings. As source data, we use the Fake News Challenge dataset[1] which contains 75.4K claim-document pairs in English with {*agree*, *disagree*, *discuss*, *unrelated*} as stance labels. As target dataset, we use 3K Arabic claim-document pairs developed in (Baly et al., 2018).[2]

We perform 5-fold cross-validation on the Arabic dataset, using each fold in turn for testing, and keeping 80% of the remaining data for training and 20% for development. We use 300-dimensional pretrained cross-lingual Wikipedia word embeddings from MUSE (Lample et al., 2018). We use 300-dimensional units for the LSTM and 100 feature maps with filter width of 5 for the CNN. We consider the first 9 paragraphs per document, which is the median number of paragraphs in source documents. We optimize all hyper-parameters on validation data using *Adam* (Kingma and Ba, 2014).

Evaluation Measures. We use the followings:

- *Accuracy*: The fraction of correctly classified examples. For multi-class classification, accuracy is equivalent to micro-average F_1 (Manning et al., 2008).
- *Macro-F_1*: The average of F_1 scores that were calculated for each class separately.
- *Weighted Accuracy*: This is a hierarchical metric, which first awards 0.25 points if the model correctly predicts a document-claim pair as *related*[3] or *unrelated*. If it is *related*, 0.75 additional points are assigned if the model correctly predicts the pair as *agree*, *disagree*, or *discuss*. The goal of this weighting schema is to balance out the large number of *unrelated* examples (Hanselowski et al., 2018).

Baselines. We consider the following baselines:

- **Heuristic**: Given the imbalanced nature of our data, we use two heuristic baselines where all test examples are labeled as *unrelated* or *agree*. The former is a majority class baseline favoring accuracy and macro-F_1, while the latter is better for weighted accuracy.
- **Gradient Boosting** (Baly et al., 2018): This is a Gradient Boosting classifier with n-gram features as well as indicators for refutation and polarity.

10. ADMN *(adversarial)*	58.6	58.4	43.4	60.2 / 16.1 / 24.2 / 72.9
11. CLMN *(contrastive)*	**61.3**	71.6	**45.2**	65.1 / 11.6 / 20.5 / 83.7

Table 2: Evaluation results on the target Arabic test dataset.

- **TFMLP** (Riedel et al., 2017): This is an MLP with normalized bag-of-words features enriched with a single TF.IDF-based similarity feature for each claim-document pair.
- **EnrichedMLP** (Hanselowski et al., 2018): This model combines five MLPs, each with six hidden layers and advanced features from topic models, latent semantic analysis, etc.
- **Ensemble** (Baird et al., 2017): It is an ensemble based on weighted average of a deep convolutional neural network and a gradient-boosted decision tree - the best model at the Fake News Challenge.
- **Mono-lingual Memory Network** (Mohtarami et al., 2018): This model is the current state-of-the-art for stance detection on our source dataset. It is an end-to-end memory network which incorporates both CNN and LSTM for prediction.
- **Adversarial Memory Network**: We use adversarial domain adaptation (Ganin et al., 2016) instead of contrastive language adaptation in our cross-lingual memory network.

Results. Table 2 shows the performance of all models on the target *Arabic* test set. The All-*unrelated* and All-*agree* baselines perform poorly across evaluation measures; All-*unrelated* performs better than All-*agree* because *unrelated* is the dominant class ($\sim 68\%$ of examples).

Rows 3–6 show that *Gradient Boosting* and *EnrichedMLP* yield similar results, while *TFMLP* performs the worst. We attribute this to the advanced features used in the two former models. *Gradient Boosting* has better accuracy due to its better performance on the dominant class. Note that *Ensemble* performs poorly because of the limited labeled data, which is insufficient to train a good CNN model.

Rows 7–9 show the results for the mono-lingual memory network (MN) from (Mohtarami et al., 2018). The performance of this model when trained on Arabic data only (row 7) is comparable to previous baselines (rows 3–6). But, it shows poor performance if trained on source English data and tested on Arabic test data (row 8). The model performs best (in terms of weighted accuracy and F1) if first pretrained on source data and then fine-tuned on target training data (row 9).

Row 10 in Table 2 shows the results for adversarial memory network (ADMN). It improves the performance of mono-lingual MN on weighted accuracy and F1, but its accuracy significantly drops. This is because adversarial approaches give higher weights to samples of the majority class (i.e., *unrelated*) which makes classification more challenging for the discriminator (Montahaei et al., 2018).

Row 11 shows the results for our cross-lingual memory network (CLMN) with ($\alpha = .7$); α controls the balance between classification and language adaptation losses (tuned using validation data). CLMN outperforms other baselines in terms of weighted accuracy and F1 while showing comparable accuracy. We show that the improvement is due to language adaptation being able to effectively transfer knowledge from the source to target language (see Section 4.2).

The last column in Table 2 shows that *unrelated* examples are the easiest ones. Also, although the *agree* and the *discuss* classes have roughly the same size, i.e., 474 and 409 examples, respectively, the results for *agree* are notably higher. This is mainly because the documents that discuss a claim often share the same topic with the claim, but they do not take a stance. In addition, the *disagree* examples are the most difficult ones; this class is by far the smallest one, with only 87 examples.

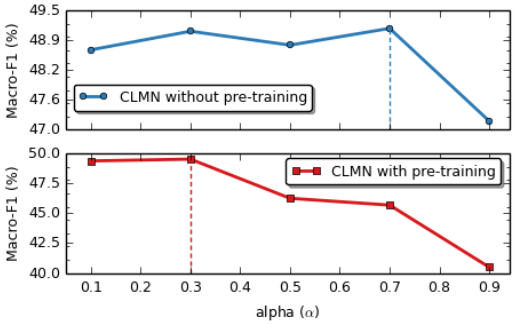

Figure 3: Impact of pretraining on the macro-F1 across α values. The Y axes show average results on the validation datasets with 5-fold cross-validation.

Methods	Weigh. Acc.	Acc.	Macro-F1
CLMN *(with pretraining)*	60.2	69.8	43.2
CLMN *(without pretraining)*	**61.3**	**71.6**	**45.2**

Table 3: CLMN results on the target test dataset.

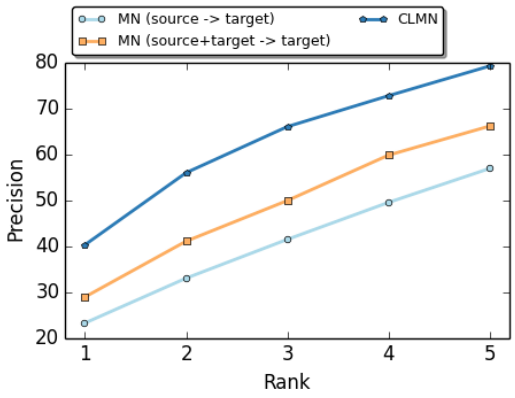
4 Discussion

4.1 Effect of Pretraining

Table 3 shows CLMN without pretraining ($\alpha = .7$) performs better on target test data than CLMN with pretraining ($\alpha = .3$), recall that α controls the balance between classification and language adaptation losses. Our further analysis shows that pretraining biases the model toward the source language. Figure 3 shows the impact of pretraining on macro-average F1 score for CLMN across different values of α on validation data. While the model without pretraining achieves its best performance with a large α ($\alpha = 0.7$), the model with pretraining performs well with a smaller α ($\alpha = 0.3$). This suggests that our model can capture the characteristics of the source dataset via pretraining when using small supervision from language adaptation (i.e., small α). However, pretraining introduces bias to the source space and the performance drops when larger weights are given to language adaptation; see the results with pretraining in Figure 3.

4.2 Assessment of Model Transferability

The improvements of CLMN model over the monolingual MN models that use the target only, the source only, or both the target and the source (rows 7–9 in Table 2 respectively) indicate its transferability. We further estimate transferability by measuring the accuracy of the models in extracting evidence that support their predictions. A more accurate model should better transfer knowledge to the target language by accurately learning the relations between claims and pieces of evidence.



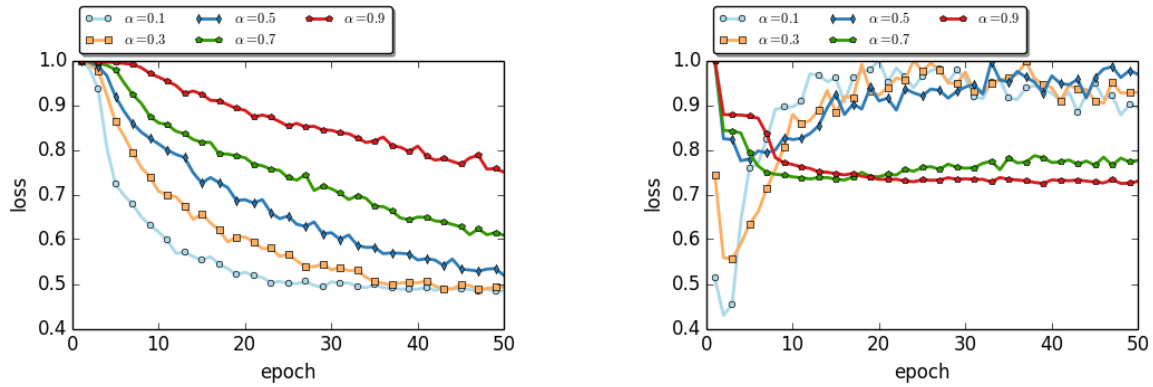


Figure 4: Transferability of our cross-lingual model.

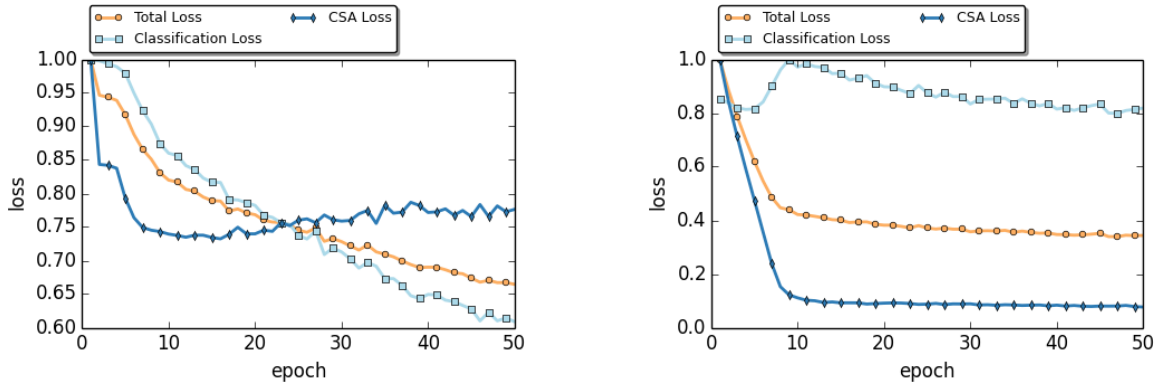
Our target data has annotations (in terms of binary labels) for each piece of evidence (here paragraph) that indicate whether it is a rationale for the *agree* or for the *disagree* class. Moreover, our inference component (I) has a claim-evidence similarity vector, P_j^{cnn}, which can be used to rank pieces of evidence from the target document against the target claim.

We use the gold data and the rankings produced by our model in order to measure its precision in extracting evidence that supports its predictions. Figure 4 shows that our CLMN model achieves precision of 40.2, 55.9, 66.0, 72.7, and 79.2 at ranks 1–5 respectively, and outperforms mono-lingual MN models. This indicates that CLMN can better generalize and transfer knowledge to the target language through learning relations between pieces of evidence and claims.

4.3 Effect of Language Adaptation



Figures 5a and 5b show the classification (L_{CA}) versus contrastive stance (L_{CSA}) losses obtained from our best language adaptation model (i.e., without pretraining) across training epochs and α values. The results are averaged on validation data when performing 5-fold cross-validation. As Figure 5a shows, there is greater reduction in the classification loss for smaller values of α, i.e., when classification loss contributes more to the overall loss; see Equation (4). On the other hand, Figure 5b shows that the CSA loss decreases with larger values of α as the model pays more attention to the CSA loss; see the red and green lines in Figure 5b. These results indicate that our language adaptation model can find a good balance between the classification loss and the CSA loss, with the value of $\alpha = .7$ yielding the best performance.

(a) Classification loss

(b) CSA loss

Figure 5: Classification vs. contrastive stance alignment (CSA) losses across training epochs and α values.

(a) without pretraining

(b) with pretraining

Figure 6: Classification loss vs. contrastive stance alignment loss (CSA) vs. total loss during training.

Figure 6 compares the classification L_{CA}, contrastive stance L_{CSA}, and total L losses obtained by our CLMN model on the validation dataset across training epochs when the loss weight parameter (α) is set to its best value. Figures 6a and 6b show the results without and with pretraining for $\alpha = .7$ and $\alpha = .3$ respectively. Without pretraining (Figure 6a), the classification (light-blue line) and CSA (dark-blue line) losses both decrease up to epoch 20, after which the classification loss keeps decreasing, but the CSA loss starts increasing. With pretraining (Figure 6b), the CSA loss rapidly decreases for the first 10 epochs (even though it has a small effect as $\alpha = .3$), and then continues with a smooth trend. This is because, during the initial training epochs, the model is biased to the *source* embedding space due to pretraining, and therefore the source and the target examples are far from each other. Then, our language adaptation model aligns the source and the target examples to form a much better shared embedding space and this alignment strategy yields a rapid decrease of the CSA loss in the first few epochs. Yet, in contrast to the CSA loss, the classification loss increases in the first few epochs. This is because the model enforces alignment between the source and the target samples due to the large distances. Finally, the total loss (orange line) indicates a good balance between the classification and the language adaptation losses, and it consistently decreases during training.

5 Related Work

Domain Adaptation. Previous work has presented several domain adaptation techniques. Unsupervised domain adaptation approaches (Ganin and Lempitsky, 2015; Long et al., 2016; Muandet et al., 2013; Gong et al., 2012) attempt to align the distribution of features in the embedding space mapped from the source and the target domains.

A limitation of such approaches is that, even with perfect alignment, there is no guarantee that the same-label examples from different domains would map nearby in the embedding space. Supervised domain adaptation (Daumé and Marcu, 2006; Becker et al., 2013; Bergamo and Torresani, 2010) attempts to encourage same-label examples from different domains to map nearby in the embedding space. While supervised approaches perform better than unsupervised ones, recent work (Motiian et al., 2017) has demonstrated superior performance by additionally encouraging class separation, meaning that examples from different domains and with different labels should be projected as far apart as possible in the embedding space. Here, we combined both types of alignments for cross-lingual stance detection.

Stance Detection. This is an important component for automatic fact-checking systems and veracity inference (Nadeem et al., 2019; Zhang et al., 2019; Atanasova et al., 2019). There have been some nuances in the way researchers have defined the stance detection task. Mohammad et al. (2016) and Zarrella and Marsh (2016) worked on stances regarding target propositions, e.g., entities, concepts or events, as *in-favor*, *against*, or *neither*. Most commonly, stance detection has been defined with respect to a *claim* as *agree*, *disagree*, *discuss* or *unrelated* (Hanselowski et al., 2018; Xu et al., 2018; Fang et al., 2019). Previous work mostly developed the models with rich hand-crafted features such as words, word embeddings, and sentiment lexicons (Riedel et al., 2017; Baird et al., 2017; Hanselowski et al., 2018). More recently, Mohtarami et al. (2018) presented a mono-lingual and feature-light memory network for stance detection. In this paper, we built on this work to extend previous efforts in stance detection to a cross-lingual setting, achieving the state-of-the-art result on the target language.

6 Conclusion and Future Work

We proposed an effective language adaptation approach to align class labels in source and target languages for accurate cross-lingual stance detection. Moreover, we investigated the behavior of our model in details and we have shown that it offers sizable performance gains over a number of competing approaches. In future, we will extend our language adaptation model to document retrieval and check-worthy claim detection tasks.

Jointly Learning to Align and Translate with Transformer Models

Sarthak Garg Stephan Peitz Udhyakumar Nallasamy Matthias Paulik

Abstract

The state of the art in machine translation (MT) is governed by neural approaches, which typically provide superior translation accuracy over statistical approaches. However, on the closely related task of word alignment, traditional statistical word alignment models often remain the go-to solution. In this paper, we present an approach to train a Transformer model to produce both accurate translations and alignments. We extract discrete alignments from the attention probabilities learnt during regular neural machine translation model training and leverage them in a multi-task framework to optimize towards translation and alignment objectives. We demonstrate that our approach produces competitive results compared to GIZA++ trained IBM alignment models without sacrificing translation accuracy and outperforms previous attempts on Transformer model based word alignment. Finally, by incorporating IBM model alignments into our multi-task training, we report significantly better alignment accuracies compared to GIZA++ on three publicly available data sets. Our implementation has been open-sourced[1].

1 Introduction

Neural machine translation (NMT) constitutes the state of the art in MT, with the Transformer model architecture (Vaswani et al., 2017) beating other neural architectures in competitive MT evaluations. The attention mechanism used in NMT models was motivated by the need to model word alignments, however it is now well known that the attention probabilities can differ significantly from word alignments in the traditional sense (Koehn and Knowles, 2017), since attending to the context words rather than the aligned source words might be helpful for translation. The presence of multi-layer, multi-head attention mechanisms in the Transformer model further complicate interpreting the attention probabilities and extracting high quality discrete alignments from them.

Finding source to target word alignments has many applications in the context of MT. A straightforward application of word alignments is to generate bilingual lexica from parallel corpora. Word alignments have also been used for external dictionary assisted translation (Chatterjee et al., 2017; Alkhouli et al., 2018; Arthur et al., 2016) to improve translation of low frequency words or to comply with certain terminology guidelines. Documents and webpages often contain word annotations such as formatting styles and hyperlinks, which need to be preserved in the translation. In such cases, word alignments can be used to transfer these annotations from the source sentence to its translation. In user facing translation services, providing word alignments as additional information to the users might improve their trust and confidence, and also help them to diagnose problems such as under-translation (Tu et al., 2016).

In this work, we introduce an approach that teaches Transformer models to produce translations and interpretable alignments simultaneously:

- We use a multi-task loss function combining negative log likelihood (NLL) loss used in regular NMT model training and an alignment loss supervising one attention head to learn alignments (Section 4.2).
- Conditioning on past target context is essential for maintaining the auto-regressive property for translation but can be limiting for alignment. We alleviate this problem by conditioning the different components of our multi-task objective on different amounts of context (Section 4.3).

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4453–4462, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

- We demonstrate that the system can be supervised using seed alignments obtained by carefully averaging the attention probabilities of a regular NMT model (Section 4.1) or alignments obtained from statistical alignment tools (Section 4.4)

We show that our model outperforms previous neural approaches (Peter et al., 2017; Zenkel et al., 2019) and statistical alignment models (Och and Ney, 2003) in terms of alignment accuracy without suffering any degradation of translation accuracy.

2 Preliminaries

2.1 Word Alignment Task

Given a sentence $f_1^J = f_1, \ldots, f_j, \ldots f_J$ in the source language *and* its translation $e_1^I = e_1, \ldots, e_i, \ldots e_I$ in the target language, an alignment $\mathcal{A}$ is defined as a subset of the Cartesian product of the word positions (Och and Ney, 2003).

$$\mathcal{A} \subseteq \{(j, i) : j = 1, \ldots, J; i = 1, \ldots, I\} \quad (1)$$

The word alignment task aims to find a discrete alignment representing a many-to-many mapping from the source words to their corresponding translations in the target sentence.

2.2 Transformer Model

The Transformer model (Vaswani et al., 2017) is an encoder-decoder model that only relies on attention for computing the contextual representations for source and target sentences. Both the encoder and decoder are composed of multiple layers, each of which includes a multi-head self-attention and a feed-forward sub-layer. Layers in the decoder additionally apply a multi-head encoder-decoder attention between the self-attention and the feed-forward sub-layers. To maintain the auto-regressive property, the self-attention sub-layer in the decoder attends to the representations of only the *past* tokens computed by the lower layer.

In this work, we will be focusing on guiding the encoder-decoder attention sub-layer in the decoder. Let d_{emb}, d_k, d_v, N denote the embedding dimension, dimensions of the key and value projections and number of heads, respectively. As described in Vaswani et al. (2017), for this sub-layer, the output of the previous decoder layer corresponding to the i^{th} target token is used as a query vector $\mathbf{q}^i \in \mathbb{R}^{1 \times d_{emb}}$ and the encoder output for all the source tokens are packed together as the value $V \in \mathbb{R}^{J \times d_{emb}}$ and key $K \in \mathbb{R}^{J \times d_{emb}}$ matrices. To compute the output $\mathcal{M}(\mathbf{q}^i, K, V)$, N heads first project the query vector and the key and value matrices into different subspaces, compute attention in their own subspaces, aggregate their outputs and project back to the original space:

$$\tilde{\mathbf{q}}_n^i = \mathbf{q}^i W_n^Q, \tilde{K}_n = K W_n^K, \tilde{V}_n = V W_n^V \quad (2)$$

$$H_n^i = \text{Attention}(\tilde{\mathbf{q}}_n^i, \tilde{K}_n, \tilde{V}_n) \quad (3)$$

$$\mathcal{M}(\mathbf{q}^i, K, V) = \text{Concat}(H_1^i, \ldots, H_N^i) W^O, \quad (4)$$

where the projection matrices W_n^Q, W_n^K, W_n^V and W^O are learnt parameters of the n^{th} head. Each head employs a scaled dot-product attention:

$$\text{Attention}(\tilde{\mathbf{q}}_n^i, \tilde{K}_n, \tilde{V}_n) = \mathbf{a}_n^i \tilde{V}_n, \quad (5)$$

$$\text{where } \mathbf{a}_n^i = \text{softmax}(\frac{\tilde{\mathbf{q}}_n^i \tilde{K}_n^T}{\sqrt{d_k}}). \quad (6)$$

The vector $\mathbf{a}_n^i \in \mathbb{R}^{1 \times J}$ denotes the attention probabilities for the i^{th} target token over all the source tokens, computed by the n^{th} attention head. For any particular head, an attention matrix $A_{I \times J}$ can be constructed by grouping together the vectors $\mathbf{a}_n^i$ corresponding to all the target tokens. In the following sections, we analyze the quality of alignments that can be extracted from these attention matrices $A_{I \times J}$ and describe how they can be effectively supervised to learn word alignments.

3 Baseline Methods

A common baseline approach to extract word alignments from a regular NMT trained Transformer, is to average over all attention matrices $A_{I \times J}$ computed across all layers and heads. The resulting matrix gives a probability distribution over all source tokens for each target token. This distribution is then converted to a discrete alignment by aligning each target word to the corresponding source word with the highest attention probability.

Peter et al. (2017) guide the attention probabilities to be close to the alignments obtained from statistical MT toolkits by imposing an additional loss based on the distance between the alignment and attention distributions. They get improvements in alignment accuracy over previous works based on guided alignment training by feeding the *current* target word to the attention module, providing it more context about the target sentence.

Zenkel et al. (2019) proposed an method that does not rely on alignments from external toolkits for training. They instead add an extra attention layer on top of the Transformer architecture and directly optimize its activations towards predicting the given target word.

All the above methods involve training models for both the directions to get bidirectional alignments. These bidirectional alignments are then merged using the `grow diagonal` heuristic (Koehn et al., 2005).

4 Proposed Method

4.1 Averaging Layer-wise Attention Scores

The attention heads in a single layer are symmetrical, but the different layers themselves can learn drastically different alignments. To better understand the behavior of the encoder-decoder attention learnt at different layers, we average the attention matrices computed across all heads within each layer and evaluate the obtained alignments. We show that the attention probabilities from the penultimate layer naturally tend to learn alignments and provide significantly better results compared to naively averaging across all layers (cf. Section 5.3). For the rest of the paper, we refer to the former method as the layer average baseline.

4.2 Multi-task Learning

Translation and alignment tasks are very closely related. NMT models with attention (Bahdanau et al., 2015) have also shown to learn alignments in the intermediate attention layer. A neural model receiving supervision from given translations *and* given alignments can therefore benefit from multi-task learning by exploiting the correlations between these two tasks.

Annotating word alignments is a laborious and expensive task, but the layer average baseline described in Section 4.1 is able to generate reasonably good alignments in an unsupervised manner. We thus use the alignments generated by the layer average baseline as labels for supervising our model. We first convert the alignments into a probability distribution over source tokens for every target token. Let $G_{I\times J}$ denote a 0-1 matrix such that $G_{i,j} = 1$ if the j^{th} source token is aligned to the i^{th} target token. We simply normalize the rows of matrix G corresponding to target tokens that are aligned to at least one source token to get a matrix G^p. As described in Section 2.2, the Transformer model computes multiple attention probability distributions over source tokens for every target token across different heads and layers of the network. Since we observed that the attention probabilities from the penultimate layer most naturally tend to learn alignments (Section 5.3), we arbitrarily select one head from the penultimate layer (subsequently referred to as the alignment head) and supervise its attention probability distribution to be close to the labeled alignment distribution (G^p). Let $A_{I\times J}$ denote the attention matrix computed by the alignment head. For every target word i, we minimize the Kullback-Leibler divergence between G^p_i and A_i which is equivalent to optimizing the following cross-entropy loss $\mathcal{L}_a$

$$\mathcal{L}_a(A) = -\frac{1}{I}\sum_{i=1}^{I}\sum_{j=1}^{J} G^p_{i,j}\log(A_{i,j}). \quad (7)$$

The motivation behind supervising one head is that it gives the model the flexibility to either use the representation computed by the alignment head, or depend more on the representations computed by other heads. We train our model to minimize $\mathcal{L}_a$ in conjunction with the standard NLL translation loss $\mathcal{L}_t$. The overall loss $\mathcal{L}$ is:

$$\mathcal{L} = \mathcal{L}_t + \lambda\mathcal{L}_a(A), \quad (8)$$

where λ is a hyperparameter.

4.3 Providing Full Target Context

The Transformer decoder computes the probability of the next target token conditioned on the past target tokens and all source tokens. This is implemented by masking the self attention probabilities, i.e. while computing the representation for the i^{th} target token, the decoder can only self-attend to the representations of $\{1, 2 \ldots i-1\}$ tokens from the previous layer. This auto-regressive behavior of the decoder is crucial for the model to represent a valid probability distribution over the target sentence. However, conditioning on just the past target tokens is limiting for the alignment task. As described in Section 4.2, the alignment head is trained to model the alignment distribution for the i^{th} target token given only the past target tokens and all source tokens. Since the alignment head does not know the identity of the next target token, it becomes difficult for it to learn this token's alignment to the source tokens. Previous work has also identified this problem and alleviate

it by feeding the target token to be aligned as an input to the module computing the alignment (Peter et al., 2017), or forcing the module to predict the target token (Zenkel et al., 2019) or its properties, e.g. POS tags (Li et al., 2018). Feeding the next target token assumes that we know it in advance and thus calls for separate translation and alignment models. Forcing the alignment module to predict target token's properties helps but still passes the information of the target token in an indirect manner. We overcome these limitations by conditioning the two components of our loss function on different amounts of context. The NLL loss $\mathcal{L}_t$ is conditioned on the past target tokens to preserve the auto-regressive property:

$$\mathcal{L}_t = -\frac{1}{I}\sum_{i=1}^{I}\log(p(e_i|f_1^J, e_1^{i-1})). \quad (9)$$

However, the alignment loss $\mathcal{L}_a^{'}$ is now conditioned on the whole target sentence:

$$\mathcal{L}_a^{'} = \mathcal{L}_a(A|f_1^J, e_1^I). \quad (10)$$

This is implemented by executing two forward passes of the decoder model, one with the masking of the future target tokens for computing the NLL loss $\mathcal{L}_t$ and the other one with no masking for computing the alignment loss $\mathcal{L}_a^{'}$from the alignment head. Although this formulation forces the network to learn representations adapting to both full and partial target context, Section 5.5 shows that this approach does not degrade the translation quality while improving the alignment accuracy.

4.4 Alignment Training Data

Our method described so far does not rely on alignments from external statistical toolkits but performs self-training on alignments extracted from the layer average baseline. However, GIZA++ provides a robust method to compute accurate alignments. If achieving better alignment accuracy is paramount, then our multi-task framework can also leverage alignments from GIZA++ to produce even better alignment accuracy (Section 5.4). In this setting we use the GIZA++ alignments as labels instead of those obtained from the layer average baseline for supervising the alignment head.

5 Experiments

5.1 Setup

Our experiments show that our proposed approach is able to achieve state-of-the-art results in terms of alignment *and* maintain the same translation performance. In the following, we describe two setups to compare with previously established state-of-the-art results.

For all setups and models used in this work, we learn a joint source and target Byte-Pair-Encoding (BPE, Sennrich et al. (2016)) with 32k merge operations. We observe that even for statistical alignment models sub-word units are beneficial. To convert the alignments from sub-word-level back to word-level, we consider each target word as being aligned to a source word if an alignment between any of the target sub-words and source sub-words exists.

The alignment quality is evaluated by using the alignment error rate (AER) introduced in (Och and Ney, 2000). Significance of the differences in AER between two models is tested using a two-sided Wilcoxon signed-rank test ($\alpha = 0.1\%$).

5.1.1 Alignment Task

The purpose of the this task is to fairly compare with state-of-the-art results in terms of alignment quality and perform a hyperparameter search. We use the same experimental setup as described in (Zenkel et al., 2019). The authors provide pre-processing and scoring scripts[2] for three different datasets: Romanian→English, English→French and German→English. Training data and test data for Romanian→English and English→French are provided by the NAACL'03 *Building and Using Parallel Texts* word alignment shared task[3] (Mihalcea and Pedersen, 2003). The Romanian→English training data are augmented by the Europarl v8 corpus increasing the amount of parallel sentences from 49k to 0.4M. For German→English we use the Europarl v7 corpus as training data and the gold alignments[4] provided by Vilar et al. (2006). The reference alignments were created by randomly selecting a subset of the Europarl v7 corpus and manually annotating them following the guidelines suggested in (Och

[2] https://github.com/lilt/alignment-scripts

[3] http://web.eecs.umich.edu/~mihalcea/wpt/index.html#resources

[4] https://www-i6.informatik.rwth-aachen.de/goldAlignment/

and Ney, 2003). Data statistics are shown in Table 1.

Table 1: Number of sentences for three datasets: German→English (DeEn), Romanian→English (RoEn) and English→French (EnFr). The datasets include training data and test data with gold alignments.

	DeEn	RoEn	EnFr
training	1.9M	0.5k	1.1M
test	508	248	447

In all experiments for this task, we employ the `base` transformer configuration with an embedding size of 512, 6 encoder and decoder layers, 8 attention heads, shared input and output embeddings (Press and Wolf, 2017), the standard `relu` activation function and sinusoidal positional embedding. The total number of parameters is 60M. We train with a batch size of 2000 tokens on 8 Volta GPUs and use the validation translation loss for early stopping. Furthermore, we use Adam optimizer (Loshchilov and Hutter, 2019) with a learning rate of 3e-4, $\beta_1 = 0.9, \beta_2 = 0.98$, learning rate warmup over the first 4000 steps and inverse square root as learning rate scheduler. The dropout probability is set to 0.1. Additionally, we apply label smoothing with a factor of 0.1. To conveniently extract word alignments for both translation directions, we train bidirectional models, i.e. our models are able to translate and align from Romanian to English and vice versa.

5.1.2 Align and Translate Task

The second setup is based on the WMT'18 English-German news translation task (Bojar et al., 2018). We apply the same corpus selection for bilingual data and model architecture as suggested by Edunov et al. (2018). However, we slightly modify the preprocessing pipeline to be able to evaluate the alignment quality against the gold alignments provided by Vilar et al. (2006). We use all available bilingual data (Europarl v7, Common Crawl corpus, News Commentary v13 and Rapid corpus of EU press releases) excluding the ParalCrawl corpus. We remove sentences longer than 100 words and sentence pairs with a source/target length ratio exceeding 1.5. This results in 5.2M parallel sentences. We apply the Moses tokenizer (Koehn et al., 2007) without aggressive hyphen splitting and without performing HTML escaping of apostrophes and quotes. Furthermore, we do not normalize punctuation marks. We use newstest2012 as validation and newstest2014 as test set.

To achieve state-of-the-art translation results, all models in this setup are trained unidirectional and we change to the `big` transformer configuration with an embedding size of 1024 and 16 attention heads. The total number of parameters is 213M. We train the layer average baseline with a batch size of 7168 tokens on 64 Volta GPUs for 30k updates and apply a learning rate of 1e-3, $\beta_1 = 0.9, \beta_2 = 0.98$. The dropout probability is set to 0.3. All other hyperparameters are as described in the previous section. Since training the multi-task models consumes more memory, we need to half the batch size, increase the number of updates accordingly and adapt the learning rate to 7e-4. We average over the last 10 checkpoints and run inference with a beam size of 5.

To fairly compare against state-of-the-art translation setups, we compute BLEU (Papineni et al., 2002) with `sacreBLEU` (Post, 2018).

5.2 Statistical Baseline

For both setups, the statistical alignment models are computed with the multi-threaded version of the GIZA++ toolkit[5] implemented by Gao and Vogel (2008). GIZA++ estimates IBM1-5 models and a first-order hidden Markov model (HMM) as introduced in (Brown et al., 1993) and (Vogel et al., 1996), respectively. In particular, we perform 5 iterations of IBM1, HMM, IBM3 and IBM4. Furthermore, the alignment models are trained in both translation directions and symmetrized by employing the `grow-diagonal` heuristic (Koehn et al., 2005). We use the resulting word alignments to supervise the alignment loss for the method described in Section 4.4.

5.3 Averaging Attention Results

For our experiments, we use the data and Transformer model setup described in Section 5.1.1. We perform the evaluation of alignments obtained by layer wise averaging of attention probabilities as described in Section 4.1. As shown in Table 2, all three language pairs exhibit a very similar pattern, wherein the attentions do not seem to learn meaningful alignments in the initial layers and show a remarkable improvement in the higher layers. This indicates that the initial layers are fo-

[5] https://github.com/moses-smt/mgiza/

Table 2: AER [%] per layer for all three language pairs: German→English (DeEn), Romanian→English (RoEn) and English→French (EnFr).

Layer	DeEn	RoEn	EnFr
1 (bottom)	90.0	92.9	80.7
2	91.0	93.6	81.7
3	94.5	92.0	73.4
4	41.2	37.5	20.5
5	**32.6**	**33.4**	**17.0**
6 (top)	56.3	48.4	37.9
average	55.8	38.6	23.2

cusing more on learning good representations of the sentence generated by the decoder so far by self attention. Once good contextual representations are learnt, the higher layers fetch the relevant representations from the encoder's output via the encoder-decoder attention. However, interestingly the penultimate layer outperforms the final layer suggesting the final layer uses the alignment-based features in the penultimate layer to derive its own representation.

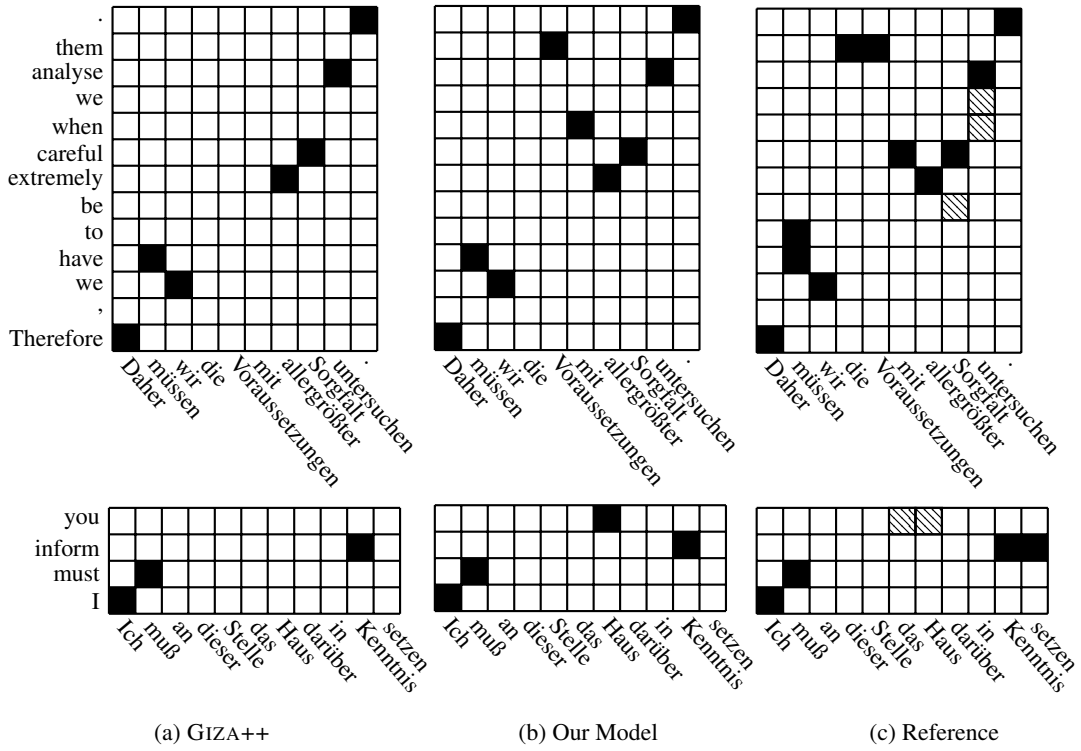
5.4 Alignment Task Results

Table 3 compares the performance of our methods against statistical baselines and previous neural approaches. The layer average baseline provides relatively weak alignments, which are used for training our *multi-task* model. The improvement of the multi-task approach over the layer average baseline suggests that learning to translate helps produce better alignments as well. However still the multi-task approach falls short of the statistical and neural baselines, which have a strong advantage of having access to the full/partial target context. Exposing our model to the full target context gives the largest gains in terms of AER. Note that *full context* results are directly comparable to Zenkel et al. (2019) since both approaches do not leverage external knowledge from statistical models. We suspect that we are able to outperform Zenkel et al. (2019) because we provide the full target context instead of only the to-be aligned target word. Finally, by supervising our model on the alignments obtained from GIZA++ (GIZA++ *supervised*) rather than layer average baseline, we outperform GIZA++ and Peter et al. (2017).

We tuned the alignment loss weight λ (Equation 8) using grid search on the German→English dataset. We achieve the best results with $\lambda = 0.05$.

Table 3: Results on the alignment task (in AER [%]). ‡Difference in AER w.r.t. GIZA++ (BPE-based) is statistically significant ($p<0.001$).

Model	DeEn	RoEn	EnFr
GIZA++ (word-based)	21.4	27.9	5.9
GIZA++ (BPE-based)	18.9	27.0	5.5
Layer average baseline	32.6	33.4	17.0
Multi-task	25.4	30.7	12.6
+ full-context	20.2	26.0	7.7
++ GIZA++ supervised	**16.0**‡	**23.1**‡	**4.6**‡
Peter et al. (2017)	19.0	-	-
Zenkel et al. (2019)	21.2	27.6	10.0



5.5 Align and Translate Task Results

For fair comparison of our approach to the state-of-the-art translation models, we use the setup described in Section 5.1.2. Table 4 summarizes the results on alignment and translation tasks. The layer average baseline is based on regular NMT model training, therefore ideally it should achieve the same BLEU as Edunov et al. (2018), however we see a small drop of 0.3 BLEU points in practice which could be caused by the slightly different preprocessing procedure (cf. Section 5.1.2, no aggressive hyphen splitting/no punctuation normalization). The layer average baseline performs poorly in terms of the AER. The Precision and Recall results for the layer average baseline demonstrate the effectiveness of symmetrization. Symmetrization removes a majority of incorrect alignments and gives a high precision (94.2%) but low recall (29.6%). The high precision of the layer average baseline ensures that the multi-task model receives correct alignments for supervision, enabling it to get large improvements in AER over the layer average baseline.

Similar to the trend observed in 5.4, providing full target sentence context in the decoder helps the model to improve further and perform comparably to GIZA++. Lastly, supervision with GIZA++ gives the best AER and significantly outperforms GIZA++. The improvements in alignment quality and no degradation in BLEU compared to the layer average baseline shows the effectiveness of the proposed multi-task approach.

Table 4: Results on the align and translate task. Alignment quality is reported in AER, translation quality in BLEU. †baseline (without back-translation) `sacreBLEU` results were provided in https://github.com/pytorch/fairseq/issues/506#issuecomment-464411433. ‡Difference in AER w.r.t. GIZA++ (BPE-based) is statistically significant ($p<0.001$)

(a) GIZA++ (b) Our Model (c) Reference

Figure 1: Two examples from the German→English alignment test set. Alignments in (a) show the output from GIZA++ and (b) from our model (*Multi-task* with full-context and GIZA++ supervised). Gold Alignments in shown in (c). Black squares and hatched squares in the reference represent *sure* and *possible* alignments, respectively.

6 Analysis

To further investigate why our proposed approach is superior to GIZA++ in terms of AER, we analyze the generated word alignments of both models. We observe that our model tends to align pronouns (e.g. *you* or *them*) with regular nouns (e.g. objects or subjects). Given the gold alignments, it seems that these alignment links are correct or at least possible (Och and Ney (2003) provided annotators two options to specify alignments: *sure* and *possible* for unambiguous and ambiguous alignments respectively). Figure 1 shows two examples from the German→English alignment test set. In the first example, our model correctly aligns *them* with *Voraussetzungen (criteria)*. The German parliament speaker indeed mentioned *Verfahrensvoraussetzungen (procedural criteria)* in one of the preceding sentences and refers later to them by using the term *Voraussetzungen (criteria)*. In the second example, the pronoun *you* is correctly aligned to the noun *Haus*

(house) which is just another way to address the audience in the European parliament. Both alignment links are not generated by GIZA++. This could be related to fact that a statistical model is based on counting co-occurrences. We speculate that to generate such alignment links, a model needs to be able to encode contextual information. Experimental results in (Tang et al., 2018) suggest that NMT models learn to encode contextual information, which seems to be necessary for word sense disambiguation. Since pronouns can be ambiguous references, we assume that both problems are closely related and therefore believe that the ability to encode contextual information may be beneficial for generating word alignments.

From our experiments on the WMT'18 dataset, we observe that the alignment quality of the layer average baseline is quite low (cf. Table 4). To further investigate this, we plot the test AER and the validation NLL loss per epoch (Figure 2). The graph shows that the lowest AER of 42.7% is already reached in the fifth epoch. This suggests that

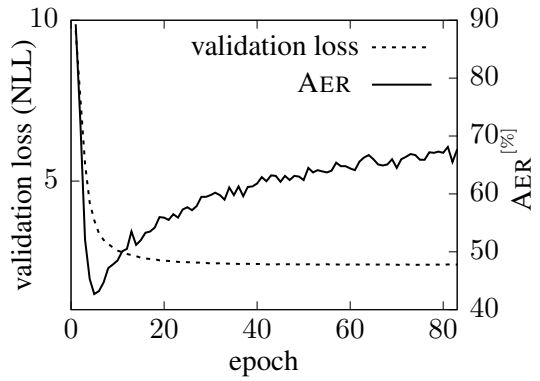

Figure 2: Test AER and validation loss (NLL) per epoch on the WMT'18 English→German task.

picking an earlier checkpoint for generating word alignments could be beneficial for better supervision. Unfortunately, an alignment validation set does not exist for this task.

7 Related Work

Leveraging alignments obtained from statistical MT toolkits to guide NMT attention mechanisms has been explored in the past. Mi et al. (2016), Chen et al. (2016), Liu et al. (2016) and Alkhouli and Ney (2017) supervise the attention mechanisms of recurrent models (Bahdanau et al., 2015) in this way. Our multi-task framework is inspired by these publications. However, we examine its effect on the Transformer model (Vaswani et al., 2017), which provides state-of-the-art results on several translation benchmarks. Previous works report significant gains in translation accuracy in low resource settings, however gains remain modest given larger amounts of parallel data (millions of sentences). These approaches also fail to achieve significantly better alignment accuracy than the statistical MT toolkits. Peter et al. (2017) and Li et al. (2018) improve upon the previous works in terms of alignment accuracy by providing an alignment module with additional information about the to-be-aligned target word. Expanding on this idea, we propose to leverage the full target sentence context leading to AER improvements. Zenkel et al. (2019) presents an approach that eliminates the reliance on statistical word aligners by instead by directly optimizing the attention activations for predicting the target word. We empirically compare our approach of obtaining high quality alignments without the need of statistical word aligners to Zenkel et al. (2019).

Augmenting the task objective with linguistic information, such as word alignments, also has had applications beyond MT. Strubell et al. (2018) showed that adding linguistic information from parse trees into one of the attention heads of the transformer model can help in the semantic role labeling. Inspired by Strubell et al. (2018), we inject the alignment information through one of the attention heads for the translation task instead.

As a by-product of developing our model, we present a simple way to quantitatively evaluate and analyze the quality of attention probabilities learnt by different parts of the Transformer model with respect to modeling alignments, which contributes to previous work on understanding attention mechanisms (Ghader and Monz, 2017; Raganato and Tiedemann, 2018; Tang et al., 2018).

8 Conclusions

This paper addresses the task of jointly learning to produce translations and alignments with a single Transformer model. By using a multi-task objective along with providing full target sentence context to our alignment module, we are able to produce better alignments than previous approaches not relying on external alignment toolkits. We demonstrate that our framework can be extended to use external alignments from GIZA++ to achieve significantly better alignment results compared to GIZA++, while maintaining the same

translation performance.

Currently, our self-training based approach needs two training runs. To train our model in a single run, we would like to investigate a training method which alternates between alignment extraction and model training.

Acknowledgments

We would like to thank the LILT team for releasing scripts and datasets for alignment evaluation. We are also grateful to Andrew Finch, Matthias Sperber, Barry Theobald and the anonymous reviewers for their helpful comments. Many thanks to Dorothea Peitz for helpful discussions about significance testing, Yi-Hsiu Liao for suggesting interesting extensions and the rest of Siri Machine Translation Team for their support.

Abstract

We introduce SOCIAL IQA, the first large-scale benchmark for commonsense reasoning about social situations. SOCIAL IQA contains 38,000 multiple choice questions for probing *emotional* and *social* intelligence in a variety of everyday situations (e.g., Q: "*Jordan wanted to tell Tracy a secret, so Jordan leaned towards Tracy. Why did Jordan do this?*" A: "*Make sure no one else could hear*"). Through crowdsourcing, we collect commonsense questions along with correct and incorrect answers about social interactions, using a new framework that mitigates stylistic artifacts in incorrect answers by asking workers to provide the right answer to a different but related question. Empirical results show that our benchmark is challenging for existing question-answering models based on pretrained language models, compared to human performance (>20% gap). Notably, we further establish SOCIAL IQA as a resource for transfer learning of commonsense knowledge, achieving state-of-the-art performance on multiple commonsense reasoning tasks (Winograd Schemas, COPA).

1 Introduction

Social and emotional intelligence enables humans to reason about the mental states of others and their likely actions (Ganaie and Mudasir, 2015). For example, when someone spills food all over the floor, we can infer that they will likely want to clean up the mess, rather than taste the food off the floor or run around in the mess (Figure 1, middle). This example illustrates how Theory of Mind, i.e., the ability to reason about the implied emotions and behavior of others, enables humans to navigate social situations ranging from simple conversations with friends to complex negotiations in courtrooms (Apperly, 2010).

Figure 1: Three context-question-answers triples from SOCIAL IQA, along with the type of reasoning required to answer them. In the top example, humans can trivially infer that Tracy pressed upon Austin because there was no room in the elevator. Similarly, in the bottom example, commonsense tells us that people typically root for the hero, not the villain.

While humans trivially acquire and develop such social reasoning skills (Moore, 2013), this is still a challenge for machine learning models, in part due to the lack of large-scale resources to train and evaluate modern AI systems' social and emotional intelligence. Although recent advances in pretraining large language models have yielded promising improvements on several commonsense inference tasks, these models still struggle to reason about social situations, as shown in this and previous work (Davis and Marcus,

[⋆] Both authors contributed equally.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4463–4473, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

2015; Nematzadeh et al., 2018; Talmor et al., 2019). This is partly due to language models being trained on written text corpora, where reporting bias of knowledge limits the scope of commonsense knowledge that can be learned (Gordon and Van Durme, 2013; Lucy and Gauthier, 2017).

In this work, we introduce Social Intelligence QA (SOCIAL IQA), the first large-scale resource to learn and measure *social* and *emotional* intelligence in computational models.[1] SOCIAL IQA contains 38k multiple choice questions regarding the pragmatic implications of everyday, social events (see Figure 1). To collect this data, we design a crowdsourcing framework to gather contexts and questions that explicitly address social commonsense reasoning. Additionally, by combining handwritten negative answers with adversarial question-switched answers (Section 3.3), we minimize annotation artifacts that can arise from crowdsourcing incorrect answers (Schwartz et al., 2017; Gururangan et al., 2018).

This dataset remains challenging for AI systems, with our best performing baseline reaching 64.5% (BERT-large), significantly lower than human performance. We further establish SOCIAL IQA as a resource that enables transfer learning for other commonsense challenges, through *sequential finetuning* of a pretrained language model on SOCIAL IQA before other tasks. Specifically, we use SOCIAL IQA to set a new state-of-the-art on three commonsense challenge datasets: COPA (Roemmele et al., 2011) (83.4%), the original Winograd (Levesque, 2011) (72.5%), and the extended Winograd dataset from Rahman and Ng (2012) (84.0%).

Our contributions are as follows: (1) We create SOCIAL IQA, the first large-scale QA dataset aimed at testing social and emotional intelligence, containing over 38k QA pairs. (2) We introduce question-switching, a technique to collect incorrect answers that minimizes stylistic artifacts due to annotator cognitive biases. (3) We establish baseline performance on our dataset, with BERT-large performing at 64.5%, well below human performance. (4) We achieve new state-of-the-art accuracies on COPA and Winograd through sequential finetuning on SOCIAL IQA, which implicitly endows models with social commonsense knowledge.

2 Task description

SOCIAL IQA aims to measure the social and emotional intelligence of computational models through multiple choice question answering (QA). In our setup, models are confronted with a question explicitly pertaining to an observed *context*, where the correct answer can be found among three competing options.

By design, the questions require *inferential* reasoning about the social causes and effects of situations, in line with the type of intelligence required for an AI assistant to interact with human users (e.g., know to call for help when an elderly person falls; Pollack, 2005). As seen in Figure 1, correctly answering questions requires reasoning about motivations, emotional reactions, or likely preceding and following actions. Performing these inferences is what makes us experts at navigating social situations, and is closely related to Theory of Mind, i.e., the ability to reason about the beliefs, motivations, and needs of others (Baron-Cohen et al., 1985).[2] Endowing machines with this type of intelligence has been a longstanding but elusive goal of AI (Gunning, 2018).

[2] Theory of Mind is well developed in most neurotypical adults (Ganaie and Mudasir, 2015), but can be influenced by age, culture, or developmental disorders (Korkmaz, 2011).

ATOMIC

As a starting point for our task creation, we draw upon social commonsense knowledge from ATOMIC (Sap et al., 2019) to seed our contexts and question types. ATOMIC is a large knowledge graph that contains inferential knowledge about the causes and effects of 24k short events. Each triple in ATOMIC consists of an event phrase with person-centric variables, one of nine inference dimensions, and an inference object (e.g., "PersonX pays for PersonY's ___", "xAttrib", "generous"). The nine inference dimensions in ATOMIC cover causes of an event (e.g., "X needs money"), its effects on the agent (e.g., "X will get thanked") and its effect on other participants (e.g., "Y will want to see X again"); see Sap et al. (2019) for details.

Given this base, we generate natural language contexts that represent specific instantiations of the event phrases found in the knowledge graph. Furthermore, the questions created probe the commonsense reasoning required to navigate such contexts. Critically, since these contexts are based off of ATOMIC, they explore a diverse range of motivations and reactions, as well as likely preceding or following actions.

3 Dataset creation

SOCIAL IQA contains 37,588 multiple choice questions with three answer choices per question. Questions and answers are gathered through three phases of crowdsourcing aimed to collect the *context*, the *question*, and a set of *positive* and *negative* answers. We run crowdsourcing tasks on Amazon Mechanical Turk (MTurk) to create each of the three components, as described below.

3.1 Event Rewriting

In order to cover a variety of social situations, we use the base events from ATOMIC as prompts for context creation. As a pre-processing step, we run an MTurk task that asks workers to turn an ATOMIC event (e.g., "PersonX spills ___ all over the floor") into a sentence by adding names, fixing potential grammar errors, and filling in placeholders (e.g., "Alex spilled food all over the floor.").[3]

3.2 Context, Question, & Answer Creation

Next, we run a task where annotators create full context-question-answers triples. We automatically generate question templates covering the nine commonsense inference dimensions in ATOMIC.[4] Crowdsourcers are prompted with an event sentence and an inference question to turn into a more detailed context[5] (e.g. "Alex spilled food all over the floor and it made a huge mess.") and an edited version of the question if needed for improved specificity (e.g. "What will Alex want to do next?"). Workers are also asked to contribute two potential correct answers.

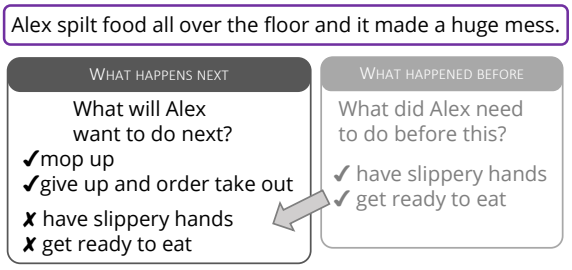

Figure 2: Question-Switching Answers (QSA) are collected as the correct answers to the wrong question that targets a different type of inference (here, reasoning about what happens before instead of after an event).

3.3 Negative Answers

In addition to correct answers, we collect four incorrect answer options, of which we filter out two. To create incorrect options that are adversarial for models but easy for humans, we use two different approaches to the collection process. These two methods are specifically designed to avoid different types of annotation artifacts, thus making it more difficult for models to rely on data biases. We integrate and filter answer options and validate final QA tuples with human rating tasks.

Handwritten Incorrect Answers (HIA) The first method involves eliciting handwritten incorrect answers that require reasoning about the context. These answers are handwritten to be similar to the correct answers in terms of topic, length, and style but are subtly incorrect. Two of these answers are collected during the same MTurk task as the original context, questions, and correct answers. We will refer to these negative responses as handwritten incorrect answers (HIA).

Question-Switching Answers (QSA) We collect a second set of negative (incorrect) answer

[3]This task paid $0.35 per event.

[4]We do not generate templates if the ATOMIC dimension is annotated as "none."

[5]Workers were asked to contribute a context 7-25 words longer than the event sentence.

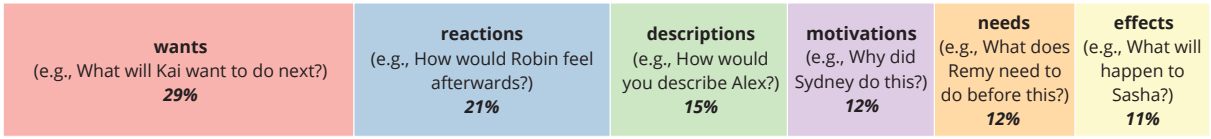

Figure 3: SOCIAL IQA contains several question types which cover different types of inferential reasoning. Question types are derived from ATOMIC inference dimensions.

candidates by switching the questions asked about the context, as shown in Figure 2. We do this to avoid cognitive biases and annotation artifacts in the answer candidates, such as those caused by writing incorrect answers or negations (Schwartz et al., 2017; Gururangan et al., 2018). In this crowdsourcing task, we provide the same context as the original question, as well as a question automatically generated from a different but similar ATOMIC dimension,[6] and ask workers to write two correct answers. We refer to these negative responses as question-switching answers (QSA).

By including answers to a different question about the same context, we ensure that these adversarial responses have the stylistic qualities of correct answers and strongly relate to the context topic, while still being incorrect, making it difficult for models to simply perform pattern-matching. To verify this, we compare valence, arousal, and dominance (VAD) levels across answer types, computed using the VAD lexicon by Mohammad (2018). Figure 4 shows effect sizes (Cohen's d) of the differences in VAD means, where the magnitude of effect size indicates how different the answer types are stylistically. Indeed, QSA and correct answers differ substantially less than HIA answers ($|d| \leq .1$).[7]

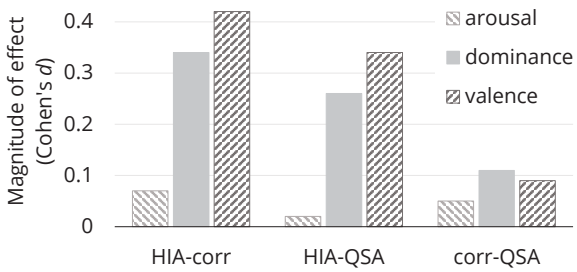

Figure 4: Magnitude of effect sizes (Cohen's d) when comparing average dominance, arousal and valence values of different answer types where larger $|d|$ indicates more stylistic difference. For valence (sentiment polarity) and dominance, the effect sizes comparing QSA and correct answers are much smaller, indicating that these are more similar tonally. Notably, all three answer types have comparable levels of arousal (intensity).

3.4 QA Tuple Creation

As the final step of the pipeline, we aggregate the data into three-way multiple choice questions. For each created context-question pair contributed by crowdsourced workers, we select a random correct answer and the incorrect answers that are least entailed by the correct one, following inspiration from Zellers et al. (2019a).

For the training data, we validate our QA tuples through a multiple-choice crowdsourcing task where three workers are asked to select the right answer to the question provided.[8] In order to ensure even higher quality, we validate the dev and test data a second time with five workers. Our final dataset contains questions for which the correct answer was determined by human majority voting, discarding cases without a majority vote. We also apply a lightweight form of adversarial filtering to make the task more challenging by using a deep stylistic classifier to remove easier examples on the dev and test sets (Sakaguchi et al., 2019).[9]

To obtain human performance, we run a separate task asking three new workers to select the correct answer on a random subset of 900 dev and 900 test examples. Human performance on these subsets is 87% and 84%, respectively.

3.5 Data Statistics

To keep contexts separate across train/dev/test sets, we assign SOCIAL IQA contexts to the same partition as the ATOMIC event the context was based on. Shown in Table 1 (top), this yields a

[6] Using the following three groupings of ATOMIC dimensions: {xWant, oWant, xNeed, xIntent}, {xReact oReact, xAttr}, and {xEffect, oEffect}.

[7] Cohen's $|d| < .20$ is considered small (Sawilowsky, 2009). We find similarly small effect sizes using other sentiment/emotion lexicons.

[8] Agreement on this task was high (Cohen's κ=.70)

[9] We also tried filtering to remove examples from the training set but found it did not significantly change performance. We will release tags for the easier training examples with the full data.

total set of around 33k training, 2k dev, and 2k test tuples. We additionally include statistics on word counts and vocabulary of the training data. We report the averages of correct and incorrect answers in terms of: token length, number of unique tokens, and number of times a unique answer appears in the dataset. Note that due to our three-way multiple choice setup, there are twice as many incorrect answers which influences these statistics.

We also include a breakdown (Figure 3) across question types, which we derive from ATOMIC inference dimensions.[10] In general, questions relating to what someone will feel afterwards or what they will likely do next are more common in SOCIAL IQA. Conversely, questions pertaining to (potentially involuntary) effects of situations on people are less frequent.

Model	Accuracy (%) Dev	Test
Random baseline	33.3	33.3
GPT	63.3	63.0
BERT-base	63.3	63.1
BERT-large	**66.0**	**64.5**
w/o context	52.7	–
w/o question	52.1	–
w/o context, question	45.5	–
Human	86.9*	84.4*

Table 2: Experimental results. We additionally perform an ablation by removing contexts and questions, verifying that both are necessary for BERT-large's performance. Human evaluation results are obtained using 900 randomly sampled examples.

4 Methods

We establish baseline performance on SOCIAL IQA, using large pretrained language models based on the Transformer architecture (Vaswani et al., 2017). Namely, we finetune OpenAI-GPT (Radford et al., 2018) and BERT (Devlin et al., 2019), which have both shown remarkable improvements on a variety of tasks. OpenAI-GPT is a uni-directional language model trained on the BookCorpus (Zhu et al., 2015), whereas BERT is a bidirectional language model trained on both the BookCorpus and English Wikipedia. As per previous work, we finetune the language model representations but fully learn the classifier specific parameters described below.

Multiple choice classification To classify sequences using these language models, we follow the multiple-choice setup implementation by the respective authors, as described below. First, we concatenate the context, question, and answer, using the model specific separator tokens. For OpenAI-GPT, the format becomes `_start_ <context> <question> _delimiter_ <answer> _classify_`, where `_start_`, `_delimiter_`, and `_classify_` are special function tokens. For BERT, the format is similar, but the classifier token comes before the context.[11]

For each triple, we then compute a score l by passing the hidden representation from the classifier token $h_{CLS} \in \mathbb{R}^H$ through an MLP:

$$l = W_2 \tanh(W_1 h_{CLS} + b_1)$$

where $W_1 \in \mathbb{R}^{H \times H}$, $b_1 \in \mathbb{R}^H$ and $W_2 \in \mathbb{R}^{1 \times H}$. Finally, we normalize scores across all triples for a given context-question pair using a softmax layer. The model's predicted answer corresponds to the triple with the highest probability.

5 Experiments

5.1 Experimental Set-up

We train our models on the 33k SOCIAL IQA training instances, selecting hyperparameters based on the best performing model on our dev set, for which we then report test results. Specifically, we perform finetuning through a grid search over the hyper-parameter settings (with a learning rate in $\{1e{-}5, 2e{-}5, 3e{-}5\}$, a batch size in $\{3, 4, 8\}$, and a number of epochs in $\{3, 4, 10\}$) and report the maximum performance.

Models used in our experiments vary in sizes: OpenAI-GPT (117M parameters) has a hidden size H=768, BERT-base (110M params) and BERT-large (340M params) hidden sizes of H=768 and H=1024, respectively. We train using the HuggingFace PyTorch (Paszke et al., 2017) implementation.[12]

[10] We group agent and theme ATOMIC dimensions together (e.g., "xReact" and "oReact" become the "reactions" question type).

[11] BERT's format is `[CLS] <context> [UNUSED] <question> [SEP] <answer> [SEP]`

[12] https://github.com/huggingface/pytorch-pretrained-BERT

	Context	Question		Answer
(1)	Jesse was pet sitting for Addison, so Jesse came to Addison's house and walked their dog.	What does Jesse need to do before this?	✓ 🤖	(a) feed the dog (b) get a key from Addison (c) walk the dog
(2)	Kai handed back the computer to Will after using it to buy a product off Amazon.	What will Kai want to do next?	✓ 🤖	(a) wanted to save money on shipping (b) Wait for the package (c) Wait for the computer
(3)	Remy gave Skylar, the concierge, her account so that she could check into the hotel.	What will Remy want to do next?	🤖 ✓	(a) lose her credit card (b) arrive at a hotel (c) get the key from Skylar
(4)	Sydney woke up and was ready to start the day. They put on their clothes.	What will Sydney want to do next?	🤖 ✓	(a) go to bed (b) go to the pool (c) go to work
(5)	Kai grabbed Carson's tools for him because Carson could not get them.	How would Carson feel as a result?	🤖 ✓	(a) inconvenienced (b) grateful (c) angry
(6)	Although Aubrey was older and stronger, they lost to Alex in arm wrestling.	How would Alex feel as a result?	🤖 ✓	(a) they need to practice more (b) ashamed (c) boastful

Table 3: Example CQA triples from the SOCIAL IQA dev set with BERT-large's predictions (🤖: BERT's prediction, ✓: true correct answer). The model predicts correctly in (1) and (2) and incorrectly in the other four examples shown here. Examples (3) and (4) illustrate the model choosing answers that might have happened before, or that might happen much later after the context, as opposed to right after the context situation. In Examples (5) and (6), the model chooses answers that may apply to people other than the ones being asked about.

5.2 Results

Our results (Table 2) show that SOCIAL IQA is still a challenging benchmark for existing computational models, compared to human performance. Our best performing model, BERT-large, outperforms other models by several points on the dev and test set. We additionally ablate our best model's representation by removing the context and question from the input, confirming that reasoning over both is necessary for this task.

Learning Curve To better understand the effect of dataset scale on model performance on our task, we simulate training situations with limited knowledge. We present the learning curve of BERT-large's performance on the dev set as it is trained on more training set examples (Figure 5). Although the model does significantly improve over a random baseline of 33% with only a few hundred examples, the performance only starts to converge after around 20k examples, providing evidence that large-scale benchmarks are required for this type of reasoning.

Error Analysis We include a breakdown of our best model's performance on various question types in Figure 6 and specific examples of errors in the last four rows of Table 3. Overall, questions related to pre-conditions of the context (people's motivations, actions needed before the context) are less challenging for the model. Conversely, the model seems to struggle more with questions relating to (potentially involuntary) effects, stative descriptions, and what people will want to do next.

Examples of errors in Table 3 further indicate that, instead of doing advanced reasoning about situations, models may only be learning lexical associations between the context, question, and answers, as hinted at by Marcus (2018) and Zellers et al. (2019b). This leads the model to select answers with incorrect timing (examples 3 and 4) or answers pertaining to the wrong participants (examples 5 and 6), despite being trained on large amounts of examples that specifically distinguish proper timing and participants. For instance, in (3) and (4), the model selects answers which

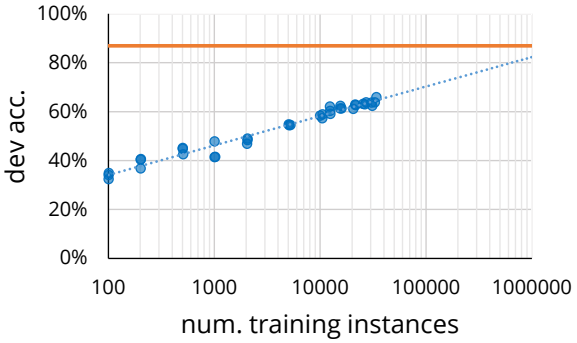

Figure 5: Dev accuracy when training BERT-large with various number of examples (multiple runs per training size), with human performance (86.9%) shown in orange. In order to reach >80%, the model would require nearly 1 million training examples.

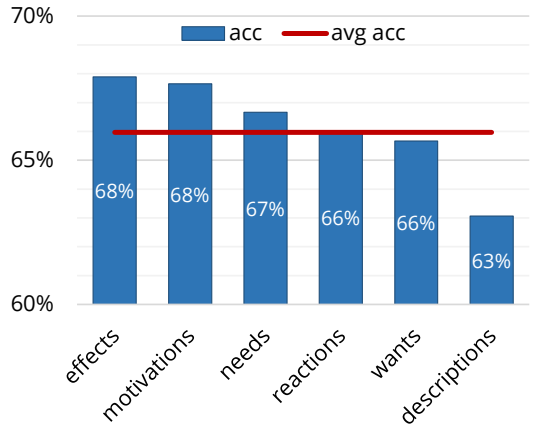

Figure 6: Average dev accuracy of BERT-large on different question types. While questions about effects and motivations are easier, the model still finds wants and descriptions more challenging.

are incorrectly timed with respect to the context and question (e.g., "arrive at a hotel" is something Remy likely did before checking in with the concierge, not afterwards). Additionally, the model often chooses answers related to a person other than the one asked about. In (6), after the arm wrestling, though it is likely that Aubrey will feel ashamed, the question relates to what Alex might feel–not Aubrey.

Overall, our results illustrate how reasoning about social situations still remains a challenge for these models, compared to humans who can trivially reason about the causes and effects for multiple participants. We expect that this task would benefit from models capable of more complex reasoning about entity state, or models that are more explicitly endowed with commonsense (e.g., from knowledge graphs like ATOMIC).

6 SOCIAL IQA for Transfer Learning

In addition to being the first large-scale benchmark for social commonsense, we also show that SOCIAL IQA can improve performance on downstream tasks that require commonsense, namely the Winograd Schema Challenge and the Choice of Plausible Alternatives task. We achieve state of the art performance on both tasks by sequentially finetuning on SOCIAL IQA before the task itself.

COPA The Choice of Plausible Alternatives task (COPA; Roemmele et al., 2011) is a two-way multiple choice task which aims to measure commonsense reasoning abilities of models. The dataset contains 1,000 questions (500 dev, 500 test) that ask about the causes and effects of a premise. This has been a challenging task for computational systems, partially due to the limited amount of training data available. As done previously (Goodwin et al., 2012; Luo et al., 2016), we finetune our models on the dev set, and report performance only on the test set.

Winograd Schema The Winograd Schema Challenge (WSC; Levesque, 2011) is a well-known commonsense knowledge challenge framed as a coreference resolution task. It contains a collection of 273 short sentences in which a pronoun must be resolved to one of two antecedents (e.g., in "The city councilmen refused the demonstrators a permit because *they* feared violence", *they* refers to the councilmen). Because of data scarcity in WSC, Rahman and Ng (2012) created 943 Winograd-style sentence pairs (1886 sentences in total), henceforth referred to as DPR, which has been shown to be slightly less challenging than WSC for computational models.

We evaluate on these two benchmarks. While the DPR dataset is split into train and test sets (Rahman and Ng, 2012), the WSC dataset contains a single (*test*) set of only 273 instances for evaluation purposes only. Therefore, we use the DPR dataset as training set when evaluating on the WSC dataset.

6.1 Sequential Finetuning

We first finetune BERT-large on SOCIAL IQA, which reaches 66% on our dev set (Table 2). We then finetune that model further on the task-specific datasets, considering the same set of hyperparameters as in §5.1. On each of the test sets,

Task	Model	Acc. (%) best	mean	std
COPA	Sasaki et al. (2017)	71.2	–	–
	BERT-large	80.8	75.0	3.0
	BERT-SOCIAL IQA	**83.4**	80.1	2.0
WSC	Kocijan et al. (2019)	72.5	–	–
	BERT-large	67.0	65.5	1.0
	BERT-SOCIAL IQA	**72.5**	69.6	1.7
DPR	Peng et al. (2015)	76.4	–	–
	BERT-large	79.4	71.2	3.8
	BERT-SOCIAL IQA	**84.0**	81.7	1.2

Table 4: Sequential finetuning of BERT-large on SOCIAL IQA before the task yields state of the art results (bolded) on COPA (Roemmele et al., 2011), Winograd Schema Challenge (Levesque, 2011) and DPR (Rahman and Ng, 2012). For comparison, we include previous published state of the art performance.

we report best, mean, and standard deviation of all models, and compare sequential finetuning results to a BERT-large baseline.

Results Shown in Table 4, sequential finetuning on SOCIAL IQA yields substantial improvements over the BERT-only baseline (between 2.6 and 5.5% max performance increases), as well as the general increase in performance stability (i.e., lower standard deviations). As hinted at by Phang et al. (2019), this suggests that BERT-large can benefit from both the large scale and the QA format of commonsense knowledge in SOCIAL IQA, which it struggles to learn from small benchmarks only. Notably, we find that sequentially finetuned BERT-SOCIAL IQA achieves state-of-the-art results on all three tasks, showing improvements of previous best performing models.[13]

Effect of scale and knowledge type To better understand these improvements in downstream task performance, we investigate the impact on COPA performance of sequential finetuning on less SOCIAL IQA training data (Figure 7), as well as the impact of the type of commonsense knowledge used in sequential finetuning. As expected, the downstream performance on COPA improves when using a model pretrained on more of SOCIAL IQA, indicating that the scale of the dataset

[13]Note that OpenAI-GPT was reported to achieve 78.6% on COPA, but that result was not published, nor discussed in the OpenAI-GPT white paper (Radford et al., 2018).

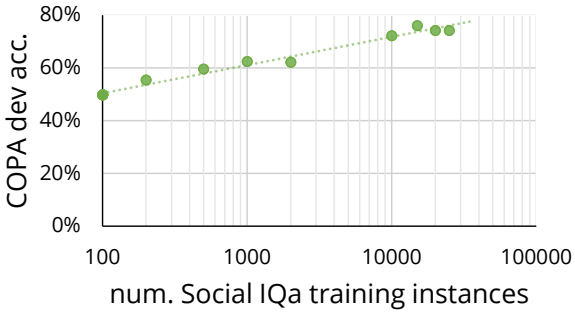

Figure 7: Effect of finetuning BERT-large on varying sizes of the SOCIAL IQA training set on the dev accuracy of COPA. As expected, the more SOCIAL IQA instances the model is finetuned on, the better the accuracy on COPA.

is one factor that helps in the fine-tuning. However, when using SWAG (a similarly sized dataset) instead of SOCIAL IQA for sequential finetuning, the downstream performance on COPA is lower (76.2%). This indicates that, in addition to its large scale, the social and emotional nature of the knowledge in SOCIAL IQA enables improvements on these downstream tasks.

7 Related Work

Commonsense Benchmarks: Commonsense benchmark creation has been well-studied by previous work. Notably, the WinoGrad Schema Challenge (WSC; Levesque, 2011) and the Choice Of Plausible Alternatives dataset (COPA; Roemmele et al., 2011) are expert-curated collections of commonsense QA pairs that are trivial for humans to solve. Whereas WSC requires physical and social commonsense knowledge to solve, COPA targets the knowledge of causes and effects surrounding social situations. While both benchmarks are of high-quality and created by experts, their small scale (150 and 1,000 examples, respectively) poses a challenge for modern modelling techniques, which require many training instances.

More recently, Talmor et al. (2019) introduce CommonsenseQA, containing 12k multiple-choice questions. Crowdsourced using ConceptNet (Speer and Havasi, 2012), these questions mostly probe knowledge related to factual and physical commonsense (e.g., "Where would I not want a fox?"). In contrast, SOCIAL IQA explicitly separates contexts from questions, and focuses on the types of commonsense inferences humans perform when navigating social situations.

Commonsense Knowledge Bases: In addition to large-scale benchmarks, there is a wealth of work aimed at creating commonsense knowledge repositories (Speer and Havasi, 2012; Sap et al., 2019; Zhang et al., 2017; Lenat, 1995; Espinosa and Lieberman, 2005; Gordon and Hobbs, 2017) that can be used as resources in downstream reasoning tasks. While SOCIAL IQA is formatted as a natural language QA benchmark, rather than a taxonomic knowledge base, it also can be used as a resource for external tasks, as we have demonstrated experimentally.

Constrained or Adversarial Data Collection: Various work has investigated ways to circumvent annotation artifacts that result from crowdsourcing. Sharma et al. (2018) extend the Story Cloze data by severely restricting the incorrect story ending generation task, reducing the sentiment and negation artifacts. Rajpurkar et al. (2018) create an adversarial version of the extractive question-answering challenge, SQuAD (Rajpurkar et al., 2016), by creating 50k unanswerable questions. Instead of using human-generated incorrect answers, Zellers et al. (2018, 2019b) use adversarial filtering of machine generated incorrect answers to minimize surface patterns. Our dataset also aims to reduce annotation artifacts by using a multi-stage annotation pipeline in which we collect negative responses from multiple methods including a unique adversarial question-switching technique.

8 Conclusion

We present SOCIAL IQA, the first large-scale benchmark for social commonsense. Consisting of 38k multiple-choice questions, SOCIAL IQA covers various types of inference about people's actions being described in situational contexts. We design a crowdsourcing framework for collecting QA pairs that reduces stylistic artifacts of negative answers through an adversarial question-switching method. Despite human performance of close to 90%, computational approaches based on large pretrained language models only achieve accuracies up to 65%, suggesting that these social inferences are still a challenge for AI systems. In addition to providing a new benchmark, we demonstrate how transfer learning from SOCIAL IQA to other commonsense challenges can yield significant improvements, achieving new state-of-the-art performance on both COPA and Winograd Schema Challenge datasets.

Self-Assembling Modular Networks for Interpretable Multi-Hop Reasoning

Yichen Jiang and **Mohit Bansal**
UNC Chapel Hill
{yichenj, mbansal}@cs.unc.edu

Abstract

Multi-hop QA requires a model to connect multiple pieces of evidence scattered in a long context to answer the question. The recently proposed HotpotQA (Yang et al., 2018) dataset is comprised of questions embodying four different multi-hop reasoning paradigms (two bridge entity setups, checking multiple properties, and comparing two entities), making it challenging for a single neural network to handle all four. In this work, we present an interpretable, controller-based Self-Assembling Neural Modular Network (Hu et al., 2017, 2018) for multi-hop reasoning, where we design four novel modules (Find, Relocate, Compare, NoOp) to perform unique types of language reasoning. Based on a question, our layout controller RNN dynamically infers a series of reasoning modules to construct the entire network. Empirically, we show that our dynamic, multi-hop modular network achieves significant improvements over the static, single-hop baseline (on both regular and adversarial evaluation). We further demonstrate the interpretability of our model via three analyses. First, the controller can softly decompose the multi-hop question into multiple single-hop sub-questions to promote compositional reasoning behavior of the main network. Second, the controller can predict layouts that conform to the layouts designed by human experts. Finally, the intermediate module can infer the entity that connects two distantly-located supporting facts by addressing the sub-question from the controller.[1]

1 Introduction

The task of multi-hop question answering (QA) requires the model to answer a natural language question by finding multiple relevant information pieces scattered in a given natural language context. It has attracted more attention recently and multiple datasets have been proposed, including the recent HotpotQA (Yang et al., 2018) that is comprised of questions embodying four different multi-hop reasoning paradigms: inferring the bridge entity to complete the 2nd-hop question (first question in Fig. 1), inferring the answer through a bridge entity, checking multiple properties to select the answer, and comparing two entities (second question in Fig. 1). For the first question, it is necessary to first find the person "who portrayed Corliss Archer in the film Kiss and Tell", and then find out the "government position" she held. For the second question, one may arrive at the answer by finding the country where Scott and Ed are from, and then comparing the two nationalities to conclude whether they are the same.

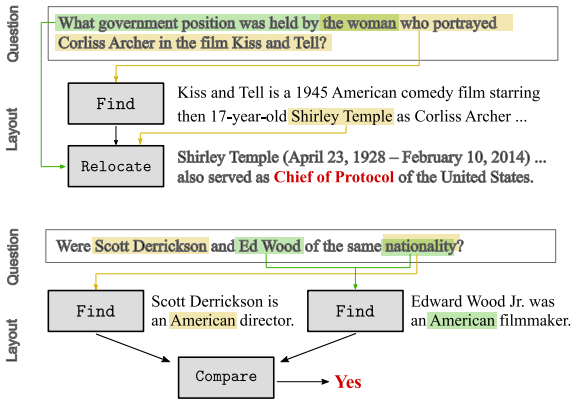

Figure 1: Two HotpotQA examples and the modular network layout predicted by the controller.

Multi-hop QA is more challenging than single-hop QA for two main reasons. First, the techniques used for single-hop QA are not sufficient to answer a multi-hop question. In single-hop QA tasks like SQuAD (Rajpurkar et al., 2016), the evidence necessary to answer the question is concentrated in a short context (Q: "What is the color of the grass", Context: "The grass is green.", An-

swer: "Green"). Such datasets emphasize the role of matching the information between the question and the short context surrounding the answer ("sky→sky, color→blue"), and can be solved by building a question-aware context representation (Seo et al., 2017; Xiong et al., 2017). In contrast, for multi-hop QA, directly matching the semantics of the question and context leads to the entity that bridges the two supporting facts (e.g., "Shirley Temple"), or the entities that need to be compared against each other (e.g., nationalities of Scott and Ed). In both cases, further action is required on top of direct semantic matching in order to get to the final answer. Second, HotpotQA is comprised of questions of four different types of multi-hop reasoning paradigms. In Fig. 1, the first question embodies a sequential reasoning path where the model has to solve a sub-question to get an entity "Shirley Temple", which then leads to the answer to the main question about her "government position". The second question, on the other hand, requires a tree-structured reasoning path where the model first locates two entities on the leaves and then compares them to get the answer. The difference in the required reasoning skills makes it hard for a single static model to handle all types of questions.

To automatically discover the multiple elaborated reasoning steps as required in HotpotQA, a model needs to dynamically adopt a sequence of different reasoning behaviors based on specific questions, which is still unexplored in the field of large-scale text-based QA. In our work, we present a highly-interpretable self-assembling Neural Modular Network (Andreas et al., 2016a; Hu et al., 2017) with three novel modules designed for multi-hop NLP tasks: `Find`, `Relocate`, `Compare`, where each module embodies a unique type of reasoning behavior. The `Find` module is similar to the previously-introduced 1-hop bi-attention model (Seo et al., 2017; Xiong et al., 2017), which produces an attention map over the context words given the context and the question representation. For the first example in Fig. 1, a `Find` module is used to find the answer ("Shirley Temple") to the sub-question ("who portrayed Corliss Archer ..."). The `Relocate` module takes the intermediate answer to the previous sub-question ("Shirley Temple"), combines it with the current sub-question ("What government position was held by ..."), and then outputs a new attention map conditioned on the previous one. The `Compare` module intuitively "compares" the outputs from two previous modules based on the question. For the second example in Fig. 1, after previous modules find the nationality of "Scott" and "Ed" (both American), the `Compare` module outputs the answer "Yes" based on the word "same" in the question. We also use the `NoOp` module that keeps the current state of the network unchanged when the model decides no more action is needed. After all the reasoning steps are performed, the final attention map is used to predict the answer span, and the vector output from the `Compare` module is used to predict whether the answer should be a context span or "Yes/No".

Next, to dynamically assemble these modules into a network based on the specific question, we use a controller RNN that, at each step, infers the required reasoning behavior from the question, outputs the sub-question, and predicts a soft combination of all available modules. As shown in Fig. 1, a modular network `Relocate(Find())` is constructed for the bridge-type question and another network with the layout `Compare(Find(), Find())` is built for the comparison-type question. In order to make the entire model end-to-end differentiable in gradient descent, we follow Hu et al. (2018) to use continuous and soft layout prediction and maintain a differentiable stack-based data structure to store the predicted modules' output. This approach to optimize the modular network is shown to be superior to using a Reinforcement Learning approach which makes hard module decisions. Fig. 2 visualizes this controller that predicts the modular layout and the network assembled with the selected modules. We further apply intermediate supervision to the first produced attention map to encourage finding the bridge entity ("Shirley Temple" in Fig. 1). The entire model is trained end-to-end using cross entropy loss for all supervision.

Overall, our self-assembling controller-based Neural Modular Network achieves statistically significant improvements over both the single-hop bi-attention baseline and the original modular network (Hu et al., 2018) designed for visual-domain QA. We also present adversarial evaluation (Jiang and Bansal, 2019), where single-hop reasoning shortcuts are eliminated and compositional reasoning is enforced; and here our NMN again outperforms the BiDAF baseline significantly in the

EM score (as well as after adversarial training). We further demonstrate the interpretability of our modular network with three analyses. First, the controller understands the multi-hop semantics of the question and can provide accurate step-by-step sub-questions to the module to lead the main network to follow the reasoning path. Second, the controller can successfully predict layouts that conform to the layouts designed by human experts. Finally, before arriving at the final answer, the intermediate module can infer the bridge entity that connects two distantly-located supporting facts by leveraging the step-specific sub-question from the controller. All of these analyses show that our Modular Network is not operating as a black box, but demonstrates highly interpretable compositional reasoning behavior, which is beneficial in transparent model development and safe, trustworthy real-world applications. In summary, the contribution of this work is three-fold: 1) This is the first work to apply self-assembling modular networks to text-based QA; 2) We design three novel modules to handle multi-hop questions in HotpotQA; 3) The resulting network is interpretable in terms of the model's intermediate outputs and the assembled layout.

2 Related Works

Multi-hop Reading Comprehension The last few years have witnessed significant progress on large-scale QA datasets including cloze-style tasks (Hermann et al., 2015), open-domain QA (Yang et al., 2015), and more (Rajpurkar et al., 2016, 2018). However, all of the above datasets are confined to a single-document context per question domain. Joshi et al. (2017) introduced a multi-document QA dataset with some questions requiring cross-sentence inferences to answer. The bAbI dataset (Weston et al., 2016) requires the model to combine multiple pieces of evidence in the synthetic text. Welbl et al. (2017) uses Wikipedia articles as the context and a subject-relation pair as the query, and constructs the multi-hop QAngaroo dataset by traversing a directed bipartite graph so that the evidence required to answer a query could be spread across multiple documents. HotpotQA (Yang et al., 2018) is a more recent multi-hop QA dataset that has crowd-sourced questions with more diverse syntactic and semantic features compared to QAngaroo. It includes four types of questions, each requiring a different reasoning paradigm. Some examples require inferring the bridge entity from the question (Type I in Yang et al. (2018)), while others demand fact-checking or comparing subjects' properties from two different documents (Type II and comparison question). Concurrently to our work, Min et al. (2019b) also tackle HotpotQA by decomposing its multi-hop questions into single-hop sub-questions to achieve better performance and interpretability. However, their system approaches the question decomposition by having a decomposer model trained via human labels, while our controller accomplishes this task automatically with the soft attention over the question-words' representation and is only distantly supervised by the answer and bridge-entity supervision, with no extra human labels. Moreover, they propose a pipeline system with the decomposers, an answer-prediction model, and a decomposition scorer trained separately on the previous stage's output. Our modular network, on the other hand, is an end-to-end system that is optimized jointly.

Neural Modular Network Neural Modular Network (NMN) is a class of models that are composed of a number of sub-modules, where each sub-module is capable of performing a specific subtask. In NMN (Andreas et al., 2016b), N2NMN (Hu et al., 2017), PG+EE (Johnson et al., 2017) and TbD (Mascharka et al., 2018), the entire reasoning procedure starts by analyzing the question and decomposing the reasoning procedure into a sequence of sub-tasks, each with a corresponding module. This is done by either a parser (Andreas et al., 2016b) or a layout policy (Hu et al., 2017; Johnson et al., 2017; Mascharka et al., 2018) that turns the question into a module layout. Then the module layout is executed with a neural module network. Overall, given an input question, the layout policy learns what sub-tasks to perform, and the neural modules learn how to perform each individual sub-task.

However, since the the modular layout is sampled from the controller, the controller itself is not end-to-end differentiable and has to be optimized using Reinforcement Learning Algorithms like Reinforce (Williams, 1992). Hu et al. (2018) used soft program execution where the output of each step is the average of outputs from all modules weighted by the module distribution, and showed its superiority over hard-layout NMNs. All previous works in NMN, including Hu et al. (2018)

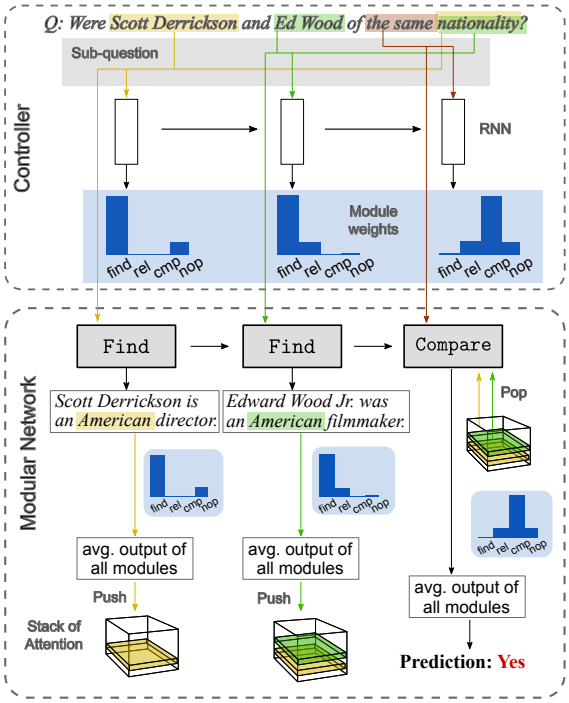

Figure 2: Modular network with a controller (top) and the dynamically-assembled modular network (bottom). At every step, the controller produces a sub-question vector and predicts a distribution to weigh the averages of the modules' outputs.

targeted visual question answering or structured knowledge-based GeoQA, and hence the modules are designed to process image or KB inputs. We are the first to apply modular networks to unstructured, text-based QA, where we redesigned the modules for language-based reasoning by using bi-attention (Seo et al., 2017; Xiong et al., 2017) to replace convolution and multiplication of the question vector with the image feature. Our model also has access to the full-sized bi-attention vector before it is projected down to the 1-d distribution.

Architecture Learning Our work also shares the spirit of recent research on Neural Architecture Search (NAS) (Zoph and Le, 2016; Pham et al., 2018; Liu et al., 2018), since the architecture of the model is learned dynamically based on controllers instead of being manually-designed. However, Neural Architecture Search aims to learn the structure of the individual CNN/RNN cell with fixed inter-connections between the cells, while Modular Networks have preset individual modules but learns the way to assemble them into a larger network. Moreover, Modular Networks' architectures are predicted dynamically on each data point, while previous NAS methods learn a single cell structure independent of the example.

3 Model

In this section, we describe how we apply the Neural Modular Network to the multi-hop HotpotQA task (Yang et al., 2018). In Sec. 3.2 and Sec. 3.3, we describe the controller, which sketches the model layout for a specific example, and introduce how it assembles the network with the predicted modules. In Sec. 3.4, we go into details of every novel module that we design for this task.

3.1 Encoding

We use a Highway Network (Srivastava et al., 2015) to merge the character embeddings and GloVe word embeddings (Pennington et al., 2014), building word representations for the context and the question as $\mathbf{x} \in \mathbb{R}^{S \times v}$ and $\mathbf{q} \in \mathbb{R}^{J \times v}$ respectively, where S and J are the lengths of the context and the question. We then apply a bi-directional LSTM-RNN (Hochreiter and Schmidhuber, 1997) of d hidden units to get the contextualized word representations for the context and question: $\mathbf{h} = \text{BiLSTM}(\mathbf{x})$; $\mathbf{u} = \text{BiLSTM}(\mathbf{q})$ so that $\mathbf{h} \in \mathbb{R}^{S \times 2d}$ and $\mathbf{u} \in \mathbb{R}^{J \times 2d}$. We also use a self attention layer (Zhong et al., 2019) to get qv, a fixed-sized vector representation of the question.

3.2 Model Layout Controller

In a modular network, the controller reads the question and predicts a series of our novel modules that could be executed in order to answer the given question. For multi-hop QA, each module represents a specific 1-hop reasoning behavior and the controller needs to deduce a chain of reasoning behavior that uncovers the evidence necessary to infer the answer. Similar to the model in Hu et al. (2018), at the step t, the probability of selecting module i is calculated as:

$$\begin{aligned} q_t &= W_{1,t} \cdot qv + b_{1,t} \\ cq_t &= W_2 \cdot [c_{t-1}; q_t] + b_2 \\ s_t &= W_3 \cdot cq_t \\ p_{t,i} &= \text{Softmax}(s_t) \end{aligned} \tag{1}$$

where c_{t-1} is the controller's hidden state and q_t is the vector representation of the question coming out of the encoding LSTM. W_3 projects the output to the dimension of $1 \times I$, where I is the number of available modules. When predicting the next module, the controller also supplies the current module, which we design for the language domain, with a fixed-sized vector as the sub-question at the

current reasoning step (the gray-shaded area of the controller in Fig. 2). Consider the first example in Fig. 1. At the first reasoning step, the `Find` module's sub-question is "the woman who portrayed Corliss Archer in the film Kiss and Tell". To generate this sub-question vector, the controller first calculates a distribution over all question words and then computes the weighted average of all the word representations:

$$\begin{aligned} e_{t,j} &= W_4 \cdot (cq_t \cdot u_j) + b_4 \\ cv_t &= \text{Softmax}(e_t) \\ c_t &= \sum_j cv_{t,j} \cdot u_j \end{aligned} \tag{2}$$

The sub-question vector c_t also serves as the controller's hidden state and is used to calculate the module probability in the next reasoning step. Similarly, in the second reasoning step, the sub-question of the `Relocate` module is "What government position was held by" and the answer from the `Find` module at the first step.

3.3 Stack NMN with Soft Program Execution

In our NMN, some modules may interact with the attention output from previous modules to collect information that could benefit the current reasoning step. For tree-structured layouts, such as `Compare(Find(), Find())` as shown in Fig. 1, the latter `Compare` module requires access to previous outputs. We follow Hu et al. (2018) to use a stack to store attention outputs generated by our modules. In the tree-structured layout, the two `Find` modules push two attention outputs onto the stack, and the `Compare` module pops these two attention outputs to compare the content they each focus on. To make the entire model differentiable, we also adopt soft program execution from Hu et al. (2018), where the output of each step is the sum of outputs from all modules weighted by the module distribution (blue-shaded area in Fig. 2) computed by the controller.

3.4 NMN Modules

We next describe all the modules we designed for our Neural Modular Network. All modules take the question representation $\mathbf{u}$, context representation $\mathbf{h}$, and sub-question vector $\mathbf{c_t}$ as input. The core modules that produce the attention map over the context are based on bi-attention (Seo et al., 2017) between the question and context, instead of relying on convolution as in previous NMNs (Hu et al., 2017, 2018). Every module outputs a fixed-size vector/zero vector as the memory state of the NMN, and is also able to push/pop attention maps onto/from the stack. These modules, each solving a single-hop sub-question, are chained together according to the layout predicted by the controller to infer the final answer to the multi-hop question.

`Find` This module performs the bidirectional attention (Seo et al., 2017) between question $\mathbf{u}$ and context $\mathbf{h'} = \mathbf{h} \cdot \mathbf{c_t}$. By multiplying the original context representation by $\mathbf{c_t}$, we inject the sub-question into the following computation. The model first computes a similarity matrix $M^{J \times S}$ between every question and context word and use it to derive context-to-query attention:

$$\begin{aligned} M_{j,s} &= W_1 \mathbf{u}_j + W_2 \mathbf{h'}_s + W_3 (\mathbf{u}_j \odot \mathbf{h'}_s) \\ p_{j,s} &= \frac{\exp(M_{j,s})}{\sum_{j=1}^{J} \exp(M_{j,s})} \\ \mathbf{c_{q}}_s &= \sum_{j=1}^{J} p_{j,s} \mathbf{u}_j \end{aligned} \tag{3}$$

where W_1, W_2 and W_3 are trainable parameters, and $\odot$ is element-wise multiplication. Then the query-to-context attention vector is derived as:

$$\begin{aligned} m_s &= \max_{1 \le s \le S} M_{j,s} \\ p_s &= \frac{\exp(m_s)}{\sum_{s=1}^{S} \exp(m_s)} \\ \mathbf{q_c} &= \sum_{s=1}^{S} p_s \mathbf{h}_S \end{aligned} \tag{4}$$

We then obtain the question-aware context representation as: $\widetilde{\mathbf{h}} = [\mathbf{h'}; \mathbf{c_q}; \mathbf{h'} \odot \mathbf{c_q}; \mathbf{c_q} \odot \mathbf{q_c}]$, and push this bi-attention result onto the stack. This process is visualized in the first two steps in Fig. 2.

`Relocate` For the first example in Fig. 1, the second reasoning step requires finding the "government position" held by the woman, who is identified in the first step. We propose the `Relocate` module to model this reasoning behavior of finding the answer based on the information from the question as well as the previous reasoning step. The `Relocate` module first pops an attention map att_1 from the stack and computes the bridge entity's representation $\mathbf{b}$ as the weighted average over $\mathbf{h}$ using the popped attention. It then computes a bridge-entity-awared representation of context $\mathbf{h_b}$, and then applies a `Find`

module between $\mathbf{h_b}$ and question $\mathbf{u}$:

$$\begin{aligned} \mathbf{b} &= \sum_s att_{1,s} \cdot \mathbf{h}_s \\ \mathbf{h_b} &= \mathbf{h} \odot \mathbf{b} \\ \widetilde{\mathbf{h}} &= \texttt{Find}(\mathbf{u}, \mathbf{h_b}, \mathbf{c_t}) \end{aligned} \tag{5}$$

The output $\widetilde{\mathbf{h}}$ is then pushed onto the stack.

`Compare` As shown in the final step in Fig. 2, the `Compare` module pops two attention maps att_1 and att_2 from the stack and computes two weighted averages over $\mathbf{h}$ using the attention maps. It then merges these two vectors with c_t to update the NMN's memory state m.

$$\begin{aligned} hs_1 = \sum_s att_{1,s} \cdot \mathbf{h}_s; \quad hs_2 = \sum_s att_{2,s} \cdot \mathbf{h}_s \\ o_{in} = [c_t; hs_1; hs_2; c_t \cdot (hs_1 - hs_2)] \\ m = W_1 \cdot (\text{ReLU}(W_2 \cdot o_{in})) \end{aligned} \tag{6}$$

The intuition is that the `Compare` module aggregates the information from two attention maps and compares them according to the sub-question c_t.

`NoOp` This module updates neither the stack nor the memory state. It can be seen as a skip command when the controller decides no more computation is required for the current example.

3.5 Bridge Entity Supervision

Even with the multi-hop architecture to capture the hop-specific distribution over the question, there is no supervision on the controller's output distribution c about which part of the question is related to the current reasoning step, thus preventing the controller from learning the composite reasoning skill. To address this problem, we supervise the first `Find` module to predict the bridge entity ("Shirley Temple" in Fig. 1), which indirectly encourages the controller to look for question information related to this entity ("the woman who portrayed Corliss Archer...") at the first step. Since the original dataset does not label the bridge entity, we apply a simple heuristic to detect the bridge entity that is the title of one supporting document while also appearing in the other supporting document.[2]

3.6 Prediction Layer

After all the reasoning steps have completed, to predict a span from the context as the answer, we pop the top attention map from the stack, apply self-attention (Yang et al., 2018), and project it down to get the span's start index and end index. To predict yes/no, we take the final memory (m in Eqn. 6) and project it down to a 2-way classifier. We concatenate the question vector qv and memory m and then project down to a 2-way classifier to decide whether to output a span or yes/no.

3.7 Optimization

Previous works on modular network (Hu et al., 2017, 2018) optimize the controller parameters θ jointly with the modules parameters ω on the training set. However, we found that our controller converges[3] in less than 20 iterations under this training routine. It is also likely that this setup causes the model to overfit to the single-hop reasoning shortcuts in the training set. Hence, to prevent such premature convergence and reasoning-shortcut overfitting, we adopt the 2-phase training strategy that is widely used in Neural Architecture Search (Zoph and Le, 2016; Pham et al., 2018). The first phase updates ω for an entire epoch, followed by the second phase that updates θ over the entire dev set. We alternate between the two phases until the entire system converges.

4 Experimental Setup

Dataset and Metric We conduct our training and evaluation on the HotpotQA (Yang et al., 2018) dataset's distractor setting, which has 90,447 training examples (72991 bridge-type questions and 17456 comparison-type questions) and 7,405 dev examples (5918 bridge-type questions and 1487 comparison-type questions). Since there is no public test set available, we split the original dev set into a dev set of 3,702 examples on which we tune our models, and a test set of 3,703 examples that is only used for the final test results. Each question is paired with 10 documents, among which 2 are supporting documents that contain the evidence necessary to infer the answer, and the other 8 are distracting documents. We evaluate our models based on the exact-match and F1 score between the prediction and ground-truth answer.

Data Augmentation We augment the comparison-type questions in the training set to promote the model's robustness on this reasoning paradigm. We start with getting the

[2] There are two supporting documents per example.

part-of-speech tags and NER tag of the question using Corenlp (Manning et al., 2014). For each question whose answer is either "yes" or "no", we generate a new question by randomly sampling two titles of the same type (based on POS and NER) from the training set to substitute the original entities in the question and corresponding supporting documents (1st row in Table 1). We then employ three strategies to generate 5,342 extra questions by mutating original questions. First, if the question contains the word "same" and the answer is yes or no, we substitute "same" with "different" and vice versa (2nd row in Table 1). Second, we detect the comparative and superlative adjectives/adverbs in the original question, transform them into their antonyms using wordnet, and then transform the antonyms back to their comparative form (3rd row in Table 1). Finally, if the question has a comparative adj./adv., we flip the order of the two entities compared (4th row in Table 1). In all three cases, the answer to the mutated question is also flipped.

Training Details We use 300-d GloVe pre-trained embeddings (Pennington et al., 2014). The model is supervised to predict either the start and end index of a span or "Yes/No" for specific questions. The entire model (controller + modular network) is trained end-to-end using the Adam optimizer (Kingma and Ba, 2014) with an initial learning rate of 0.001.

5 Results

5.1 Baseline

Our baseline is the bi-attention (Seo et al., 2017) + self-attention model as in (Clark and Gardner, 2018; Yang et al., 2018), which was shown to be able to achieve strong performance on single-hop QA tasks like SQuAD (Rajpurkar et al., 2016) and TriviaQA (Joshi et al., 2017). Our baseline shares the preprocessing and encoding layer with the modular network.

5.2 Primary NMN Results

We first present our model's performance on the HotpotQA (Yang et al., 2018) dev and test set of our split. As shown in the first three rows of Table 2, our modular network achieves significant improvements over both the baseline and the convolution-based NMN (Hu et al., 2018) on our test set. In Table 3, we further break down the dev-set performance on different question types,[4] and our modular network obtains higher scores in both question types compared to the BiDAF baseline.

5.3 Ablation Studies

Data Augmentation: We also conduct ablation studies on our modeling choices. Augmenting the comparison-type questions in the training set boosts the performance on the comparison-type questions in the dev set (comparing row 3 and 4 in Table 3) without harming the scores on the bridge-type questions too much.

Bridge-entity Supervision: Supervising the bridge entity (described in 3.5) proves to be

[4]The 3 types of question other than "comparison" are all classified as "bridge-type" questions by Yang et al. (2018)

beneficial for the modular network to achieve good performance (row 5 in Table 2 and Table 3).

Modules: As shown in the 6th to 8th row, removing either the `Compare`, `Relocate` or `NoOp` module also causes drops in the metric scores. Specifically, removing the `Relocate` module causes significant degrade in bridge-type questions, which solidifies our claim that relocating the attention based on the inferred bridge entity is important for compositional reasoning. Similarly, removing the `Compare` module harms the model's performance on comparison-type questions, suggesting the effectiveness of the module in addressing questions that require comparing two entities' properties. These results demonstrate the contribution of each module toward achieving a self-assembling modular network with the strong overall performance.

5.4 Comparison with Original NMN Modules

One primary contribution of this work is that we adapt neural modular networks (NMN) (Andreas et al., 2016a; Hu et al., 2017, 2018), which were designed for visual-domain QA, to text-domain QA by rebuilding every reasoning module. We substitute convolution and multiplication between question vectors and context features with bi-attention as the basic reasoning component in the `Find` and `Relocate`. Moreover, our model maintains a stack of attention outputs before it is projected down to 1-d, thus enabling skip connections when predicting the answer span. As shown in Table 2 and Table 3, our adapted modular network outperforms the original NMN significantly.

5.5 Adversarial Evaluation

Multiple previous works (Chen and Durrett, 2019; Min et al., 2019a) have shown that models performing strongly on HotpotQA are not necessarily capable of compositional reasoning. Jiang and Bansal (2019) proposed to construct adversarial distractor documents to eliminate the reasoning shortcut and necessitate compositional reasoning on HotpotQA dataset. To test whether our modular network can perform robust multi-hop reasoning against such adversaries, we evaluate our models on the adversarial dev set. The second column of Table 4 shows that our NMN outperforms the baseline significantly (+10 points in EM score) on the adversarial evaluation, suggesting that our NMN is indeed learning stronger compositional reasoning skills compared to the BiDAF baseline. We further train both models on the adversarial training set, and the results are shown in the last two columns of Table 4. We observe that after adversarial training, both the baseline and our NMN obtain significant improvement on the adversarial evaluation, while our NMN maintains a significant advantage over the BiDAF baseline.

6 Analysis

In this section, we present three analysis methods to show that our multi-hop NMN is highly interpretable and makes decisions similar to human actions. Combining the analyses below, we can understand how our model reasons to break the multi-step task into multiple single-step subtasks that are solvable by specific modules, and harnesses intermediate outputs to infer the answer.

6.1 Controller's Attention on Questions

Different from single-hop questions, a multi-hop question usually encodes a sequence of sub-questions, among which the final sub-question requires an explicit answer. Therefore, the first step of solving a multi-hop question is to identify the hidden sub-questions and to sort them according to the correct reasoning order. Our controller handles this task by computing an attention distribution over all question words (see details in Sec. 3.2) at every reasoning step, which signifies which part of the question forms a sub-question that should be answered at the current step. Fig. 3 visualizes four

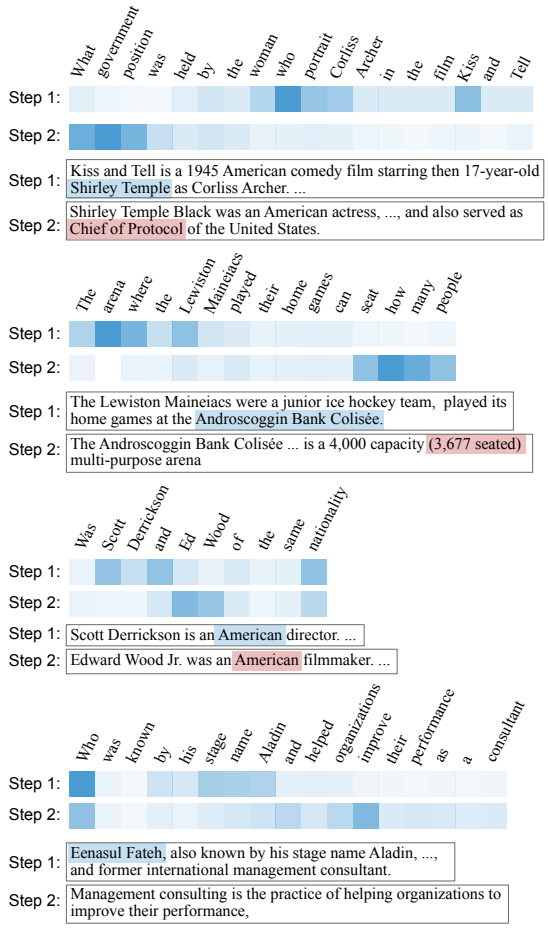

Figure 3: The controller's multi-hop attention map on the question (randomly chosen from the first 10 dev examples). This attention is used to compute the sub-question representation that is passed to the modules.

attention maps from the controller when dealing with questions of different reasoning paradigms (randomly chosen from the first 10 dev examples), suggesting that our controller is able to accurately identify the sub-questions in the correct order. In the first example, the controller is able to attend to the first sub-question "who portrayed Corliss Archer in ...", and then relocate the attention to the next sub-question "What government position was held by ..." to complete the 2-step reasoning.

6.2 Predicting Network Layouts

After the controller decides the sub-question at the current reasoning step, it then predicts a soft layout of the the current step by outputting a distribution cv over all available modules (`Find`, `Relocate`, `Compare`, `NoOp`). As elaborated in Sec. 3.3, the output vector and attention map of all modules are weighted by cv. To quantitatively evaluate the layout predicted by the controller, we label the expert layout for each question in the dev set (`Find-Relocate` for bridge-type questions and `Find-Find/Relocate-Compare` for comparison-type questions). Next, we convert the soft module predictions into hard modular layouts by picking the module with the largest prediction probability at each step. Intuitively, we want the controller to assign higher weights to the module that can perform the desired reasoning. We then compute the percentage of dev set examples where the predicted layout matches the expert layout exactly. The empirical study shows that the layouts predicted by our NMN controller match the expert layout in 99.9% of bridge-type questions and 68.6% of comparison-type questions with Yes/No answer (examples shown in Fig. 1 and Fig. 2).

6.3 Finding Intermediate Bridge-Entities

The final action of an intermediate reasoning step is the predicted module reasoning through the question and context to answer the sub-question. For bridge-type questions (e.g., the first example in Fig. 3), the required action is to find the name ("Shirley Temple") of "the woman who portrait Corliss Archer ..." to complete the next sub-question "What government position was held by Shirley Temple". For comparison questions (e.g., the third example in Fig. 3), the model needs to infer the nationalities of "Scott" and "Ed" that will be compared in the following step.

7 Conclusion

In this work, we proposed a self-assembling neural modular network for multi-hop QA. We designed three modules that reason between the question and text-based context. The resulting model outperforms both the single-hop baseline and the original NMN on HotpotQA (Yang et al., 2018). Because of the interpretable nature of our model, we presented analyses to show that our model does in fact learn to perform compositional reasoning and can dynamically assemble the modular network based on the question.

Abstract

Deep learning models for semantics are generally evaluated using naturalistic corpora. Adversarial methods, in which models are evaluated on new examples with known semantic properties, have begun to reveal that good performance at these naturalistic tasks can hide serious shortcomings. However, we should insist that these evaluations be *fair* – that the models are given data sufficient to support the requisite kinds of generalization. In this paper, we define and motivate a formal notion of fairness in this sense. We then apply these ideas to natural language inference by constructing very challenging but provably fair artificial datasets and showing that standard neural models fail to generalize in the required ways; only task-specific models that jointly compose the premise and hypothesis are able to achieve high performance, and even these models do not solve the task perfectly.

1 Introduction

Evaluations of deep learning approaches to semantics generally rely on corpora of naturalistic examples, with quantitative metrics serving as a proxy for the underlying capacity of the models to learn rich meaning representations and find generalized solutions. From this perspective, when a model achieves human-level performance on a task according to a chosen metric, one might be tempted to say that the task is "solved". However, recent adversarial testing methods, in which models are evaluated on new examples with known semantic properties, have begun to reveal that even these state-of-the-art models often rely on brittle, local solutions that fail to generalize even to examples that are similar to those they saw in training. These findings indicate that we need a broad and deep range of evaluation methods to fully characterize the capacities of our models.

However, for any evaluation method, we should ask whether it is *fair*. Has the model been shown data sufficient to support the kind of generalization we are asking of it? Unless we can say "yes" with complete certainty, we can't be sure whether a failed evaluation traces to a model limitation or a data limitation that no model could overcome.

In this paper, we seek to address this issue by defining a formal notion of fairness for these evaluations. The definition is quite general and can be used to create fair evaluations for a wide range of tasks. We apply it to Natural Language Inference (NLI) by constructing very challenging but provably fair artificial datasets. We evaluate a number of different standard architectures (variants of LSTM sequence models with attention and tree-structured neural networks) as well as NLI-specific tree-structured neural networks that process aligned examples. Our central finding is that only task-specific models are able to achieve high performance, and even these models do not solve the task perfectly, calling into question the viability of the standard models for semantics.

2 Related Work

There is a growing literature that uses targeted generalization tasks to probe the capacity of learning models. We seek to build on this work by developing a formal framework in which one can ask whether one of these tasks is even possible.

In adversarial testing, training examples are systematically perturbed and then used for testing. In computer vision, it is common to adversarially train on artificially noisy examples to create a more robust model (Goodfellow et al., 2015; Szegedy et al., 2014). However, in the case of question answering, Jia and Liang (2017) show that training on one perturbation does not result in generalization to similar perturbations, revealing a

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4485–4495,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

need for models with stronger generalization capabilities. Similarly, adversarial testing has shown that strong models for the SNLI dataset (Bowman et al., 2015a) have significant holes in their knowledge of lexical and compositional semantics (Glockner et al., 2018; Naik et al., 2018; Nie et al., 2018; Yanaka et al., 2019; Dasgupta et al., 2018). In addition, a number of recent papers suggest that even top models exploit dataset artifacts to achieve good quantitative results (Poliak et al., 2018; Gururangan et al., 2018; Tsuchiya, 2018), which further emphasizes the need to go beyond naturalistic evaluations.

Artificially generated datasets have also been used extensively to gain analytic insights into what models are learning. These methods have the advantage that the complexity of individual examples can be precisely characterized without reference to the models being evaluated. Evans et al. (2018) assess the ability of neural models to learn propositional logic entailment. Bowman et al. (2015b) conduct similar experiments using natural logic, and Veldhoen and Zuidema (2018) analyze models trained on those same tasks, arguing that they fail to discover the kind of global solution we would expect if they had truly learned natural logic. Lake and Baroni (2017) apply similar methods to instruction following with an artificial language describing a simple domain.

These methods can provide powerful insights, but the issue of fairness looms large. For instance, Bowman (2013) poses generalization tasks in which entire reasoning patterns are held out for testing. Similarly, Veldhoen and Zuidema (2018) assess a model's ability to recognize De Morgan's laws without any exposure to this reasoning in training. These extremely difficult tasks break from standard evaluations in an attempt to expose model limitations. However, these tasks are not fair by our standards; brief formal arguments for these claims are given in Appendix A.

3 Compositionality and Generalization

Many problems can be solved by recursively composing intermediate representations with functions along a tree structure. In the case of arithmetic, the intermediate representations are numbers and the functions are operators such a plus or minus. In the case of evaluating the truth of propositional logic sentences, the intermediate representation are truth values and the functions are logical operators such as disjunction, negation, or the material conditional. We will soon see that, in the case of NLI, the intermediate representations are semantic relations between phrases and the functions are semantic operators such as quantifiers or negation. When tasked with learning some compositional problem, we intuitively would expect to be shown how every function operates on every intermediate value. Otherwise, some functions would be underdetermined. We now formalize the idea of recursive tree-structured composition and this intuitive notion of fairness.

Data: A composition tree $C = (T, \mathit{Dom}, \mathit{Func})$, a node $a \in N^T$, and an input $x \in \mathcal{I}_C$
Result: An output from $\mathit{Dom}(a)$

function $\texttt{compose}\,(C, a, x)$
  if $a \in N^T_{\mathit{leaf}}$ **then**
    $i \leftarrow \texttt{index}(a, T)$
    return x_i
  else
    $c_1, \ldots c_m \leftarrow \texttt{children}(a, T)$
    return $\mathit{Func}(a)($
      $\texttt{compose}(C, c_1, x), \ldots,$
      $\texttt{compose}(C, c_m, x))$
  end

Algorithm 1: Recursive composition up a tree. This algorithm uses helper functions $\texttt{children}(a, T)$, which returns the left-to-right ordered children of node a, and $\texttt{index}(a, T)$, which returns the index of a leaf according to left-to-right ordering.

We first define composition trees (Section 3.1) and show how these naturally determine baseline learning models (Section 3.2). These models implicitly define a property of fairness: a train/test split is fair if the baseline model learns the task perfectly (Section 3.3). This enables us to create provably fair NLI tasks in Section 4.

3.1 Composition Trees

A composition tree describes how to recursively compose elements from an input space up a tree structure to produce an element in an output space. Our baseline learning model will construct a composition tree using training data.

Definition 1. (Composition Tree) Let T be an ordered tree with nodes $N^T = N^T_{\text{leaf}} \cup N^T_{\text{non-leaf}}$, where N^T_{leaf} is the set of leaf nodes and $N^T_{\text{non-leaf}}$ is the set of non-leaf nodes for T. Let *Dom* be a map on N^T that assigns a set to each node, called the *domain* of the node. Let *Func* be a map on

Data: An ordered tree T and a set of training data $\mathcal{D}$ containing pairs (x, Y) where x is an input and Y is a function defined on $N^T_{\text{non-leaf}}$ providing labels at every node of T.
Result: A composition tree $(T, \mathit{Dom}, \mathit{Func})$

function `learn` $(T, \mathcal{D})$
  $\mathit{Dom}, \mathit{Func} \leftarrow$ `initialize`(T)
  for $(x, Y) \in \mathcal{D}$ **do**
    $\mathit{Dom}, \mathit{Func} \leftarrow$ `memorize`$(x, Y, T, \mathit{Dom}, \mathit{Func}, r)$
  end
  return $(T, \mathit{Dom}, \mathit{Func})$

function `memorize` *(x,Y,T,Dom,Func,a)*
  if $a \in N^T_{\mathit{leaf}}$ **then**
    $i \leftarrow$ `index`(a, T)
    $\mathit{Dom}[a] \leftarrow \mathit{Dom}[a] \cup \{x_i\}$
    return *Dom*, *Func*
  else
    $\mathit{Dom}[a] \leftarrow \mathit{Dom}[a] \cup \{Y(a)\}$
    $c_1, \ldots, c_m \leftarrow$ `children`(a, T)
    $\mathit{Func}[a][(Y(c_1), \ldots, Y(c_m))] \leftarrow Y(a)$
    for $k \leftarrow 1 \ldots m$ **do**
      $\mathit{Dom}, \mathit{Func} \leftarrow$ `memorize`$(x, Y, T, \mathit{Dom}, \mathit{Func}, c_k)$
    end
    return *Dom*, *Func*
  end

Algorithm 2: Given a tree and training data with labels for every node of the tree, this learning model constructs a composition tree. This algorithm uses helper functions `children`(a, T) and `index`(a, T), as in Algorithm 1, as well as `initialize`(T), which returns *Dom*, a dictionary mapping N^T to empty sets, and *Func*, a dictionary mapping $N^T_{\text{non-leaf}}$ to empty dictionaries.

$N^T_{\text{non-leaf}}$ that assigns a function to each non-leaf node satisfying the following property: For any $a \in N^T_{\text{non-leaf}}$ with left-to-right ordered children $c_1, \ldots, c_m$, we have that $\mathit{Func}(a) : \mathit{Dom}(c_1) \times \cdots \times \mathit{Dom}(c_m) \to \mathit{Dom}(a)$. We refer to the tuple $C = (T, \mathit{Dom}, \mathit{Func})$ as a *composition tree*. The *input space* of this composition tree is the cartesian product $\mathcal{I}_C = \mathit{Dom}(l_1) \times \cdots \times \mathit{Dom}(l_k)$, where $l_1, \ldots, l_k$ are the leaf nodes in left-to-right order, and the *output space* is $\mathcal{O}_C = \mathit{Dom}(r)$ where r is the root node.

A composition tree $C = (T, \mathit{Dom}, \mathit{Func})$ realizes a function $F : \mathcal{I}_C \to \mathcal{O}_C$ in the following way: For any input $x \in \mathcal{I}_C$, this function is given by $F(x) = \texttt{compose}(C, r, x)$, where r is the root node of T and `compose` is defined recursively in Algorithm 1. For a given $x \in \mathcal{I}_C$ and $a \in N^T_{\text{non-leaf}}$ with children $c_1, \ldots, c_m$, we say that the element of $\mathit{Dom}(c_1) \times \cdots \times \mathit{Dom}(c_m)$ that is input to $\mathit{Func}(a)$ during the computation of $F(x) = \texttt{compose}(C, r, x)$ is the input realized at $\mathit{Func}(a)$ on x and the element of $\mathit{Dom}(a)$ that is output by $\mathit{Func}(a)$ is the output realized at $\mathit{Func}(a)$ on x. At a high level, $\texttt{compose}(C, a, x)$ finds the output realized at a node a by computing node a's function $\mathit{Func}(a)$ with the outputs realized at node a's children as inputs. This recursion bottoms out when the components of x are provided as the outputs realized at leaf nodes.

3.2 A Baseline Learning Model

Algorithm 2 is our baseline learning model. It learns a function by constructing a composition tree. This is equivalent to learning the function that tree realizes, as once the composition tree is created, Algorithm 1 computes the realized function. Because this model constructs a composition tree, it has an inductive bias to recursively compute intermediate representations up a tree structure. At a high level, it constructs a full composition tree when provided with the tree structure and training data that provides a label at every node in the tree by looping through training data inputs and memorizing the output realized at each intermediate function for a given input. As such, any learning model we compare to this baseline model should be provided with the outputs realized at every node during training.

3.3 Fairness

We define a training dataset to be fair with respect to some function F if our baseline model perfectly learns the function F from that training data. The guiding idea behind fairness is that the training data must expose every intermediate function of a composition tree to every possible intermediate input, allowing the baseline model to learn a global solution:

Definition 2. (A Property Sufficient for Fairness) A property of a training dataset $\mathcal{D}$ and tree T that is sufficient for fairness with respect to a function F is that there exists a composition tree $C = (T, \mathit{Dom}, \mathit{Func})$ realizing F such that, for any $a \in N^T_{\text{non-leaf}}$ and for any input i to $\mathit{Func}(a)$, there exists $(x, Y) \in \mathcal{D}$ where i is the input realized at $\mathit{Func}(a)$ on x.

Not all fair datasets are challenging. For example, a scenario in which one trains and tests on the entire space of examples will be fair. The role of fairness is to ensure that, when we separately de-

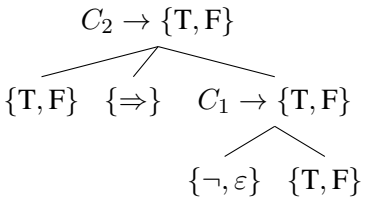

Figure 1: A composition tree that realizes a function evaluating propositional sentences. We define the functions $C_1(U, V_1) = U(V_1)$ and $C_2(V_1, \Rightarrow, V_2) = V_1 \Rightarrow V_2$ where $V_1, V_2 \in \{\mathrm{T}, \mathrm{F}\}$ and $U \in \{\neg, \varepsilon\}$.

Train	**Test**
T $\Rightarrow$ ε F	T $\Rightarrow$ $\neg$ T
T $\Rightarrow$ $\neg$ F	T $\Rightarrow$ ε T
F $\Rightarrow$ $\neg$ T	F $\Rightarrow$ $\neg$ F
F $\Rightarrow$ ε T	F $\Rightarrow$ ε F

Table 1: A fair train/test split for the evaluation problem defined by the composition tree in Figure 1. We give just the terminal nodes; the examples are full trees.

fine a challenging task, it is guaranteed to be possible. We noted in Section 2 that some challenging problems in the literature fail to meet this minimal requirement.

3.4 Fair Tasks for Propositional Evaluation

As a simple illustration of the above concepts, we consider the task of evaluating the truth of a sentence from propositional logic. We use the standard logical operators material conditional, $\Rightarrow$, and negation, $\neg$, as well as the unary operator ε, which we define to be the identity function on $\{\mathrm{T}, \mathrm{F}\}$. We consider a small set of eight propositional sentences, all which can be seen in Table 1. We illustrate a composition tree that realizes a function performing truth evaluation on these sentences in Figure 1, where a leaf node l is labeled with its domain $\mathit{Dom}(l)$ and a non-leaf node a is labeled with $\mathit{Func}(a) \rightarrow \mathit{Dom}(a)$.

A dataset for this problem is fair if and only if it has two specific properties. First, the binary operator $\Rightarrow$ must be exposed to all four inputs in $\{\mathrm{T}, \mathrm{F}\} \times \{\mathrm{T}, \mathrm{F}\}$ during training. Second, the unary operators $\neg$ and ε each must be exposed to both inputs in $\{\mathrm{T}, \mathrm{F}\}$. Jointly, these constraints ensure that a model will see all the possibilities for how our logical operators interact with their truth-value arguments. If either constraint is not met, then there is ambiguity about which operators the model is tasked with learning. An example fair train/test split is given in Table 1.

Crucial to our ability to create a fair training dataset using only four of the eight sentences is that $\Rightarrow$ operates on the intermediate representation of a truth value, abstracting away from the specific identity of its sentence arguments. Because there are two ways to realize T and F at the intermediate node, we can efficiently use only half of our sentences to satisfy our fairness property.

symbol	example	set theoretic definition
$x \equiv y$	couch $\equiv$ sofa	$x = y$
$x \sqsubset y$	crow $\sqsubset$ bird	$x \subset y$
$x \sqsupset y$	bird $\sqsupset$ crow	$x \supset y$
$x \,^\wedge\, y$	human $^\wedge$ nonhuman	$x \cap y = \emptyset \wedge x \cup y = U$
$x \mid y$	cat $\mid$ dog	$x \cap y = \emptyset \wedge x \cup y \neq U$
$x \smile y$	animal $\smile$ nonhuman	$x \cap y \neq \emptyset \wedge x \cup y = U$
$x \# y$	hungry # hippo	(all other cases)

Table 2: The seven basic semantic relations of MacCartney and Manning (2009): $\mathcal{B}$ = {# = independence, $\sqsubset$ = entailment, $\sqsupset$ = reverse entailment, $\mid$ = alternation, $\smile$ = cover, $^\wedge$ = negation, $\equiv$ = equivalence}.

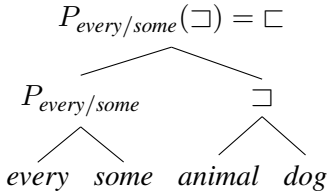

Figure 2: Natural logic inference cast as composition on aligned semantic parse trees. The joint projectivity signature $P_{every/some}$ operates on the semantic relation $\sqsupset$ determined by the aligned pair *animal/dog* to determine entailment ($\sqsubset$) for the whole. In contrast, if we reverse *every* and *some*, creating the example *some animal/every dog*, then the joint projectivity signature $P_{some/every}$ operates on $\sqsupset$, which determines reverse entailment ($\sqsupset$).

4 Fair Artificial NLI Datasets

Our central empirical question is whether current neural models can learn to do robust natural language inference if given fair datasets. We now present a method for addressing this question. To do this, we need to move beyond the simple propositional logic example explored above, to come closer to the true complexity of natural language. To do this, we adopt a variant of the *natural logic* developed by MacCartney and Manning (2007, 2009) (see also Sánchez-Valencia 1991; van Benthem 2008; Icard and Moss 2013). Natural logic

is a flexible approach to doing logical inference directly on natural language expressions. Thus, in this setting, we can work directly with natural language sentences while retaining complete control over all aspects of the generated dataset.

4.1 Natural Logic

We define natural logic reasoning over aligned semantic parse trees that represent both the premise and hypothesis as a single structure and allow us to calculate semantic relations for all phrases compositionally. The core components are *semantic relations*, which capture the direct inferential relationships between words and phrases, and *projectivity signatures*, which encode how semantic operators interact compositionally with their arguments. We employ the semantic relations of MacCartney and Manning (2009), as in Table 2. We use $\mathcal{B}$ to denote the set containing these seven semantic relations.

The essential concept for the material to come is that of *joint projectivity*: for a pair of semantic functions f and g and a pair of inputs X and Y that are in relation R, the joint projectivity signature $P_{f/g} : \mathcal{B} \to \mathcal{B}$ is a function such that the relation between $f(X)$ and $g(Y)$ is $P_{f/g}(R)$. Figure 2 illustrates this with the phrases *every animal* and *some dog*. We show the details of how the natural logic of MacCartney and Manning (2009), with a small extension, determines the joint projectivity signatures for our datasets in Appendix B.

4.2 A Fragment of Natural Language

Our fragment G consists of sentences of the form:

$$\mathrm{Q_S\ Adj_S\ N_S\ Neg\ Adv\ V\ Q_O\ Adj_O\ N_O}$$

where $\mathrm{N_S}$ and $\mathrm{N_O}$ are nouns, V is a verb, $\mathrm{Adj_S}$ and $\mathrm{Adj_O}$ are adjectives, and Adv is an adverb. Neg is *does not*, and $\mathrm{Q_S}$ and $\mathrm{Q_O}$ can be *every*, *not every*, *some*, or *no*; in each of the remaining categories, there are 100 words. Additionally, $\mathrm{Adj_S}$, $\mathrm{Adj_O}$, Adv, and Neg can be the empty string ε, which is represented in the data by a unique token. Semantic scope is fixed by surface order, with earlier elements scoping over later ones.

For NLI, we define the set of premise–hypothesis pairs $\mathcal{S} \subset G \times G$ such that $(s_p, s_h) \in \mathcal{S}$ iff the non-identical non-empty nouns, adjectives, verbs, and adverbs with identical positions in s_p and s_h are in the $\#$ relation. This constraint on $\mathcal{S}$ trivializes the task of determining the lexical relations between adjectives, nouns, adverbs, and verbs, since the relation is $\equiv$ where the two aligned elements are identical and otherwise $\#$. Furthermore, it follows that distinguishing contradictions from entailments is trivial. The only sources of contradictions are negation and the negative quantifiers *no* and *not every*. Consider $(s_p, s_h) \in \mathcal{S}$ and let C be the number of times negation or a negative quantifier occurs in s_p and s_h. If s_p contradicts s_h, then C is odd; if s_p entails s_h, then C is even.

We constrain the open-domain vocabulary to stress models with learning interactions between logically complex function words; we trivialize the task of lexical semantics to isolate the task of compositional semantics. We also do not have multiple morphological forms, use artificial tokens that do not correspond to English words, and collapse *do not* and *not every* to single tokens to further simplify the task and isolate a model's ability to perform compositional logical reasoning.

Our corpora use the three-way labeling scheme of *entailment*, *contradiction*, and *neutral*. To assign these labels, we translate each premise–hypothesis pair into first-order logic and use Prover9 (McCune, 2005–2010). We assume no expression is empty or universal and encode these assumptions as additional premises. This label generation process implicitly assumes the relation between unequal nouns, verbs, adjectives, and adverbs is independence.

When we generate training data for NLI corpora from some subset $\mathcal{S}_{train} \subset \mathcal{S}$, we perform the following balancing. For a given example, every adjective–noun and adverb–verb pair across the premise and hypothesis is equally likely to have the relation $\equiv$, $\sqsubset$, $\sqsupset$, or $\#$. Without this balancing, any given adjective–noun and adverb–verb pair across the premise and hypothesis has more than a 99% chance of being in the independence relation for values of $\mathcal{S}_{train}$ we consider. Even with this step, 98% of the sentence pairs are neutral, so we again sample to create corpora that are balanced across the three NLI labels. This balancing across our three NLI labels justifies our use of an accuracy metric rather than an F1 score.

4.3 Composition Trees for NLI

We provide a composition tree for inference on $\mathcal{S}$ in Figure 3. This is an *aligned* composition tree, as in Figure 2: it jointly composes lexical items from the premise and hypothesis. The leaf nodes come in sibling pairs where one sibling is a lexical item from the premise and the other is a lexical item

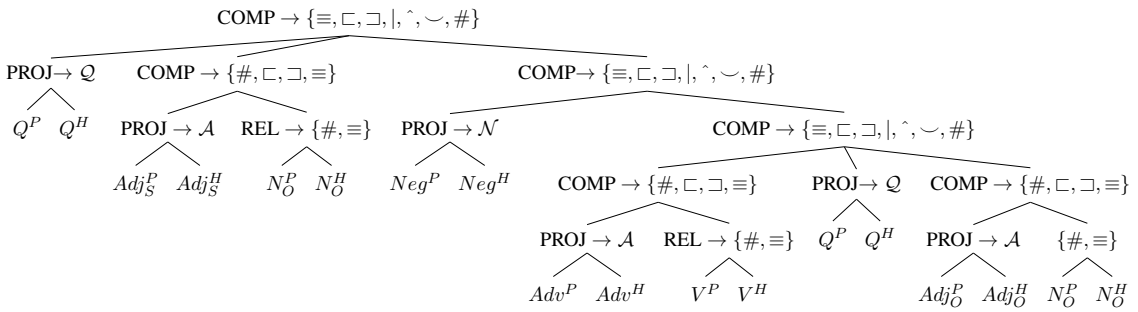

Figure 3: An aligned composition tree for inference on our set of examples $\mathcal{S}$. The superscripts P and H refer to premise and hypothesis. The semantic relations are defined in Table 2. The set Q is {*some*, *every*, *no*, *not*, *every*}. The set *Neg* is $\{\varepsilon, \textit{not}\}$. $\mathcal{Q}$ is the set of 16 joint projectivity signatures between the elements of Q. $\mathcal{N}$ is the set of 4 joint projectivity signatures between ε and *no*. $\mathcal{A}$ is the set of 4 joint projectivity signatures between ε and an intersective adjective or adverb. REL computes the semantic relations between lexical items, PROJ computes the joint projectivity between two semantic functions (Section 4.1 and Appendix B), and COMP applies semantic relations to joint projectivity signatures. This composition tree defines over 10^{26} distinct examples.

from the hypothesis. If both leaf nodes in a sibling pair have domains containing lexical items that are semantic functions, then their parent node domain contains the joint projectivity signatures between those semantic functions. Otherwise the parent node domain contains the semantic relations between the lexical items in the two sibling node domains. The root captures the overall semantic relation between the premise and the hypothesis, while the remaining non-leaf nodes represent intermediate phrasal relations.

The sets Adj_S, N_S, Adj_O, N_O, *Adv*, and *V* each have 100 of their respective open class lexical items with *Adv*, Adj_S, and Adj_O also containing the empty string ε. The set Q is {*some*, *every*, *no*, *not*, *every*} and the set *Neg* is $\{\varepsilon, \textit{not}\}$. $\mathcal{Q}$ is the set of 16 joint projectivity signatures between the quantifiers *some*, *every*, *no*, and *not every*, $\mathcal{N}$ is the set of 4 joint projectivity signatures between the empty string ε and *no*, and $\mathcal{A}$ is the set of 4 projectivity signatures between ε and an intersective adjective or adverb. These joint projectivity signatures were exhaustively determined by us by hand, using the projectivity signatures of negation and quantifiers provided by MacCartney and Manning (2009) as well as a small extension (details in Appendix B).

The function PROJ computes the joint projectivity signature between two semantic functions, REL computes the semantic relation between two lexical items, and COMP inputs semantic relations into a joint projectivity signature and outputs the result. We trimmed the domain of every node so that the function of every node is surjective. Pairs of subexpressions containing quantifiers can be in any of the seven basic semantic relations; even with the contributions of open-class lexical items trivialized, the level of complexity remains high, and all of it emerges from semantic composition, rather than from lexical relations.

4.4 A Difficult But Fair NLI Task

A fair training dataset exposes each local function to all possible inputs. Thus, a fair training dataset for NLI will have the following properties. First, all lexical semantic relations must be included in the training data, else the lexical targets could be underdetermined. Second, for any aligned semantic functions f and g with unknown joint projectivity signature $P_{f/g}$, and for any semantic relation R, there is some training example where $P_{f/g}$ is exposed to the semantic relation R. This ensures that the model has enough information to learn full joint projectivity signatures. Even with these constraints in place, the composition tree of Section 3.1 determines an enormous number of very challenging train/test splits. Appendix C fully defines the procedure for data generation.

We also experimentally verify that our baseline learns a perfect solution from the data we generate. The training set contains 500,000 examples randomly sampled from $\mathcal{S}_{train}$ and the test and development sets each contain 10,000 distinct examples randomly sampled from $\mathcal{S}_{train}$. All random sampling is balanced across adjective–noun and adverb–verb relations as well as across the three NLI labels, as described in Section 4.2.

5 Models

We consider six different model architectures:

CBoW Premise and hypothesis are represented by the average of their respective word embeddings (continuous bag of words).

LSTM Encoder Premise and hypothesis are processed as sequences of words using a recurrent neural network (RNN) with LSTM cells, and the final hidden state of each serves as its representation (Hochreiter and Schmidhuber, 1997; Elman, 1990; Bowman et al., 2015a).

TreeNN Premise and hypothesis are processed as trees, and the semantic composition function is a single-layer feed-forward network (Socher et al., 2011b,a). The value of the root node is the semantic representation in each case.

Attention LSTM An LSTM RNN with word-by-word attention (Rocktäschel et al., 2015).

CompTreeNN Premise and hypothesis are processed as a single aligned tree, following the structure of the composition tree in Figure 3. The semantic composition function is a single-layer feed-forward network (Socher et al., 2011b,a). The value of the root node is the semantic representation of the premise and hypothesis together.

CompTreeNTN Identical to the CompTreeNN, but with a neural tensor network as the composition function (Socher et al., 2013).

For the first three models, the premise and hypothesis representations are concatenated. For the CompTreeNN, CompTreeNTN, and Attention LSTM, there is just a single representation of the pair. In all cases, the premise–hypothesis representation is fed through two hidden layers and a softmax layer.

All models are initialized with random 100-dimensional word vectors and optimized using Adam (Kingma and Ba, 2014). It would not be possible to use pretrained word vectors, due to the artificial nature of our dataset. A grid hyperparameter search was run over dropout values of $\{0, 0.1, 0.2, 0.3\}$ on the output and keep layers of LSTM cells, learning rates of $\{1e{-}2, 3e{-}3, 1e{-}3, 3e{-}4\}$, L2 regularization values of $\{0, 1e{-}4, 1e{-}3, 1e{-}2\}$ on all weights, and activation functions ReLU and $\tanh$. Each hyperparameter setting was run for three epochs and parameters with the highest development set score were used for the complete training runs.

ϵ rock $\sqsupset$ large rock	kicks $\equiv$ kicks ϵ $\sqsupset$ large rock $\equiv$ rock

Figure 4: For any example sentence pair (top left) the neural models are trained using the a weighted sum of the error on 12 prediction tasks shown above. The 12 errors are weighted to regularize the loss according to the length of the expressions being predicted on.

The training datasets for this generalization task are only fair if the outputs realized at every non-leaf node are provided during training just as they are in our baseline learning model. For our neural models, we accomplish this by predicting semantic relations for every subexpression pair in the scope of a node in the tree in Figure 3 and summing the loss of the predictions together. We do not do this for the nodes labeled PROJ $\rightarrow \mathcal{Q}$ or PROJ $\rightarrow \mathcal{N}$, as the function PROJ is a bijection at these nodes and no intermediate representations are created. For any example sentence pair the neural models are trained using the a weighted sum of the error on 12 prediction tasks shown in Figure 4. The 12 errors are weighted to regularize the loss according to the length of the expressions being predicted on.

The CompTreeNN and CompTreeNTN models are structured to create intermediate representations of these 11 aligned phrases and so intermediate predictions are implemented as in the sentiment models of Socher et al. (2013). The other models process each of the 11 pairs of aligned phrases separately. Different softmax layers are used depending on the number of classes, but otherwise the networks have identical parameters for all predictions.

6 Results and Analysis

Table 3 summarizes our findings on the hardest of our fair generalization tasks, where the training sets are minimal ones required for fairness.

Model	Train	Dev	Test
CBoW	88.04 ± 0.68	54.18 ± 0.17	53.99 ± 0.27
TreeNN	67.01 ± 12.71	54.01 ± 8.40	53.73 ± 8.36
LSTM encoder	98.43 ± 0.41	53.14 ± 2.45	52.51 ± 2.78
Attention LSTM	73.66 ± 9.97	47.52 ± 0.43	47.28 ± 0.95
CompTreeNN	99.65 ± 0.42	80.17 ± 7.53	80.21 ± 7.71
CompTreeNTN	99.92 ± 0.08	90.45 ± 2.48	90.32 ± 2.71

Table 3: Mean accuracy of 5 runs on our difficult but fair generalization task, with standard 95% confidence intervals. These models are trained on the intermediate predictions described in Section 5.

The four standard neural models fail the task completely. The CompTreeNN and CompTreeNTN, while better, are not able to solve the task perfectly either. However, it should be noted that the CompTreeNN outperforms our four standard neural models by $\approx 30\%$ and the CompTreeNTN improves on this by another $\approx 10\%$. This increase in performance leads us to believe there may be some other composition function that solves this task perfectly.

Both the CompTreeNN and CompTreeNTN have large 95% confidence intervals, indicating that the models are volatile and sensitive to random initialization. The TreeNN also has a large 95% interval. On one of the five runs, the TreeNN achieved a test accuracy of 65.76%, much higher than usual, indicating that this model may have more potential than the other three.

Figure 5, left panel, provides further insights into these results by tracking dev-set performance throughout training. It is evident here that the standard models never get traction on the problem. The volatility of the CompTreeNN and CompTreeNTN is also again evident. Notably, the CompTreeNN is the only model that doesn't peak in the first four training epochs, showing steady improvement throughout training.

We can also increase the number of training examples so that the training data redundantly encodes the information needed for fairness. As we do this, the learning problem becomes one of trivial memorization. Figure 5, right panel, tracks performance on this sequence of progressively more trivial problems. The CompTreeNN and CompTreeNTN both rapidly ascend to perfect performance. In contrast, the four standard models continue to have largely undistinguished performance for all but the most trivial problems. Finally, CBoW, while competitive with other neural models initially, falls behind in a permanent way; its inability to account for word order prevents it from even memorizing the training data.

The results in Figure 5 are for models trained to predict the semantic relations for every subexpression pair in the scope of a node in the tree in Figure 3 (as discussed in Section 5), but we also trained the models without intermediate predictions to quantify their impact.

All models fail on our difficult generalization task when these intermediate values are withheld. Without intermediate values this task is unfair by our standards, so this to be expected. In the hardest generalization setting the CBoW model is the only one of the four standard models to show statistically significant improvement when intermediate predictions are made. We hypothesize that the model is learning relations between open-class lexical items, which are more easily accessible in its sentence representations. As the generalization task approaches a memorization task, the four standard models benefit more and more from intermediate predictions. In the easiest generalization setting, the four standard models are unable to achieve a perfect solution without intermediate predictions, while the CompTreeNN and CompTreeNTN models achieve perfection with or without the intermediate values. Geiger et al. (2018) show that this is due to standard models being unable to learn the lexical relations between open class lexical items when not directly trained on them. Even with intermediate predictions, the standard models are only able to learn the base case of this recursive composition.

7 The Problem is Architecture

One might worry that these results represent a failure of model capacity. However, the systematic errors remain even for much larger networks;

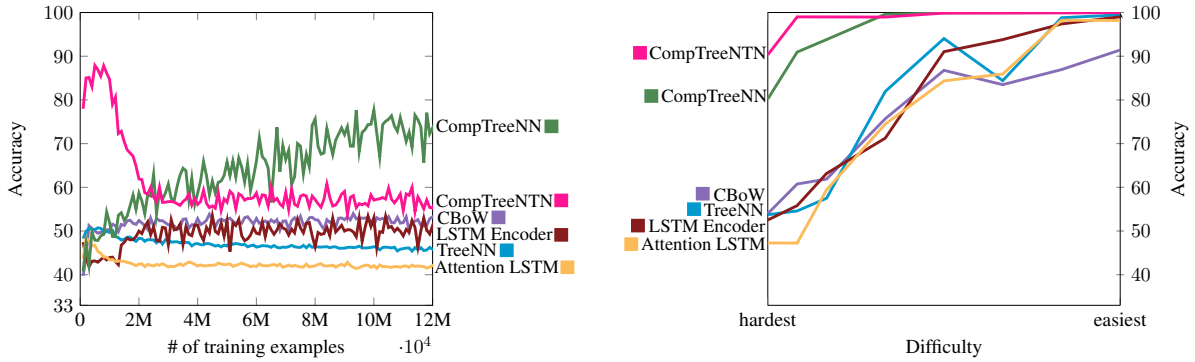

Figure 5: **Left**: Model performance on our difficult but fair generalization task throughout training. **Right**: Mean accuracy of 5 runs as we move from true generalization tasks ('hardest') to problems in which the training set contains so much redundant encoding of the test set that the task is essentially one of memorization ('easiest'). Only the task-specific CompTreeNN and CompTreeNTN are able to do well on true generalization tasks. The other neural models succeed only where memorization suffices, and the CBoW model never succeeds because it does not encode word order.

the trends by epoch and final results are virtually identical with 200-dimensional rather than 100-dimensions representations.

The reason these standard neural models fail to perform natural logic reasoning is their architecture. The CBoW, TreeNN, and LSTM Encoder models all separately bottleneck the premise and hypothesis sentences into two sentence vector embeddings, so the only place interactions between the two sentences can occur is in the two hidden layers before the softmax layer. However, the essence of natural logic reasoning is recursive composition up a tree structure where the premise and hypothesis are composed jointly, so this bottleneck proves extremely problematic. The Attention LSTM model has an architecture that can align and combine lexical items from the premise and hypothesis, but it cannot perform this process recursively and also fails. The CompTreeNN and CompTreeNTN have this recursive tree structure encoded as hard alignments in their architecture, resulting in higher performance. Perhaps in future work, a general purpose model will be developed that can learn to perform this recursive composition without a hard-coded aligned tree structure.

8 Conclusion and Future Work

It is vital that we stress-test our models of semantics using methods that go beyond standard naturalistic corpus evaluations. Recent experiments with artificial and adversarial example generation have yielded valuable insights here already, but it is vital that we ensure that these evaluations are fair in the sense that they provide our models with achievable, unambiguous learning targets. We must carefully and precisely navigate the border between meaningful difficulty and impossibility. To this end, we developed a formal notion of fairness for train/test splits.

This notion of fairness allowed us to rigorously pose the question of whether specific NLI models can learn to do robust natural logic reasoning. For our standard models, the answer is no. For our task-specific models, which align premise and hypothesis, the answer is more nuanced; they do not achieve perfect performance on our task, but they do much better than standard models. This helps us trace the problem to the information bottleneck formed by learning separate premise and hypothesis representations. This bottleneck prevents the meaningful interactions between the premise and hypothesis that are at the core of inferential reasoning with language. Our task-specific models are cumbersome for real-world tasks, but they do suggest that truly robust models of semantics will require much more compositional interaction than is typical in today's standard architectures.

Abstract

Our goal is to better comprehend procedural text, e.g., a paragraph about photosynthesis, by not only predicting what happens, but *why* some actions need to happen before others. Our approach builds on a prior process comprehension framework for predicting actions' effects, to also identify subsequent steps that those effects enable. We present our new model (XPAD) that biases effect predictions towards those that (1) explain more of the actions in the paragraph and (2) are more plausible with respect to background knowledge. We also extend an existing benchmark dataset for procedural text comprehension, ProPara, by adding the new task of explaining actions by predicting their dependencies. We find that XPAD significantly outperforms prior systems on this task, while maintaining the performance on the original task in ProPara. The dataset is available at http://data.allenai.org/propara

1 Introduction

Procedural text is common in natural language, for example in recipes, how-to guides, and science processes, but understanding it remains a major challenge. While there has been substantial prior work on extracting the sequence of actions ("scripts") from such texts, the task of identifying *why* the sequence is the way it is has received less attention, and is the goal of this work. While "why" can mean many things, we treat it here as describing how one action produces effects that are required by another. For example in Figure 1, "CO2 enters the leaf" is necessary because it results in "CO2 is at the leaf", a precondition for "CO2 forms sugar". (Note that an action does not directly depend on previous actions, but rather on the *state of the world* resulting from previous actions). If one could determine such rationales, new capabilities would become possible, including explanation, identifying alternative event orderings, and answering "*what if...*" questions. However, this task is challenging as it requires knowledge of the preconditions and effects of actions, typically unstated in the text itself.

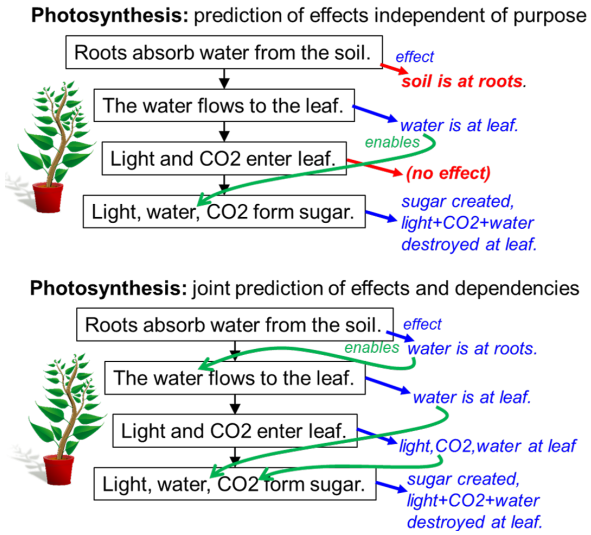

Figure 1: An action sequence (black) describes the order that actions happen, but not why. We add the new task of also predicting *why* the actions are needed, in the form of the actions' effects (blue) and subsequent actions that depend on those effects (green). While a system that predicts effects without considering dependencies can make errors (red, top part), we obtain better predictions by biasing the system to predict effects that *also* result in more dependencies (lower part).

Recent work in neural process modeling goes partway towards our goal by modeling the effects of actions, using annotated training data, allowing the states of entities to be tracked throughout a paragraph, e.g., EntNet (Henaff et al., 2017), NPN (Bosselut et al., 2018), and ProStruct (Tan-

[*]Bhavana Dalvi Mishra and Niket Tandon contributed equally to this work.

don et al., 2018). However, these systems do not consider the purpose of those effects in the overall action sequence. As a result, they are unaware if they predict effects that have no apparent purpose in the process, possibly indicating a prediction error (e.g., the erroneous predictions in red in Figure 1).

To address these limitations, we extend procedural text comprehension with an additional task of predicting the dependencies between steps, in the form of their effects and which subsequent action(s) become possible. Building upon the state-of-the-art framework for predicting effects of actions, we present a new model, called XPAD ("eXPlaining Action Dependencies") that also considers the purpose of those effects. Specifically, XPAD biases those predictions towards those that (1) explain more of the actions in the paragraph and (2) are more plausible with respect to background knowledge. On a benchmark dataset for procedural text comprehension, ProPara (Dalvi et al., 2018), XPAD significantly improves on the prediction and explanation of action dependencies compared to prior systems, while also matching state-of-the-art results on the original tasks. We thus contribute:

1. A new task for procedural text comprehension, namely predicting and explaining the dependencies between actions ("what depends on what, and why"), including an additional dependency graph dataset for ProPara.
2. A model, XPAD, that significantly outperforms prior systems at predicting and explaining action dependencies, while maintaining its performance on the original tasks in ProPara.

2 Related Work

Understanding procedural text has a long history in AI. Early work attempted to construct semantic representations ("scripts") of event sequences (or partial orders) from text, including representations of the goals, effects, and purpose of actions, e.g., (Schank and Abelson, 1977; DeJong, 1979; Cullingford, 1986; Mooney, 1986). Some of these systems could explain why actions occurred in text, similar to our goals here, but only on a handful of toy examples using hand-coded background knowledge, and proved difficult to scale. More recent work on event extraction and script learning has proved more effective at extracting event/action sequences from text using statistical methods, e.g., (Chambers and Jurafsky, 2008), and neural techniques, e.g., (Modi and Titov, 2014; Modi, 2016; Pichotta and Mooney, 2016), but have largely focused on *what* happens and in what order, rather than *why*. For example, such representations cannot answer questions about which events would fail if an earlier action in a sequence did not occur. The 2014 ProRead system (Scaria et al., 2013; Berant et al., 2014) included dependency relationships between events that it extracted, but assessed dependencies based on surface language cues, hence could not explain why those dependencies held.

There has also been a line of research in reading procedural text in which the goal has been to track how entities' states change with time, e.g., EntNet (Henaff et al., 2017), ProStruct (Tandon et al., 2018), and Neural Process Networks (Bosselut et al., 2018), applied to procedural text such as cooking recipes (Kiddon et al., 2016), science processes (Dalvi et al., 2018), or toy stories (Weston et al., 2015). Using annotated data, these systems learn to predict the effects of actions from text, allowing simple simulations of how the world changes throughout the process. We build on this line of work to identify the purpose of actions, by connecting their effects to subsequent actions.

In addition to signal from training data, many systems use background knowledge to help bias predictions towards those consistent with that knowledge. For example, (McLauchlan, 2004) predicts prepositional phrase attachments that are more consistent with unambiguous attachments derived from thesaurii; (Clark and Harrison, 2009) tune a parser to prefer bracketings consistent with frequent bracketings stored a text-derived corpus of bracketings; and (Tandon et al., 2018) predicts state changes consistent with those seen in a large text corpus. For our purposes, while KBs such as (Speer and Havasi, 2013; Chu et al., 2017; Park and Nezhad, 2018) contain useful information about action dependencies (e.g., "smoking can cause cancer"), they lack explanations for those links. Instead, we create a KB of dependency links with explanations (Section 5.3), allowing us to similarly bias predictions with background knowledge.

3 Problem Definition

The input to our system is a paragraph of procedural text, along with a list of the *participant entities* in the procedure. The output is a *state change matrix* highlighting the changes undergone by the entities, as well as a *dependency explanation graph*

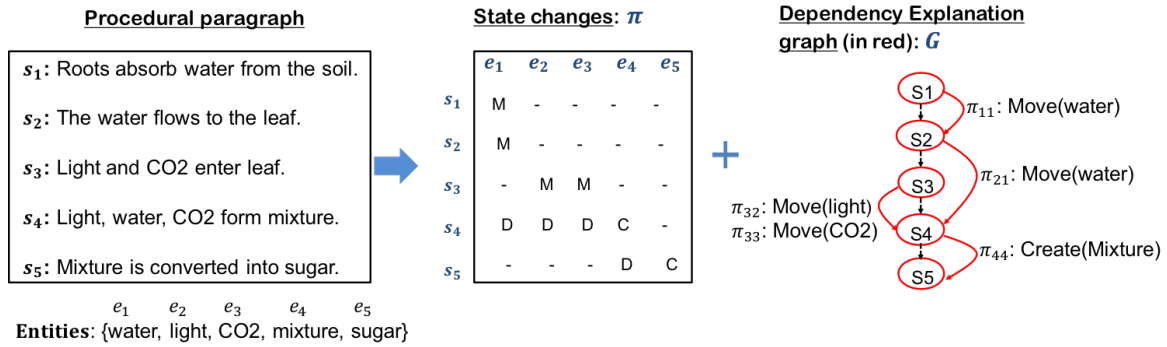

Figure 2: A procedural paragraph and target entities are provided as input. The task is to predict the state change matrix π, along with the dependency explanation graph $\mathcal{G}$ between steps (red, overlayed on the step sequence). π_{tj} refers to the state change happening to entity e_j in step s_t. In the ProPara task, there are 4 possible state changes denoted by 'M' (Move), 'C' (Create), 'D' (Destroy), and '-' (no change). Further, $\mathcal{G}$ describes which steps enable which other steps and how. For example, s_4 enables s_5 by creating `mixture`, required by s_5.

that encodes "what action[1] depends on what, and why", as illustrated in Figure 2. This problem definition is derived from the one used for the ProPara dataset (Dalvi et al., 2018), with the key addition of the dependency explanation graph. Although we use ProPara to illustrate and evaluate our work here, our approach is not specific to the details of that particular dataset.

Paragraph: We define a paragraph of procedural text $S = \langle s_1, \cdots, s_T \rangle$ as a sequence of sentences that describe a procedure (e.g., photosynthesis). We assume that sentences are chronologically ordered and treat a sentence s_t as a step executed at time t.[2]

Participant Entities: We assume that the set of participant entities $E = \{e_1, \cdots, e_n\}$ in the paragraph S is given. Notice that E includes only entities that participate in the process where their state changes at some steps.

State Change Matrix: For each entity $e_j \in E$, the system tracks how its properties change (e.g., location, existence) after each step. We enumerate all the state changes in a $T \times n$ matrix π, where π_{tj} denote how e_j has changed after step s_t. For ProPara, we use just four possible state changes for π_{tj}, namely {`Move, Create, Destroy, None`}, sufficient to model the properties tracked in the dataset. (More generally, additional state changes could be used provided their effects on entity properties is clearly defined.) `Move` means that the location of e_j changes after s_t. `Create` and `Destroy` indicate e_j starts or ceases to exist. `None` means that the state of e_j remains unchanged. A state change can optionally take arguments, e.g., `Move` is associated with before and after locations.

Dependency Explanation Graph: In addition to being able to predict when entities undergo state changes, the system also needs to understand the dependency relationships between steps in a procedure. That is, for a step s_i to be executable, the system must be able to identify which previous steps are required to have been completed first. We represent these dependency relationships in procedural text using a *dependency explanation graph* $\mathcal{G} = \langle S, \mathcal{E} \rangle$, where each **node** is a step $s_i \in S$ and a **directed edge** $(s_i, s_j) \in \mathcal{E}$ indicates that s_i is a precondition of s_j ($i < j$). Moreover, each edge is associated with the **explanation** in the form of the entity state change that begets this dependency. For example, in the example shown in Fig. 2, both s_2 and s_3 are the parent nodes of s_4. For *light, water, CO_2* to form the *mixture* in s_4, the `water` has to move to the leaf in s_2 (i.e., π_{21} = `Move`), and `light` and CO_2 also need to come to the leaf in s_3 (i.e., $\pi_{32} = \pi_{33}$ = `Move`). Note that the dependency graph is not the "script" (event sequence) of the process, but an overlay on the script that explains *why* some actions need to happen before others. Note also that the state changes are fully specified (including the from and to locations) - the location information is dropped in Figure 2 for simplicity.

4 The Dependency Graph Dataset

Dependency graphs were added to the ProPara dataset using a mixture of manual and automated methods. First, an algorithm was used to estimate

[1] We use a broad definition of action to mean any event that changes the state of the world (including non-volitional events such as roots absorbing water).

[2] This assumption holds in ProPara, the dataset used in this work. However, our techniques can generally be applied as long as a partial order of events is given.

dependencies using a heuristic method (below). Then, for the test set, these dependencies were manually reviewed and corrected. Approximately 15% of these dependencies needed to be changed, suggesting the heuristic algorithm is a reasonable approximation of the ground truth. The train and dev sets remain with the automatically generated (noisy but more numerous) dependency graphs.

As well as helping to augment the ProPara dataset, the algorithm can be used to automatically add approximate explanation graphs to existing models' state change predictions. On first sight, this might seem like a simple solution to the dependency prediction task. However, as we show later, this approach does not produce good results. This is because models' state change predictions were generated without regard for their explainability, and hence prediction errors can cascade into explainability errors. A better solution, which is the basis of XPAD, is to minimize a *joint* loss for both state change and explainability. In this way, an algorithm will be steered towards state changes that are also explainable (Figure 1).

The dependency graph algorithm is as follows, and is based on a *coherence assumption:* If step s_j changes the state of entity e_k, we assume that the reason s_j was included in the paragraph is because the next step mentioning e_k requires that change as a precondition. By searching forward for the first subsequent step s_j in which e_k is again mentioned, or changes state again, we add an enable edge in the dependency explanation graph that points from s_i to s_j, with the explanation label π_{ik}. As shown in Sec. 7.1, these dependency graphs that we added are mostly accurate (F1 $\approx$ 0.85).

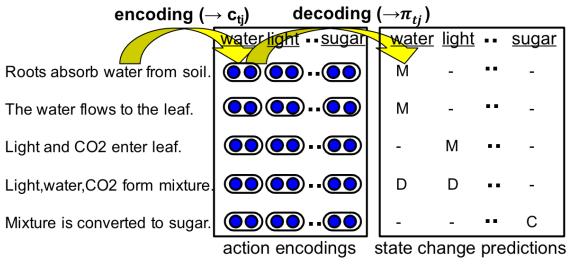

Figure 3: Encoder-decoder architecture used in XPAD: First encode the action of each sentence s_t on entity e_j, then decode to a predicted state change (state change arguments not shown). For example, the action *Roots absorb water from soil* is predicted to `Move` (M) the `water` (from soil to roots, not shown). Global predictions are generated through beam search.

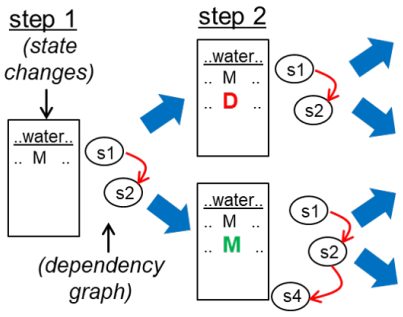

Figure 4: XPAD's beam search for the best decoding, one sentence (step) at a time, showing the predicted state changes and the resulting dependency graph after each step. In step 2, XPAD chooses between predicting whether `water` is `destroyed` (**D**, upper figure) or `moved` (**M**, lower). Predicting `M` results in a more connected dependency graph (as water is mentioned again in step 4), hence the lower choice is likely preferred (Eq. (4)) by our ***dependency graph score***. This score also assesses how a priori likely it is that s_4's movement of water enables s_5, using a background KB (Eq. (5)).

5 XPAD Model

Our model builds on the approach used in the ProStruct system (Tandon et al., 2018), namely an encoder-decoder approach with beam search decoding. We follow its design for the encoder, but use a modified decoder that also generates dependency graphs, and biases search towards graphs that are both more connected and more a priori likely.

5.1 Encoder

For each sentence s_t and each entity e_j, the encoder creates a vector c_{tj}, capturing how the actions in s_t affect e_j (Figure 3). During encoding, each word w_i in s_t is first represented by its GloVe vector, concatenated with two indicator variables: whether the word refers to e_j and whether the word is a verb. The sentence is then fed into a BiLSTM to generate a contextualized vector h_i, which is then passed to a bilinear attention layer: $a_i = h_i B h_{ev} + b$, where B and b are learned parameters, and h_{ev} is the concatenation of h_e and h_v (the averaged contextualized embedding of the entity and the verb words, respectively). The output vector c_{tj} is the attention-weighted sum of the h_i: $c_{tj} = \sum_{i=1}^{I} a_i \cdot h_i$.

Each c_{tj} will be decoded (Sec. 5.2) into one of K possible state *changes*. (For the ProPara application, $K = 4$ for {`create`, `move`, `destroy`, `none`}). As preparation for this, we pass each c_{tj} through a feedforward layer to generate K logits that denote how likely each entity e_j is to undergo each state change during step s_t. For changes that take addi-

tional arguments (e.g., `move`), the arguments are chosen using standard span prediction techniques over the encoded input h_i (Seo et al., 2017a).

5.2 Decoder

The goal of decoding is to determine the state change matrix π and the dependency graph $\mathcal{G}$. While each element π_{tj} of the state change matrix π could be determined solely by choosing the state change with the highest logit value, this greedy, *local* approach often results in nonsensical predictions (e.g., an entity is moved before being created). To avoid this, XPAD instead performs a beam search of possible decodings, one sentence s_t at a time, using a scoring function that includes terms that ensure *global* consistency, as shown in Fig. 4. Let π_t be the state change matrix up to step t, and $\mathcal{G}_t$ be the dependency graph up to step t. As π_t is constructed, $\mathcal{G}_t$ is derived from it deterministically using the same heuristic procedure described in Section 4. Most importantly, the scoring function used in the beam search is a function of *both* π_t and $\mathcal{G}_t$. This directs search towards state change predictions that are both globally consistent and produce a dependency graph that is well connected and a priori likely. Finally, the decoder outputs the complete state change grid π (= π_T) and dependency graph $\mathcal{G}$ (= $\mathcal{G}_T$) from step 1 to T.

5.3 Dependency Aware Scoring Function

At each decoding step t, XPAD explores different options of π_t (state changes for all entities) and $\mathcal{G}_t$ (corresponding dependency explanation graphs) as illustrated in Fig. 4. In particular, it scores the candidates at step t based on two components:

$$\phi(\pi_t, \mathcal{G}_t) = \lambda \cdot f(\pi_t) + (1 - \lambda) \cdot g(\mathcal{G}_t|\pi_t), \quad (1)$$

where (1) $f(\pi_t)$ is the ***state change score*** based on the likelihood of selected state changes at step t given the text and the state change history from steps s_1 to s_{t-1}, (2) $g(\mathcal{G}_t|\pi_t)$ is the ***dependency graph score*** based on the connectivity and likelihood of the resulting dependency explanation graph $\mathcal{G}_t$, and (3) λ is a hyper-parameter that determines the importance of the accuracy of the state changes vs. the coherence of the action dependency graph.

State Change Score: To compute $f(\pi_t)$, we reuse the scoring function proposed by ProStruct:

$$f(\pi_t) = \sum_{j=1}^{|E|} \Big(\alpha \cdot \text{logit}(\pi_{tj}) + (1 - \alpha) \cdot \log P_{\text{ext}}(\pi_{tj}|e_j) \Big), \quad (2)$$

where α is a hyper-parameter controlling the degree of bias, $\text{logit}(\pi_{tj})$ is the logit value supplied by the encoder for the local prediction, and $P_{\text{ext}}(\pi_{tj}|e_j)$ indicates how likely entity e_j will go through some change defined in π_{tj}, based on the topic of the procedural text. We use the knowledge base published by Tandon et al. (2018) to compute $P_{\text{ext}}(\pi_{tj}|e_j)$.

Dependency Graph Score: $g(\mathcal{G}_t|\pi_t)$ is the score of the resulting dependency graph given the selected state changes π_t, defined as:

$$g(\mathcal{G}_t|\pi_t) = \beta \cdot g_{edge}(\mathcal{G}_t|\pi_t) + (1 - \beta) \cdot g_{kb}(\mathcal{G}_t) \quad (3)$$

where (1) $g_{edge}(\mathcal{G}_t|\pi_t)$ scores π_t's contributions to the dependency graph, (2) $g_{kb}(\mathcal{G}_t)$ encodes how *a priori* likely the added dependency edges, computed using background knowledge, and (3) β is a hyperparameter tuned on the dev set.

With the help of the ***dependency graph score***, XPAD is able to bias the search toward predictions that have an identifiable purpose (i.e., dependency edges), and toward dependency graphs that are more likely according to the background knowledge. Next, we describe scores g_{edge} and g_{kb} in more details.

(a) Score g_{edge}: Actions with Purpose
We compute g_{edge} in Eq. (3) to bias the search toward dependency graphs that are more connected:

$$g_{edge}(\mathcal{G}_t|\pi_t) = \sum_{j=1}^{|E|} \log\Big(1 + \text{score}_p(\mathcal{G}_t|\pi_{tj})\Big), \quad (4)$$

where $score_p$ is assigned based on whether π_{tj} results in a purpose for step s_t or not, as follows:

$$\text{score}_p(\mathcal{G}_t|\pi_{tj}) = \begin{cases} +c, & \text{if } \pi_{tj} \text{ adds an edge to } \mathcal{G}_t; \\ 0, & \text{if no edge can be added} \\ & \text{to } \mathcal{G}_t \text{ as } e_j \text{ isn't mentioned later;} \\ -c, & \text{if } \pi_{tj} \text{ doesn't add an edge} \\ & \text{to } \mathcal{G}_t \text{ and } e_j \text{ is mentioned later.} \end{cases}$$

where $0 < c < 1$ is a hyper-parameter tuned on the dev set. Conceptually, this scoring function checks whether a particular state change prediction results in a connection in the dependency explanation graph $\mathcal{G}_t$. For example, if π_{tj} = `Create entity` e and e is mentioned in a later step s_k, then an edge will be added between s_t and s_k to $\mathcal{G}_t$. Consequently, $\text{score}_p = c > 0$, resulting in a positive boost in the score for π_{tj}.

(b) Score g_{kb}: Action Dependency Priors
To distinguish likely dependency links (e.g., $\mathcal{E}_{ij}$ in $\mathcal{G}_t$) from unlikely ones, we also bias the predictions in Equation 3 with g_{kb}. The scoring function g_{kb} computes the prior likelihood of each dependency link $\mathcal{E}_{ij}$ that would be added to $\mathcal{G}_t$, as a result of the predicted actions $\pi_{ik} \in \pi_i$. This bias is particularly helpful when there is a limited amount of training data. If $\mathcal{E}_t$ is the set of edges added to $\mathcal{G}_t$ because of selected state changes π_t, then

$$g_{KB}(\mathcal{G}_t) = \sum_{\mathcal{E}_{ij} \in \mathcal{E}_t} log\Big(1 + score_e(\mathcal{E}_{ij})\Big) \quad (5)$$

where $score_e(\mathcal{E}_{ij})$ scores the action dependency link (if any, 0 otherwise) added by action π_{ik} on an entity e_k that is common to steps s_i and s_j. For example, in Figure 2, action π_{11} adds an edge `MOVE(water)`, between sentences "*Roots absorb water.*" and "*The water flows to the leaf.*"

We need to estimate the likelihood of $\mathcal{E}_{ij}$ (i.e., the likelihood that s_i can enable s_j via π_{ik}). This information (especially π_{ik}) is not present in any existing KB. Therefore, we train a model using a large collection of positive and negative examples of valid/invalid edges. To generate these training examples, we first extract a large collection of procedural texts from WikiHow.com, which contains 1.75M steps from 227K processes across real-world domains, including health, finance, education, home, food, hobbies, etc. On each text, we apply a rule-based system (Clark et al., 2018) that noisily generates π_{train}, and then apply the heuristics from Section 4 to obtain $\mathcal{G}_{train}$. The distribution in $\mathcal{G}_{train}$ can be quite different from that in ProPara (the current task), so we append $\mathcal{G}_{train}$ with dependency graphs obtained from the training set in ProPara. We then decompose $\mathcal{G}_{train}$ into its $\mathcal{E}_{ij}$ edges (negative examples are created by reversing these edges). This leads to 324,462 training examples. We then add 2,201 examples derived from the ProPara train set. This use of hand-written rules to generate a large number of potentially noisy examples follows others in the literature, e.g. (Sharp et al., 2016; Ahn et al., 2016; Bosselut et al., 2018).

To accommodate for lexical variations, we embed the database of training data in a neural model. Our model itself takes as input $\mathcal{E}_{ij}$ and outputs the likelihood of $\mathcal{E}_{ij}$. To do this, an embedding for $\mathcal{E}_{ij}$ is created using a deep network of biLSTMs, producing a contextual embedding based on the token level embeddings of s_i, s_j and the state change vector π_{ik}. This contextual embedding is then decoded using a feedforward network to predict a score for whether s_i enabled s_j through π_{ik}. The loss function is designed such that errors on the training examples coming from ProPara are penalized θ times more than those from WikiHow, where θ is a hyperparameter tuned on the dev set.

While g_{edge} only scores whether the same entity is used in the two connected events or not, ignoring location information, g_{kb} models how likely there is a dependency between the two events, including using the from/to location of an entity. For example, g_{kb} can model that moving 'light' and 'CO2' to 'location=leaf' is important before they can be turned into a 'mixture' (Figure 2).

5.4 Training and Testing XPAD

At training time, XPAD follows only the correct (gold) path through the search space, and learns to minimize the joint loss of predicting the correct state changes and dependency explanation graph for the paragraph. At test time, XPAD performs a beam search to predict the most likely state changes and dependency explanation graph.

5.5 Implementation Details for XPAD

We implement XPAD in PyTorch using AllenNLP (Gardner et al., 2018). We use the dataset reader published in ProStruct's publicly available code. We use 100D Glove embeddings (Pennington et al., 2014), trained on Wikipedia 2014 and Gigaword 5 corpora (6B tokens, 400K vocab, uncased). Starting from glove embeddings appended by entity and verb indicators, we use bidirectional LSTM layer to create contextual representation for every word. We use 100D hidden representations for the bidirectional LSTM (Hochreiter and Schmidhuber, 1997) shared between all inputs (each direction uses 50D hidden vectors). The attention layer on top of BiLSTM, uses a bilinear similarity function similar to (Chen et al., 2016) to compute attention weights over the contextual embedding for every word.

To compute the likelihood of all state changes individually, we use a single layer feedforward network with input dimension of 100 and output 4. We then use constrained decoder during training as explained in Section 5.2. We tune the hyperparameters in Equations 1, 2, and 3 as $\lambda = 0.5$, $\alpha = 0.8$, $\beta = 0.8$. We use Adadelta optimizer (Zeiler, 2012) with learning rate 0.2 to minimize total loss.

To make predictions, we use a constrained decoder with beam size of 20, i.e. top 20 choices are explored at each step.

6 Experiments

6.1 Evaluation metric and baselines

To evaluate XPAD, we measure its performance on dependency explanations, as well as its performance on the original state change prediction task. For state change prediction, we use the same dataset and evaluation metric described in (Tandon et al., 2018), consisting of 1095 test questions for the inputs, outputs, conversions, and movements in the process (straighforwardly derivable from the predicted state change matrix). For dependency explanations, we compare the curated, gold graphs $\mathcal{G}_{gold}$ that we added to ProPara (Section 4) with the predicted dependency graphs $\mathcal{G}_{pred}$. Each edge in a graph contains 3 elements of explanation for "Why s_t?", namely "s_t enables s_u due to a state change π_{tk} in entity e_k", resulting in 2,814 elements to predict in the test set. We compute the precision and recall of predicting these elements for all steps s_t, yielding an overall F_1 score.

We consider the state-of-the-art process comprehension models reported in (Tandon et al., 2018) as our baselines, including Recurrent Entity Networks (EntNet) (Henaff et al., 2017), Query Reduction Networks (QRN) (Seo et al., 2017b), ProLocal and ProGlobal (Dalvi et al., 2018) and finally, ProStruct (Tandon et al., 2018). These models output state-change predictions, which are used to create the corresponding dependency explanation graph using the method in Section 4, but do not bias their state change predictions towards those that appear purposeful.

6.2 Results

Results on the proposed dependency task:

Model	P	R	F_1
ProLocal	24.7	18.0	20.8
QRN	32.6	30.3	31.4
EntNet	32.8	38.6	35.5
ProStruct	76.3	21.3	33.4
ProGlobal	43.4	37.0	39.9
XPAD	62.0	32.9	**43.0**

Table 1: Results on the **dependency** task (test set).

Table 1 reports results of all models on the new **dependency** task. XPAD significantly outperforms the strongest baselines, ProGlobal and ProStruct, by more than 3 points F_1. XPAD has much higher precision than ProGlobal with similar recall, suggesting that XPAD's dependency-aware decoder helps it select more accurate dependencies. Compared with ProStruct, it yields more than 11.6 points improvement on recall. As XPAD adds a novel dependency layer on top of the ProStruct architecture, we note that all these gains come exclusively from the dependency layer.

Impact of XPAD components:

Table 2 shows the impact of removing dependency graph scores from XPAD. Removing g_{kb}, results in a substantial (9 points) drop in recall, since the action dependency priors uses background knowledge to help the model discover dependency links that the model could not infer from the current paragraph. Further, removing g_{edge} score results in around 2 points drop in recall and a substantial increase in precision (F_1 is still lower). This is because the g_{edge} score encourages the model to predict state changes that result in more action dependency links, often at the cost of a drop in precision. Thus, the g_{edge} and g_{kb} scores together help XPAD discover meaningful action dependency links.

	Dependency Task		
Ablation	P	R	F_1
XPAD	62.0	32.9	**43.0**
- g_{kb}	67.9	23.1	34.5
- g_{kb} - g_{edge}	76.3	21.3	33.4

Table 2: Effect of ablating g_{edge} and g_{kb} from XPAD (test set).

Results on the previous state-change task:

On the original state-change prediction task, we find that XPAD performs slightly better (by 0.7 points F1) than the best published state-of-the-art system ProStruct[3], even though Equation 1 is not optimized solely for that task (Table 3). This illustrates that encouraging purposefulness in action prediction not only produces more explainable action sequences, but can improve the accuracy of those action predictions themselves.

[3]Since XPAD was developed, two higher unpublished results of 57.6 and 62.5 on the state-change task have appeared on arXiv (Das et al., 2019; Gupta and Durrett, 2019), their systems developed contemporaneously with XPAD. In principle XPAD's approach of jointly learning both state changes and dependencies could be also applied in these new systems. Our main contribution is to show that jointly learning state changes and dependencies can produce more rational (explainable) results, without damaging (here, slightly improving) the state change predictions themselves.

	P	R	F_1
ProStruct	74.3	43.0	54.5
XPAD	70.5	45.3	**55.2**

7 Analysis and Discussion

7.1 Dependency Graph Computation Errors

Our heuristic algorithm for estimating the dependency graph from state change predictions (Section 4) makes a *coherence assumption*, namely that the purpose of a state change on entity *e* is to enable the next event mentioning *e*. We now describe classes of errors that the algorithm makes, by summarizing errors that had to be corrected when curating the gold explanation graphs for the test set.

1. Coreference (synonymy) (35% of errors): Reference to a changed entity is missed if an alternative wording is used, e.g.,

snow becomes **ice**...**the mass** *grows smaller...*

2. Unstated Linkage (25%): Sometimes use of an entity will be implicit, e.g.,

Animals eat plants...Animals make waste **[from the plants]**...

preventing finding what "eat plants" enables.

3. Ellipsis (15%): (Sometimes ungrammatical) elided references to earlier entities will hide the purpose of those entity's state changes, e.g.,

Water *flows downwards... Enters the dam...*

Thus, this analysis suggests several ways that the dependency graph computation could be improved.

4. Bridging Anaphora (15%): In some cases, a sentence will refer indirectly to a changed entity, e.g., by referring to its part, whole, or some other association (i.e., an associative/bridging anaphoric reference (Wei, 2014)). As the algorithm does not resolve such indirect references, the purpose of the action changing that entity is unrecognized, e.g.,

spark plug causes a **spark**...**explosion** *occurs...*

The **leaf** *absorbs CO_2... The* **plant** *produces O2..*

5. Bad State Change Annotations (5%): In a few cases, state change annotations are missing or in error in the gold dataset, resulting in missing or incorrect prediction of their purpose.

6. Long-Range Dependencies (5%): We assume that an entity's change is to enable the next mentioned use of that entity. This assumption is based solely on typical protocols of discourse, and occasionally is violated. For example:

Rainwater picks up CO_2... Rainwater goes into the soil... The water dissolves limestone...

Here the first action is a prerequisite for the third, not the second, thus violating our assumption and creating an error in the dependency graph.

Note that around 45% of the sentences in ProPara have no associated state change because of unmodeled state changes (other than create/destroy/move) or the presence of stative sentences (no resultant state changes). As a result, the purpose of such sentences is inherently unrecoverable given these annotations, and out of reach of XPAD (and any other model).

7.2 Qualitative Analysis of XPAD's Results

Corrected Predictions

In many cases, the bias toward `enables` links results in XPAD predicting a state change when previously `none` had been predicted. For example, in sentence (6) of the paragraph snippet below:

(6) Millions of years later the fossil forms.
(7) A person finds the fossil.
ProStruct (for step 6): `None`
XPAD: `CREATE(fossil)` **[correct]**

ProStruct incorrectly predicted no state changes from (6), while XPAD (correctly) predicted that a fossil was created. The extra evidence causing XPAD to make this prediction is that it adds an edge in the dependency graph, giving step (6) a purpose, namely to enable step (7) in which the fossil is found. There are many such examples.

Erroneous Predictions

Both of XPAD's new biases encourage XPAD to make state-change predictions that result in more `enables` edges, either by counting them (g_{edge}) or summing their likelihoods (g_{kb}), resulting in some overlap in their overall effect (Table 6.2). The bias can help predict missing state changes (e.g., above), but can also cause XPAD to "hallucinate" state changes with weak evidence, simply to give each sentence a purpose. An example is:

(5) Carbon-based mixture stays underground.
(6) Humans discover this carbon-based mixture.
ProStruct (for step 5): None **[correct]**
XPAD: CREATE (carbon-based mixture)

Here, there is no action associated with step (5). However, in part because this is the first mention of carbon-based mixture, XPAD incorrectly labels it as being created, giving step (5) a purpose of enabling step (6). Although such errors occur, they

are less common than the corrected predictions, hence the improved overall performance.

Comparing the ablated versions of XPAD, we can also see how the different biases play out. Without g_{kb}, XPAD can sometimes predict `enables` edges that are nonsensical with respect to background knowledge, for example,

(1) Nitrogen exists naturally in the atmosphere.
(9) Bacteria turn nitrogen into a gas.
XPAD (no g_{kb}) (for step 1): CREATE (gas)
XPAD: None **[correct]**

In this example, XPAD without g_{kb} produces an incorrect prediction for (1) (that `gas` has been created), as it results in an `enables` link from step (1) to (9). However, the background KB deems it unlikely that (1) enables (9); as a result, the full XPAD makes no such prediction.

8 Conclusion

Our goal is to better comprehend procedural text by not only predicting *what* happens, but *why*. To do this, we have expanded the traditional state-tracking task with the additional task of predicting and explaining dependencies between steps, and presented a new model, XPAD, for these tasks. XPAD is biased to prefer predictions that have an identifiable purpose (enables a subsequent step), and where that purpose is more plausible (judged using a large corpus). Experiments show that XPAD significantly improves the predictions of correct dependencies between actions, while matching state-of-the-art results on the earlier tasks.

Although our experiments have been with ProPara, there is nothing intrinsic to XPAD's architecture that limits it to that dataset's design: Given appropriate annotations, XPAD could be trained with a richer set of state change operators, longer paragraphs, and (with the addition of a temporal ordering module, e.g., (Ning et al., 2017)) non-chronological event orderings. In addition, given additional hand-labeled training data, a system might learn to directly predict dependency links (instead of deriving them heuristically from state changes). These would be valuable new directions to pursue. The Dependency Graph dataset is available within `http://data.allenai.org/propara`

Abstract

The recent success of natural language understanding (NLU) systems has been troubled by results highlighting the failure of these models to generalize in a systematic and robust way. In this work, we introduce a diagnostic benchmark suite, named CLUTRR, to clarify some key issues related to the robustness and systematicity of NLU systems. Motivated by classic work on inductive logic programming, CLUTRR requires that an NLU system infer kinship relations between characters in short stories. Successful performance on this task requires both extracting relationships between entities, as well as inferring the logical rules governing these relationships. CLUTRR allows us to precisely measure a model's ability for systematic generalization by evaluating on held-out combinations of logical rules, and it allows us to evaluate a model's robustness by adding curated noise facts. Our empirical results highlight a substantial performance gap between state-of-the-art NLU models (e.g., BERT and MAC) and a graph neural network model that works directly with symbolic inputs—with the graph-based model exhibiting both stronger generalization and greater robustness.

1 Introduction

Natural language understanding (NLU) systems have been extremely successful at reading comprehension tasks, such as question answering (QA) and natural language inference (NLI). An array of existing datasets are available for these tasks. This includes datasets that test a system's ability to extract factual answers from text (Rajpurkar et al., 2016; Nguyen et al., 2016; Trischler et al., 2016; Mostafazadeh et al., 2016; Su et al., 2016), as well as datasets that emphasize commonsense inference, such as entailment between sentences (Bowman et al., 2015; Williams et al., 2018).

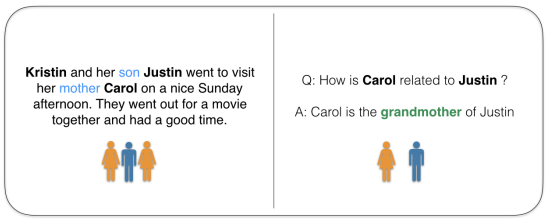

Figure 1: CLUTRR inductive reasoning task.

However, there are growing concerns regarding the ability of NLU systems—and neural networks more generally—to generalize in a systematic and robust way (Bahdanau et al., 2019; Lake and Baroni, 2018; Johnson et al., 2017). For instance, recent work has highlighted the brittleness of NLU systems to adversarial examples (Jia and Liang, 2017), as well as the fact that NLU models tend to exploit statistical artifacts in datasets, rather than exhibiting true reasoning and generalization capabilities (Gururangan et al., 2018; Kaushik and Lipton, 2018). These findings have also dovetailed with the recent dominance of large pre-trained language models, such as BERT, on NLU benchmarks (Devlin et al., 2018; Peters et al., 2018), which suggest that the primary difficulty in these datasets is incorporating the statistics of the natural language, rather than reasoning.

An important challenge is thus to develop NLU benchmarks that can precisely test a model's capability for robust and systematic generalization. Ideally, we want language understanding systems that can not only answer questions and draw inferences from text, but that can also do so in a systematic, logical, and robust way. While such reasoning capabilities are certainly required for many existing NLU tasks, most datasets combine several challenges of language understanding into one, such as co-reference/entity resolution, incorporating world knowledge, and semantic parsing—making it difficult to isolate and diagnose a model's capabilities for systematic generalization and robustness.

Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Our work. Inspired by the classic AI challenge of inductive logic programming (Quinlan, 1990)—as well as the recently developed CLEVR dataset for visual reasoning (Johnson et al., 2017)—we propose a semi-synthetic benchmark designed to explicitly test an NLU model's ability for systematic and robust logical generalization.

Our benchmark suite—termed CLUTRR (**C**ompositional **L**anguage **U**nderstanding and **T**ext-based **R**elational **R**easoning)—contains a large set of semi-synthetic stories involving hypothetical families. Given a story, the goal is to infer the relationship between two family members, whose relationship is not explicitly mentioned (Figure 1). To solve this task, a learning agent must extract the relationships mentioned in the text, induce the logical rules governing the kinship relationships (e.g., the transitivity of the sibling relation), and use these rules to infer the relationship between a given pair of entities. Crucially, the CLUTRR benchmark allows us to test a learning agent's ability for *systematic generalization* by testing on stories that contain unseen combinations of logical rules. CLUTRR also allows us to precisely test for the various forms of *model robustness* by adding different kinds of superfluous *noise facts* to the stories.

We compare the performance of several state-of-the-art NLU systems on this task—including Relation Networks (Santoro et al., 2017), Compositional Attention Networks (Hudson and Manning, 2018) and BERT (Devlin et al., 2018). We find that the generalization ability of these NLU systems is substantially below that of a Graph Attention Network (Veličković et al., 2018), which is given direct access to symbolic representations of the stories. Moreover, we find that the robustness of the NLU systems generally does not improve by training on noisy data, whereas the GAT model is able to effectively learn robust reasoning strategies by training on noisy examples. Both of these results highlight important open challenges for closing the gap between machine reasoning models that work with unstructured text and models that are given access to more structured input.

2 Related Work

We draw inspiration from the classic work on inductive logic programming (ILP), a long line of reading comprehension benchmarks in NLP, as well as work combining language and knowledge graphs.

Reading comprehension benchmarks. Many datasets have been proposed to test the reading comprehension ability of NLP systems. This includes the SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2016), and MCTest (Richardson et al., 2013) benchmarks that focus on factual questions; the SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018) benchmarks for sentence understanding; and the bABI tasks (Weston et al., 2015), to name a few. Our primary contribution to this line of work is the development of a carefully designed *diagnostic* benchmark to evaluate model robustness and systematic generalization in the context of NLU.

Question-answering with knowledge graphs. Our work is also related to the domain of question answering and reasoning in knowledge graphs (Das et al., 2018; Xiong et al., 2018; Hamilton et al., 2018; Wang et al., 2018; Xiong et al., 2017; Welbl et al., 2018; Kartsaklis et al., 2018), where either the model is provided with a knowledge graph to perform inference over or where the model must infer a knowledge graph from the text itself. However, unlike previous benchmarks in this domain—which are generally *transductive* and focus on leveraging and extracting knowledge graphs as a source of background knowledge about a fixed set of entities—CLUTRR requires *inductive logical reasoning*, where every example requires reasoning over a new set of previously unseen entities.

3 Benchmark Design

In order to design an NLU benchmark that explicitly tests inductive reasoning and systematic generalization, we build upon the classic ILP task of inferring family (i.e., kinship) relations (Hinton et al., 1986; Muggleton, 1991; Lavrac and Dzeroski, 1994; Kok and Domingos, 2007; Rocktäschel and Riedel, 2017). For example, given the facts that *"Alice is Bob's mother"* and *"Jim is Alice's father"*, one can infer with reasonable certainty that *"Jim is Bob's grandfather."* While this example may appear trivial, it is a challenging task to design models that can learn from data to *induce* the logical rules necessary to make such inferences, and it is even more challenging to design models that can systematically generalize by composing these induced rules.

Inspired by this classic task of logical induction and reasoning, the CLUTRR benchmark requires an NLU system to infer and reason about kinship

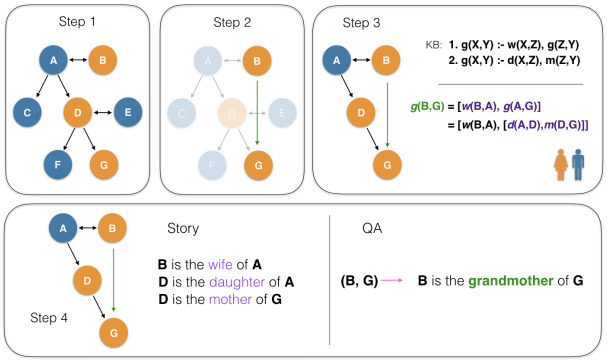

Figure 2: Data generation pipeline. Step 1: generate a kinship graph. Step 2: sample a target fact. Step 3: Use backward chaining to sample a set of facts. Step 4: Convert sampled facts to a natural language story.

relations by reading short stories. Requiring that the models learn directly from natural language makes this task much more challenging than the purely symbolic ILP setting. However, we leverage insights from traditional ILP to generate these stories in a semi-synthetic manner, providing precise control over the complexity of the reasoning required to solve the task.

In its entirety, the CLUTRR benchmark suite allows researchers to generate diverse semi-synthetic short stories to test different aspects of inductive reasoning capabilities. We publicly release the entire benchmark suite, including code to generate the semi-synthetic examples, the specific datasets that we introduce here, and the different baselines that we compare with.[1]

3.1 Overview of data generation process

The core idea behind the CLUTRR benchmark suite is the following: Given a natural language story describing a set of kinship relations, the goal is to infer the relationship between two entities, whose relationship is *not* explicitly stated in the story. To generate these stories, we first design a knowledge base (KB) with rules specifying how kinship relations resolve, and we use the following steps to create semi-synthetic stories based on this knowledge base:

Step 1. **Generate** a random kinship graph that satisfies the rules in our KB.

Step 2. **Sample a target fact** (i.e., relation) to predict from the kinship graph.

Step 3. **Apply backward chaining** to sample a set of facts that can prove the target relation (and optionally sample a set of "distracting" or "irrelevant" noise facts).

Step 4. **Convert the sampled facts into a natural language story** through pre-specified text templates and crowd-sourced paraphrasing.

Figure 2 provides a high-level overview of this idea, and the following subsections describe the data generation process in detail, as well as the diagnostic flexibility afforded by CLUTRR.

3.2 Story generation

The short stories in CLUTRR are essentially narrativized renderings of a set of logical facts. In this section, we describe how we sample the logical facts that make up a story by generating random kinship graphs and using backward chaining to produce logical reasoning chains. The conversion from logical facts to natural language narratives is then described in Section 3.3.

Terminology and background. Following standard practice in formal semantics, we use the term *atom* to refer to a *predicate* symbol and a list of terms, such as $[\texttt{grandfatherOf}, X, Y]$, where the predicate $\texttt{grandfatherOf}$ denotes the *relation* between the two *variables*, X and Y. We restrict the predicates to have an arity of 2, i.e., binary predicates. A logical *rule* in this setting is of the form $\mathcal{H} \vdash \mathcal{B}$, where $\mathcal{B}$ is the *body* of the rule, i.e., a conjunction of two *atoms* ($[\alpha_1, \alpha_2]$) and $\mathcal{H}$ is the *head*, i.e., a single atom (α) that can be viewed as the goal or query. For instance, given a knowledge base (KB) R that contains the single rule $[\texttt{grandfatherOf}, X, Y] \vdash [[\texttt{fatherOf}, X, Z], [\texttt{fatherOf}, Z, Y]]$, the query $[\texttt{grandfatherOf}, X, Y]$ evaluates to true if and only if the body $\mathcal{B} = [[\texttt{fatherOf}, X, Z], [\texttt{fatherOf}, Z, Y]]$ is also true in a given world. A rule is called a *grounded* rule if all atoms in the rule are themselves *grounded*, i.e., all variables are replaced with *constants* or entities in a world. A *fact* is a grounded binary predicate. A *clause* is a conjunction of two or more atoms ($\mathcal{C} = (\mathcal{H}_\mathcal{C} \vdash \mathcal{B}_\mathcal{C} = ([\alpha_1, ..., \alpha_n]))$) which can be built using a set of rules.

In the context of our data generation process, we distinguish between the knowledge base, R, which contains a finite number of predicates and rules specifying how kinship relations in a family resolve, and a particular kinship graph G, which

[1] Benchmark suite code can be obtained from https://github.com/facebookresearch/clutrr. Generated datasets are available to view in this link.

contains a grounded set of atoms specifying the particular kinship relations that underlie a single story. In other words, R contains the logical rules that govern all the generated stories in CLUTRR, while G contains the grounded facts that underlie a specific story.

Graph generation. To generate the kinship graph G underlying a particular story, we first sample a set of gendered[2] entities and kinship relations using a stochastic generation process. This generation process contains a number of tunable parameters—such as the maximum number of children at each node, the probability of an entity being married to another entity, etc.—and is designed to produce a valid, but possibly incomplete "backbone graph". For instance, this backbone graph generation process will specify "parent"/"child" relations between entities but does not add "grandparent" relations. After this initial generation process, we recursively apply the logical rules in R to the backbone graph to produce a final graph G that contains the full set of kinship relations between all the entities.

Backward chaining. The resulting graph G provides the *background knowledge* for a specific story, as each edge in this graph can be treated as a grounded predicate (i.e., fact) between two entities. From this graph G, we sample the facts that make up the story, as well as the target fact that we seek to predict: First, we (uniformly) sample a target relation $\mathcal{H}_\mathcal{C}$, which is the fact that we want to predict from the story. Then, from this target relation $\mathcal{H}_\mathcal{C}$, we run a simple variation of the backward chaining (Gallaire and Minker, 1978) algorithm for k iterations starting from $\mathcal{H}_\mathcal{C}$, where at each iteration we uniformly sample a subgoal to resolve and then uniformly sample a KB rule that resolves this subgoal. Crucially, unlike traditional backward chaining, we do not stop the algorithm when a proof is obtained; instead, we run for a fixed number of iterations k in order to sample a set of k facts $\mathcal{B}_\mathcal{C}$ that imply the target relation $\mathcal{H}_\mathcal{C}$.

3.3 Adding natural language

So far, we have described the process of generating a conjunctive logical clause $\mathcal{C} = (\mathcal{H}_\mathcal{C} \vdash \mathcal{B}_\mathcal{C})$, where $\mathcal{H}_\mathcal{C} = [\alpha^*]$ is the target fact (i.e., relation) we seek to predict and $\mathcal{B}_\mathcal{C} = [\alpha_1, ..., \alpha_k]$ is the set of supporting facts that imply the target relation. We now describe how we convert this logical representation to natural language through crowd-sourcing.

[2]Kinship and gender roles are oversimplified in our data (compared to the real world) to maintain tractability.

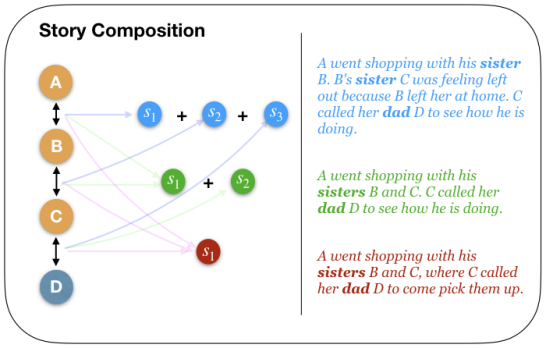

Figure 3: Illustration of how a set of facts can split and combined in various ways across sentences.

Paraphrasing using Amazon Mechanical Turk. The basic idea behind our approach is that we show Amazon Mechanical Turk (AMT) crowd-workers the set of facts $\mathcal{B}_\mathcal{C}$ corresponding to a story and ask the workers to paraphrase these facts into a narrative. Since workers are given a set of facts $\mathcal{B}_\mathcal{C}$ to work from, they are able to combine and split multiple facts across separate sentences and construct diverse narratives (Figure 3). Appendix 1.6 contains further details on our AMT interface (based on the ParlAI framework (Miller et al., 2017)), data collection, and the quality controls we employed.

Reusability and composition. One challenge for data collection via AMT is that the number of possible stories generated by CLUTRR grows combinatorially as the number of supporting facts increases, i.e., as $k = |\mathcal{B}_\mathcal{C}|$ grows. This combinatorial explosion for large k—combined with the difficulty of maintaining the quality of the crowd-sourced paraphrasing for long stories—makes it infeasible to obtain a large number of paraphrased examples for $k > 3$. To circumvent this issue and increase the flexibility of our benchmark, we reuse and compose AMT paraphrases to generate longer stories. In particular, we collected paraphrases for stories containing $k = 1, 2, 3$ supporting facts and then replaced the entities from these collected stories with placeholders in order to re-use them to generate longer semi-synthetic stories. An example of a story generated by stitching together two shorter paraphrases is provided below:

> [Frank] went to the park with his father, [Brett].
> [Frank] called his brother [Boyd] on the phone.
> He wanted to go out for some beers. [Boyd] went
> to the baseball game with his son [Jim].
> Q: What is [Brett] and [Jim]'s relationship?

Thus, instead of simply collecting paraphrases for a fixed number of stories, we instead obtain a diverse

Table 1: Statistics of the AMT paraphrases. Jaccard word overlap is calculated within the templates of each individual clause of length k.

Number of Paraphrases			# clauses
	$k = 1$	1,868	20
	$k = 2$	1,890	58
	$k = 3$	2,258	236
	Total	6,016	
Unique Word Count		3,797	
Jaccard Word Overlap	Unigrams	0.201	
	Bigrams	0.0385	

collection of natural language templates that can be programmatically recombined to generate stories with various properties.

Dataset statistics. At the time of submission, we have collected 6,016 unique paraphrases with an average of 19 paraphrases for every possible logical clause of length $k = 1, 2, 3$. Table 1 contains summary statistics of the collected paraphrases. Overall, we found high linguistic diversity in the collected paraphrases. For instance, the average Jaccard overlap in unigrams between pairs paraphrases corresponding to the same logical clause was only 0.201 and only 0.0385 for bigrams. The Appendix contains further examples of the paraphrases.

Human performance. To get a sense of the data quality and difficulty involved in CLUTRR, we asked human annotators to solve the task for random examples of length $k = 2, 3, ..., 6$. We found that time-constrained AMT annotators performed well (i.e., $> 70\%$) accuracy for $k \leq 3$ but struggled with examples involving longer stories, achieving 40-50% accuracy for $k > 3$. However, trained annotators with unlimited time were able to solve 100% of the examples (Appendix 1.7), highlighting the fact that this task requires attention and involved reasoning, even for humans.

3.4 Query representation and inference

Representing the question. The AMT paraphrasing approach described above allows us to convert the set of supporting facts $\mathcal{B}_\mathcal{C}$ to a natural language story, which can be used to predict the target relation/query $\mathcal{H}_\mathcal{C}$. However, instead of converting the target query, $\mathcal{H}_\mathcal{C} = [\alpha^*]$, to a natural language question, we instead opt to represent the target query as a K-way classification task, where the two entities in the target relation are provided as input and the goal is to classify the relation that holds between these two entities. This representation avoids the pitfall of revealing information about the answer in the question (Kaushik and Lipton, 2018).

Representing entities. When generating stories, entity names are randomly drawn from a set of 300 common gendered English names. Thus, depending on each run, the entities are never the same. This ensures that the entity names are simply placeholders and uncorrelated from the task.

3.5 Variants of CLUTRR

The modular nature of CLUTRR provides rich diagnostic capabilities for evaluating the robustness and generalization abilities of neural language understanding systems. We highlight some key diagnostic capabilities available via different variations of CLUTRR below. These diagnostic variations correspond to the concrete datasets that we generated in this work, and we describe the results on these Datasets in Section 4.

Systematic generalization. Most prominently, CLUTRR allows us to explicitly evaluate a model's ability for systematic generalization. In particular, we rely on the following hold-out procedures to test systematic generalization:

- During training, we hold out a subset of the collected paraphrases, and we only use this held-out subset of paraphrases when generating the test set. Thus, to succeed on CLUTRR, an NLU system must exhibit *linguistic generalization* and be robust to linguistic variation at test time.
- We also hold out a subset of the logical clauses during training (for clauses of length $k > 2$).[3] In other words, during training, the model sees all logical rules but does not see all *combinations* of these logical rules. Thus, in addition to linguistic generalization, success on this task also requires *logical generalization*.
- Lastly, as a more extreme form of both logical and linguistic generalization, we consider the setting where the models are trained on stories generated from clauses of length $\leq k$ and evaluated on stories generated from larger clauses of length $> k$. Thus, we explicitly test the ability for models to generalize on examples that require more steps of reasoning that any example they encountered during training.

[3] One should not holdout clauses from length $k = 2$ in order to allow models to learn the compositionality of all possible binary predicates.

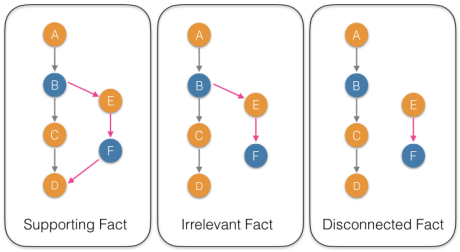

Figure 4: Noise generation procedures of CLUTRR.

Robust Reasoning. In addition to evaluating systematic generalization, the modular setup of CLUTRR also allows us to diagnose model robustness by adding *noise facts* to the generated narratives. Due to the controlled semi-synthetic nature of CLUTRR, we are able to provide a precise taxonomy of the kinds of noise facts that can be added (Figure 4). In order to structure this taxonomy, it is important to recall that any set of supporting facts $\mathcal{B}_\mathcal{C}$ generated by CLUTRR can be interpreted as a path, $p_\mathcal{C}$, in the corresponding kinship graph G (Figure 2). Based on this interpretation, we view adding noise facts from the perspective of sampling three different types of noise paths, p_n, from the kinship graph G:

- *Irrelevant facts*: We add a path p_n, which has exactly one shared end-point with p_c. In this way, this is a *distractor* path, which contains facts that are connected to one of the entities in the target relation, $\mathcal{H}_\mathcal{C}$, but do not provide any information that could be used to help answer the query.
- *Supporting facts*: We add a path p_n, whose two end-points are on the path $p_\mathcal{C}$. The facts on this path p_n are noise because they are not needed to answer the query, but they are supporting facts because they can, in principle, be used to construct alternative (longer) reasoning paths that connect the two target entities.
- *Disconnected facts*: We add paths which neither originate nor end in any entity on p_c. These disconnected facts involve entities and relations that are completely unrelated to the target query.

4 Experiments

We evaluate several neural language understanding systems on the proposed CLUTRR benchmark to surface the relative strengths and shortcomings of these models in the context of inductive reasoning and combinatorial generalization.[4] We aim to answer the following key questions:

(Q1) How do state-of-the-art NLU models compare in terms of systematic generalization? Can these models generalize to stories with unseen combinations of logical rules?

(Q2) How does the performance of neural language understanding models compare to a graph neural network that has full access to graph structure underlying the stories?

(Q3) How robust are these models to the addition of noise facts to a given story?

4.1 Baselines

Our primary baselines are neural language understanding models that take unstructured text as input. We consider bidirectional LSTMs (Hochreiter and Schmidhuber, 1997; Cho et al., 2014) (with and without attention), as well as recently proposed models that aim to incorporate inductive biases towards relational reasoning: Relation Networks (RN) (Santoro et al., 2017) and Compositional Memory Attention Network (MAC) (Hudson and Manning, 2018). We also use the large pretrained language model, BERT (Devlin et al., 2018), as well as a modified version of BERT having a trainable LSTM encoder on top of the pretrained BERT embeddings. All of these models (except BERT) were re-implemented in PyTorch 1.0 (Paszke et al., 2017) and adapted to work with the CLUTRR benchmark.

Since the underlying relations in the stories generated by CLUTRR inherently form a graph, we also experiment with a Graph Attention Network (GAT) (Veličković et al., 2018). Rather than taking the textual stories as input, the GAT baseline receives a structured graph representation of the facts that underlie the story.

Entity and query representations. We use the various baseline models to encode the natural language story (or graph) into a fixed-dimensional embedding. With the exception of the BERT models, we do not use pre-trained word embeddings and learn the word embeddings from scratch using end-to-end backpropagation. An important note, however, is that we perform Cloze-style anonymization (Hermann et al., 2015) of the entities (i.e., names) in the stories, where each entity name is replaced by a *@entity-k* placeholder, which is randomly sampled from a small, fixed pool of placeholder tokens. The embeddings for these placeholders are randomly initialized and fixed during training.[5]

[4] Code to reproduce all the results in this section will be released at https://github.com/facebookresearch/clutrr/.

[5] See Appendix 1.5 for a comparison of placeholder em-

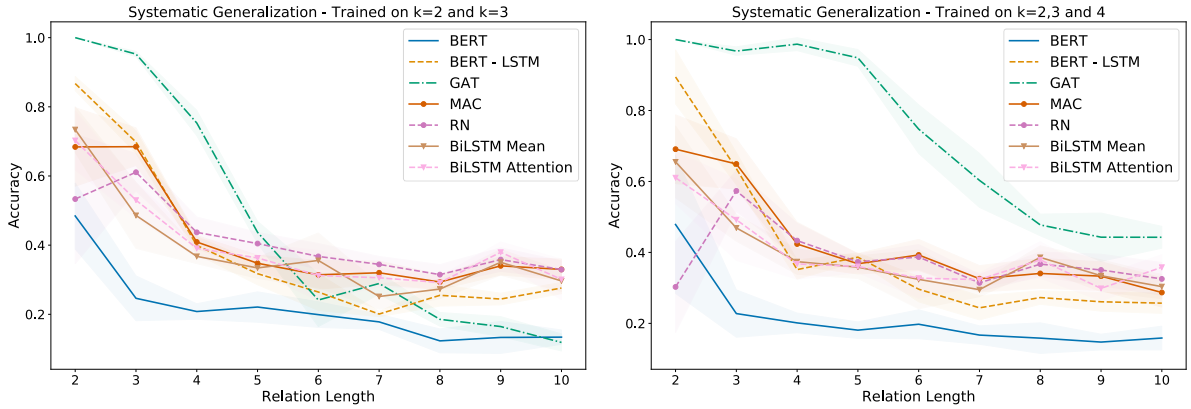

Figure 5: Systematic generalization performance of different models when trained on clauses of length $k = 2, 3$ (Left) and $k = 2, 3, 4$ (Right).

To make a prediction about a target query given a story, we concatenate the embedding of the story (generated by the baseline model) with the embeddings of the two target entities and we feed this concatenated embedding to a 2-layer feed-forward neural network with a softmax prediction layer.

4.2 Experimental Setup

Hyperparameters. We selected hyperparameters for all models using an initial grid search on the systematic generalization task (described below). All models were trained for 100 epochs with Adam optimizer and a learning rate of 0.001. The Appendix provides details on the selected hyperparameters.

Generated datasets. For all experiments, we generated datasets with 10-15k training examples. In many experiments, we report training and testing results on stories with different clause lengths k. (For brevity, we use the phrase "clause length" throughout this section to refer to the value $k = |\mathcal{B}_\mathcal{C}|$, i.e., the number of steps of reasoning that are required to predict the target query.) In all cases, the training set contains 5000 train stories per k value, and, during testing, all experiments use 100 test stories per k value. All experiments were run 10 times with different randomly generated stories, and means and standard errors over these 10 runs are reported. As discussed in Section 3.5, during training we holdout 20% of the paraphrases, as well as 10% of the possible logical clauses.

4.3 Results and Discussion

With our experimental setup in place, we now address the three key questions (**Q1-Q3**) outlined at the beginning of Section 4.

bedding approaches.

Q1: Systematic Generalization

We begin by using CLUTRR to evaluate the ability of the baseline models to perform systematic generalization (**Q1**). In this setting, we consider two training regimes: in the first regime, we train all models with clauses of length $k = 2, 3$, and in the second regime, we train with clauses of length $k = 2, 3, 4$. We then test the generalization of these models on test clauses of length $k = 2, ..., 10$.

Figure 5 illustrates the performance of different models on this generalization task. We observe that the GAT model is able to perform near-perfectly on the held-out logical clauses of length $k = 3$, with the BERT-LSTM being the top-performer among the text-based models but still significantly below the GAT. Not surprisingly, the performance of all models degrades monotonically as we increase the length of the test clauses, which highlights the challenge of "zero-shot" systematic generalization (Lake and Baroni, 2018; Sodhani et al., 2018). However, as expected, all models improve on their generalization performance when trained on $k = 2, 3, 4$ rather than just $k = 2, 3$ (Figure 5, right). The GAT, in particular, achieves the biggest gain by this expanded training.

Q2: The Benefit of Structure

The empirical results on systematic generalization also provide insight into how the text-based NLU systems compare against the graph-based GAT model that has full access to the logical graph structure underlying the stories (**Q2**). Indeed, the relatively strong performance of the GAT model (Figure 5) suggests that the language-based models fail to learn a robust mapping from the natural language narratives to the underlying logical facts.

To further confirm this trend, we ran experiments

Table 2: Testing the robustness of the various models when training and testing on stories containing various types of noise facts. The types of noise facts (supporting, irrelevant, and disconnected) are defined in Section 3.5.

Models		Unstructured models (no graph)						Structured model (with graph)
Training	Testing	BiLSTM - Attention	BiLSTM - Mean	RN	MAC	BERT	BERT-LSTM	GAT
Clean	Clean	0.58 ±0.05	0.53 ±0.05	0.49 ±0.06	0.63 ±0.08	0.37 ±0.06	0.67 ±0.03	**1.0** ±0.0

Average		**0.61** ±0.08	0.59 ±0.08	0.54 ±0.07	**0.61** ±0.06	0.30 ±0.07	0.56 ±0.05	**0.77** ±0.09

with modified train and test splits for the text-based models, where the same set of natural language paraphrases were used to construct the narratives in both the train and test splits (see Appendix 1.3 for details). In this simplified setting, the text-based models must still learn to reason about held-out logical patterns, but the difficulty of parsing the natural language is essentially removed, as the same natural language paraphrases are used during testing and training. We found that the text-based models were competitive with the GAT model in this simplified setting (Appendix Figure 1), confirming that the poor performance of the text-based models on the main task is driven by the difficulty of parsing the unseen natural language narratives.

Q3: Robust Reasoning

Finally, we use CLUTRR to systematically evaluate how various baseline neural language understanding systems cope with noise (**Q3**). In all the experiments we provide a combination of $k = 2$ and $k = 3$ length clauses in training and testing, with noise facts being added to the train and/or test set depending on the setting (Table 2). We use the different types of noise facts defined in Section 3.5.

Overall, we find that the GAT baseline outperforms the unstructured text-based models across most testing scenarios (Table 2), which showcases the benefit of a structured feature space for robust reasoning. When training on clean data and testing on noisy data, we observe two interesting trends that highlight the benefits and shortcomings of the various model classes:

1. All the text-based models excluding BERT actually perform better when testing on examples that have *supporting* or *irrelevant* facts added. This suggests that these models actually benefit from having more content related to the entities in the story. Even though this content is not strictly useful or needed for the reasoning task, it may provide some linguistic cues (e.g., about entity genders) that the models exploit. In contrast, the BERT-based models do not benefit from the inclusion of this extra content, which is perhaps due to the fact that they are already built upon a strong language model (e.g., that already adequately captures entity genders.)

2. The GAT model performs poorly when *supporting* facts are added but has no performance drop when *disconnected* facts are added. This suggests that the GAT model is sensitive to changes that introduce cycles in the underlying graph structure but is robust to the addition of noise that is disconnected from the target entities.

Moreover, when we trained on noisy examples, we found that only the GAT model was able to consistently improve its performance (Table 2). Again, this highlights the performance gap between the unstructured text-based models and the GAT.

5 Conclusion

In this paper we introduced the CLUTRR benchmark suite to test the systematic generalization and inductive reasoning capababilities of NLU systems. We demonstrated the diagnostic capabilities of CLUTRR and found that existing NLU systems exhibit relatively poor robustness and systematic generalization capabilities—especially when compared to a graph neural network that works directly with symbolic input. These results highlight the gap that remains between machine reasoning models that work with unstructured text and models that are given access to more structured input. We hope that by using this benchmark suite, progress can be made in building more compositional, modular, and robust NLU systems.

Abstract

A significant barrier to progress in data-driven approaches to building dialog systems is the lack of high quality, goal-oriented conversational data. To help satisfy this elementary requirement, we introduce the initial release of the Taskmaster-1 dataset which includes 13,215 task-based dialogs comprising six domains. Two procedures were used to create this collection, each with unique advantages. The first involves a two-person, spoken "Wizard of Oz" (WOz) approach in which trained agents and crowdsourced workers interact to complete the task while the second is "self-dialog" in which crowdsourced workers write the entire dialog themselves. We do not restrict the workers to detailed scripts or to a small knowledge base and hence we observe that our dataset contains more realistic and diverse conversations in comparison to existing datasets. We offer several baseline models including state of the art neural seq2seq architectures with benchmark performance as well as qualitative human evaluations. Dialogs are labeled with API calls and arguments, a simple and cost effective approach which avoids the requirement of complex annotation schema. The layer of abstraction between the dialog model and the service provider API allows for a given model to interact with multiple services that provide similar functionally. Finally, the dataset will evoke interest in written vs. spoken language, discourse patterns, error handling and other linguistic phenomena related to dialog system research, development and design.[1]

1 Introduction

Voice-based "personal assistants" such as Apple's SIRI, Microsoft's Cortana, Amazon Alexa, and the Google Assistant have finally entered the mainstream. This development is generally attributed to major breakthroughs in speech recognition and text-to-speech (TTS) technologies aided by recent progress in deep learning (Lecun et al., 2015), exponential gains in compute power (Steinkrau et al., 2005; Jouppi et al., 2017), and the ubiquity of powerful mobile devices. The accuracy of machine learned speech recognizers (Hinton et al., 2012) and speech synthesizers (van den Oord et al., 2016) are good enough to be deployed in real-world products and this progress has been driven by publicly available labeled datasets. However, conspicuously absent from this list is equal progress in machine learned conversational natural language understanding (NLU) and generation (NLG). The NLU and NLG components of dialog systems starting from the early research work (Weizenbaum, 1966) to the present commercially available personal assistants largely rely on rule-based systems. The NLU and NLG systems are often carefully programmed for very narrow and specific cases (Google, 2019; Amazon, 2019). General understanding of natural spoken behaviors across multiple dialog turns, even in single task-oriented situations, is by most accounts still a long way off. In this way, most of these products are very much hand crafted, with inherent constraints on what users can say, how the system responds and the order in which the various subtasks can be completed. They are high precision but relatively low coverage. Not only are such systems unscalable, but they lack the flexibility to engage in truly natural conversation.

Yet none of this is surprising. Natural language is heavily context dependent and often ambiguous, especially in multi-turn conversations across multiple topics. It is full of subtle discourse cues and pragmatic signals whose patterns have yet to be thoroughly understood. Enabling an automated

system to hold a coherent task-based conversation with a human remains one of computer science's most complex and intriguing unsolved problems (Weizenbaum, 1966). In contrast to more traditional NLP efforts, interest in statistical approaches to dialog understanding and generation aided by machine learning has grown considerably in the last couple of years (Rojas-Barahona et al., 2017; Bordes et al., 2017; Henderson et al., 2013). However, the dearth of high quality, goal-oriented dialog data is considered a major hindrance to more significant progress in this area (Bordes et al., 2017; Lowe et al., 2015).

To help solve the data problem we present Taskmaster-1, a dataset consisting of 13,215 dialogs, including 5,507 spoken and 7,708 written dialogs created with two distinct procedures. Each conversation falls into one of six domains: ordering pizza, creating auto repair appointments, setting up ride service, ordering movie tickets, ordering coffee drinks and making restaurant reservations. For the spoken dialogs, we created a Wizard of Oz (WOz) system (Kelley, 1984) to collect two-person, spoken conversations. Crowdsourced workers playing the "user" interacted with human operators playing the digital assistant using a web-based interface. In this way, users were led to believe they were interacting with an automated system while it was in fact a human, allowing them to express their turns in natural ways but in the context of an automated interface. We refer to this spoken dialog type as "two-person dialogs". For the written dialogs, we engaged crowdsourced workers to write the full conversation themselves based on scenarios outlined for each task, thereby playing roles of both the user and assistant. We refer to this written dialog type as "self-dialogs". In a departure from traditional annotation techniques (Henderson et al., 2013; Rojas-Barahona et al., 2017; Budzianowski et al., 2018), dialogs are labeled with simple API calls and arguments. This technique is much easier for annotators to learn and simpler to apply. As such it is more cost effective and, in addition, the same model can be used for multiple service providers.

Taskmaster-1 has richer and more diverse language than the current popular benchmark in task-oriented dialog, MultiWOZ (Budzianowski et al., 2018). Table 1 shows that Taskmaster-1 has more unique words and is more difficult for language models to fit. We also find that Taskmaster-1 is more realistic than MultiWOZ. Specifically, the two-person dialogs in Taskmaster-1 involve more real-word entities than seen in MutliWOZ since we do not restrict conversations to a small knowledge base. Beyond the corpus and the methodologies used to create it, we present several baseline models including state-of-the-art neural seq2seq architectures together with perplexity and BLEU scores. We also provide qualitative human performance evaluations for these models and find that automatic evaluation metrics correlate well with human judgments. We will publicly release our corpus containing conversations, API call and argument annotations, and also the human judgments.

Statistic	Self-dialogs	MultiWOZ
# unique words	**21,894**	19,175
# unique named entities	**8,218**	1,338
# utterances	**169,469**	132,610
# dialogs	7,708	**10,438**
Avg. utterances per dialog	**21.99**	13.70
Avg. tokens per utterance	8.62	**13.82**
Perplexity	**17.08**	15.62
BLEU	**6.53**	11.02

Table 1: Statistics comparison: Self-dialogs vs MultiWOZ corpus both containing approximately 10k dialogues each.

2 Related work

2.1 Human-machine vs. human-human dialog

Serban et al. (2017) discuss the major features and differences among the existing offerings in an exhaustive and detailed survey of available corpora for data driven learning of dialog systems. One important distinction covered is that of human-human vs. human-machine dialog data, each having its advantages and disadvantages. Many of the existing task-based datasets have been generated from deployed dialog systems such as the Lets Go Bus Information System (Raux et al., 2003) and the various Dialog State Tracking Challenges (DSTCs) (Williams et al., 2016). However, it is doubtful that new data-driven systems built with this type of corpus would show much improvement since they would be biased by the existing system and likely

mimic its limitations (Williams and Young, 2007). Since the ultimate goal is to be able to handle complex human language behaviors, it would seem that human-human conversational data is the better choice for spoken dialog system development (Budzianowski et al., 2018). However, learning from purely human-human based corpora presents challenges of its own. In particular, human conversation has a different distribution of understanding errors and exhibits turn-taking idiosyncrasies which may not be well suited for interaction with a dialog system (Williams and Young, 2007; Serban et al., 2017).

2.2 The Wizard of Oz (WOz) Approach and MultiWOZ

The WOz framework, first introduced by Kelley (1984) as a methodology for iterative design of natural language interfaces, presents a more effective approach to human-human dialog collection. In this setup, users are led to believe they are interacting with an automated assistant but in fact it is a human behind the scenes that controls the system responses. Given the human-level natural language understanding, users quickly realize they can comfortably and naturally express their intent rather than having to modify behaviors as is normally the case with a fully automated assistant. At the same time, the machine-oriented context of the interaction, i.e. the use of TTS and slower turn taking cadence, prevents the conversation from becoming fully fledged, overly complex human discourse. This creates an idealized spoken environment, revealing how users would openly and candidly express themselves with an automated assistant that provided superior natural language understanding.

Perhaps the most relevant work to consider here is the recently released MultiWOZ dataset (Budzianowski et al., 2018), since it is similar in size, content and collection methodologies. MultiWOZ has roughly 10,000 dialogs which feature several domains and topics. The dialogs are annotated with both dialog states and dialog acts. MultiWOZ is an entirely written corpus and uses crowdsourced workers for both assistant and user roles. In contrast, Taskmaster-1 has roughly 13,000 dialogs spanning six domains and annotated with API arguments. The two-person spoken dialogs in Taskmaster-1 use crowdsourcing for the user role but trained agents for the assistant role. The assistant's speech is played to the user via TTS. The

ASSISTANT:	How can I help you?
USER:	Hi, could you help me with booking movie tickets for tonight?
ASSISTANT:	What movie are you interested in?
USER:	The Upside.
ASSISTANT:	Did you have a theater in mind?
USER:	Could you check if the Regal Neshaminy... No, AMC Neshaminy in Neshaminy, PA is playing it?
ASSISTANT:	Could you spell that?
USER:	Sure, n e s h a m i n y.
ASSISTANT:	I have a showtime at 7:30 and at 10:30, is that okay?
USER:	Yes, could you get two tickets for the 7:30?
ASSISTANT:	One moment. Okay so that's 2 tickets for 7:30 at the AMC Neshaminy 24?
USER:	Yes.
ASSISTANT:	It'll be twenty-four ninety-nine for your tickets.
USER:	That sounds great.
ASSISTANT:	I've confirmed your tickets, they'll arrive via text shortly. Did you need any other information?
USER:	No, that was it. Thank you so much for your help.
ASSISTANT:	Great, no problem. I hope you have fun.
USER:	I hope so, too. Thank you so much.

Figure 1: Sample Taskmaster-1 two-person dialog

remaining 7,708 conversations in Taskmaster-1 are self-dialogs, in which crowdsourced workers write the entire conversation themselves. As Krause et al. (2017); Moghe et al. (2018) show, self dialogs are surprisingly rich in content.

3 The Taskmaster Corpus

3.1 Overview

There are several key attributes that make Taskmaster-1 both unique and effective for data-driven approaches to building dialog systems and for other research.

Spoken and written dialogs: While the spoken sources more closely reflect conversational language (Chafe and Tannen, 1987), written dialogs are significantly cheaper and easier to gather. This allows for a significant increase in the size of the corpus and in speaker diversity.

Goal-oriented dialogs: All dialogs are based on one of six tasks: ordering pizza, creating auto repair appointments, setting up rides for hire, ordering movie tickets, ordering coffee drinks and making restaurant reservations.

Two collection methods: The two-person dialogs and self-dialogs each have pros and cons, revealing interesting contrasts.

MAIN TASK: Users will pretend they are using a voice-powered personal digital assistant to book movie tickets for a film they ALREADY have in mind.

1. In several turns (not just one!), cover the following:
   (a) Film name
   (b) Number of people
   (c) City
   (d) Theater
   (e) Time
   (f) If applicable: 3D vs. IMAX vs. standard.
2. They may also want to know things like:
   (a) Run time
   (b) End time
   (c) Director, actors, etc.
3. Make sure to CONFIRM all the relevant ticket details before the end of the dialogue INCLUDING:
   (a) Total cost for two tickets
   (b) Time, location, theater
4. You can assume you have the users account info with the ticket service–so no credit card information is necessary.
5. After confirming the details, end the conversation by confirming that the tickets are being sent to the users mobile device as a text message.

Figure 2: Sample instructions for agents playing "assistant" role

MAIN TASK: Pretend you are using your voice-powered digital assistant to book movie tickets.

1. Start by thinking of a particular movie PLAYING NOW in theaters that you'd like to see. (Use the internet to find one if necessary.)
2. Choose a DIFFERENT CITY from where you live, work, or happen to be at the moment.
3. Pretend you've decided to see this movie tonight and you're taking a friend.
4. The assistant will ask about all relevant details BUT you should make sure it covers all your needs.
5. You can assume you already have an account with the ticket service–so no credit card information is necessary.
6. The assistant will end the conversation by confirming that your tickets are being sent to your mobile device as a text message. (And you can respond thanks, goodbye, ok, etc. for a final closing turn, if you like).

Figure 3: Sample instructions for crowdsourced workers playing "user" role

Multiple turns: The average number of utterances per dialog is about 23 which ensures context-rich language behaviors.

API-based annotation: The dataset uses a simple annotation schema providing sufficient grounding for the data while making it easy for workers to apply labels consistently.

Size: The total of 13,215 dialogs in this corpus is on par with similar, recently released datasets such as MultiWOZ (Budzianowski et al., 2018).

3.2 Two-person, spoken dataset

In order to replicate a two-participant, automated digital assistant experience, we built a WOz platform that pairs agents playing the digital assistant with crowdsourced workers playing the user in task-based conversational scenarios. An example dialog from this dataset is given in Figure 1.

3.2.1 WOz platform and data pipeline

While it is beyond the scope of this work to describe the entire system in detail, there are several platform features that help illustrate how the process works.

Modality: The agents playing the assistant type their input which is in turn played to the user via text-to-speech (TTS) while the crowdsourced workers playing the user speak aloud to the assistant using their laptop and microphone. We use WebRTC to establish the audio channel. This setup creates a digital assistant-like communication style.

Conversation and user quality control: Once the task is completed, the agents tag each conversation as either successful or problematic depending on whether the session had technical glitches or user behavioral issues. We are also then able to root out problematic users based on this logging.

Agent quality control: Agents are required to login to the system which allows us to monitor performance including the number and length of each session as well as their averages.

User queuing: When there are more users trying to connect to the system than available agents, a queuing mechanism indicates their place in line and connects them automatically once they move to the front of the queue.

Transcription: Once complete, the user's audio-only portion of the dialog is transcribed by a second set of workers and then merged with the assistant's

typed input to create a full text version of the dialog. Finally, these conversations are checked for transcription errors and typos and then annotated, as described in Section 3.4.

3.2.2 Agents, workers and training

Both agents and crowdsourced workers are given written instructions prior to the session. Examples of each are given in Figure 2 and Figure 3. The instructions continue to be displayed on screen to the crowdsourced workers while they interact with the assistant. Instructions are modified at times (for either participant or both) to ensure broader coverage of dialog scenarios that are likely to occur in actual user-assistant interactions. For example, in one case users were asked to change their mind after ordering their first item and in another agents were instructed to tell users that a given item was not available. Finally, in their instructions, crowdsourced workers playing the user are told they will be engaging in conversation with a digital assistant. However, it is plausible that some suspect human intervention due to the advanced level of natural language understanding from the assistant side.

Agents playing the assistant role were hired from a pool of dialog analysts and given two hours of training on the system interface as well as on how to handle specific scenarios such as uncooperative users and technical glitches. Uncooperative users typically involve those who either ignored agent input or who rushed through the conversation with short phrases. Technical issues involved dropped sessions (e.g. WebRTC connections failed) or cases in which the user could not hear the agent or vice-versa. In addition, weekly meetings were held with the agents to answer questions and gather feedback on their experiences. Agents typically work four hours per day with dialog types changing every hour. Crowdsourced workers playing the user are accessed using Amazon Mechanical Turk. Payment for a completed dialog session lasting roughly five to seven minutes was typically in the range of $1.00 to $1.30. Problematic users are detected either by the agent involved in the specific dialog or by post-session assessment and removed from future requests.

3.3 Self-dialogs (one-person written dataset)

While the two-person approach to data collection creates a realistic scenario for robust, spoken dialog data collection, this technique is time consuming, complex and expensive, requiring considerable technical implementation as well as administrative procedures to train and manage agents and crowdsourced workers. In order to extend the Taskmaster dataset at minimal cost, we use an alternative self-dialog approach in which crowdsourced workers write the full dialogs themselves (i.e. interpreting the roles of both user and assistant).

1. Think of a particular movie PLAYING NOW in theaters that you'd like to see. (Use the internet to find one if necessary.)
2. Choose a DIFFERENT CITY from where you live, work, or happen to be at the moment.
3. Pretend you've decided to see this movie tonight and you're taking a friend.
4. Use the internet to look up the details of the city, the theater name, showtimes offered, ticket prices, and any additional options like 3D, etc.
5. MAIN TASK: Pretend you call your personal assistant on the phone who will book the ticket for you. Write the conversation that would happen between you and your assistant in order to buy two tickets.
6. MAKE SURE the assistant asks about all relevant details (see 4) INCLUDING the number of tickets needed. BUT you should choose the order that makes sense to you as far what details to ask (theater, times, etc)
7. You can assume you already have an account with the ticket service–so no credit card information is necessary.
8. The assistant should end the conversation by confirming that your tickets are being sent to your mobile device as a text message. (And you can respond thanks, goodbye, ok, etc. for a final closing turn, if you like).

- **YOUR TASK**: Write the conversation that results between you and your assistant. It must be at least 10 turns long (for both you and the assistant). Below we have provided 15 turns in case you need more. KEEP IT NEW AND FRESH! DON'T REPEAT DIALOGUES FROM THE PAST!

Figure 4: Sample instructions for written "self-dialogs"

3.3.1 Task scenarios and instructions

Targeting the same six tasks used for the two-person dialogs, we again engaged the Amazon Mechanical Turk worker pool to create self-dialogs, this time as a written exercise. In this case, users are asked to pretend they have a personal assistant who can help them take care of various tasks in real time. They are told to imagine a scenario in which they are speaking to their assistant on the phone while the assistant accesses the services for one of the given tasks. They then write down the entire conversation. Figure 4 shows a sample set of

USER:	Hi I would like to buy 2 tickets for Shazam!
ASSISTANT:	What city would you like to see this movie?
USER:	Ontario, California
ASSISTANT:	Ok, I'll check that location for you.
USER:	I would prefer the Edwards Ontario Mountain Village, since it's closest to me and my guest.
ASSISTANT:	What time is best for you?
USER:	Either 4 or 6 pm.
ASSISTANT:	I'm sorry, but it looks like the 4:10 and the 6:10 pm showings are sold out.
USER:	That's too bad. I really wanted to see that movie.
ASSISTANT:	I'm sorry. Is there another movie you would like to see?
USER:	How about Captain Marvel at the Edwards Ontario Mountain theater.
ASSISTANT:	Show times are 3:45, 7:10 and 10:10 pm. Which would you like?
USER:	I am interested in the 7:10 showing.
ASSISTANT:	I'm sorry, it looks like the 7:10 showing is also sold out.
USER:	Wow, that's too bad.
ASSISTANT:	I'm sorry. Is there another movie you would like me to look up?
USER:	No, I think I'll pass on the movies tonight since those were the two I really wanted to see.
ASSISTANT:	If you want, I can check another theater.
USER:	No, that's fine. Thank you for your help.
ASSISTANT:	You're welcome.

Figure 5: Sample one-person, written dialog

instructions.

3.3.2 Pros and cons of self-dialogs

The self-dialog technique renders quality data and avoids some of the challenges seen with the two-person approach. To begin, since the same person is writing both sides of the conversation, we never see misunderstandings that lead to frustration as is sometimes experienced between interlocutors in the two-person approach. In addition, all the self-dialogs follow a reasonable path even when the user is constructing conversations that include understanding errors or other types of dialog glitches such as when a particular choice is not available. As it turns out, crowdsourced workers are quite effective at recreating various types of interactions, both error-free and those containing various forms of linguistic repair. The sample dialog in Figure 5 shows the result of a self-dialog exercise in which workers were told to write a conversation with various ticket availability issues that is ultimately unsuccessful.

Two more benefits of the self-dialog approach are its efficiency and cost effectiveness. We were able to gather thousands of dialogs in just days without transcription or trained agents, and spent roughly six times less per dialog. Despite these advantages, the self-dialog written technique cannot recreate the disfluencies and other more complex error patterns that occur in the two-person spoken dialogs which are important for model accuracy and coverage.

USER:	Finally, I need the table to be for three people and 8pm.
ASSISTANT:	One moment....OK, I have your table for three (**num.guests.accept**) at 8pm (**time.reservation.accept**) reserved.

Figure 6: Indicating transaction status with "accept" or "reject"

3.4 Annotation

We chose a highly simplified annotation approach for Taskmaster-1 as compared to traditional, detailed strategies which require robust agreement among workers and usually include dialog state and slot information, among other possible labels. Instead we focus solely on API arguments for each type of conversation, meaning just the variables required to execute the transaction. For example, in dialogs about setting up UBER rides, we label the "to" and "from" locations along with the car type (UberX, XL, Pool, etc). For movie tickets, we label the movie name, theater, time, number of tickets, and sometimes screening type (e.g. 3D vs. standard). A complete list of labels is included with the corpus release.

As discussed in Section 3.2.2, to encourage diversity, at times we explicitly ask users to change their mind in the middle of the conversation, and the agents to tell the user that the requested item is not available. This results in conversations having multiple instances of the same argument type. To handle this ambiguity, in addition to the labels mentioned above, the convention of either "accept or "reject" was added to all labels used to execute the transaction, depending on whether or not that transaction was successful.

In Figure 6, both the number of people and the time variables in the assistant utterance would have the ".accept" label indicating the transaction was completed successfully. If the utterance describing a transaction does not include the variables by name, the whole sentence is marked with the dialog type. For example, a statement such as *The table has been booked for you* would be labeled as

Statistic	Self-dialogs	Two Person
# unique words	17,275	13,490
# utterances	110,074	132,407
# dialogs	5000	5000
Avg. utterances per dialog	22.01	24.04
Avg. tokens per utterance	8.62	7.54
Perplexity	16.28	6.44
BLEU	4.73	15.16
Joint-Perplexity	16.44	6.04
Joint-BLEU	5.80	13.09

Table 2: Statistics comparison: Self-dialogs vs two person corpus both containing 5k dialogs. Perplexity and BLEU are reported for Transformer baseline. Joint-Perplexity and Joint-BLEU are perplexity/BLEU scores from the joint training of self-dialogs and two-person but evaluated with their respective test sets.

reservation.accept.

4 Dataset Analysis

4.1 Self-dialogs vs MultiWOZ

We quantitatively compare our self-dialogs (Section 3.3) with the MultiWOZ dataset in Table 1. Compared to MultiWOZ, we do not ask the users and assistants to stick to detailed scripts and do not restrict them to have conversations surrounding a small knowledge base. Table 1 shows that our dataset has more unique words, and has almost twice the number of utterances per dialog than the MultiWOZ corpus. Finally, when trained with the Transformer (Vaswani et al., 2017) model, we observe significantly higher perplexities and lower BLEU scores for our dataset compared to MultiWOZ suggesting that our dataset conversations are difficult to model. Finally, Table 1 also shows that our dataset contains close to 10 times more real-world named entities than MultiWOZ and thus, could potentially serve as a realistic baseline when designing goal oriented dialog systems. MultiWOZ has only 1338 unique named entities and only 4510 unique values (including date, time etc.) in their datatset.

4.2 Self-dialogs vs Two-person

In this section, we quantitatively compare 5k conversations each of self-dialogs (Section 3.3) and two-person (Section 3.2). From Table 2, we find that self-dialogs exhibit higher perplexity (almost 3 times) compared to the two-person conversations suggesting that self-dialogs are more diverse and contains more non-conventional conversational flows which is inline with the observations in Section-3.3.2. While the number of unique words are higher in the case of self-dialogs, conversations are longer in the two-person conversations. We also report metrics by training a single model on both the datasets together.

4.3 Baseline Experiments: Response Generation

We evaluate various seq2seq architectures (Sutskever et al., 2014) on our self-dialog corpus using both automatic evaluation metrics and human judgments. Following the recent line of work on generative dialog systems (Vinyals and Le, 2015), we treat the problem of response generation given the dialog history as a conditional language modeling problem. Specifically we want to learn a conditional probability distribution $P_\theta(U_t|U_{1:t-1})$ where U_t is the next response given dialog history $U_{1:t-1}$. Each utterance U_i itself is comprised of a sequence of words $w_{i_1}, w_{i_2} \dots w_{i_k}$. The overall conditional probability is factorized autoregressively as

$$P_\theta(U_t|U_{1:t-1}) = \prod_{i=1}^{n} P_\theta(w_{t_i}|w_{t_{1:i-1}}, U_{1:t-1})$$

P_θ, in this work, is parameterized by a recurrent, convolution or Transformer-based seq2seq model.

n-gram: We consider 3-gram and 4-gram conditional language model baseline with interpolation. We use random grid search for the best coefficients for the interpolated model.

Convolution: We use the *fconv* architecture (Gehring et al., 2017) and default hyperparameters from the fairseq (Ott et al., 2019) framework.[2] We train the network with ADAM optimizer (Kingma and Ba, 2015) with learning rate of 0.25 and dropout probability set to 0.2.

LSTM: We consider LSTM models (Hochreiter and Schmidhuber, 1997) with and without attention (Bahdanau et al., 2015) and use the tensor2tensor (Vaswani et al., 2018) framework for the LSTM baselines. We use a two-layer LSTM network for both the encoder and the decoder with 128 dimensional hidden vectors.

Transformer: As with LSTMs, we use the tensor2tensor framework for the Transformer model.

[2]https://github.com/pytorch/fairseq

Baseline Models	PPL	BLEU	Ratings (LIKERT)	Rank
GPT-2 (117M)	-	0.26	-	-
3-gram	38.12	0.20	-	-
4-gram	34.49	0.21	-	-
LSTM	25.73	4.45	-	-
Convolution	21.25	5.09	2.89	3
LSTM-attention	20.05	5.12	**3.51**	2
Transformer	**18.19**	**6.11**	3.22	**1**

Table 3: Evaluation of various seq2seq architectures (Sutskever et al., 2014) on our self-dialog corpus using both automatic evaluation metrics and human judgments. Human evaluation ratings in the 1-5 LIKERT scale (higher the better), and human ranking are averaged over 500 x 3 ratings (3 crowdsourced workers per rating).

Our Transformer (Vaswani et al., 2017) model uses 256 dimensions for both input embedding and hidden state, 2 layers and 4 attention heads. For both LSTMs and Transformer, we train the model with ADAM optimizer ($\beta_1 = 0.85$, $\beta_2 = 0.997$) and dropout probability set to 0.2.

GPT-2: Apart from supervised seq2seq models, we also include results from pre-trained GPT-2 (Radford et al., 2019) containing 117M parameters.

We evaluate all the models with perplexity and BLEU scores (Table 3). Additionally, we perform two kinds of human evaluation - Ranking and Rating (LIKERT scale) for the top-3 performing models - Convolution, LSTM-attention and Transformer. For the ranking task, we randomly show 500 partial dialogs and generated responses of the top-3 models from the test set to three different crowdsourced workers and ask them to rank the responses based on their relevance to the dialog history. For the rating task, we show the model responses individually to three different crowdsourced workers and ask them to rate the responses on a 1-5 LIKERT scale based on their appropriateness to the dialog history. From Table-4, we see that inter-annotator reliability scores (Krippendorfs Alpha) are higher for the ranking task compared to the rating task. From Table 3, we see that Transformer is the best performing model on automatic evaluation metrics. It is interesting to note that there is a strong correlation between BLEU score and human ranking judgments.

Evalation method	Inter-Annotator Reliability (Krippendorfs Alpha)
Rating (1-5 LIKERT)	0.21
Ranking	0.29

Table 4: Inter-Annotator Reliability scores of seq2seq model responses computed for 500 self-dialogs from the test set, each annotated by 3 crowdsourced workers.

Model	Micro F1 (%)
Transformer	48.73
Transformer + copy	51.79

Table 5: API Argument prediction accuracy for Self-dialogs. API arguments are annotated as spans in the utterances.

4.4 Baseline Experiments: Argument Prediction

Next, we discuss a set of baseline experiments for the task of argument prediction. API arguments are annotated as spans in the dialog (Section 3.4). We formulate this problem as mapping text conversation to a sequence of output arguments. Apart from the seq2seq Transformer baseline, we consider an additional model - an enhanced Transformer seq2seq model where the decoder can choose to copy from the input or generate from the vocabulary (Merity et al., 2017; Gu et al., 2016). Since all the API arguments are input spans, the copy model having the correct inductive bias achieves the best performance.

5 Conclusion

To address the lack of quality corpora for data-driven dialog system research and development, this paper introduces Taskmaster-1, a dataset that provides richer and more diverse language as compared to current benchmarks since it is based on unrestricted, task-oriented conversations involving more real-word entities. In addition, we present two data collection methodologies, both spoken and written, that ensure both speaker diversity and conversational accuracy. Our straightforward, API-oriented annotation technique is much easier for annotators to learn and simpler to apply. We give several baseline models including state-of-the-art neural seq2seq architectures, provide qualitative human performance evaluations for these models, and find that automatic evaluation metrics correlate well with human judgments.

Abstract

The need for high-quality, large-scale, goal-oriented dialogue datasets continues to grow as virtual assistants become increasingly widespread. However, publicly available datasets useful for this area are limited either in their size, linguistic diversity, domain coverage, or annotation granularity. In this paper, we present strategies toward curating and annotating large scale goal oriented dialogue data. We introduce the `MultiDoGO` dataset to overcome these limitations. With a total of over 81K dialogues harvested across six domains, `MultiDoGO` is over 8 times the size of `MultiWOZ`, the other largest comparable dialogue dataset currently available to the public. Over 54K of these harvested conversations are annotated for intent classes and slot labels. We adopt a Wizard-of-Oz approach wherein a crowd-sourced worker (the "customer") is paired with a trained annotator (the "agent"). The data curation process was controlled via biases to ensure a diversity in dialogue flows following variable dialogue policies. We provide distinct class label tags for agents vs. customer utterances, along with applicable slot labels. We also compare and contrast our strategies on annotation granularity, i.e. turn vs. sentence level. Furthermore, we compare and contrast annotations curated by leveraging professional annotators vs the crowd. We believe our strategies for eliciting and annotating such a dialogue dataset scales across modalities and domains and potentially languages in the future. To demonstrate the efficacy of our devised strategies we establish neural baselines for classification on the agent and customer utterances as well as slot labeling for each domain.

1 Introduction

Modern Natural Language Understanding (NLU) frameworks for dialogues are by definition data hungry. They require large amounts of training data representative of goal oriented conversations reflecting both context and diversity. But human responses in goal-oriented dialogues are less predictable than automated systems (Bordes et al., 2016). For example, "Please do this" cannot be interpreted without a broader context. Only by seeing previous utterances, such as requests to book a flight on a specific day to a specific destination, can this task be performed. Additionally, a single intent can be phrased in multiple ways depending on context; "book my flight", "finalize my reservation", "Yes, the 6 pm one" may all be referring to a flight-booking intent. Hence, entire conversations, rather than independent utterances, must be collected. Such data is even more pertinent to modeling NLU and related tasks as they require large, varied, and ideally human-generated datasets. Moreover, recent work (Dong et al., 2015; Devlin et al., 2018) has shown the benefit of applying joint-training and transfer learning techniques to natural language processing tasks. However, these approaches have yet to become widely used in dialogue tasks, due to a lack of large-scale datasets. Furthermore, the latest state of the art end-to-end neural approaches benefit from such training data even more so than past work on goal-oriented dialogues structured around slot filling (Lemon et al., 2006; Wang and Lemon, 2013). One way to simulate data—and not risk releasing personally identifying information—for a domain is to use a Wizard-of-Oz data gathering technique, which requires that participants in a conver-

Role	Turn	Annotations
A	Hey there! Good morning. You're connected to LMT Airways. How may I help you?	DA = { elicitgoal }
C	Hi, I wonder if you can confirm my seat assignment on my flight tomorrow?	IC = { SeatAssignment }
A	Sure! I'd be glad to help you with that. May I know your last name please?	DA = { elicitslot }
C	My last name is Turker.	IC = { contentonly }, SL = {Name : Turker }
A	Alright Turker! Could you please share the booking confirmation number?	DA = { elicitslot }
C	I believe it's AMZ685.	IC = { contentonly }, SL = { Confirmation Number : AMZ685 }
...	...	...

Table 1: A segment of a dialogue from the airline domain annotated at the turn level. This data is annotated with agent dialogue acts (DA), customer intent classes (IC), and slot labels (SL). Roles C and A stand for "Customer" and "Agent", respectively.

sation fulfill a role (Kelley, 1984). This approach has been used in popular public goal-oriented datasets: DSTC and MultiWOZ (Williams et al., 2016; Budzianowski et al., 2018).

Conversations between people and automated systems occur with increasing frequency, especially in customer service. Customers reach out to agents, which could be automated bots or real individuals, to achieve a domain-specific goal. This creates a disparate conversation: agents are incentivized to operate within a set procedure and convey a patient and professional tone. In contrast, customers do not have this incentive. However, to date, the largest available multi-domain goal-oriented dialogue dataset assigns similar dialogue act annotations to both agents and customers (Budzianowski et al., 2018).

To solve the aforementioned challenges, we present our efforts to curate, annotate, and evaluate a large scale multi-domain set of goal oriented dialogues. The dataset is primarily gathered from workers in the crowd paired with professional annotators. The dataset elicited, MultiDoGO, comprises over 86K raw conversations of which 54,818 conversations are annotated at the turn level. We investigate multiple levels of annotation granularity. We annotate a subset of the data on both turn and sentence levels. A turn is defined as a sequence of one or more speech/text sentences by a participant in a conversation. A sentence is a period delimited sequence of words in a turn. A turn may comprise one or more sentences. We do use the term utterance to refer to a unit (turn or sentence, spoken or written by a participant).[1]

In our devised annotation strategy, we distinguish between dialogue speech acts for agents vs. customers. In MultiDoGO, the agents' speech acts [DA] are annotated with generic class labels common across all domains, while customer speech acts are labeled with intent classes [IC]. Moreover, we annotate customer utterances with the appropriate slot labels [SL], which consist of the SL span and corresponding tokens with that SL tag. We present the strategies we use to curate and annotate such data given its contextual setting. We furthermore illustrate the efficacy of our devised approaches and annotation decisions against intrinsic metrics and via extrinsic evaluation, namely by applying neural baselines for DA, IC and SL classification leveraging joint models.

2 Existing Dialogue Datasets

There are multiple existing goal-oriented dialogue collections generated by humans through Wizard-of-Oz techniques. The Dialog State Tracking Challenge, *aka* Dialog Systems Technology Challenge, (DSTC) spans 8 iterations and entails the domains of bus timetables, restaurant reservations, and hotel bookings, travel, alarms, movies, etc. (Williams et al., 2016). Frames (Asri et al., 2017) has 1369 dialogues about vacation packages. MultiWOZ contains 10,438 dialogues about Cambridge hotels and restaurants (Budzianowski et al., 2018). There are several dialogue datasets that specialize in a single domain. ATIS (Hemphill et al., 1990) comprises speech data about airlines structured around formal airline flight tables. Similarly, the Google Airlines dataset purportedly contains 400,000 templated dialogues about airline reservations (Wei

[1] We acknowledge that the term utterance is controversial in the literature (Pareti and Lando, 2018)

et al., 2018).[2] The Ubuntu Dialogue Corpus has over a million dialogues about Ubuntu technical support (Lowe et al., 2015).

On the other hand, Chit-chat style dialogues without goals have been popular since ELIZA and have been investigated with neural techniques (Weizenbaum, 1966; Li et al., 2016, 2017). However, these datasets cannot be used for modeling goal-oriented tasks. Related dialogue dataset collections used for Sequential Question Answering rely on dialogue to answer questions, but the task is notably different from our use case of modeling goal oriented conversational AI, hence leading to different evaluation considerations (Reddy et al., 2019; Choi et al., 2018).

3 MultiDoGO Dataset Curation

3.1 Data Collection Procedure

We employ both internal data associates, who we train, and crowd-sourced workers from Mechanical Turk (MTurkers) to generate conversational data using a Wizard-of-Oz approach. In each conversation, the data associates assumes the role of an agent while the MTurkers act as customers. In an effort to source competent MTurkers, we require that each MTurker have a Human Intelligence Task (HIT) accuracy minimum of 90%, a location in the United States, and have completed a significant number of HITs in the past. To facilitate goal-oriented conversations between the customer and agent, we give each agent a prompt listing the supported request types (dialog acts)and pieces of information (slots) needed to complete each request. We also specify criteria such as minimal conversation length, number of goals,number of complex requests, etc, to increase conversation diversity. See Figure 2 for an example prompt. In addition, we explicitly request that neither agents nor customers use any personally identifiable information. At an implementation level,we create a custom, web interface for the MTurkers and data associates that displays our instructions next to the current dialogue. This allows each participant to quickly refer to our guidelines without stopping the conversation. Despite following a familiar wizard-of-oz elicitation procedure, and curating data for multiple domains in a fashion similar to previous data collection efforts such as MultiWOZ, MultiDoGO comprises more varied domains, it is collected at an unprecedented scale, and it is curated with control over generating explicit biases in the conversations to allow for diverse conversation representation. To our knowledge this is a novel collection strategy as we explicitly guide/prod the participants in a dialogue to engage in conversations with specific biases such as intent change, slot change, multi-intent, multiple slot values, slot overfilling and slot deletion. For example, in the Fast Food domain, participants were instructed to pretend that they were ordering fast food from a drive-thru. After making their initial order, they were instructed to change their mind about what they were ordering ("I'd like a burger. No wait, can you make that a chicken sandwich?"). In the Financial domain, we asked participants to make sure that they requested multiple intents such as "I'd like to find my routing number and check my balance."[3] To that end, our collection procedure deliberately attempts to guide the dialogue flow to ensure diversity in dialogue policies.

3.2 Domain Selection

Our primary criteria for domain selection are twofold: covering a broad sweep of industries that use goal-oriented dialogues and selecting domains where conversational interfaces are already in use or likely to be implemented in the future. This set of criteria is especially well matched with domains that frequently involve customer support. Furthermore, there is a shortage of publicly available data in the domains we provide, such as Fast Food and Finance. To fulfill both of these needs, we include multiple domains in the MultiDoGO dataset. Ultimately, we curate conversations for six domains: Airline, Fast Food, Finance, Insurance, Media, and Software Support. When considered independently, the corpus of dialogues for each of these domains is the largest collection of human-elicited dialogues available for financial advice and help, media support, enterprise software support (non-technical level support, unlike the Ubuntu forum dataset (Lowe et al., 2015)), fast food, and insurance.

Domains in our Data:[4] **Airline** domain dialogues focus on booking airline flights, select-

[2]The Google Airlines dataset has not been released to date.

[3]For a full list of conversational biases with examples, please see the appendix.

[4]Detailed data collection and annotation schemata for each domain can be found in the appendix.

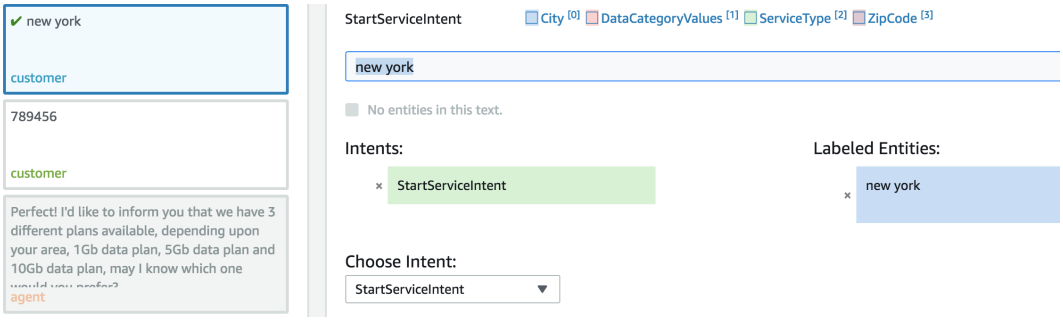

Figure 1: Crowd sourced annotators select an intent and choose a slot in our custom-built Mechanical Turk interface. Entire conversations are provided for reference. Detailed instructions are provided to users, but are not included in this figure. Options are unique per domain.

ing or changing seat assignments, and requesting boarding passes; **Fast Food** domain is the least similar to the others, as the intents primarily involve ordering food and the slots quantify their order. For example, the OrderBurgerIntent contains slots for size, quantity, and ingredients; **Finance** domain simulates dialogues a customer may have with a bank. These include opening a bank account, checking their balance, and reporting a lost credit card; **Insurance** domain simulates users calling about their insurance policy or requesting the fulfillment of a policy on their car or phone; **Media** domain simulates dialogues a customer may have ordering a service or paying bills related to telecommunications. This is our largest domain; **Software** domain involves customers inquiring about software services: products, outages, promotions, and bills. The majority of intents are domain specific.

3.3 Domain Schemata and Guidelines

Prior to dialogue collection, we develop schemata for each domain. These schemata are the set of slot labels, slot value types, and intents that pertain to the domain. To determine which slots, values, intents, and dialog acts to include, we rely on real word reference points. For instance, we populate slots for the Fast Food domain by identifying menu items, such as sodas, that are shared among popular fast food menus. Using this schema, we then write two sets of instructions. One set of instructions is for the "agents" and the other is for the "customers". The agents' instructions are meticulously detailed as we expect them to "structure" the conversation and appropriately respond to out of domain requests. Since our agents are trained for their role, we have high confidence in their ability to follow complex guidelines. In contrast, taking into consideration that the customer role is to be carried out by crowd-sourced workers, i.e. lay people, we create simplified instructions that are less detailed and shorter in length. For each task, we provide an annotated conversation, explain each answer option, and (most importantly) provide examples. Before scaling up our data collection, we run a pilot for each task and identify commonly missed questions. We use this pilot process to revise the instructions and add relevant examples iteratively.

4 Data Annotation

4.1 Annotated Dialogue Tasks

Our dataset has three types of annotation: Agent dialogue acts [DA], customer intent classes [IC], and slot labels [SL]. We intentionally decouple Agent and customer speech act tags into the categories DA and IC, respectively, to produce more fine-grained speech act tags than past iterations of dialog datasets. Intuitively, agent DAs are consistent across domains and more abstract in nature, since agents have a standard form of response. On the other hand, customer ICs are domain-specific and can entail reserving a hotel room or ordering a burger, depending on the domain. A conversation example with annotations is provided in Table 1.

Agent Dialogue Acts (DA) Agent dialogue acts are the most straightforward of our annotation tasks. There are eight possible DAs in all domains: *ElicitGoal, ElicitSlot, ConfirmGoal, ConfirmSlot, EndGoal, Pleasantries, Other*. The names are self-explanatory. *Elicit Goal/Slot* indicates that the agent is gathering information. *Confirm Goal/Slot* indicates that the agent is confirming previously provided information. The *EndGoal* and *Pleasantries* tags, identify non-task re-

lated actions. *Other* indicates that the selected utterance was not one of the other possible tags. Agent dialogue acts are consistent across domains and are often abstract (e.g. ElicitIntent, ConfirmSlot).

Customer Intent Classes (IC): Unlike Agent DA, customer IC vary for each domain and are more concrete. For example, the Airline domain has a "BookFlight" IC, Fast Food has an "OrderMeal" IC, and Insurance has an "OrderPolicy" IC in our annotation schema. Customer intents can overlap across domains (e.g. OpeningGreeting, ClosingGreeting) and other times be domain specific (e.g. RequestCreditLimitIncrease, OrderBurger, BookFlight).

Slot Labels (SL): Slot Labeling (SL) is a task contingent on Customer Intent Classes. Certain intents require that additional information, namely slot values, be captured. For instance, to open a bank account, one must solicit the customer's social security number. Slots can overlap across intents (e.g. Name, SSN Number) or they can be unique to a domain-specific intent (e.g. CarPolicy).

4.2 Data Annotation Procedure

Our annotators utilize a web interface, depicted in Figure 1, to select the appropriate intent class for an utterance out of a list of provided options. To annotate slot labels, our annotators use their cursors to highlight slot value character spans within an utterance and then select the corresponding slot label from a list of options. The output of this slot labeling process is a list of ⟨slot-label, slot-value, span⟩ triplets for each utterance.

4.3 Annotation Design Decisions

Decoupled Agents and Customers Label sets: Agents and customers have notably different goals and styles of communication. However, past dialogue datasets do not make this distinction at speech act schema level. Specificity is important for handling unique customer requests, but a relatively formulaic approach is required of agents across different industries. Our distinction between the customer and agent roles creates training data for a bot that explicitly simulates agents.

Annotation Unit Granularity: Sentence vs. Turn Level An important decision, which is often under discussed, is the proper semantic unit of text to annotate in a dialogue. Commonly, datasets provide annotations at the turn level (Budzianowski et al., 2018; Asri et al., 2017; Mihail et al., 2017). However, turn level annotations can introduce confusion for IC datasets, given multiple intents may be present in different sentences of a single turn. For instance, consider the turn "I would like to book a flight to San Francisco. Also, I want to cancel a flight to Austin." Here, the first sentence has the BookFlight intent and the second sentence has the CancelFlight intent. An turn level annotation of this utterance would yield the multi-class intent (BookFlight, CancelFlight). In contrast, a sentence level annotation of this utterance identifies that the first sentence corresponds to BookFlight while the second corresponds to CancelFlight. We annotate a subset our data, 2,500 conversation per domain for 15,000 conversations in total, at the sentence as well as turn level to access the impact of this design choice on downstream performance. The remainder of our dataset is annotated only at the turn level.

ISAA		
DA	IC	SL
0.701	0.728	0.695

Table 2: Dialogue act (DA), Intent class (IC), and slot labeling (SL) Inter Source Annotation Agreement (ISAA) scores quantifying the agreement of crowd sourced and professional annotations.

Professional vs. Crowd-Sourced Workers for annotation For annotation, we compare and contrast professional annotators to crowd sourced annotators on a subset of data. Professional annotators assign DA, IC, and SL tags to the 15,000 conversations annotated at both the turn and sentence level; statistics for these conversations are given in table 6. In an effort to decrease annotation cost, we employ crowd source annotators via Mechanical Turk to label an additional 54,818 conversations rated as Good or Excellent quality during data collection. We provide statistics for this set of crowd annotated data in Table 3. To compare the quality of crowd sourced annotations against professional annotations, we use both strategies to annotate a shared subset of 8,450 conversations. We devise an Inter Source Annotation Agreement (ISAA) metric to quantify the agreement of these crowd sourced and professionally sourced annotations. ISAA is a relaxation of Cohen Kappa, in-

tended to count partial agreement of multi-tag labels. ISAA defines two sets of tags, A and B, to be in agreement if there is at least one "shared" tag in both A and B. A and B reflect the majority labels agreed upon per source (professionals or crowd workers). Using ISAA we find that crowd sourced and professional annotations have a substantial degree of shared annotations. We report ISAA for the DA, IC, and SL tasks in Table 2.

4.4 Quality Control

We institute three processes to enforce data quality. During data collection, our data associates report on the quality of each conversation. Specifically, the data associates grade the conversation on a scale from "Unusable", "Poor", "Good", to "Excellent". They were provided with guidelines to help decide on the chosen rating such as coherence, whether the dialogue achieved the purported goal, etc. To ensure high data quality we only utilize conversations with "Good" or "Excellent" ratings in subsequent annotation.

Secondly, for data annotation, each conversation is annotated at least twice. We remove inconsistent annotations by selecting the annotation given by the majority of annotators per item. We calculate inter-annotator agreement with Fleiss Kappa and find "substantial agreement", according to the metric. Our annotators must pass a qualification test as well as maintain an on-going level of accuracy in randomly distributed test questions throughout their annotation. Third, we preprocess our data to remove issues such as duplicate conversations and improperly entered slot value spans. We refer readers to our discussion of preprocessing in Section 5 for further detail.

4.5 Dataset Characterization and Statistics

MultiDoGO dataset is more diverse by virtue of covering more domains, but more importantly, it is more controlled since it was curated rather than being scraped from existing data sources that are not necessarily synchronous (Ubuntu). Table 3 shows the statistics for MultiDoGO raw conversations harvested, rated as Excellent or Good, and annotated for DA, IC and SL.

Table 4 shows the number of conversations per domain reflecting the specific biases used.

MultiDoGO is several orders of magnitude larger than comparable datasets as reflected in nearly every dimension: the number of conversations, the length of the conversation, the number of domains, and the diversity of the utterances used. Table 5 illustrates a comparative statistics to existing data sets.

Agent Instructions

Imagine you work at a bank. Customers may contact you about the following set of issues: checking account balances (checking or savings), transferring money between accounts, and closing accounts.

GOAL: Answer the customer's question(s) and complete their request(s).

For any request, you will need to collect at least the following information to be able to identify the customer: name, account PIN *or* last 4 digits of SSN.

For giving information on balances, or for closing accounts, you will also need the last 4 digits of the account number.

For transferring money, you will also need: last 4 digits of account to move from, last 4 digits of account to move to, and the sum of money to be transferred.

Your customer may ask you to do only one thing; that's okay, but make sure you confirm you achieved everything the Customer wanted before completing the conversation. Don't forget to signal the end of the conversation (see General guidelines)

Figure 2: Agents are provided with explicit fulfillment instructions. These are quick-reference instructions for the Finance domain. Agents serve as one level of quality control by evaluating a conversation between Excellent and Unusable.

We provide summary statistics for the subset of our data annotated at both turn and sentence granularity in Table 6. This describes the total size of the data per domain in number of conversations, turns, the unique number of intents and slots, and inter-annotator agreement (IAA) for both turn and sentence level annotations. It is worth observing that the DA annotations achieve a much higher IAA in Sentence level annotations compared to Turn level annotation, most notably in the Fast Food domain. IC and SL annotations reflect a slightly higher IAA in Turn level annotation granularity compared to Sentence level.

5 Dialogue Classification Baselines

To establish baseline performance for the MultiDoGO dataset we pre-process, create dataset splits, and evaluate the performance of three baseline models for each domain.

Pre-processing: We pre-process the corpus of dialogues for each domain to remove duplicate

Domain	Elicited	Good/Excellent	IC/SL	DA/IC/SL
Airline	15100	14205	7598	6287
Fast Food	9639	8674	7712	4507
Finance	8814	8160	8002	6704
Insurance	14262	13400	7799	7434
Media	33321	32231	19877	12891
Software	5562	4924	3830	2753
Total	**86698**	**81594**	**54818**	**40576**

Table 3: Total number of conversations per domain: raw conversations Elicited; Good/Excellent is the total number of conversations rated as such by the agent annotators; (IC/SL) is the number of conversations annotated for Intent Classes and Slot Labels only; (DA/IC/SL) is the total number of conversations annotated for Dialogue Acts, Intent Classes, and Slot Labels.

Bias	Airlines	Fast Food	Finance	Insurance	Media	Software
IntentChange		1443				
MultiIntent	2200	1913	1799	1061	607	2295
MultiValue		354				
Overfill			1486	2763		
SlotChange	4207	2011	2506	3321	570	2085
SlotDeletion		333				
Total	6407	6054	5791	7145	1177	4380

Table 4: Number of conversations per domain collected with specific biases. Fast Food had the maximum number of biases. MultiIntent and SlotChange are the most used biases.

Metric	DSTC 2	WOZ2.0	FRAMES	KVRET	M2M	MULTIWOZ	MULTIDOGO
Number of Dialogues	1,612	600	1,396	2,425	1,500	8,438	40,576
Total Number of Turns	23,354	4,472	19,986	12,732	14,796	115,424	813,834
Total Number of Tokens	199,431	50,264	251,867	102,077	121,977	1,520,970	9,901,235
Avg. Turns per Dialog	14.49	7.45	14.60	5.25	9.86	15.91	20.06
Avg. Tokens Per Turn	8.54	11.24	12.60	8.02	8.24	13.18	12.16
Total Unique Tokens	986	2,142	12,043	2,842	1,008	24,071	70,003
Number of Unique Slots	8	4	61	13	14	25	73
Number of Slot Values	212	99	3,871	1,363	138	4,510	55,816
Number of Domains	1	1	1	3	1	7	6
Number of Tasks	1	1	1	2	2	2	3

Table 5: `MultiDoGO` is several times larger in nearly every dimension to the pertinent datasets as selected by Budzianowski et al. (2018). We provide counts for the training data, except for FRAMES, which does not have splits. Our number of unique tokens and slots can be attributed to us not relying on carrier phrases.

Domain	#Conv	#Turn	#Turn/Conv	#Sentence	#Intent	#Slot	Turn-level IAA	Sentence-level IAA
Airline	2,500	39,616	15.8 (15)	66,368	11	15	0.514/0.808/0.802	0.670/0.788/0.771

Software	2,500	40,093	16.0 (15)	70,268	16	15	0.508/0.748/0.745	0.709/0.764/0.698

Table 6: Data statistics by domain. Conversation length is shown in *average (median)* number of turns per conversation. Inter-annotator agreement (IAA) is measured with Fleiss' Kappa for the three annotation tasks: Agent DA (DA), Customer IC (IC), and Slot Labeling (SL).

conversations and utterances with inconsistent annotations. The most common source of inconsistent annotations in our dataset is imprecise selection of slot label spans by annotators, which results in sub-token slot labels. While much of this inconsistent data could likely be recovered by mapping each character span to the nearest token span, we drop these utterances to ensure these errors have no effect on our experimental results. Our post-processed data is pruned to approximately 90% of the original size. We form splits for each domain at the conversation level by randomly assigning 70% of conversations to train, 10% to development, and 20% to test. Conversation level splits enable the application of contextual models to our dataset, as each conversation is assigned to a single

Table 8: Joint training of ELMo on all agent DA data leads to a slight increase in test performance. However, we expect stronger joint models that leverage transfer learning should see a larger improvement. Bold text denotes the training strategy, i.e. single domain (Base) or multi-domain (Joint), with the best performance for a given annotation granularity. Red highlight denotes the strategy with the highest DA F1 score across annotation granularities.

split. However, our conversation level splits result in imbalanced intent and slot label distributions.

Models: We evaluate the performance of two neural models on each domain. The first is a bi-directional LSTM (Hochreiter and Schmidhuber, 1997) with GloVe word embeddings, a hidden state of size 512, and two fully connected output layers for slot labels and intent classes respectively. The second model, ELMO, is similar to the LSTM architecture but it addiitonally uses pre-trained ELMO (Peters et al., 2018) embeddings in addition to GloVe word embeddings, which are kept frozen during training. We combine these ELMO and GloVe embeddings via concatenation. As a sanity check, we also include a most frequent class (MFC) baseline. The MFC baseline assigns the most frequent class label in the training split to every utterance u' in the test split for both DA and IC tasks. To adapt the MFC baseline to SL, we compute the most frequent slot label MFC(w) for each word type w in the training set. Then given a test utterance u', we assign the pre-computed, most frequent slot MFC(w') to each word $w' \in u'$ if w' is present in the training set. If a given word $w' \in u'$ is not present the training set, we assign the *other* slot label, which denotes the absence of a slot, to w'. We utilize the AllenNLP (Gardner et al., 2017) library to implement these models and evaluate our performance. We use the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 0.001 to train the LSTM and ELMO models for 50 epochs, using batch sizes 256 and 128, respectively. In addition, we employ early stopping on the validation loss with a tolerance of 10 epochs to prevent over fitting.

Evaluation Metrics: We report micro F1 score to evaluate DA and IC performance of our models. Similarly, we use a span based F1 score, implemented in the seqeval library [5], to evaluate SL performance.

5.1 Results

DA/IC/SL Results. Table 7 presents the MFC, LSTM, and ELMO results for each domain, on the subset of 15,000 conversations annotated at both the turn and sentence levels. In general for both granularities Turn and Sentence, both LSTM,

[5] https://github.com/chakki-works/seqeval

and ELMO outperform MFC significantly across all domains. Relative to the LSTM, we find that ELMO obtains a modest increase in IC accuracy of 0.41 to 2.20 F1 points and a significant increase in SL F1 score on all domains. Concretely, ELMO boosts SL F1 performance by 3.16 to 13.17 F1 points. We see the biggest SL gains on the Insurance domain, where sentence level ELMO achieves the 13.17 point F1 gain and turn level ELMO achieves a 12.67 point F1 gain. Performance gains on the Airline domain are also large; here, ELMO increases sentence and turn level SL F1 score by 12.38 and 9.86 F1 points, respectively. Both LSTM and ELMO yield similar performance in terms of F1 score on DA classification for which the difference in performance of these models is within one F1 point across all domains. In general, the FastFood domain yields the overall lowest absolute F1 scores. Recall that Fastfood had the most diverse dialogues (biases) as per Table 4 and the lowest IAA as per Table 6.

Sentence vs. Turn Level Annotation Units. Regarding the performance of the LSTM and ELMO models on sentence vs. turn level annotation units, our results suggest that turn level annotations increase the difficulty of the DA classification task. This finding is evidenced by DA performance of our models on the Fast Food domain, for which F1 score is up to 25 F1 points lower for turn level annotations than sentence level annotations. We believe the increased difficulty of turn level DA relative to sentence level DA is driven by a corresponding increase in the confusability of turn level dialogue acts. This assertion of greater turn level DA confusability is supported by the lower inter annotator agreement (IAA) scores on turn level DA, which range from 0.314 to 0.521, relative to IAA scores for sentence level DA, which range from 0.598 to 0.709. This experimental result highlights the importance of collecting sentence level annotations for conversational DA datasets. Somewhat surprisingly, our models achieve similar IC F1 and SL F1 scores on turn and sentence level annotations. We hypothesize that the choice of annotation unit has a lesser impact on the IC and SL tasks because customer utterances are more likely to focus on a single speech act, whereas Agent utterances may be more complex in comparison and include a greater number of speech acts.

Joint Training on Agent DA. Agent DA classification naturally lends itself to joint training, given agent DAs are shared among all domains. To explore the benefits of multi-domain training, we jointly train an agent DA classification model on all domains and report test results for each domain separately. These results are provided in Table 8. This straightforward technique leads to a consistent but less than one point improvement in F1 scores. We expect that more sophisticated transfer learning methods (Liu et al., 2017; Howard and Ruder, 2018) could generate larger improvements for these domains.

Overall, our results demonstrate that there is still headroom for performance improvement, especially for the SL task, across all domains. Consequently, `MultiDoGO` should be a relevant benchmark for developing new state-of-the-art NLU models for the foreseeable future.

6 Future Directions

The data collection and annotation methodology that we use to gather `MultiDoGO` can efficiently scale across languages. Several pilot experiments aimed at collecting Spanish dialogues in the same domains have shown preliminary success in quality assessment. The production of a NLU dataset with parallel data in multiple languages would be a boon to the cross-lingual research community. To date, cross-lingual NLU research (Upadhyay et al., 2018; Schuster et al., 2018) has relied on much smaller parallel corpora.

7 Conclusion

We present `MultiDoGO`, a new Wizard-of-Oz dialogue dataset that is the largest human-generated, multi-domain corpora of conversations to date. The scale and range of this data provides a testbed for future work in joint training and transfer learning. Moreover, our comparison of sentence and turn level annotations provides insight into the effect of annotation granularity on downstream model performance. By pairing crowd-source labor with professional data annotators, we balance the cost, diversity, and quality of these conversations in a scalable manner. We show that by adopting a modular annotation strategy, the crowds can reliably annotate dialogues at a level commensurate with trained professional annotators.

Abstract

The detection of offensive language in the context of a dialogue has become an increasingly important application of natural language processing. The detection of trolls in public forums (Galán-García et al., 2016), and the deployment of chatbots in the public domain (Wolf et al., 2017) are two examples that show the necessity of guarding against adversarially offensive behavior on the part of humans. In this work, we develop a training scheme for a model to become robust to such human attacks by an iterative build it, break it, fix it strategy with humans and models in the loop. In detailed experiments we show this approach is considerably more robust than previous systems. Further, we show that offensive language used within a conversation critically depends on the dialogue context, and cannot be viewed as a single sentence offensive detection task as in most previous work. Our newly collected tasks and methods are all made open source and publicly available.

1 Introduction

The detection of offensive language has become an important topic as the online community has grown, as so too have the number of bad actors (Cheng et al., 2017). Such behavior includes, but is not limited to, trolling in public discussion forums (Herring et al., 2002) and via social media (Silva et al., 2016; Davidson et al., 2017), employing hate speech that expresses prejudice against a particular group, or offensive language specifically targeting an individual. Such actions can be motivated to cause harm from which the bad actor derives enjoyment, despite negative consequences to others (Bishop, 2014). As such, some bad actors go to great lengths to both avoid detection and to achieve their goals (Shachaf and Hara, 2010). In that context, any attempt to automatically detect this behavior can be expected to be adversarially attacked by looking for weaknesses in the detection system, which currently can easily be exploited as shown in (Hosseini et al., 2017; Gröndahl et al., 2018). A further example, relevant to the natural langauge processing community, is the exploitation of weaknesses in machine learning models that *generate* text, to force them to emit offensive language. Adversarial attacks on the Tay chatbot led to the developers shutting down the system (Wolf et al., 2017).

In this work, we study the detection of offensive language in dialogue with models that are robust to adversarial attack. We develop an automatic approach to the "Build it Break it Fix it" strategy originally adopted for writing secure programs (Ruef et al., 2016), and the "Build it Break it" approach consequently adapting it for NLP (Ettinger et al., 2017). In the latter work, two teams of researchers, "builders" and "breakers" were used to first create sentiment and semantic role-labeling systems and then construct examples that find their faults. In this work we instead fully automate such an approach using crowdworkers as the humans-in-the-loop, and also apply a fixing stage where models are retrained to improve them. Finally, we repeat the whole build, break, and fix sequence over a number of iterations.

We show that such an approach provides more and more robust systems over the fixing iterations. Analysis of the type of data collected in the iterations of the break it phase shows clear distribution changes, moving away from simple use of profanity and other obvious offensive words to utterances that require understanding of world knowledge, figurative language, and use of negation to detect if they are offensive or not. Further, data collected in the context of a dialogue rather than a sentence without context provides more sophisticated attacks. We show that model architectures that use the dialogue context efficiently perform much bet-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4537–4546,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ter than systems that do not, where the latter has been the main focus of existing research (Wulczyn et al., 2017; Davidson et al., 2017; Zampieri et al., 2019).

Code for our entire build it, break it, fix it algorithm is made open source, complete with model training code and crowdsourcing interface for humans. Our data and trained models will also be made available for the community via ParlAI[1].

2 Related Work

The task of detecting offensive language has been studied across a variety of content classes. Perhaps the most commonly studied class is hate speech, but work has also covered bullying, aggression, and toxic comments (Zampieri et al., 2019).

To this end, various datasets have been created to benchmark progress in the field. In hate speech detection, recently Davidson et al. (2017) compiled and released a dataset of over 24,000 tweets labeled as containing hate speech, offensive language, or neither. In order to benchmark toxic comment detection, The Wikipedia Toxic Comments dataset (which we study in this work) was collected and extracted from Wikipedia Talk pages and featured in a Kaggle competition (Wulczyn et al., 2017; Google, 2018). Each of these benchmarks examine only single-turn utterances, outside of the context in which the language appeared. In this work we recommend that future systems should move beyond classification of singular utterances and use contextual information to help identify offensive language.

Many approaches have been taken to solve these tasks – from linear regression and SVMs to deep learning (Noever, 2018). The best performing systems in each of the competitions mentioned above (for aggression and toxic comment classification) used deep learning approaches such as LSTMs and CNNs (Kumar et al., 2018; Google, 2018). In this work we consider a large-pretrained transformer model which has been shown to perform well on many downstream NLP tasks (Devlin et al., 2018).

The broad class of adversarial training is currently a hot topic in machine learning (Goodfellow et al., 2014). Use cases include training image generators (Brock et al., 2018) as well as image classifiers to be robust to adversarial examples (Liu et al., 2019). These methods find the breaking examples algorithmically, rather than by using humans breakers as we do. Applying the same approaches to NLP tends to be more challenging because, unlike for images, even small changes to a sentence can cause a large change in the meaning of that sentence, which a human can detect but a lower quality model cannot. Nevertheless algorithmic approaches have been attempted, for example in text classification (Ebrahimi et al., 2018), machine translation (Belinkov and Bisk, 2018), dialogue generation tasks (Li et al., 2017) and reading comprehension (Jia and Liang, 2017). The latter was particularly effective at proposing a more difficult version of the popular SQuAD dataset.

As mentioned in the introduction, our approach takes inspiration from "Build it Break it" approaches which have been successfully tried in other domains (Ruef et al., 2016; Ettinger et al., 2017). Those approaches advocate finding faults in systems by having humans look for insecurities (in software) or prediction failures (in models), but do not advocate an automated approach as we do here. Our work is also closely connected to the "Mechanical Turker Descent" algorithm detailed in (Yang et al., 2018) where language to action pairs were collected from crowdworkers by incentivizing them with a game-with-a-purpose technique: a crowdworker receives a bonus if their contribution results in better models than another crowdworker. We did not gamify our approach in this way, but still our approach has commonalities in the round-based improvement of models through crowdworker interaction.

3 Baselines: Wikipedia Toxic Comments

In this section we describe the publicly available data that we have used to bootstrap our *build it break it fix it* approach. We also compare our model choices with existing work and clarify the metrics chosen to report our results.

Wikipedia Toxic Comments The Wikipedia Toxic Comments dataset (WTC) has been collected in a common effort from the Wikimedia Foundation and Jigsaw (Wulczyn et al., 2017) to identify personal attacks online. The data has been extracted from the Wikipedia Talk pages, discussion pages where editors can discuss improvements to articles or other Wikipedia pages. We considered the version of the dataset that corresponds to the Kaggle competition: "Toxic Comment Classification Challenge" (Google, 2018)

[1] https://parl.ai/projects/dialogue_safety/

which features 7 classes of toxicity: toxic, severe toxic, obscene, threat, insult, identity hate and non-toxic. In the same way as in (Khatri et al., 2018), every label except non-toxic is grouped into a class OFFENSIVE while the non-toxic class is kept as the SAFE class. In order to compare our results to (Khatri et al., 2018), we similarly split this dataset to dedicate 10% as a test set. 80% are dedicated to train set while the remaining 10% is used for validation. Statistics on the dataset are shown in Table 1.

Models We establish baselines using two models. The first one is a binary classifier built on top of a large pre-trained transformer model. We use the same architecture as in BERT (Devlin et al., 2018). We add a linear layer to the output of the first token ([CLS]) to produce a final binary classification. We initialize the model using the weights provided by (Devlin et al., 2018) corresponding to "BERT-base". The transformer is composed of 12 layers with hidden size of 768 and 12 attention heads. We fine-tune the whole network on the classification task. We also compare it the fastText classifier (Joulin et al., 2017) for which a given sentence is encoded as the average of individual word vectors that are pre-trained on a large corpus issued from Wikipedia. A linear layer is then applied on top to yield a binary classification.

Experiments We compare the two aforementioned models with (Khatri et al., 2018) who conducted their experiments with a BiLSTM with GloVe pre-trained word vectors (Pennington et al., 2014). Results are listed in Table 2 and we compare them using the weighted-F1, i.e. the sum of F1 score of each class weighted by their frequency in the dataset. We also report the F1 of the OFFENSIVE-class which is the metric we favor within this work, although we report both. (Note that throughout the paper, the notation F1 is always referring to OFFENSIVE-class F1.) Indeed, in the case of an imbalanced dataset such as Wikipedia Toxic Comments where most samples are SAFE, the weighted-F1 is closer to the F1 score of the SAFE class while we focus on detecting OFFENSIVE content. Our BERT-based model outperforms the method from Khatri et al. (2018); throughout the rest of the paper, we use the BERT-based architecture in our experiments. In particular, we used this baseline trained on WTC to bootstrap our approach, to be described subsequently.

	Train	Valid	Test
SAFE	89.8%	89.7%	90.1%
OFFENSIVE	10.2%	10.3%	9.1%
Total	114656	15958	15957

Table 1: Dataset statistics for our splits of Wikipedia Toxic Comments.

	OFFENSIVE F1	Weighted F1
fastText	71.4%	94.8%
BERT-based	83.4%	96.7%
(Khatri et al., 2018)	-	95.4%

Table 2: Comparison between our models based on fastText and BERT with the BiLSTM used by (Khatri et al., 2018) on Wikipedia Toxic Comments.

4 Build it Break it Fix it Method

In order to train models that are robust to adversarial behavior, we posit that it is crucial collect and train on data that was collected in an adversarial manner. We propose the following automated build it, break it, fix it algorithm:

1. **Build it:** Build a model capable of detecting OFFENSIVE messages. This is our best-performing BERT-based model trained on the Wikipedia Toxic Comments dataset described in the previous section. We refer to this model throughout as A_0.

2. **Break it:** Ask crowdworkers to try to "beat the system" by submitting messages that our system (A_0) marks as SAFE but that the worker considers to be OFFENSIVE.

3. **Fix it:** Train a new model on these collected examples in order to be more robust to these adversarial attacks.

4. **Repeat:** Repeat, deploying the newly trained model in the **break it** phase, then **fix it** again.

See Figure 1 for a visualization of this process.

4.1 Break it Details

Definition of OFFENSIVE Throughout data collection, we characterize OFFENSIVE messages for users as messages that would not be "ok to send in a friendly conversation with someone you just met online." We use this specific language in an attempt to capture various classes of content that would be considered unacceptable in a friendly

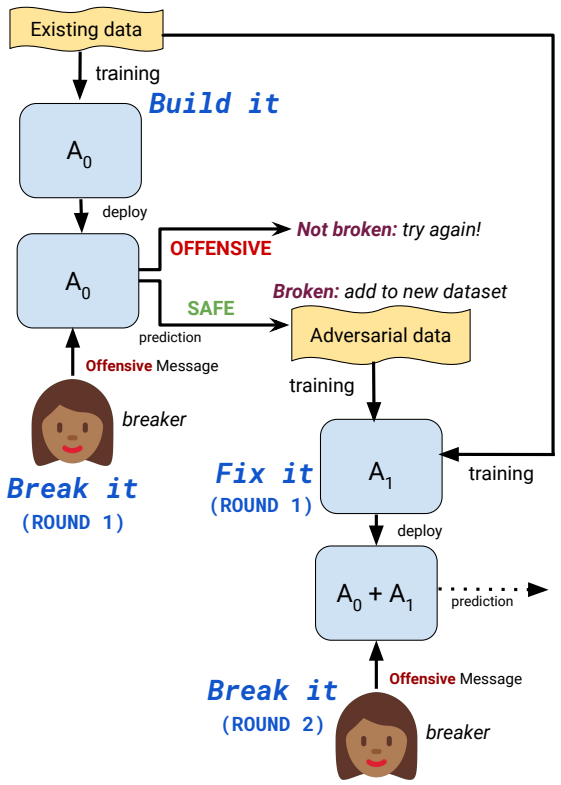

Figure 1: The build it, break it, fix it algorithm we use to iteratively train better models $A_0, \ldots, A_N$. In experiments we perform $N = 3$ iterations of the break it, fix it loop for the single-turn utterance detection task, and a further iteration for the multi-turn task in a dialogue context setting.

conversation, without imposing our own definitions of what that means. The phrase "with someone you just met online" was meant to mimic the setting of a public forum.

Crowderworker Task We ask crowdworkers to try to "beat the system" by submitting messages that our system marks as SAFE but that the worker considers to be OFFENSIVE. For a given round, workers earn a "game" point each time they are able to "beat the system," or in other words, trick the model by submitting OFFENSIVE messages that the model marks as SAFE. Workers earn up to 5 points each round, and have two tries for each point: we allow multiple attempts per point so that workers can get feedback from the models and better understand their weaknesses. The points serve to indicate success to the crowdworker and motivate to achieve high scores, but have no other meaning (e.g. no monetary value as in (Yang et al., 2018)). More details regarding the user interface and instructions can be found in Appendix B.

Models to Break During round 1, workers try to break the baseline model A_0, trained on Wikipedia Toxic Comments. For rounds i, $i > 1$, workers must break both the baseline model and the model from the previous "fix it" round, which we refer to as A_{i-1}. In that case, the worker must submit messages that both A_0 and A_{i-1} mark as SAFE but which the worker considers to be OFFENSIVE.

4.2 Fix it Details

During the "fix it" round, we update the models with the newly collected adversarial data from the "break it" round. The training data consists of all previous rounds of data, so that model A_i is trained on all rounds n for $n \leq i$, as well as the Wikipedia Toxic Comments data. We split each round of data into train, validation, and test partitions. The validation set is used for hyperparameter selection. The test sets are used to measure how robust we are to new adversarial attacks. With increasing round i, A_i should become more robust to increasingly complex human adversarial attacks.

5 Single-Turn Task

We first consider a single-turn set-up, i.e. detection of offensive language in one utterance, with no dialogue context or conversational history.

5.1 Data Collection

Adversarial Collection We collected three rounds of data with the build it, break it, fix it algorithm described in the previous section. Each round of data consisted of 1000 examples, leading to 3000 single-turn adversarial examples in total. For the remainder of the paper, we refer to this method of data collection as the *adversarial method*.

Standard Collection In addition to the *adversarial method*, we also collected data in a non-adversarial manner in order to directly compare the two set-ups. In this method – which we refer to as the *standard method*, we simply ask crowdworkers to submit messages that they consider to be OFFENSIVE. There is no model to break. Instructions are otherwise the same.

In this set-up, there is no real notion of "rounds", but for the sake of comparison we refer to each subsequent 1000 examples collected in this manner as a "round". We collect 3000 examples – or three rounds of data. We refer to a model trained on rounds $n \leq i$ of the *standard* data as S_i.

Single-Turn Adversarial (Round 1) and Standard Task OFFENSIVE Examples

	contains profanity	non-profane offending words	contains negation	contains figurative language	requires world knowledge	contains sarcasm
Standard	13%	12%	12%	11%	8%	3%
Adversarial	0%	5%	23%	19%	14%	6%

Table 3: Language analysis of the single-turn *standard* and *adversarial* (round 1) tasks by human annotation of various language properties. Standard collection examples contain more words found in an offensive words list, while *adversarial* examples require more sophisticated language understanding.

5.1.1 Task Formulation Details

Since all of the collected examples are labeled as OFFENSIVE, to make this task a binary classification problem, we will also add SAFE examples to it. The "safe data" is comprised of utterances from the ConvAI2 chit-chat task (Dinan et al., 2019; Zhang et al., 2018) which consists of pairs of humans getting to know each other by discussing their interests. Each utterance we used was reviewed by two independent crowdworkers and labeled as SAFE, with the same characterization of SAFE as described before. For each partition (train, validation, test), the final task has a ratio of 9:1 SAFE to OFFENSIVE examples, mimicking the division of the Wikipedia Toxic Comments dataset used for training our baseline models. Dataset statistics for the final task can be found in Table 5. We refer to these tasks – with both SAFE and OFFENSIVE examples – as the *adversarial* and *standard* tasks.

5.1.2 Model Training Details

Using the BERT-based model architecture described in Section 3, we trained models on each round of the *standard* and *adversarial* tasks, multi-tasking with the Wikipedia Toxic Comments task. We weight the multi-tasking with a mixing parameter which is also tuned on the validation set. Finally, after training weights with the cross entropy loss, we adjust the final bias also using the validation set. We optimize for the sensitive class (i.e. OFFENSIVE-class) F1 metric on the *standard* and *adversarial* validation sets respectively.

For each task (*standard* and *adversarial*), on round i, we train on data from all rounds n for $n \leq i$ and optimize for performance on the validation sets $n \leq i$.

5.2 Experimental Results

We conduct experiments comparing the *adversarial* and *standard* methods. We break down the results into "break it" results comparing the data collected and "fix it" results comparing the models obtained.

	% with profanity	% with "not"	avg. # chars	avg. # tokens
Std. (Rnds 1-3)	18.2	2.8	48.6	9.4
Adv. Rnd 1	2.6	5.8	53.7	10.3
Adv. Rnd 2	1.5	5.5	44.5	9
Adv. Rnd 3	1.2	9.8	45.7	9.3
Multi-turn Adv.	1.6	4.9	36.6	7.8

Table 4: Percent of OFFENSIVE examples in each task containing profanity, the token "not", as well as the average number of characters and tokens in each example. Rows 1-4 are the single-turn task, and the last row is the multi-turn task. Later rounds have less profanity and more use of negation as human breakers have to find more sophisticated language to adversarially attack our models.

Rounds {1, 2 and 3}	Train	Valid	Test
SAFE **Examples**	21,600	2700	2700
OFFENSIVE **Examples**	2400	300	300
Total Examples	24,000	3,000	3,000

Table 5: Dataset statistics for the single-turn rounds of the *adversarial* task data collection. There are three rounds in total all of identical size, hence the numbers above can be divided for individual statistics. The *standard* task is an additional dataset of exactly the same size as above.

5.2.1 Break it Phase

Examples obtained from both the *adversarial* and *standard* collection methods were found to be clearly offensive, but we note several differences in the distribution of examples from each task, shown in Table 4. First, examples from the *standard* task tend to contain more profanity. Using a list of common English obscenities and otherwise bad words[2], in Table 4 we calculate the percentage of examples in each task containing such obscenities, and see that the *standard* examples contain

[2]https://github.com/LDNOOBW/List-of-Dirty-Naughty-Obscene-and-Otherwise-Bad-Words

		WTC Baseline	*Standard* models			*Adversarial* models		
Task Type	Task Round	A_0	S_1	S_2	S_3	A_1	A_2	A_3
WTC	-	**83.3**	80.6	81.1	82.1	81.3	78.9	78.0
Standard Task	All (1-3)	68.1	83.3	85.8	**88.0**	83.0	85.3	83.7
Adversarial Task	1	0.0	51.7	69.3	68.6	71.8	**79.0**	78.2
	2	0.0	10.8	26.4	31.8	0.0	**64.4**	62.1
	3	0.0	12.3	17.1	13.7	32.1	0.0	**59.9**
	All (1-3)	0.0	27.4	41.7	41.8	40.6	55.5	**67.6**

Table 6: Test performance of best standard models trained on *standard* task rounds (models S_i for each round i) and best *adversarial* models trained on adversarial task rounds (models A_i). All models are evaluated using OFFENSIVE-class F1 on each round of both the *standard* task and *adversarial* task. A_0 is the baseline model trained on the existing Wiki Toxic Comments (WTC) dataset. Adversarial models prove to be more robust than standard ones against attack (Adversarial Task 1-3), while still performing reasonably on Standard and WTC tasks.

at least seven times as many as each round of the *adversarial* task. Additionally, in previous works, authors have observed that classifiers struggle with negations (Hosseini et al., 2017). This is borne out by our data: examples from the single-turn *adversarial* task more often contain the token "not" than examples from the *standard* task, indicating that users are easily able to fool the classifier with negations.

We also anecdotally see figurative language such as "snakes hiding in the grass" in the adversarial data, which contain no individually offensive words, the offensive nature is captured by reading the entire sentence. Other examples require sophisticated world knowledge such as that many cultures consider eating cats to be offensive. To quantify these differences, we performed a blind human annotation of a sample of the data, 100 examples of standard and 100 examples of adversarial round 1. Results are shown in Table 3. Adversarial data was indeed found to contain less profanity, fewer non-profane but offending words (such as "idiot"), more figurative language, and to require more world knowledge.

We note that, as anticipated, the task becomes more challenging for the crowdworkers with each round, indicated by the decreasing average scores in Table 7. In round 1, workers are able to get past A_0 most of the time – earning an average score of 4.56 out of 5 points per round – showcasing how susceptible this baseline is to adversarial attack despite its relatively strong performance on the Wikipedia Toxic Comments task. By round 3, however, workers struggle to trick the system, earning an average score of only 1.6 out of 5. A finer-grained assessment of the worker scores can be found in Table 11 in the appendix.

	Single-Turn			Multi
Round	1	2	3	("4")
Avg. score (0-5)	4.56	2.56	1.6	2.89

Table 7: Adversarial data collection worker scores. Workers received a score out of 5 indicating how often (out of 5 rounds) they were able to get past our classifiers within two tries. In later single-turn rounds it is harder to defeat our models, but switching to multi-turn makes this easier again as new attacks can be found by using the dialogue context.

5.2.2 Fix it Phase

Results comparing the performance of models trained on the *adversarial* (A_i) and *standard* (S_i) tasks are summarized in Table 6, with further results in Table 13 in Appendix A.2. The adversarially trained models A_i prove to be more robust to adversarial attack: on each round of adversarial testing they outperform standard models S_i.

Further, note that the *adversarial* task becomes harder with each subsequent round. In particular, the performance of the standard models S_i rapidly deteriorates between round 1 and round 2 of the *adversarial* task. This is a clear indication that models need to train on adversarially-collected data to be robust to adversarial behavior.

Standard models (S_i), trained on the *standard* data, tend to perform similarly to the *adversarial* models (A_i) as measured on the *standard* test sets, with the exception of training round 3, in which A_3 fails to improve on this task, likely due to being too optimized for adversarial tasks. The *standard* models S_i, on the other hand, are improving

with subsequent rounds as they have more training data of the same distribution as the evaluation set. Similarly, our baseline model performs best on its own test set, but other models are not far behind.

Finally, we remark that all scores of 0 in Table 6 are by design, as for round i of the *adversarial* task, both A_0 and A_{i-1} classified each example as SAFE during the 'break it' data collection phase.

6 Multi-Turn Task

In most real-world applications, we find that adversarial behavior occurs in context – whether it is in the context of a one-on-one conversation, a comment thread, or even an image. In this work we focus on offensive utterances within the context of two-person dialogues. For dialogue safety we posit it is important to move beyond classifying single utterances, as it may be the case that an utterance is entirely innocuous on its own but extremely offensive in the context of the previous dialogue history. For instance, "Yes, you should definitely do it!" is a rather inoffensive message by itself, but most would agree that it is a hurtful response to the question "Should I hurt myself?"

6.1 Task Implementation

To this end, we collect data by asking crowdworkers to try to "beat" our best single-turn classifier (using the model that performed best on rounds 1-3 of the *adversarial* task, i.e., A_3), in addition to our baseline classifier A_0. The workers are shown truncated pieces of a conversation from the ConvAI2 chit-chat task, and asked to continue the conversation with OFFENSIVE responses that our classifier marks as SAFE. The resulting conversations – including the newly provided OFFENSIVE responses – are between 3 and 6 turns long. As before, workers have two attempts per conversation to try to get past the classifier and are shown five conversations per round. They are given a score (out of five) at the end of each round indicating the number of times they successfully fooled the classifier.

We collected 3000 offensive examples in this manner. As in the single-turn set up, we combine this data with SAFE examples with a ratio of 9:1 SAFE to OFFENSIVE for classifier training. The safe examples are dialogue examples from ConvAI2 for which the responses were reviewed by two independent crowdworkers and labeled as SAFE, as in the s single-turn task set-up. We refer to this overall task as the *multi-turn adversarial* task. Dataset statistics are given in Table 9.

6.2 Models

To measure the impact of the context, we train models on this dataset with and without the given context. We use the fastText and the BERT-based model described in Section 3. In addition, we build a BERT-based model variant that splits the last utterance (to be classified) and the rest of the history into two dialogue segments. Each segment is assigned an embedding and the input provided to the transformer is the sum of word embedding and segment embedding, replicating the setup of the Next Sentence Prediction that is used in the training of BERT (Devlin et al., 2018).

6.3 Experimental Results

6.3.1 Break it Phase

During data collection, we observed that workers had an easier time bypassing the classifiers than in the single-turn set-up. See Table 7. In the single-turn set-up, the task at hand gets harder with each round – the average score of the crowdworkers decreases from 4.56 in round 1 to 1.6 in round 3. Despite the fact that we are using our best single-turn classifier in the multi-turn set-up (A_3), the task becomes easier: the average score per round is 2.89. This is because the workers are often able to use contextual information to suggest something offensive rather than say something offensive outright. See examples of submitted messages in Table 8. Having context also allows one to express something offensive more efficiently: the messages supplied by workers in the multi-turn setting were significantly shorter on average, see Table 4.

6.3.2 Fix it Phase

During training, we multi-tasked the *multi-turn adversarial* task with the Wikipedia Toxic Comments task as well as the single-turn *adversarial* and *standard* tasks. We average the results of our best models from five different training runs. The results of these experiments are given in Table 10.

As we observed during the training of our baselines in Section 3, the fastText model architecture is ill-equipped for this task relative to our BERT-based architectures. The fastText model performs worse given the dialogue context (an average of 23.56 OFFENSIVE-class F1 relative to 37.1) than without, likely because its bag-of-

Multi-Turn Adversarial Task Examples		
Context	*[P1:]*	greetings and salutations my friend
	[P2:]	hi how are you doing?
	[P1:]	i'm well. enjoying some r r from the navy station
	[P2:]	i love to cook. do you cook?
	[P1:]	i do on occasion. i love to read more though.
OFFENSIVE **Response**	*[P2:]*	**reading the menu doesnt count**
Context	*[P1:]*	hey how are you
	[P2:]	good but i keep thinking about the time i almost played for nba
	[P1:]	aww why did not you play
	[P2:]	lost my nerve i guess. what do you do?
	[P1:]	oh that's to bad. i work at a gas station
OFFENSIVE **Response**	*[P2:]*	**i need to follow my dream to not work in a gas station**

Table 8: Examples from the *multi-turn adversarial* task. Responses can be offensive only in context.

Multi-Turn Adversarial Task	Train	Valid	Test
SAFE **Examples**	21,600	2,700	2,700
OFFENSIVE **Examples**	2,400	300	300
Total Examples	24,000	3,000	3,000

Table 9: *Multi-turn adversarial* task data statistics.

Multi-Turn Adversarial Task Results		
	F1	Weighted-F1
fastText		
with context	23.6 ± 1.9	85.9 ± 0.5
without context	37.1 ± 2.6	88.8 ± 0.6
BERT-based *(no segments)*		
with context	60.5 ± 1.3	92.2 ± 0.3
without context	56.8 ± 1.6	90.6 ± 0.7
BERT-based *(dialogue segments)*		
with context	66.4 ± 2.2	93.2 ± 0.4
without context	59.0 ± 2.5	91.2 ± 0.8

Table 10: Results of experiments on the multi-turn *adversarial* task. We denote the average and one standard deviation from the results of five runs. Models that use the context as input ("with context") perform better. Encoding this in the architecture as well (via BERT *dialogue segment* features) gives us the best results.

embeddings representation is too simple to take the context into account.

We see the opposite with our BERT-based models, indicating that more complex models are able to effectively use the contextual information to detect whether the response is SAFE or OFFENSIVE. With the simple BERT-based architecture (that does not split the context and the utterance into separate segments), we observe an average of a 3.7 point increase in OFFENSIVE-class F1 with the addition of context. When we use segments to separate the context from the utterance we are trying to classify, we observe an average of a 7.4 point increase in OFFENSIVE-class F1. Thus, it appears that the use of contextual information to identify OFFENSIVE language is critical to making these systems robust, and improving the model architecture to take account of this has large impact.

7 Conclusion

We have presented an approach to build more robust offensive language detection systems in the context of a dialogue. We proposed a build it, break it, fix it, and then repeat strategy, whereby humans attempt to break the models we built, and we use the broken examples to fix the models. We show this results in far more nuanced language than in existing datasets. The adversarial data includes less profanity, which existing classifiers can pick up on, and is instead offensive due to figurative language, negation, and by requiring more world knowledge, which all make current classifiers fail. Similarly, offensive language in the context of a *dialogue* is also more nuanced than standalone offensive utterances. We show that classifiers that learn from these more complex examples are indeed more robust to attack, and that using the dialogue context gives improved performance if the model architecture takes it into account.

In this work we considered a binary problem (offensive or safe). Future work could consider classes of offensive language separately (Zampieri et al., 2019), or explore other dialogue tasks, e.g. from social media or forums. Another interesting direction is to explore how our build it, break it, fix it strategy would similarly apply to make neural generative models safe (Henderson et al., 2018).

Abstract

Ellipsis and co-reference are common and ubiquitous especially in multi-turn dialogues. In this paper, we treat the resolution of ellipsis and co-reference in dialogue as a problem of generating omitted or referred expressions from the dialogue context. We therefore propose a unified end-to-end Generative Ellipsis and CO-reference Resolution model (GECOR) in the context of dialogue. The model can generate a new pragmatically complete user utterance by alternating the generation and copy mode for each user utterance. A multi-task learning framework is further proposed to integrate the GECOR into an end-to-end task-oriented dialogue. In order to train both the GECOR and the multi-task learning framework, we manually construct a new dataset on the basis of the public dataset CamRest676 with both ellipsis and co-reference annotation. On this dataset, intrinsic evaluations on the resolution of ellipsis and co-reference show that the GECOR model significantly outperforms the sequence-to-sequence (seq2seq) baseline model in terms of EM, BLEU and F_1 while extrinsic evaluations on the downstream dialogue task demonstrate that our multi-task learning framework with GECOR achieves a higher success rate of task completion than TSCP, a state-of-the-art end-to-end task-oriented dialogue model (Lei et al., 2018).

1 Introduction

Due to the rhetorical principle of saving words and avoiding repetitions, ellipsis and co-reference occur frequently in multi-turn dialogues leaving utterances paragmatically incomplete if they are separate from context. Humans can easily understand utterances with anaphorically referenced or absent information (e.g., Q_2 and Q_3 in Table 1) based on the dialogue context while dialogue systems often fail to understand such utterances correctly, which may result in false or incoherent responses.

If user utterances can be automatically supplemented with information that is left out or substituted by anaphora according to the dialogue context as humans do (e.g., *Q_2: I want cheap Italian restaurants. Q_3: Yes, I would like the phone number please.*), dialogue models may understand user requests correctly and would not generate wrong responses caused by ellipsis and co-reference phenomena. Especially in task-oriented dialogue systems, explicitly providing such information to the models can effectively improve the success rate of task completion.

In order to achieve this goal, we propose an end-to-end generative ellipsis and co-reference resolution model (GECOR) for task-oriented dialogue in this paper. The essential idea behind GECOR is that we treat the resolution of ellipsis and co-reference in user utterances as a generation task: transforming a user utterance with ellipsis or anaphora into a new utterance where the left-out or referred expressions are automatically generated from the dialogue context. We refer to the new utterance as the complete version of the original utterance. We use an end-to-end sequence-to-sequence model with two encoders for this transformation task, where one encoder reads the user utterance and the other the dialogue context and the decoder generates the complete utterance. Since most omitted expressions or antecedents can be found in the dialogue context, we resort to the attention and copy mechanism to detect such fragments in previous context and copy them into the generated complete utterance.

We then incorporate GECOR into an end-to-end task-oriented dialogue system in a multi-task

learning framework. The entire model contains two encoders (one for user utterance and the other for the dialogue context) and three decoders: one decoder for predicting dialogue states, the second decoder for generating complete user utterances and the third decoder for generating system responses. The three decoders are jointly trained.

In order to train GECOR with the task-oriented dialogue model, we manually annotate the public task-oriented dialogue dataset CamRest676 with omitted expressions and substitute anaphora in the dataset with corresponding antecedents. The new dataset can be used either to train a standalone ellipsis or co-reference resolution model or to jointly train a task-oriented dialogue model equipped with the ellipsis / co-reference resolution model.

We conduct a series of experiments and analyses, demonstrating that the proposed method can significantly outperform a strong baseline model. Our contributions are threefold:

- We propose an end-to-end generative resolution model that attempts to solve the ellipsis and co-reference reolution in a single unified framework, significantly different from previous end-to-end co-reference resolution network with two phases of detection and candidate ranking.
- To the best of our knowledge, this is the first attempt to combine the task of ellipsis and co-reference resolution with the multi-turn task-oriented dialogue. The success rate of task completion is significantly improved with the assistance of the ellipsis and co-reference resolution.
- We construct a new dataset based on CamRest676 for ellipsis and co-reference resolution in the context of task-oriented dialogue.[1]

2 Related Work

Ellipsis recovery: The earliest work on ellipsis as far as we know is the PUNDIT system (Palmer et al., 1986) which discusses the communication between the syntactic, semantic and pragmatic modules that is necessary for making implicit linguistic information explicit. Dalrymple et al. (1991) and Shieber et al. (1996) establish a set of linguistic theories in the ellipsis recovery of English verb phrases. Nielsen (2003) first proposes an end-to-end computable system to perform English verb phrase ellipsis recovery on the original input text. Liu et al. (2016) propose to decompose the resolution of the verb phrase ellipsis into three sub-tasks: target detection, antecedent head resolution, and antecedent boundary detection.

Co-reference resolution: Co-reference resolution is mainly concerned with two sub-tasks, referring expressions (i.e., mentions) detection, and entity candidate ranking. Uryupina and Moschitti (2013) propose a rule-based approach for co-reference detection which employs parse tree features with an SVM model. Peng et al. (2015) improve the performance of mention detection by applying a binary classifier on their feature set. In recent years, applying deep neural networks to the co-reference resolution has gained great success. Clark and Manning (2016) apply reinforcement learning on mention-ranking co-reference resolution. Lee et al. (2017) introduce the first end-to-end co-reference resolution model. Lee et al. (2018) present a high-order co-reference resolution model with coarse-to-fine inference.

Ellipsis and co-reference resolution in QA and Dialogue: The methods mentioned above do not generalize well to dialogues because they normally require a large amount of well-annotated contextual data with syntactic norms and candidate antecedents. In recent years, a few studies try to solve ellipsis / co-reference resolution tailored for dialogue or QA tasks. Kumar and Joshi (2016) train a semantic sequence model to learn semantic patterns and a syntactic sequence model to learn linguistic patterns to tackle with the non-sentential (incomplete) questions in a question answering system. Zheng et al. (2018) builds a seq2seq neural network model for short texts to identify and recover ellipsis. However, these methods are still limited to short texts or one-shot dialogues. Our work is the first attempt to provide both solution and dataset for ellipsis and co-reference resolution in multi-turn dialogues.

End-to-end task-oriented dialogue: Task-oriented dialogue systems have evolved from traditional modularized pipeline architectures (Rudnicky et al., 1999; Zue et al., 2000; Zue and Glass, 2000) to recent end-to-end neural frameworks (Eric and Manning, 2017a,b; Lei et al.,

[1]The new dataset and the code of our proposed system are available at https://multinlp.github.io/GECOR/

Table 1: Examples of ellipsis and co-reference resolution

2018; Jin et al., 2018). Our work is an innovative combination of ellipsis and co-reference resolution and the end-to-end task-oriented dialogue.

3 The GECOR Model

In this section, we reformulate the ellipsis and co-reference resolution task in the context of multi-turn dialogue and detail the proposed GECOR model.

3.1 Ellipsis and Co-Reference Resolution Reformulation

Our task is to reconstruct a pragmatically complete utterance from a user utterance where the ellipsis and/or co-reference phenomena are present according to the dialogue context. Table 1 provides examples of reconstructed utterances in which the omitted information is recovered or the anaphor is substituted with referred expressions.

We attempt to solve the resolution of ellipsis and co-reference in a unified framework because in essence both ellipsis and co-reference can be understood from contextual clues. We consider these two problems in multi-turn dialogue and reformulate the resolution of them as a generation problem: generating the omitted or referred expressions. In this way, the modeling of ellipsis and co-reference is in line with response generation in dialogue modeling.

Unlike previous methods that combine detection and ranking models, our generation-based formulation is not constrained by the syntactic forms of ellipsis or co-reference in sentences. They can be either words (e.g., *noun, verb*) or phrases or even clauses. Furthermore, the formulation does not need to provide a set of candidate antecedents to be resolved. Previous studies usually need to traverse the text when there are multiple ellipsis or anaphora to be resolved, which leads to a high computational complexity.

In this reformulation, we assume that the dialogue context is composed of all utterances from the beginning of the dialogue to the current user utterance. Both the context and the user utterance in question are input to the GECOR model to generate the complete version of the user utterance.

3.2 Model Structure

The GECOR model is shown in Figure 1. The model essentially contains an embedding module, a user utterance encoder, a dialogue context encoder and a decoder with either copy (Gu et al., 2016) or gated copy mechanism (modified from See et al. (2017)). Both the generation probability over the entire vocabulary and the copy probability over all words from the dialogue context are taken into account for predicting the complete user utterance.

Embedding Layer In GECOR, we first tokenize the input user utterance and the dialogue context. We then use GloVe (Pennington et al., 2014) (the pre-trained 50-dimensional word vectors) in the embedding layer to obtain word embeddings. Let $\mathbf{U} = \{u_1, ..., u_m\}$, $\mathbf{C} = \{c_1, ..., c_n\}$ be representations of the tokenized utterance and context sequence.

Utterance and Context Encoder We use a single-layer bidirectional GRU to construct both encoders. The forward and backward hidden states over the input embeddings from the embedding layer are concatenated to form the hidden states of the two encoders.

Decoder The decoder is a single-layer unidirectional GRU. In the decoder, the attention distribution a^t is calculated as in Bahdanau et al. (2015):

$$e_i^t = v^T tanh(W_h h_i + W_s s_{t-1} + b_{attn}) \quad (1)$$

$$a^t = softmax(e^t) \quad (2)$$

where v, W_h, W_s and b_{attn} are learnable parameters, h_i is the hidden state for word u_i from the sequence produced by the utterance encoder. The attention distribution a^t is used to produce a weighted sum of the encoder hidden states, known as the context vector h_t^*:

$$h_t^* = \sum_i a_i^t h_i \quad (3)$$

It is fed into the single-layer unidirectional GRU together with the previous decoder state s_t and the word embedding y_{t-1} of the previously generated

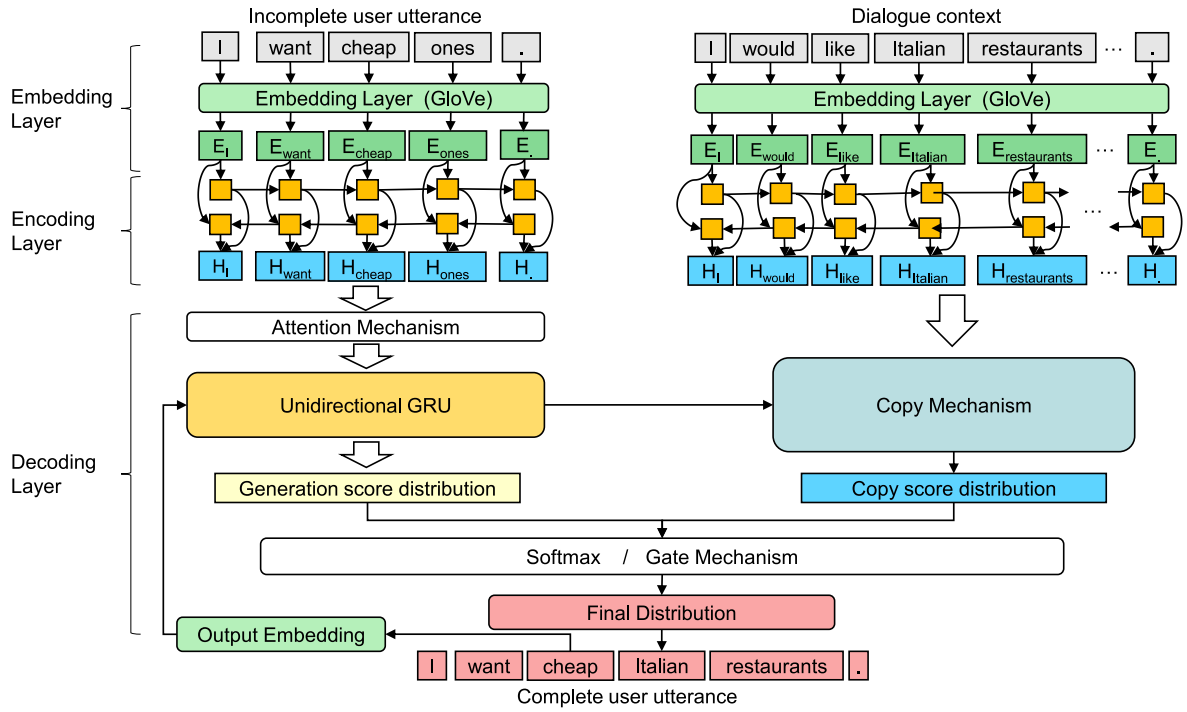

Figure 1: The end-to-end generative model for ellipsis and co-reference resolution (GECOR).

word to obtain the decoder state s_t. The updated s_{t-1} is then concatenated with the context vector h_t^* to produce the generation probability distribution over the vocabulary $\mathbf{V}$ as follows:

$$P^g(y_t) = \frac{1}{Z} e^{\psi_g(y_t)}, \quad y_t \in \mathbf{V} \tag{4}$$

$$\psi_g(y_t = v_i) = \mathbf{v}_i{}^T (W_g^h h_t^* + W_g^s s_t + b_g) \tag{5}$$

$$s_t = GRU([y_{t-1}; h_t^*], s_{t-1}) \tag{6}$$

where W_g^h, W_g^s and b_g are learnable parameters and $\mathbf{v}_i$ is the one-hot indicator vector for word $v_i \in \mathbf{V}$. ψ_g is the score function for the generation-mode and Z is the normalization term shared by the generation-mode and copy-mode.

Copy Network The copy network (Gu et al., 2016) is used to calculate the probabilities for words copied from the dialogue context. These words are parts of the omitted or referred expressions to be predicted. We build the copy network on the top of the context encoder. The probability for copying each word from the dialogue context is computed as follows:

$$P^c(y_t) = \frac{1}{Z} \sum_{i:c_i = y_t}^{|\mathbf{C}|} e^{\psi_c(c_i)}, \quad y_t \in \mathbf{C} \tag{7}$$

$$\psi_c(y_t = c_i) = \sigma(W_c h_i^c + b_c) s_t \tag{8}$$

where W_c and b_c are learnable parameters, h_i^c is the output for word c_i from the context encoder, and σ is a non-linear activation function. ψ_c is the score function for the copy-mode and Z is the normalization term shared by equation (4) and (7).

Both probabilities from the two modes contribute to the final probability distribution over the extended vocabulary (the vocabulary plus the words from the dialogue context) which is calculated as follows:

$$P(y_t) = P^g(y_t) + P^c(y_t), \; y_t \in \mathbf{V} \cup \mathbf{C} \tag{9}$$

which is used to predict the final output word.

Gated Copy An alternative to the copy network is the gated copy mechanism that use a gate to regulate the contributions of the generation and copy mode to the final prediction. The gate p_{gen} is calculated as follows:

$$p_{gen} = \sigma(W_h h_t^* + W_s s_t + W_y y_{t-1} + b_t) \tag{10}$$

$$P(y_t) = p_{gen} P^g(y_t) + (1 - p_{gen}) P^c(y_t) \tag{11}$$

where W_h, W_s, W_y and b_t are learnable parameters and σ is the sigmoid function.

Training The standard cross-entropy loss is adopted as the loss function to train the GECOR model.

4 Task-Oriented Dialogue with GECOR

We integrate the proposed GECOR into an end-to-end task-oriented dialogue system TSCP proposed

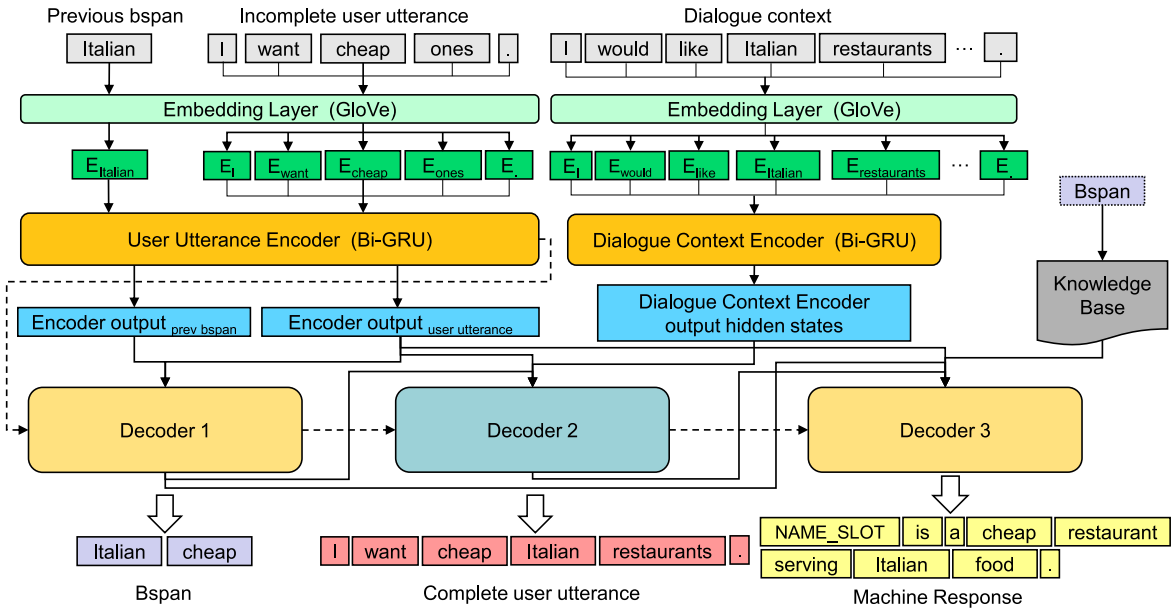

Figure 2: The architecture of the end-to-end task-oriented dialogue enhanced with the GECOR model. Decoder 1: BSpan decoder. Decoder 2: completed user utterance decoder. Decoder 3: machine response decoder.

by Lei et al. (2018) in a multi-task learning framework, which is shown in Figure 2. The GECOR-equipped TSCP model contains the embedding layer, the utterance and context encoders, and three decoders: decoder 1 for generating belief spans (BSpan) defined in (Lei et al., 2018) which are text spans for tracking dialogue states (e.g., $\langle inf \rangle Italian, cheap \langle /inf \rangle; \langle req \rangle phone \langle /req \rangle$), decoder 2 for complete user utterances and decoder 3 for machine responses. The embedding layer and encoders are the same as described in section 3.

BSpan Decoder Unlike Lei et al. (2018), we do not concatenate current user utterance with previously generated machine response. At each turn of dialogue, the user utterance and the previous BSpan (the dialogue states updated to the previous turn) are used as the inputs to the user utterance encoder. The outputs of this encoder are then fed into the BSpan decoder for predicting the new BSpan for the current turn and a cross-entropy loss L_1 is calculated. The user utterance encoder hidden states, the last hidden state and the output of the BSpan decoder are input into the other two decoders.

Complete User Utterance Decoder The basic structure of this decoder is the same as the decoder described in the last section.We pass the last hidden state of the BSpan decoder to the initial state of this decoder. In addition to the inputs from the user utterance encoder and the dialogue context encoder, we also input the output of the BSpan decoder into this decoder. The generation probability P_t^g, copy probability P_t^{c1} for copying tokens in BSpan, and copy probability P_t^{c2} for copying words in the dialogue context are calculated with a shared normalization term and combined for the final probability computation:

$$P_t = P_t^g + P_t^{c1} + P_t^{c2} \tag{12}$$

P_t is then used to decode the words in the complete user utterance. For this decoder, the second cross-entropy loss L_2 is calculated.

Machine Response Decoder Similar to the previous two decoders, the machine response decoder is also a single-layer unidirectional GRU, the initial state of which is set to the last hidden state of the complete user utterance decoder. In this decoder, we compute three context vectors for each decoder state s_t. The first context vector h_{t1}^* is calculated over the user utterance encoder hidden states while the other two context vectors h_{t2}^*, h_{t3}^* are calculated over the BSpan decoder hidden states and the complete user utterance decoder hidden states, respectively. The concatenation of s_t, h_{t1}^*, h_{t2}^*, h_{t3}^* and the Knowledge Base (KB) matching vector K_t (a one-hot representation of the retrieval results in KB according to the constraints in the corresponding BSpan) is used to generate the output and update the decoder state. The generated output is then concatenated with the three context vectors to feed into a layer to produce the gener-

Turn	Dialogue
Q_1	I would like a traditional food restaurant.
A_1	What price range do you have in mind?
Q_2	I don't care.
Q_2 (Complete)	I don't care about the price range.
Q_2 (Ellipsis)	I don't care.
Q_2 (Co-reference)	I don't care about it.

Table 2: An example of the ellipsis / co-reference annotation

ation probability distribution over the vocabulary. Similar to the complete user utterance decoder, we also use the copy mechanism in the machine response decoder. The third cross-entropy loss L_3 is then calculated.

Training The final loss for the multi-task learning framework is estimated as follows:

$$L = L_1 + L_2 + L_3 \quad (13)$$

We learn parameters to minimize the final loss.

5 Data Annotation for Ellipsis and Co-Reference Rosultion in Dialogue

Since there are no publicly available labeled data for the resolution of ellipsis and co-reference in dialogue, we manually annotate such a new dataset based on the public dataset CamRest676 (Wen et al., 2016a,b) from the restaurant domain.

Annotation Specification Annotation cases for user utterances can be summarized into the following three conventions:

- As shown in Table 2, if a user utterance contains an ellipsis or anaphor, we manually resolve the ambiguity of ellipsis or anaphor and supplement the user utterance with a correct expression by checking the dialogue context. In doing so, we create a pragmatically *complete* version for the utterance. If the utterance only contains an ellipsis and the ellipsis can be replaced with an anaphor, we create a *co-reference* version for it. Similarly, if the utterance only contains an anaphor and the anaphor can be omitted, we create an *ellipsis* version for the utterance.

- If the user utterance itself is pragmatically complete, without any ellipsis or anaphora, we create an anaphor and ellipsis version for it if such a creation is appropriate.

- If the utterance itself is complete and it is not suitable to create an ellipsis or anaphor version, we just do nothing.

With the annotation convention described above, for each user utterance in the dataset, we can label it as $l \in \{$*ellipsis*, *co-reference*, *complete*$\}$ or create two other versions for it if appropriate. Please notice that these labels are used only for dataset statistics or for designing experiments, not for training our models.

Dataset statistics The CamRest676 dataset contains 676 dialogues, with 2,744 user utterances. After annotation, 1,174 *ellipsis* versions and 1,209 *co-reference* versions are created from the 2,744 user utterances. 1,331 incomplete utterances are created that they are an either *ellipsis* or *co-reference* version. 1,413 of the 2,744 user utterances are complete and not amenable to change. No new versions are created from these 1,413 utterances.

Dataset Split for Experiments We split the new dataset into a training set (accounting for 80%) and validation set (accounting for 20%) which can be used for the stand-alone ellipsis/co-reference resolution task and the multi-task learning of both the ellipsis/co-reference resolution and end-to-end task-oriented dialogue.

6 Experiments

In this section we conducted experiments on the new dataset to examine the generative ellipsis/co-reference resolution model and its integration into the end-to-end task-oriented dialogue.

6.1 Evaluation Metrics

As far as we know, there is no end-to-end generative ellipsis and co-reference resolution model applied to multi-turn dialogues. Therefore there are no off-the-shelf metrics tailored to this evaluation. Since we deal with two tasks: the task of ellipsis/co-reference resolution (resolution task for short) and the task-oriented dialogue with integrated ellipsis/co-reference resolution (hereafter dialogue task), we use two sets of evaluation metrics. For the resolution task, we use the exact match rate (EM) that measures whether the generated utterances exatly match the gold utterances.

BLEU (Papineni et al., 2002) and F_1 score (a balance between word-level precision and recall) are also used for the resolution task to evaluate the quality of generated utterances at the n-gram and word level. We use the success F_1 which is defined as the F_1 score of requested slots correctly answered in dialogues to evaluate task comple-

Data	Model	Resolution Task							
		EM(%)	EM 1(%)	EM 2(%)	BLEU(%)	F_1(%)	Prec.(%)	Rec.(%)	Reso.F_1(%)
Ellipsis	Baseline	49.99	68.88	27.31	73.26	90.89	92.14	89.67	44.47
	GECOR 1	67.56	92.07	37.18	83.69	96.25	98.28	94.30	70.48

	GECOR 1	71.35	91.67	47.68	85.89	96.49	98.19	94.86	64.93
	GECOR 2	71.18	93.80	44.92	85.93	97.09	98.46	95.76	71.26
Mixed	Baseline	50.38	70.89	28.57	74.11	90.93	91.72	90.15	44.10
	GECOR 1	68.52	92.03	42.04	83.91	95.88	98.12	93.74	66.06
	GECOR 2	66.22	91.64	37.45	82.98	96.47	98.41	94.60	66.16

Table 3: Results of the resolution task on the dataset. GECOR 1/2: the GECOR model with the copy/gated copy mechanism. EM 1 and EM 2 respectively indicate the situation that the input utterance is complete or incomplete while EM is the comprehensive evaluation of the two situations. Reso.F_1: Resolution_F_1

tion rate for the dialogue task, similar to Lei et al. (2018).

6.2 Parameter Settings

For all our models, both the size of hidden states and word embeddings were set to 50. The vocabulary size $|\mathbf{V}|$ was set to 800 and the batch size was set to 32. We trained our models via the Adam optimizer (Kingma and Ba, 2015), with a learning rate of 0.003 and a decay parameter of 0.5. Early stopping and dropout were used to prevent overfitting, and the dropout rate was set to 0.5.

6.3 Baselines and Comparisons

For the resolution task, we compared our GECOR model with the baseline model proposed by Zheng et al. (2018) which is a seq2seq neural network model that identifies and recovers ellipsis for short texts.

For the dialogue task, we compared our multi-task learning framework with the baseline model TSCP proposed by Lei et al. (2018) which is a seq2seq model enhanced with reinforcement learning. We ran the source code[2] on our dataset to get the baseline results for comparison.

For the resolution task, we also performed a comparison study to examine the impacts of the gate mechanism incorporated into the copy network on the GECOR model and on the multi-task learning dialogue model.

6.4 The GECOR Model

Our generative resolution model was trained on three types of data: the ellipsis data where only ellipsis version utterances from the annotated dataset were used, the co-reference data where only co-reference version utterances from the annotated dataset were used, and the mixed data where we randomly selected a version for each user utterance from {*ellipsis*, *co-reference*, *complete*}. In the mixed data, 633 turns are with ellipsis user utterances, 698 turns are with co-reference user utterances, and the rest are with complete user utterances. The experimental results of the GECOR and baseline model (Zheng et al., 2018) on the three different datasets are shown in Table 3.

Overall results From the third column of the table, we find that the GECOR model with the copy mechanism (GECOR 1) improves the exact match rate (EM) by more than 17 points on the ellipsis version data, more than 15 points on the co-reference data, and more than 18 points on the mixed data. We further define a metric we term as **Resolution_F_1** that is an F_1 score calculated by comparing machine-generated words with ground truth words for only the ellipsis / co-reference part of user utterances. The GECOR model achieves consistent and significant improvements over the baseline in terms of BLEU, F_1 and Resolution_F_1 in addition to the EM metric . The major difference between the GECOR and the baseline is that the former tries to copy words from the dialogue context. The improvements, especially the improvements on the ellipsis resolution (higher than those on the co-reference resolution) indicate that the copy mechanism is crucial for the recovery of ellipsis and co-reference.

Effect of the two copy mechanisms Comparing the GECOR 1 against the GECOR 2 (with the gated copy mechanism), we can find that the gating between copy and generation is helpful in terms of the word-level quality (F_1 and Resolution_F_1 score) but not in terms of the fragment

Table 4: Results of the multi-task learning model. This table is split into two parts: performance of resolution for the integrated GECOR on the left side and performance of dialogue task on the right side.

or sequence-based metrics (i.e., BLEU and EM). Therefore, we only integrate the GECOR model with the copy mechanism into the dialogue system.

Incomplete vs. complete utterances In multi-turn dialogues, user utterances may be incomplete or complete. A robust resolution model needs to be able to accurately identify whether the input utterance is complete or not. The model needs to keep it unchanged when it is complete and to predict the corresponding complete version when it is incomplete. For these cases, we tested our models and made statistical analysis on the three versions of data as shown in column 3, 4 and 5 of Table 3 (EM, EM 1, EM 2). We can find that the GECOR model beats the baseline model in all respects. However, the GECOR model needs further improvement when the input utterances are incomplete, compared with its good performance on complete utterances.

Analysis on GECOR results for complete utterances We then analyzed the experimental results of the GECOR 1 on the mixed data in detail. When the input user utterances are complete, the GECOR model can amazingly generate 92.03% utterances that exactly match the input utterances. Only 7.97% do not match perfectly. Most unmatched cases, as we found, are with: **(1) missed words** (e.g., User: *Can I get a Korean restaurant in the town centre?* GECOR: *Can I get a Korean restaurant in the town?*) **(2) Repetition** (e.g., User: *OK, thank you. That is all for today then.* GECOR: *OK, thank you. That is all for today for today then.*)

Analysis on GECOR results for incomplete utterances For incomplete input user utterances, GECOR can generate 42.04% exactly matched cases. Among the 57.96% cases that do not exactly match ground truth utterances, only 6.3% are not complete, which still contains unresolved ellipsis or co-reference, while 93.7% of these cases are complete with GECOR-generated words that do not match ground truth words. An in-depth analysis on these show that they can be clustered into 4 classes. **(1) Paraphrases.** We found that the majority of the unmatched complete utterances generated by GECOR are actually paraphrases to the ground truth complete utterances (e.g., User: *Any will be fine.* GECOR: *Any food type will be fine.* Reference: *Any type of restaurant will be fine.*). This is also confirmed by the high scores of the word-level evaluation metrics in Table 3. **(2) Partial resolution.** When a pronoun refers to more than one items, GECOR sometimes generate a partial resolution for the pronoun (e.g., User: *I do not care about them.* GECOR: *I do not care about the price range.* Reference: *I do not care about the price range or location.*). **(3) Minor errors.** In a few cases, the resolution part is correct while there are some errors elsewhere. (e.g., User: *How about Chinese food?* Prediction: *How about international food on the south side of town?* Reference: *How about Chinese food on the south side of town?*) **(4) Repetition.** Some cases contain repeatedly generated words.

We think that although not exactly matched, paraphrased complete utterances generated by GECOR are acceptable. These utterances are helpful for the downstream dialogue task. For other errors, such as partial resolution or repetition, it may be necessary to enhance the attention or copy mechanism further in GECOR.

6.5 The Multi-Task Learning Model

We further conducted experiments to extrinsically evaluate the GECOR model in task-oriented dialogue with the success F_1 metric. This is also to evaluate our multi-task learning framework in integrating the GECOR model into the end-to-end dialogue model. In addition to training the base-

line TSCP model on the ellipsis, co-reference and mixed dataset, we also trained it on the dataset with only complete user utterances. This is to examine the ability of the baseline model in using correct contextual information presented in user utterances. The experimental results are shown in Table 4.

Overall results In comparison to the baseline, we can see that our model improves the success F_1 score by nearly 4 points on the co-reference dataset, which is close to the score obtained by the baseline trained with the complete user utterances. On the mixed and ellipsis dataset, our model also achieves 2.7 points and 0.8 points of success F_1 score improvements, respectively.

Resolution performance of the integrated GECOR We also provide the performance of the integrated GECOR on the resolution task in Table 4. The performance is slightly lower than when the GECOR is trained independently as a standalone system. This suggests that the GECOR is able to perform well when integrated into a dialogue system. The overall results demonstrate that the proposed multi-task learning framework for the end-to-end dialogue is able to improve the task completion rate by incorporating an auxiliary ellipsis/co-reference resolution task.

Since the BSpan decoder is also used in the baseline system to capture contextual information and track dialogue states, we believe that our multi-task learning model with the integrated GECOR will play a more important role in end-to-end dialgoue models that do not use state tracking modules, e.g., neural open-domain conversation models (Vinyals and Le, 2015; Li et al., 2016).

7 Conclusion and Future Work

In this paper, we have extensively investigated the ellipsis and co-reference resolution in the context of multi-turn task-oriented dialogues. We have presented the GECOR, a unified end-to-end generative model for both ellipsis and co-reference resolution in multi-turn dialogues. A multi-task learning framework is further proposed to integrate the GECOR into the end-to-end task-oriented dialogue. In order to train and test the proposed model and framework, we manually created a new dataset with annotated ellipsis and co-reference information based on the publicly available CamRest676 dataset. Experiments on the resolution task show that the GECOR is able to significantly improve the performance in terms of the exact match rate, BLEU and word-level F_1 score. Experiments on the dialogue task demonstrate that the task completion rate of the task-oriented dialogue system is significantly improved with the aid of ellipsis and co-reference resolution.

Our work could be extended to end-to-end open-domain multi-turn dialogue. We will further improve our model by incorporating syntactic and location information. We would also like to adapt the proposed methods to document-level neural machine translation in the future.

Abstract

How to incorporate external knowledge into a neural dialogue model is critically important for dialogue systems to behave like real humans. To handle this problem, memory networks are usually a great choice and a promising way. However, existing memory networks do not perform well when leveraging heterogeneous information from different sources. In this paper, we propose a novel and versatile external memory networks called Heterogeneous Memory Networks (HMNs), to simultaneously utilize user utterances, dialogue history and background knowledge tuples. In our method, historical sequential dialogues are encoded and stored into the context-aware memory enhanced by gating mechanism while grounding knowledge tuples are encoded and stored into the context-free memory. During decoding, the decoder augmented with HMNs recurrently selects each word in one response utterance from these two memories and a general vocabulary. Experimental results on multiple real-world datasets show that HMNs significantly outperform the state-of-the-art data-driven task-oriented dialogue models in most domains.

1 Introduction

Compared with chitchat, task-oriented dialogue systems aim at solving tasks in specific domains with grounding knowledge. Though far from handling conversation like a real human, existing task-oriented dialogue systems have shown cheerful prospect in a specific domain, e.g. Siri and Cortana are personal assistants, helping people a lot in daily life and business work.

In general, knowledge-grounded task-oriented dialogue system can be divided into three important components: understanding user utterances, fetching right knowledge from external storage and replying right answer. As shown in Figure 1, agent is required to do a point-of-interest navigation. According to dialogue history, agent will fetch related knowledge base information, in our case represented as tuples (e.g. [$hotel_keen$, poi_type, $rest_stop$], which indicates the point-of-i nterests type of $hotel\ keen$ is $rest\ stop$), as an external knowledge to answer correctly and complete task.

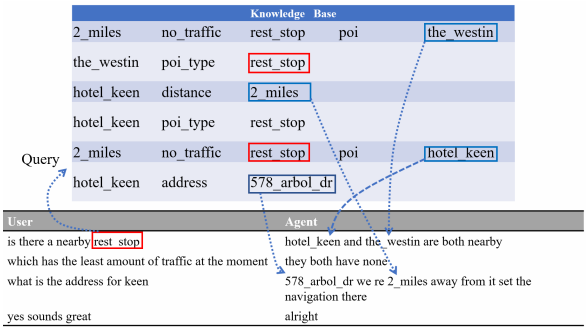

Figure 1: A multi-turn dialogue example. The upper table shows several n-tuples sampled from knowledge base. Lower table shows multi-turn dialogues. Agent needs to retrieve appropriate knowledge tuples to generate the proper response.

Traditional pipeline dialogue systems(Yan et al., 2017; Rojas-Barahona et al., 2017) and some end-to-end dialogue systems rely on the predefined the slot filling labels. Despite the consumption of human efforts, these kinds of systems are difficult to adapt to new domains.

Many works, e.g. (Vinyals and Le, 2015; Shang et al., 2015), show that training a fully data-driven end-to-end model is a promising way to build domain-agnostic dialogue system. Their models mostly try to use the attention mechanism, including memory networks techniques, to fetch the most similar knowledge (Sukhbaatar et al., 2015), then incorporate grounding knowledge into a seq2seq neural model to generate a suitable re-

sponse (Madotto et al., 2018).

However, existing memory networks equally treat information from multiple sources, e.g. sequential dialogue history and structure knowledge bases. Therefore two weaknesses arise in such methods: (1) It is difficult to model different types of structured information in only one memory network. (2) It is also difficult to model the effectiveness of knowledge from different sources in such a single memory network. To address these issues, we expand the architecture of memory networks used in a seq2seq neural model.

Our contributions are mainly three-fold:

- We propose a novel seq2seq neural conversation model augmented with Heterogeneous Memory Networks. We first model sequential dialogue history and grounding external knowledge with two different kinds of memory networks and then feed the output of context-aware memory to the context-free memory to search the representations of similar knowledge.

- Our context-aware memory networks is able to learn the context-aware latent representations and stores them into memory slots, by employing a gating mechanism when encoding dialogue history and user utterance.

- Experimental results demonstrate that our neural approach significantly outperforms the examined neural methods automatic metrics, and context-aware memory networks can learn and store more meaningful representations than the examined memory approaches.

2 Related Works

The end-to-end model uses deep neural net instead of several parts in pipeline models to generate responses. (Rojas-Barahona et al., 2017) propose a data-driven goal-oriented neural dialogue system by adding database operator and policy networks modules to introduce database information and track state which need extra labeling step that breaks differentiability. (Bordes and Weston, 2016) propose a testbed to break down the strengths and shortcomings of end-to-end dialog systems in goal-oriented applications. Those methods treated dialogue system as the problem of learning a mapping policy from dialogue histories to agents' responses.

The booming internet dialogue data lay the foundation of building data-driven models. (Ritter et al., 2011) first applied phrase-based Statistical Machine Translation(Setiawan et al., 2005). It treats the conversation system as a translation problem, a user utterance needs to be translated into an agent response.

(Sutskever et al., 2014) propose Sequence to sequence model (SEQ2SEQ) architecture and apply it to neural machine translation task. SEQ2SEQ has become a general basis of natural language generation tasks, e.g. question answering(Tan et al., 2018) and question generation (Zhou et al., 2017). By applying the RNN based encoder-decoder framework to generate responses, models(Shang et al., 2015; Cho et al., 2014b; Luong et al., 2015b) are able to utilize neural networks to learn the representation of dialogue histories and generate appropriate responses.

To deal with multi-turn information, (Sordoni et al., 2015) propose a model that represents the whole dialogue history (including the current message) with continuous representations or embeddings of words and phrases to address the challenge of the context-sensitive response generation.

By adding a knowledge base module, recent works (Ghazvininejad et al., 2018; Young et al., 2018) have shown the possibility of training an end-to-end task-oriented dialogue system on the sequence to sequence architecture. Ghazvininejad et al. (Ghazvininejad et al., 2018) generalize the SEQ2SEQ approach by conditioning responses on both conversation history and external knowledge, aiming at producing more contextual responses without slot filling.

CopyNet (Gu et al., 2016) and Pointer Networks (Vinyals et al., 2015) improve model's accuracy and ability of handling of out-of-vocabulary words using neural attention. Pointer-Generator networks (See et al., 2017) apply copy mechanism to the neural generation model. Their work shows copy mechanism can improve quality in text generation. (Dhingra et al., 2017) and (Li et al., 2017) apply reinforcement learning to make it differentiable.

Recent works on external memory (Graves et al., 2014; Henaff et al., 2016) provide an efficient method of introducing and reasoning different types of external information. (Sukhbaatar

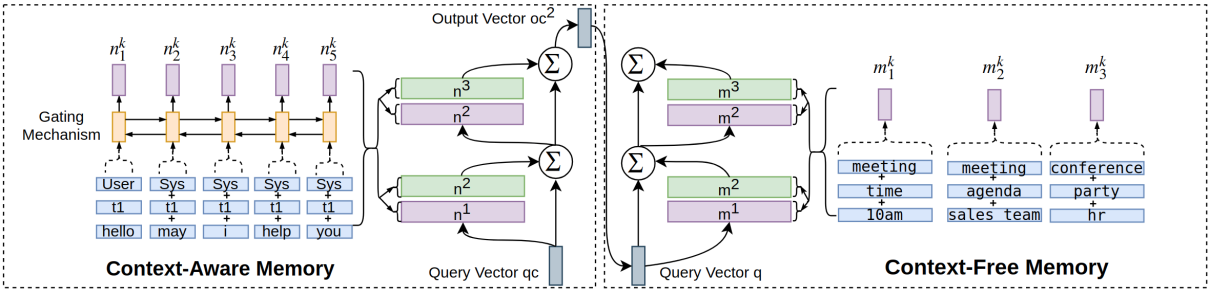

Figure 2: An example of Heterogeneous Memory Networks with two-hop attention. Context-aware memory which encodes dialog history to a context vector oc^2 while context-free memory loads knowledge base information. The output of context-aware memory will be employed as the query vector to the context-free memory.

et al., 2015) propose end-to-end memory networks with multiple attention hops model over a possibly large external memory. (Madotto et al., 2018) propose Mem2Seq that combines the end-to-end memory networks with the idea of pointer networks. (Chen et al., 2018) add the hierarchical structure and the variational memory network to capture both the high-level abstract variations and long-term memories during the dialogue tracking. To take care of information from different sources, (Fu and Feng, 2018) propose an attention mechanism to encourage the decoder to actively interact with the memory by taking its heterogeneity into account.

3 Proposed Framework

To generate responses using dialogue history and grounding knowledge, we introduce a novel encoder-decoder neural conversation model augmented with Heterogeneous Memory Networks (HMNs). The encoder module adopts a context-aware memory network to better understand the dialogue history and query. The decoder is enhanced with HMNs, which is able to incorporate external knowledge and dialog history when generating words.

3.1 Encoder

The encoder encodes the dialogue history into a fixed context vector. Here we adopt the context-aware memory as our encoder module. As shown in the left part of Figure 2, each word will be extended to the following parts: 1) token itself. 2) A turn tag. 3) An identity tag. For example, in the first turn a user says "hello" and the response from system is "may I help you", it will be concatenated as [(hello, t1, user),(may, t1, sys),(I, t1, sys),(help, t1, sys), (you, t1, sys)], *sys* means the word comes

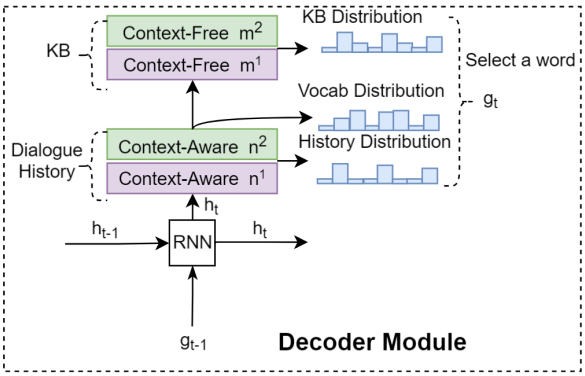

Figure 3: Decoder module with two attention hops

from the dialog system, so does *user*. *t1* indicates the word is from the first turn. Each word can be transformed into vector by embedding lookup, and we sum up vectors in each tuple to be the input sequence of the context-aware memory. Using a fixed vector to query the memory, a context vector c can be obtained.

3.1.1 Context-Aware Memory

To efficiently model the context information of sequential data, we present the context-aware memory. Memory slots n^k are structured by concatenating all input vectors as $n^k = cat[n_1^k, n_2^k, ..., n_l^k]$, k stands for the k-th hop in memory, and l means the length of the input. n_l^k is the sum of each word tag embedding using each hop own randomly initialized embedding matrix C^k. And we adopt the adjacent weight sharing scheme, which means C^k is not only the input embedding matrix in the k-th hop, but also the output embedding matrix in the (k-1)-th hop. We add a gating mechanism between memory cells. The gating mechanism applied is adopted from Bidirectional GRU (Cho et al., 2014a) in our case. Thus the context-dependent representation of in-

puts, denoted as $n^k = [\overrightarrow{n^k}, \overleftarrow{n^k}]$, where $\overrightarrow{n^k}$ and $\overleftarrow{n^k}$ are the forward and backward representation of inputs, respectively. The forward process can be illustrated as equations:

$$r_t = \sigma(W_1 v_t^k + W_2 \overrightarrow{n^k}_{(t-1)} + b_1) \quad (1)$$

$$z_t = \sigma(W_3 v_t^k + W_4 \overrightarrow{n^k}_{(t-1)} + b_2) \quad (2)$$

$$e_t = \tanh(W_5 v_t^k + r_t(W_6 \overrightarrow{n^k}_{(t-1)} + b_3)) \quad (3)$$

$$\overrightarrow{n_t^k} = (1 - z_t)e_t + z_t \overrightarrow{n^k}_{(t-1)} \quad (4)$$

where W_1, W_2, W_3, W_4, W_5, W_6 and b_1, b_2, b_3 are trainable weights and biases.

Given the query vector qc^k, attention weights over memory cells n^k can be calculated by the equation:

$$p^k = Softmax(n^k \cdot qc^k) \quad (5)$$

the readout vector is the sum of output memory matrix n^{k+1} with corresponding attention weights p^k.

$$u^k = \sum_i (p_i^k \cdot n_i^{k+1}) \quad (6)$$

By summing query and readout vector together, we can get the output from the k-th hop.

$$oc^k = qc^k + u^k \quad (7)$$

Note oc^k is also the query vector of the (k+1)-th hop.

3.2 Decoder

The decoder contains HMNs and an RNN controller, as shown in Figure 3. The controller controls the process of querying HMNs.

In each time step, HMNs will generate: 1) a readout vector oc^1, which is the output of the first hop in history memory, and 2) attention weights of the last hop in two memories, called history word distribution P_{his} and knowledge tuple distribution P_{kb}. The readout vector is concatenated with h_t to predict the vocabulary distribution P_{vocab}. Formally,

$$P_{vocab} = Softmax(W_7[h_t, oc^1]) \quad (8)$$

where W_7 is trainable weight matrix.
We adopt a simple strategy (Section 3.5) to select a word from three distributions P_{vocab}, P_{his} and P_{kb}.

3.2.1 Heterogeneous Memory Networks

HMNs stacks two types of memory: 1) context-aware memory and 2) context-free memory. Dialog history is loaded into context-aware memory, and knowledge base triples are loaded into context-free memory. Firstly, HMNs accepts query vector as inputs, then walk through context-aware memories. The final output u^k in the last hop will be employed to query context-free memory. Context-aware memory has been detailed in Section 3.1.1.

Context-Free memory itself is end-to-end memory networks (Sukhbaatar et al., 2015). Compared with our context-aware memory, it has no gating mechanism. The input to the memory is the summed vectors in each knowledge triple, as depicted in the right part of Figure 2. Each hop owns randomly initialized embedding matrix $C^{k'}$ We denote memory slots as m^k. It accepts a query vector and then follows the same process 5 to 7, the output $u^{k'}$ can be obtained.

3.2.2 Controller

We adopt GRU as our controller. It accepts the output c from encoder as initial hidden state h_0. In each time step, it takes the previous generated word g_{t-1}'s embedding $E(g_{t-1})$ and last time hidden state h_{t-1} as inputs. Formally:

$$h_t = GRU(E(g_{t-1}), h_{t-1}) \quad (9)$$

then h_t is used to query the HMNs.

3.3 Copy Mechanism

We adopt copy mechanism to copy words from memories. Attention weights in the last hop of the two memories,P_{kb} and P_{his} will be the probability of the target word from those memories. If the target word does not appear in inputs, the position index will be the last position in memories, which is a sentinel added in preprocessing stage.

3.4 Joint Learning

To learn the distribution of three vocabularies P_{vocab}, P_{kb} and P_{his} in each time step, the loss in the t-th time step is the negative log-likelihood of the predict probability of the target word for that time step. Formally:

$$Loss = -\frac{1}{T} \sum_{t=0}^{t=T} \sum_i (\log p_{ti}) \quad (10)$$

Note that p_{it} means the t-th word's probability in $i \in \{P_{vocab}, P_{kb}, P_{his}\}$.

Table 1: The statistics of the bAbI-3, 4, 5, DSTC2 and Key-Value Retrieval datasets

Datasets	Key-Value Retrieval dataset	DSTC 2	bAbI-3	bAbI-4	bAbI-5
Avg. History words	25.5	63.4	49.9	20.5	62.6
Avg. KB pairs	64.7	42.7	23.4	7.0	23.6
Avg. Response Length	8.7	10.2	7.2	5.7	6.5
Vocabulary Size	1554	1066	739	1004	1135
Dialogue Turns	2.8	9.9	10.9	4.5	19.3

3.5 Word Selection Strategy

In our case, if words with the highest probability in P_{his} and P_{kb} vocabularies are not on sentinel positions, we directly compare the probability of each word and select the higher one. If one of the vocabularies points to the sentinel position, the model will select the word with the highest probability in the other vocabulary. At last, if both vocabularies get to sentinel positions, the word from P_{vocab} will be selected.

4 Experimental Setup

4.1 Datasets

As the proposed approach is quite general, the model can be applied to any task-oriented dialogue datasets with conversation and knowledge base data. To evaluate and compare the results with the state-of-the-art methods in multiple dimensions, we choose three popular task conversation datasets including DSTC 2, Key-Value Retrieval dataset and the (6) dialog bAbI tasks. Table 1 shows the statistics of datasets.

- *Key-Value Retrieval dataset* (Eric and Manning, 2017). This dataset releases a corpus of 3,031 multi-turn dialogues. The dialogues consist of three different domains: calendar scheduling, weather information retrieval, and point-of-interest navigation.

- *The (6) dialog bAbI tasks* (Bordes and Weston, 2016). The (6) dialog bAbI tasks are a set of five subtasks within the goal-oriented context of restaurant reservations. Conversations are grounded with an underlying knowledge base of restaurants and their properties (location, type of cuisine, etc.). As task 1 and 2 have been achieved very well, we only test our model on task 3 to 5 and their OOV(out-of-vocabulary), where entities (e.g. restaurant names) in test sets may not have been able to see during training.

- *The Dialog State Tracking Challenge 2* (DSTC 2). DSTC 2 is a research challenge focused on improving the state-of-the-art in tracking the state of spoken dialogue systems. DSTC 2's training dialogues were gathered using Amazon Mechanical Turk related to restaurant search.

For all datasets, we employ the original conversation and knowledge base information only and drop the other labels e.g. slot filling labels. We take several metrics over all datasets to evaluate the performance on multiple dimensions. And to evaluate the context-aware memory networks, we also test the HMNs with only context-free memory on the dialog bAbI tasks.

4.2 Evaluation Method

To compare with the original datasets baselines, we apply evaluation methods on each datasets the same as datasets' original papers described in 4.1.

- Bilingual Evaluation Understudy (BLEU) (Papineni et al., 2002). BLEU has been widely employed in evaluating sequence generation including machine translation, text summarization, and dialogue systems. BLEU calculates the n-gram precision which is the fraction of n-grams in the candidate text which is present in any of the reference texts.

- F1 Score (F-measure): F1 evaluates the model's ability in terms of precision and recall, which is more comprehensive than just using precision or recall measure. We adopt F1 to evaluate if a model can extract information from a knowledge base precisely.

- Per-response accuracy and Per-dialog accuracy. Per-response and Per-dialog accuracy count the percentage of responses that are correct. Any incorrect words will make a response or a dialogue negative. Accuracy shows if the model is able to learn the distribution of reproducing factual details.

Table 2: Results on Key-Value Retrieval dataset. F1 score, including Entity F1, is micro-average over the entire set, and three subtasks. Human results are reported by Eric et al.(Eric and Manning, 2017)

Model name	BLEU	Ent. F1	Scheduling Ent. F1	Weather Ent. F1	Navigation Ent. F1

4.3 Baselines and Training Setup

The hyper-parameter settings are adopted as the best practice settings for each training set following the Madotto's (Madotto et al., 2018) and Manning's (Manning and Eric, 2017) best experimental results on baselines SEQ2SEQ and Mem2Seq. Detailed models and their settings are as follows:

- Sequence to sequence. For SEQ2SEQ, we adopt one layer LSTMs as encoder and decoder. For Key-Value Retrieval dataset, hidden size is placed at 512 and the dropout rate is 0.3. On dataset bAbI, the hidden size and dropout rate are 128 and 0.1 for task 3, 256 and 0.1 for task 4 and 5. Learning rates are set to 0.001 for bAbI and 0.0001 for DSTC 2 and Key-Value Retrieval dataset.

- SEQ2SEQ + Attention. We adopt the attention mechanism (Luong et al., 2015a) commonly used in neural machine translation. On dataset bAbI, hidden size and the dropout rate are 256 and 0.1 for task 3 and 4, 128 and 0.1 for task 5. For Key-Value Retrieval dataset, hidden size and dropout rate are 512 and 0.3. On the DSTC 2 task, hidden size is set to 353 and word embedding size is 300 (same with original work).

- Mem2Seq. Except 128 in task 3, hidden size in other tasks is 256. The dropout rate is set to 0.2 in task 3, 4 and Key-Value Retrieval dataset, 0.1 in task 5 and DSTC 2 dataset. We adopt three hops in DSTC 2 and Key-Value Retrieval dataset.

- HMNs with context-free only (HMNs-CFO). To test the performance of context-aware memory, we apply other context-free to encode dialogue history instead of context-aware memory in HMNs. All the other structure and parameter settings are the same as HMNs in this model.

All models are tested with various hyper-parameter settings to get their best performance, e.g. hidden size selected from [64, 128, 256, 512]. Note that settings from datasets are also tested like SEQ2SEQ + Attention's hidden size is 353 on Key-Value Retrieval dataset.

During the training, all experiments employ the teacher-forcing scheme, feeding the gold target of last time or highest probability word into decoder with probability 50%. We also randomly mask input with UNK according to the dropout rate.

Table 5: A generated example from Key-Value Retrieval dataset with correct knowledge entities in **bold**. Given the knowledge base and user's request, we list the generated responses of three models and the gold answers. This example is randomly selected from all generated sentences and we only show tuples been used by models.

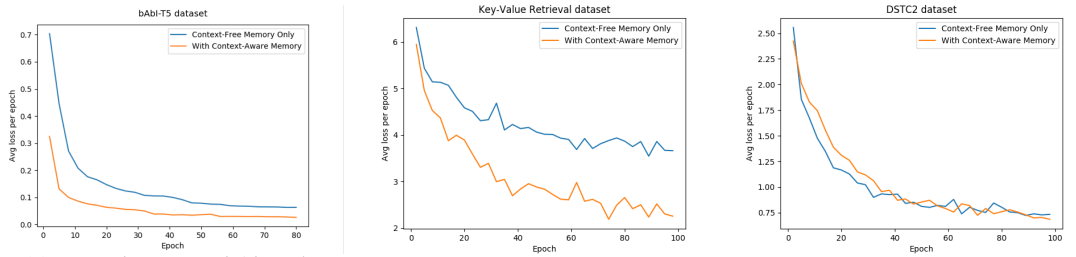
Dataset	
Knowledge Base	... valero poi_type gas_station valero distance 2_miles valero address 200_alester_ave 1_miles moderate_traffic parking_garage poi palo_alto_garage_r ...
User	address to the **gas_station**
Gold	**valero** is located at **200_alester_ave**
Generated Sentence	
SEQ2SEQ+Attn.	the closest **gas_station** is located at **200_alester_ave** 7_miles away would you like directions there
Mem2Seq	there is a **valero** 1_miles away
HMNs	there is a **gas_station** located **2_miles** away at **200_alester_ave**

4.4 HMNs Training Settings

We test the hidden size in [64, 128, 256] and set dropout rate in [0.1, 0.2]. Learning rate is initiated with 0.001 and training batch is set to 64. The metrics results are coming from the best result settings for each dataset. We select hidden size and dropout rate at (256, 0.1) on bAbI task 3 and task 5, (256,0.2) on task 4. On the DSTC 2 task, we set hidden size and dropout rate at (128, 0.1). For Key-Value Retrieval dataset, the setting is hidden size 256 and dropout rate 0.1. Except for bAbI tasks' 1 layer, all HMNs and Mem2Seq tasks employ 3 layer memories.

5 Results and Discussion

5.1 Results and Analysis



The best results of the baselines and HMNs are gathered into tables and figures. Table 2 show the result of models on Key-Value Retrieval dataset. Except for F1 scores on Calendar Scheduling, HMNs get significantly better results on all benchmarks comparing the state-of-the-art models. HMMs' BLEU score is even higher than human results which are reported in (Eric and Manning, 2017). Results show our model's outstanding performance in generating a fluent and accurate response in most tasks.

Examples generated by our approach and baselines are given in Table 5. These two examples are randomly selected from all generated sentences. Comparing the generated sentences by humans, although entities and sentences are different with gold answer in example one, our approach is able to produce more fluent and accurate sentences. However, the result on task weather forecasting neither HMNs and Mem2Seq can outperform SEQ2SEQ. We will discuss it in the next section.

Table 4 shows our model gets the best F1 score on dataset DSTC 2, while SEQ2SEQ with attention gets the best BLEU result.

Table 3 shows results of models on bAbI tasks. HMNs and Mem2Seq adopt one hop attention only and note that all results are the best performance of each model in 100 epochs. HMNs achieved the best results on most tasks except T5. HMNs-CFO also outperforms the other models. This demonstrates that both training multiple distributions over heterogeneous information and employment of context-aware memory benefit the end-to-end dialogue system. The improvements in per-dialogue accuracy on out-of-vocabulary tests are even more significant. Figure 4 shows the changes of HMNs and HMNs-CFO's total loss across time. HMNs learns significantly faster.

Though automatic metrics cannot really examine human beings' diversified expression, existing dialogue systems aim at generating sentence by learning the patterns of training data, so we believe BLEU is still a metric of great concern in comparing the similar models' ability in learning the sentence patterns. Though human results show end-to-end machines have still a long way to go (60.7 to 43.1). Compared to other models, HMNs sig-

Figure 4: The total loss by epochs on three different datasets in 100 epochs. One line with context-aware memory and the other with only context-free memory

nificantly improves performance in retrieving correct knowledge entities.

5.2 Discussion

5.2.1 Context-Aware Memory

To show whether context-aware memory benefits conversation learning, on bAbI tasks, we also tested HMNs-CFO memory only. From Table 3, we observe that HMNs-CFO is significantly better than original Mem2Seq as well as SEQ2SEQ + attention in several results and only loses slightly on task 4 (89.3 to 90.5). One reason is that one memory is difficult to learn best distribution over different sources. Respectively encoding sequential dialogue history and grounding knowledge can learn two better distributions than one general but not best distribution. This also indicates that using the query vector generated by history memory to retrieve information in knowledge base memory is reasonable.

As the HMNs model get the best results in all tasks except one, in addition the results of training speed of HMNs and HMNs-CFO (Figure 4), the context-aware memory is clearly to learn representation of the dialogue history much better and faster and also demonstrates that the importance of incorporating context information for dialogue systems. HMNs outperform the HMNs-CFO not only on BLEUs but also entity F1 on most tasks, showing building a good representation of dialogue history benefits knowledge reasoning, and help to improve the context-free memory by issuing a good query vector.

From above all, we can conclude that both stacked memory networks architecture and using context-aware memory to load sequential information can improve the performance of retrieving knowledge and generating sentences.

5.2.2 Shortcomings

From the results in Table 2, we note that HMNs and Mem2Seq failed on weather forecasting task. We analysed the average knowledge pairs of weather forecasting tasks and find it near three times the knowledge pairs of the other two tasks. Then we carried out another experiment that first narrows the KB candidates by performing a matching preprocessing operation, and the Weather Ent. F1 result of our method will climb to more than 48 which is the best. This may indicates that this kind of memory networks may have difficulties in handling large scale knowledge base. So perform a matching operation to narrow the candidate knowledge space is critical in a real-world large scale knowledge base.

And in this paper, we only show sequential data and knowledge triples data. For more types of information to integrate, model needs to add other memory networks, e.g. graph neural networks augmented memory networks (Zhou et al., 2018) for graph structured data.

6 Conclusion

In this paper, we propose a model that is able to incorporate heterogeneous information in an end-to-end dialogue system. The model applies Heterogeneous Memory Networks (HMNs) to model sequential history and structured database. Results on several datasets show model can significantly improve the performance of generating the response. Our proposed context-aware memory networks show outstanding performance in learning the distribution over dialogue history and retrieving knowledge. We present the possibility of efficiently using various structured data in end-to-end task-oriented dialogue without any extra labeling and module training.

Abstract

Due to their inherent capability in semantic alignment of aspects and their context words, attention mechanism and Convolutional Neural Networks (CNNs) are widely applied for aspect-based sentiment classification. However, these models lack a mechanism to account for relevant syntactical constraints and long-range word dependencies, and hence may mistakenly recognize syntactically irrelevant contextual words as clues for judging aspect sentiment. To tackle this problem, we propose to build a Graph Convolutional Network (GCN) over the dependency tree of a sentence to exploit syntactical information and word dependencies. Based on it, a novel aspect-specific sentiment classification framework is raised. Experiments on three benchmarking collections illustrate that our proposed model has comparable effectiveness to a range of state-of-the-art models[1], and further demonstrate that both syntactical information and long-range word dependencies are properly captured by the graph convolution structure.

1 Introduction

Aspect-based (also known as aspect-level) sentiment classification aims at identifying the sentiment polarities of aspects explicitly given in sentences. For example, in a comment about a laptop saying "*From the speed to the multi-touch gestures this operating system beats Windows easily.*", the sentiment polarities for two aspects *operating system* and *Windows* are *positive* and *negative*, respectively. Generally, this task is formulated as predicting the polarity of a provided (sentence, aspect) pair.

Given the inefficiency of manual feature refinement (Jiang et al., 2011), early works of aspect-based sentiment classification are mainly based on neural network methods (Dong et al., 2014; Vo and Zhang, 2015). Ever since Tang et al. (2016a) pointed out the challenge of modelling semantic relatedness between context words and aspects, attention mechanism coupled with Recurrent Neural Networks (RNNs) (Bahdanau et al., 2014; Luong et al., 2015; Xu et al., 2015) starts to play a critical role in more recent models (Wang et al., 2016; Tang et al., 2016b; Yang et al., 2017; Liu and Zhang, 2017; Ma et al., 2017; Huang et al., 2018).

While attention-based models are promising, they are insufficient to capture syntactical dependencies between context words and the aspect within a sentence. Consequently, **the current attention mechanism may lead to a given aspect mistakenly attending to syntactically unrelated context words as descriptors** (Limitation 1). Look at a concrete example "*Its size is ideal and the weight is acceptable.*". Attention-based models often identify *acceptable* as a descriptor of the aspect *size*, which is in fact not the case. In order to address the issue, He et al. (2018) imposed some syntactical constraints on attention weights, but the effect of syntactical structure was not fully exploited.

In addition to the attention-based models, Convolutional Neural Networks (CNNs) (Xue and Li, 2018; Li et al., 2018) have been employed to discover descriptive multi-word phrases for an aspect, based on the finding (Fan et al., 2018) that the sentiment of an aspect is usually determined by key phrases instead of individual words. Nevertheless, the CNN-based models can only perceive multi-word features as consecutive words with the convolution operations over word sequences, but are **inadequate to determine sentiments depicted by multiple words that are not next to each other** (Limitation 2). In the sentence "*The*

staff should be a bit more friendly" with *staff* as the aspect, a CNN-based model may make an incorrect prediction by detecting *more friendly* as the descriptive phrase, disregarding the impact of *should be* which is two words away but reverses the sentiment.

In this paper, we aim to tackle the two limitations identified above by using Graph Convolutional Networks (GCNs) (Kipf and Welling, 2017). GCN has a multi-layer architecture, with each layer encoding and updating the representation of nodes in the graph using features of immediate neighbors. Through referring to syntactical dependency trees, a GCN is potentially capable of drawing syntactically relevant words to the target aspect, and exploiting long-range multi-word relations and syntactical information with GCN layers. GCNs have been deployed on document-word relationships (Yao et al., 2018) and tree structures (Marcheggiani and Titov, 2017; Zhang et al., 2018), but how they can be effectively used in aspect-based sentiment classification is yet to be explored.

To fill the gap, this paper proposes an Aspect-specific Graph Convolutional Network (ASGCN), which, to the best of our knowledge, is the first GCN-based model for aspect-based sentiment classification. ASGCN starts with a bidirectional Long Short-Term Memory network (LSTM) layer to capture contextual information regarding word orders. In order to obtain aspect-specific features, a multi-layered graph convolution structure is implemented on top of the LSTM output, followed by a masking mechanism that filters out non-aspect words and keeps solely high-level aspect-specific features. The aspect-specific features are fed back to the LSTM output for retrieving informative features with respect to the aspect, which are then used to predict aspect-based sentiment.

Experiments on three benchmarking datasets show that ASGCN effectively addresses both limitations of the current aspect-based sentiment classification approaches, and outperforms a range of state-of-the-art models.

Our contributions are as follows:

- We propose to exploit syntactical dependency structures within a sentence and resolve the long-range multi-word dependency issue for aspect-based sentiment classification.
- We posit that Graph Convolutional Network (GCN) is suitable for our purpose, and propose a novel Aspect-specific GCN model. To our best knowledge, this is the first investigation in this direction.
- Extensive experiment results verify the importance of leveraging syntactical information and long-range word dependencies, and demonstrate the effectiveness of our model in capturing and exploiting them in aspect-based sentiment classification.

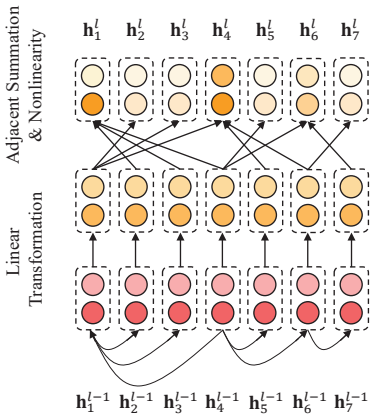

Figure 1: An example of GCN layer.

2 Graph Convolutional Networks

GCNs can be considered as an adaptation of the conventional CNNs for encoding local information of unstructured data. For a given graph with k nodes, an adjacency matrix[2] $\mathbf{A} \in \mathbb{R}^{k \times k}$ is obtained through enumerating the graph. For convenience, we denote the output of the l-th layer for node i as $\mathbf{h}_i^l$, where $\mathbf{h}_i^0$ represents the initial state of node i. For an L-layer GCN, $l \in [1, 2, \cdots, L]$ and $\mathbf{h}_i^L$ is the final state of node i. The graph convolution operated on the node representation can be written as:

$$\mathbf{h}_i^l = \sigma(\sum_{j=1}^{k} \mathbf{A}_{ij} \mathbf{W}^l \mathbf{h}_j^{l-1} + \mathbf{b}^l) \quad (1)$$

where $\mathbf{W}^l$ is a linear transformation weight, $\mathbf{b}^l$ is a bias term, and σ is a nonlinear function, e.g. ReLU. For a better illustration, an example of GCN layer is shown in Figure 1.

As the graph convolution process only encodes information of immediate neighbors, a node in the graph can only be influenced by the neighbouring nodes within L steps in an L-layer GCN. In

[2] $\mathbf{A}_{ij}$ indicates whether the i-th token is adjacent to the j-th token or not.

this way, the graph convolution over the dependency tree of a sentence provides syntactical constraints for an aspect within the sentence to identify descriptive words based on syntactical distances. Moreover, GCN is able to deal with the circumstances where the polarity of an aspect is described by non-consecutive words, as GCN over dependency tree will gather the non-consecutive words into a smaller scope and aggregate their features properly with graph convolution. Therefore, we are inspired to adopt GCN to leverage syntactical information and long-range word dependencies for aspect-based sentiment classification.

3 Aspect-specific Graph Convolutional Network

Figure 2 gives an overview of ASGCN. The components of ASGCN will be introduced separately in the rest of the section.

3.1 Embedding and Bidirectional LSTM

Given a n-word sentence $c = \{w_1^c, w_2^c, \cdots, w_{\tau+1}^c, \cdots, w_{\tau+m}^c, \cdots, w_{n-1}^c, w_n^c\}$ containing a corresponding m-word aspect starting from the $(\tau+1)$-th token, we embed each word token into a low-dimensional real-valued vector space (Bengio et al., 2003) with embedding matrix $\mathbf{E} \in \mathbb{R}^{|V| \times d_e}$, where $|V|$ is the size of vocabulary and d_e denotes the dimensionality of word embeddings. With the word embeddings of the sentence, a bidirectional LSTM is constructed to produce hidden state vectors $\mathbf{H}^c = \{\mathbf{h}_1^c, \mathbf{h}_2^c, \cdots, \mathbf{h}_{\tau+1}^c, \cdots, \mathbf{h}_{\tau+m}^c, \cdots, \mathbf{h}_{n-1}^c, \mathbf{h}_n^c\}$, where $\mathbf{h}_t^c \in \mathbb{R}^{2d_h}$ represents the hidden state vector at time step t from the bidirectional LSTM, and d_h is the dimensionality of a hidden state vector output by an unidirectional LSTM.

3.2 Obtaining Aspect-oriented Features

Different from general sentiment classification, aspect-based sentiment classification targets at judging sentiments from the view of aspects, and thus calls for an aspect-oriented feature extraction strategy. In this study, we obtain aspect-oriented features by applying multi-layer graph convolution over the syntactical dependency tree of a sentence, and imposing an aspect-specific masking layer on its top.

3.2.1 Graph Convolution over Dependency Trees

Aiming to address the limitations of existing approaches (as discussed in previous sections), we leverage a graph convolutional network over dependency trees of sentences. Specifically, after the dependency tree[3] of the given sentence is constructed, we first attain an adjacency matrix $\mathbf{A} \in \mathbb{R}^{n \times n}$ according to the words in the sentence. It is important to note that dependency trees are directed graphs. While GCNs generally do not consider directions, they could be adapted to the direction-aware scenario. Accordingly, we propose two variants of ASGCN, i.e. ASGCN-DG on dependency graphs which are un-directional, and ASGCN-DT concerning dependency trees which are directional. Practically, the only difference between ASGCN-DG and ASGCN-DT lies in their adjacency matrices: The adjacency matrix of ASGCN-DT is much more sparse than that of ASGCN-DG. Such setting is in accordance with the phenomenon that parents nodes are broadly influenced by their children nodes. Furthermore, following the idea of self-looping in Kipf and Welling (2017), each word is manually set adjacent to itself, i.e. the diagonal values of $\mathbf{A}$ are all ones.

The ASGCN variants are performed in a multi-layer fashion, on top of the bidirectional LSTM output in Section 3.1, i.e. $\mathbf{H}^0 = \mathbf{H}^c$ to make nodes aware of context (Zhang et al., 2018). Then the representation of each node is updated with graph convolution operation with normalization factor (Kipf and Welling, 2017) as below:

$$\tilde{\mathbf{h}}_i^l = \sum_{j=1}^{n} \mathbf{A}_{ij} \mathbf{W}^l \mathbf{g}_j^{l-1} \tag{2}$$

$$\mathbf{h}_i^l = \mathrm{ReLU}(\tilde{\mathbf{h}}_i^l / (d_i + 1) + \mathbf{b}^l) \tag{3}$$

where $\mathbf{g}_j^{l-1} \in \mathbb{R}^{2d_h}$ is the j-th token's representation evolved from the preceding GCN layer while $\mathbf{h}_i^l \in \mathbb{R}^{2d_h}$ is the product of current GCN layer, and $d_i = \sum_{j=1}^{n} \mathbf{A}_{ij}$ is degree of the i-th token in the tree. The weights $\mathbf{W}^l$ and bias $\mathbf{b}^l$ are trainable parameters.

It is worth noting that we do not have $\mathbf{h}_i^l$ immediately fed into successive GCN layer, but conduct a position-aware transformation in the first place:

$$\mathbf{g}_i^l = \mathcal{F}(\mathbf{h}_i^l) \tag{4}$$

[3]We use spaCy toolkit: https://spacy.io/.

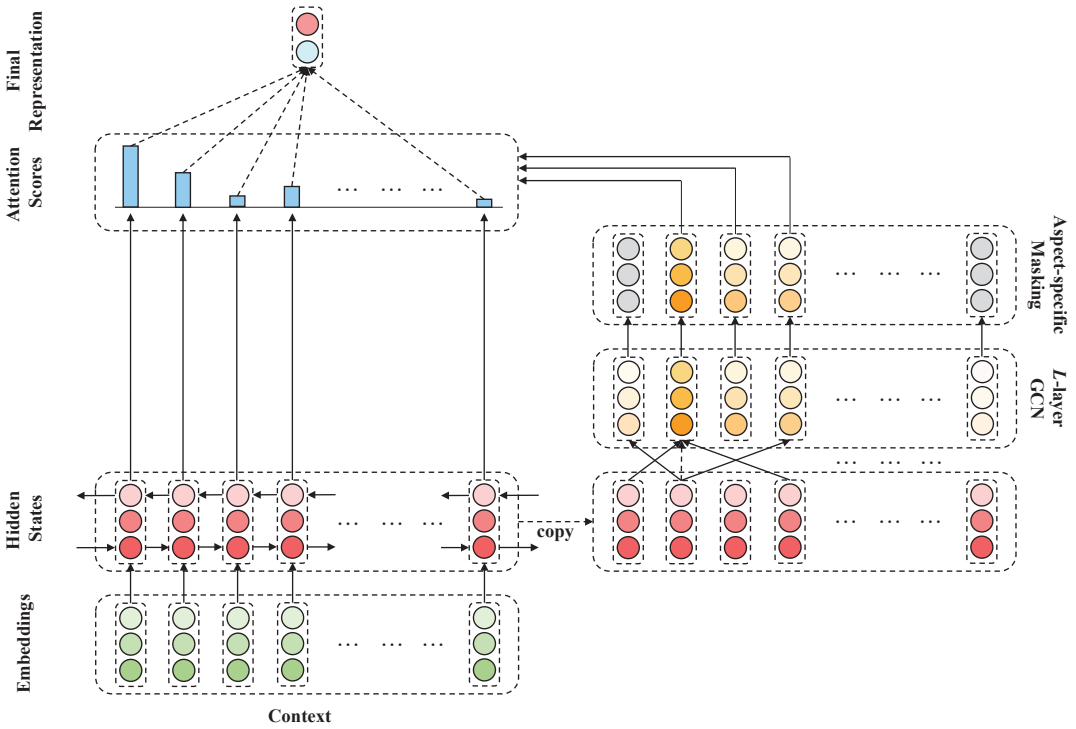

Figure 2: Overview of aspect-specific graph convolutional network.

where $\mathcal{F}(\cdot)$ is a function assigning position weights, widely adopted by previous works (Li et al., 2018; Tang et al., 2016b; Chen et al., 2017), for augmenting the importance of context words close to the aspect. By doing so we aim at reducing the noise and bias that may have naturally arisen from the dependency parsing process. Specifically, the function $\mathcal{F}(\cdot)$ is:

$$q_i = \begin{cases} 1 - \frac{\tau+1-i}{n} & 1 \leq i < \tau+1 \\ 0 & \tau+1 \leq i \leq \tau+m \\ 1 - \frac{i-\tau-m}{n} & \tau+m < i \leq n \end{cases} \quad (5)$$

$$\mathcal{F}(\mathbf{h}_i^l) = q_i \mathbf{h}_i^l \quad (6)$$

where $q_i \in \mathbb{R}$ is the position weight to i-th token. The final outcome of the L-layer GCN is $\mathbf{H}^L = \{\mathbf{h}_1^L, \mathbf{h}_2^L, \cdots, \mathbf{h}_{\tau+1}^L, \cdots, \mathbf{h}_{\tau+m}^L, \cdots, \mathbf{h}_{n-1}^L, \mathbf{h}_n^L\}$, $\mathbf{h}_t^L \in \mathbb{R}^{2d_h}$.

3.2.2 Aspect-specific Masking

In this layer, we mask out hidden state vectors of non-aspect words and keep the aspect word states unchanged:

$$\mathbf{h}_t^L = \mathbf{0} \quad 1 \leq t < \tau+1, \tau+m < t \leq n \quad (7)$$

The outputs of this zero-masking layer are the aspect-oriented features $\mathbf{H}_{\text{mask}}^L = \{\mathbf{0}, \cdots, \mathbf{h}_{\tau+1}^L, \cdots, \mathbf{h}_{\tau+m}^L, \cdots, \mathbf{0}\}$. Through graph convolution, these features $\mathbf{H}_{\text{mask}}^L$ have perceived contexts around the aspect in such a way that considers both syntactical dependencies and long-range multi-word relations.

3.3 Aspect-aware Attention

Based on the aspect-oriented features, a refined representation of the hidden state vectors $\mathbf{H}^c$ is produced via a novel retrieval-based attention mechanism. The idea is to retrieve significant features that are semantically relevant to the aspect words from the hidden state vectors, and accordingly set a retrieval-based attention weight for each context word. In our implementation, the attention weights are computed as below:

$$\beta_t = \sum_{i=1}^{n} \mathbf{h}_t^{c\top} \mathbf{h}_i^L = \sum_{i=\tau+1}^{\tau+m} \mathbf{h}_t^{c\top} \mathbf{h}_i^L \quad (8)$$

$$\alpha_t = \frac{\exp(\beta_t)}{\sum_{i=1}^{n} \exp(\beta_i)} \quad (9)$$

Here, the dot product is used to measure the semantic relatedness between aspect component words and words in the sentence so that aspect-specific masking, i.e. zero masking, could take effect as shown in Equation 8. The final representation for prediction is therefore formulated as:

$$\mathbf{r} = \sum_{t=1}^{n} \alpha_t \mathbf{h}_t^c \tag{10}$$

3.4 Sentiment Classification

Having obtained the representation $\mathbf{r}$, it is then fed into a fully-connected layer, followed by a softmax normalization layer to yield a probability distribution $\mathbf{p} \in \mathbb{R}^{d_p}$ over polarity decision space:

$$\mathbf{p} = \text{softmax}(\mathbf{W}_p \mathbf{r} + \mathbf{b}_p) \tag{11}$$

where d_p is the same as the dimensionality of sentiment labels while $\mathbf{W}_p \in \mathbb{R}^{d_p \times 2d_h}$ and $\mathbf{b}_p \in \mathbb{R}^{d_p}$ are the learned weight and bias, respectively.

3.5 Training

This model is trained by the standard gradient descent algorithm with the cross-entropy loss and L_2-regularization:

$$\text{Loss} = -\sum_{(c,\hat{p}) \in C} \log \mathbf{p}_{\hat{p}} + \lambda \|\Theta\|_2 \tag{12}$$

where C denotes the collection of data sets, $\hat{p}$ is the label and $\mathbf{p}_{\hat{p}}$ means the $\hat{p}$-th element of $\mathbf{p}$, Θ represents all trainable parameters, and λ is the coefficient of L_2-regularization.

4 Experiments

4.1 Datasets and Experimental Settings

Our experiments are conducted on five datasets: one (TWITTER) is originally built by Dong et al. (2014) containing twitter posts, while the other four (LAP14, REST14, REST15, REST16) are respectively from SemEval 2014 task 4 (Pontiki et al., 2014), SemEval 2015 task 12 (Pontiki et al., 2015) and SemEval 2016 task 5 (Pontiki et al., 2016), consisting of data from two categories, i.e. laptop and restaurant. Following previous work (Tang et al., 2016b), we remove samples with conflicting[4] polarities or without explicit aspects in the sentences in REST15 and REST16. The statistics of datasets are reported in Table 1.

For all our experiments, 300-dimensional pretrained GloVe vectors (Pennington et al., 2014) are used to initialize word embeddings. All model weights are initialized with uniform distribution. The dimensionality of hidden state vectors is set to 300. We use Adam as the optimizer with a learning rate of 0.001. The coefficient of L_2-regularization is 10^5 and batch size is 32. Moreover, the number of GCN layers is set to 2, which is the best-performing depth in pilot studies.

[4] An opinion target is associated with different sentiment polarities.

Dataset		# Pos.	# Neu.	# Neg.
TWITTER	Train	1561	3127	1560
	Test	173	346	173
LAP14	Train	994	464	870
	Test	341	169	128
REST14	Train	2164	637	807
	Test	728	196	196
REST15	Train	912	36	256
	Test	326	34	182
REST16	Train	1240	69	439
	Test	469	30	117

Table 1: Dataset statistics.

The experimental results are obtained by averaging 3 runs with random initialization, where Accuracy and Macro-Averaged F1 are adopted as the evaluation metrics. We also carry out paired t-test on both Accuracy and Macro-Averaged F1 to verify whether the improvements achieved by our models over the baselines are significant.

4.2 Models for Comparison

In order to comprehensively evaluate the two variants of our model, namely, ASGCN-DG and ASGCN-DT, we compare them with a range of baselines and state-of-the-art models, as listed below:

- SVM (Kiritchenko et al., 2014) is the model which has won SemEval 2014 task 4 with conventional feature extraction methods.
- LSTM (Tang et al., 2016a) uses the last hidden state vector of LSTM to predict sentiment polarity.
- MemNet (Tang et al., 2016b) considers contexts as external memories and benefits from a multi-hop architecture.
- AOA (Huang et al., 2018) borrows the idea of attention-over-attention from the field of machine translation.
- IAN (Ma et al., 2017) interactively models the relationships between aspects and their contexts.

Model	TWITTER		LAP14		REST14		REST15		REST16	
	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1

ASGCN-DG	72.15†	70.40†	**75.55**†‡	**71.05**†‡	80.77‡	72.02‡	**79.89**†‡	**61.89**†‡	**88.99**†	**67.48**†

Table 2: Model comparison results (%). Average accuracy and macro-F1 score over 3 runs with random initialization. The best two results with each dataset are in bold. The results with $\natural$ are retrieved from the original papers and the results with $\sharp$ are retrieved from Dong et al. (2014). The marker $\dagger$ refers $p < 0.05$ by comparing with ASCNN in paired t-test and the marker $\ddagger$ refers $p < 0.05$ by comparing with TNet-LF in paired t-test.

- TNet-LF (Li et al., 2018) puts forward Context-Preserving Transformation (CPT) to preserve and strengthen the informative part of contexts.

In order to examine to what degrees GCN would outperform CNN, we also involve a model named ASCNN in the experiment, which replaces 2-layer GCN with 2-layer CNN in ASGCN[5].

4.3 Results

As is shown in Table 2, ASGCN-DG consistently outperforms all compared models on LAP14 and REST15 datasets, and achieves comparable results on TWITTER and REST16 datasets compared with baseline TNet-LF and on REST14 compared with ASCNN. The results demonstrate the effectiveness of ASGCN-DG and the insufficiency of directly integrating syntax information into attention mechanism as in He et al. (2018). Meanwhile, ASGCN-DG performs better than ASGCN-DT by a large margin on TWITTER, LAP14, Rest15 and REST16 datasets. And ASGCN-DT's result is lower than TNet-LF's on LAP14. A possible reason is that the information from parents nodes is as important as that from children nodes, so treating dependency trees as directed graphs leads to information loss. Additionally, ASGCN-DG outperforms ASCNN on all datasets except REST14, illustrating ASGCN is better at capturing long-range word dependencies, while to some extent ASCNN shows an impact brought by aspect-specific masking. We suspect REST14 dataset is not so sensitive to syntactic information. Moreover, the sentences from TWITTER dataset are less grammatical, restricting the efficacy. We conjecture this is likely the reason why ASGCN-DG and ASGCN-DT get sub-optimal results on TWITTER dataset.

4.4 Ablation Study

To further examine the level of benefit that each component of ASGCN brings to the performance, an ablation study is performed on ASGCN-DG. The results are shown in Table 3. We also present the results of BiLSTM+Attn as a baseline, which uses two LSTMs for the aspect and the context respectively.

First, removal of position weights (i.e. ASGCN-DG w/o pos.) leads to performance drops on LAP14, REST15 and REST16 datasets but performance boosts on TWITTER and REST14 datasets. Recall the main results on REST14 dataset, we conclude that the integration of position weights is not helpful to reduce noise of user generated contents if syntax is not crucial for the data. Moreover, after we get rid of aspect-specific masking (i.e. ASGCN-DG w/o masking), the model could not keep as competitive as TNet-LF. This verifies the significance of aspect-specific masking.

Compared with ASGCN-DG, ASGCN-DG w/o GCN (i.e. preserving position weights and aspect-specific masking, but without using GCN layers) is much less powerful on all five datasets except F1 metric on TWITTER dataset. However, ASGCN-DG w/o GCN is still slightly better than BiL-

[5]In order to ensure the length of input and output is consistent, kernel length is set to 3 and padding is 1.

Model	TWITTER		LAP14		REST14		REST15		REST16	
	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1	Acc.	F1
BiLSTM+Attn	71.24	69.55	72.83	67.82	79.85	70.03	78.97	58.18	87.28	68.18
ASGCN-DG	72.15	70.40	75.55	71.05	80.77	72.02	79.89	61.89	88.99	67.48
ASGCN-DG w/o pos.	72.69	70.59	73.93	69.63	81.22	72.94	79.58	61.55	88.04	66.63
ASGCN-DG w/o mask	72.64	70.63	72.05	66.56	79.02	68.29	77.80	57.51	86.36	61.41
ASGCN-DG w/o GCN	71.92	70.63	73.51	68.83	79.40	69.43	79.40	61.18	87.55	66.19

Table 3: Ablation study results (%). Accuracy and macro-F1 scores are the average value over 3 runs with random initialization.

STM+Attn on all datasets except REST14 dataset, due to the strength of the aspect-specific masking mechanism.

Thus it could be concluded that GCN contributes to ASGCN to a considerable extent since GCN captures syntatic word dependencies and long-range word relations at the same time. Nevertheless, the GCN does not work well as expected on the datasets not sensitive to syntax information, as we have seen in TWITTER and REST14 datasets.

4.5 Case Study

To better understand how ASGCN works, we present a case study with several testing examples. Particularly, we visualize the attention scores offered by MemNet, IAN, ASCNN and ASGCN-DG in Table 4, along with their predictions on these examples and the corresponding ground truth labels.

The first sample "*great food but the service was dreadful!*" has two aspects within one sentence, which may hinder attention-based models from aligning the aspects with their relevant descriptive words precisely. The second sample sentence "*The staff should be a bit more friendly.*" uses a subjunctive word "*should*", bringing extra difficulty in detecting implicit semantics. The last example contains negation in the sentence, that can easily lead models to make wrong predictions.

MemNet fails in all three presented samples. While IAN is capable of differing modifiers for distinct aspects, it fails to infer sentiment polarities of sentences with special styles. Armed with position weights, ASCNN correctly predicts the label for the second sample as the phrase *should be* is close to the aspect *staff*, but failed for the third one with a longer-range word dependency. Our ASGCN-DG correctly handles all the three samples, implying that GCN effectively integrates syntactic dependency information into an enriched semantic representation. In particular, ASGCN-DG makes correct predictions on the second and the third sample, both having a seemingly biased focus. This shows ASGCN's capability of capturing long-range multi-word features.

5 Discussion

5.1 Investigation on the Impact of GCN Layers

As ASGCN involves an L-layer GCN, we investigate the effect of the layer number L on the final performance of ASGCN-DG. Basically, we vary the value of L in the set {1,2,3,4,6,8,12} and check the corresponding Accuracy and Macro-Averaged F1 of ASGCN-DG on the LAP14 dataset. The results are illustrated in Figure 3.

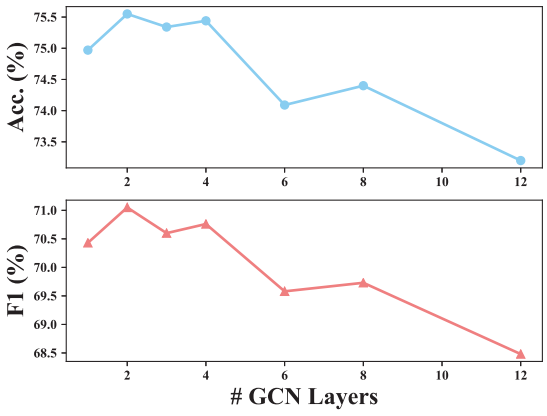

Figure 3: Effect of the number of GCN layers. Accuracy and macro-F1 scores are the average value over 3 runs with random initialization.

On both metrics, ASGCN-DG achieves the best performance when L is 2, which justifies the selection on the number of layers in the experiment sec-

Model	Aspect	Attention visualization	Prediction	Label
MemNet	food	great food but the service was dreadful !	negative✗	positive
	staff	The staff should be a bit more friendly .	positive✗	negative
	Windows 8	Did not enjoy the new Windows 8 and touchscreen functions .	positive✗	negative
IAN	food	great food but the service was dreadful !	positive✓	positive
	staff	The staff should be a bit more friendly .	positive✗	negative
	Windows 8	Did not enjoy the new Windows 8 and touchscreen functions .	neutral✗	negative
ASCNN	food	great food but the service was dreadful !	positive✓	positive
	staff	The staff should be a bit more friendly .	negative✓	negative
	Windows 8	Did not enjoy the new Windows 8 and touchscreen functions .	positive✗	negative
ASGCN-DG	food	great food but the service was dreadful !	positive✓	positive
	staff	The staff should be a bit more friendly .	negative✓	negative
	Windows 8	Did not enjoy the new Windows 8 and touchscreen functions .	negative✓	negative

Table 4: Case study. Visualization of attention scores from MemNet, IAN, ASCNN and ASGCN-DG on testing examples, along with their predictions and correspondingly, golden labels. The marker ✓ indicates correct prediction while the marker ✗ indicates incorrect prediction.

tion. Moreover, a dropping trend on both metrics is present as L increases. For large L, especially when L equals to 12, ASGCN-DG basically becomes more difficult to train due to large amount of parameters.

5.2 Investigation on the Effect of Multiple Aspects

In the datasets, there might exist multiple aspect terms in one sentence. Thus, we intend to measure whether such phenomena would affect the effectiveness of ASGCN. We divide the training samples in LAP14 and REST14 datasets into different groups based on the number of aspect terms in the sentences and compute the training accuracy differences between these groups. It is worth noting that the samples with more than 7 aspect terms are removed as outliers because the sizes of these samples are too small for any meaningful comparison.

It can be seen in Figure 4 that when the number of aspects in the sentences is more than 3, the accuracy becomes fluctuated, indicating a low robustness in capturing multiple-aspect correlations and suggesting the need of modelling multi-aspect dependencies in future work.

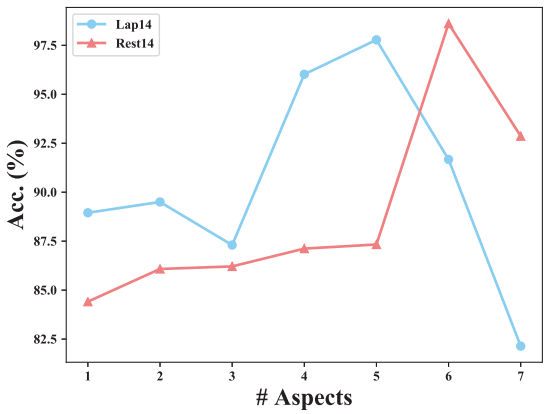

Figure 4: Accuracy versus the number of aspects (# Aspects) in the sentences.

6 Related Work

Constructing neural network models over word sequences, such as CNNs (Kim, 2014; Johnson and Zhang, 2015), RNNs (Tang et al., 2016a) and Recurrent Convolutional Neural Networks (RC-

NNs) (Lai et al., 2015), has achieved promising performances in sentiment analysis. However, the importance but lack of an effective mechanism of leveraging dependency trees for capturing distant relations of words has also been recognized. Tai et al. (2015) showed that LSTM with dependency trees or constituency trees outperformed CNNs. Dong et al. (2014) presented an adaptive recursive neural network using dependency trees, which achieved competitive results compared with strong baselines. More recent research showed that general dependency-based models are difficult to achieve comparable results to the attention-based models, as dependency trees are not capable of catching long-term contextualized semantic information properly. Our work overcomes this limitation by adopting Graph convolutional networks (GCNs) (Kipf and Welling, 2017) .

GCN has recently attracted a growing attention in the area of artificial intelligence and has been applied to Natural Language Processing (NLP). Marcheggiani and Titov (2017) claimed that GCN could be considered as a complement to LSTM, and proposed a GCN-based model for semantic role labeling. Vashishth et al. (2018) and Zhang et al. (2018) used graph convolution over dependency trees in document dating and relation classification, respectively. Yao et al. (2018) introduced GCN to text classification utilizing document-word and word-word relations, and gained improvements over various state-of-the-art methods. Our work investigates the effect of dependency trees in depth via graph convolution, and develops aspect-specific GCN model that integrates with the LSTM architecture and attention mechanism for more effective aspect-based sentiment classification.

7 Conclusions and Future Work

We have re-examined the challenges encountering existing models for aspect-specific sentiment classification, and pointed out the suitability of graph convolutional network (GCN) for tackling these challenges. Accordingly, we have proposed a novel network to adopt GCN for aspect-based sentiment classification. Experimental results have indicated that GCN brings benefit to the overall performance by leveraging both syntactical information and long-range word dependencies.

This study may be further improved in the following aspects. First, the edge information of the syntactical dependency trees, i.e. the label of each edge, is not exploited in this work. We plan to design a specific graph neural network that takes into consideration the edge labels. Second, domain knowledge can be incorporated. Last but not least, the ASGCN model may be extended to simultaneously judge sentiments of multiple aspects by capturing dependencies between the aspects words.

Abstract

Aspect words, indicating opinion targets, are essential in expressing and understanding human opinions. To identify aspects, most previous efforts focus on using sequence tagging models trained on human-annotated data. This work studies *unsupervised* aspect extraction and explores how words appear in **global context** (on sentence level) and **local context** (conveyed by neighboring words). We propose a novel neural model, capable of coupling global and local representation to discover aspect words. Experimental results on two benchmarks, laptop and restaurant reviews, show that our model significantly outperforms the state-of-the-art models from previous studies evaluated with varying metrics. Analysis on model output show our ability to learn meaningful and coherent aspect representations. We further investigate how words distribute in global and local context, and find that aspect and non-aspect words do exhibit different context, interpreting our superiority in unsupervised aspect extraction.

1 Introduction

Opinion, one of the main factors shaping human behavior, is crucial to our daily activities (Liu, 2012). Every choice we make in our life, ranging from where to go for a Friday dinner to which job offer to pick up, is largely influenced by what other people think. To help individuals navigate decision-making processes, there exists growing attentions on opinion mining algorithms that distill massive opinion-rich texts — such as digital product reviews (Poddar et al., 2017) and social media discussions (Dusmanu et al., 2017) — into the opinionated information we need.

[R1]: It's truly a great **laptop** for the **price**.
[R2]: If you have the money, I suggest going for the **i7**

Table 1: Two sample laptop review sentences. **Aspect words** are in boldface and blue. Wavy underlines indicate local context words indicating aspect word "*i7*".

Towards human opinion understanding, it is essential to figure out what target the opinion centers around. After all, previous studies have long pointed out that human language mostly conveys opinion with aspect and sentiment words (Liu, 2012). In this work, we focus on aspect extraction, targeting at the recognition of words indicating opinion aspects (henceforth **aspect words**). We believe developing effective aspect extraction models will benefit a broad range of compelling applications, such as aspect-based sentiment classification (Tang et al., 2016), opinion summarization (Wu et al., 2016), trending event tracking (Feng et al., 2016), and so forth.

To date, most progress made in aspect extraction has focused on training sequence tagging models on human-annotated data (Li and Lam, 2017; Xu et al., 2018; Wang and Pan, 2018). However, acquiring manual labels will inevitably undergo an expensive data annotation process and is hence difficult to scale for datasets from new domain or language. In this work, we explore how aspect words can be discovered in a fully *unsupervised* manner. We are inspired by the linguistic phenomenon that *aspect words generally distinguish themselves from other words in their occurrence patterns within global and local context*. Here **global context** refers to how pairs of words co-occur with each other at sentence level (without considering word order and can be extended to capture document-level context), while **local context** means what neighbors a word has.

To illustrate why global and local context can work together to indicate aspect words, Table 1

*This work was partially done when Ming Liao was an intern at Tencent AI Lab, Shenzhen, China.

†Jing Li is the corresponding author and conducted most of the work at Tencent AI Lab, Shenzhen, China.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4579–4589, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

shows two sentences from laptop review benchmark (Pontiki et al., 2016). As can be seen from R1, aspect words "*price*" and "*laptop*" tend to appear together in R1-like sentences concerning "*laptop price*". As for R2, its aspect words "*i7*", though not co-occurring with other aspects, have similar neighbors "*for the*" in local context with "*price*", which reveals its high likelihood of being aspect words, the same as "*price*".

Inspired by the phenomenon above, we propose a novel *unsupervised* model capable of coupling global and local context to discover aspect word clusters. Our model is built on the success of topic models in aspect extraction (Lin and He, 2009; Brody and Elhadad, 2010; Zhao et al., 2010). It is attributed to their ability to form latent topics with words likely to co-occur in a subset of sentences instead of widely appearing in the entire corpus (Blei et al., 2003). These words happen to exhibit similar patterns of how aspect words occur on sentence level (Lin and He, 2009). However, the above methods, only exploiting global context, are arguably suboptimal for largely ignoring the rich information delivered by local context. Some recent work (He et al., 2017), on the other way around, focus on using local context, yet ignore its coupled effects with global context.

Our work, to the best of our knowledge, is the first to explore *how global and local context jointly indicate aspect words*. Moreover, taken advantage of the recent advances in neural topic models (Miao et al., 2017; Srivastava and Sutton, 2017), we enable end-to-end learning of global and local representation, where the interaction between them contributed to aspect recognition can be automatically captured.

In experiments, we first compare our model with existing unsupervised models on aspect extraction. The results on restaurant and laptop reviews show that our model outperforms state-of-the-art approaches using global or local context only. For example, we achieve 36.1 F1 on laptop dataset, compared with 32.9 produced by He et al. (2017). Further discussions demonstrate our capability of capturing meaningful representations from global and local context, which interprets our superiority in aspect extraction. In addition, we empirically analyze global and local word context on our datasets. The results confirm that aspect words indeed vary in their global and local context compared with non-aspect ones, hence providing useful clues for aspect identification.

2 Related Work

Our work is mainly in the line with aspect extraction research. On this task, early studies mostly focus on the design of hand crafted rules (Hu and Liu, 2004; Zhuang et al., 2006; Qiu et al., 2011) or features (Jin et al., 2009; Li et al., 2010). Recently, the propose of neural models enables automatic representation learning without labor-intensive feature engineering (Wang et al., 2016, 2017; Li and Lam, 2017; Xu et al., 2018; Wang and Pan, 2018). These supervised models, rely on manually annotated data, thus restricted in their scaling ability for new domain or language. Instead, our work, focusing on *unsupervised* aspect extraction, can discover aspect words via exploiting how words occur in global and local context.

Our work is inspired by the unsupervised methods capturing latent aspect factors with LDA-style topic models (Lin and He, 2009; Brody and Elhadad, 2010; Zhao et al., 2010). We are also related with *non-neural* models incorporating word embeddings (encoding local context) to learn latent topics (discovered from global context) (Nguyen et al., 2015; Li et al., 2016; Shi et al., 2017). Compared with them — relying on expertise to customize inference algorithms, our model — in a neural architecture — does not require model-specific derivation, and enables interactions between global and local representations to be automatically learned. Though some neural models were recently proposed for our task (Wang et al., 2015; He et al., 2017), they focus on local context, unable to leverage global information. Distinguishing from them, we examine *how the coupled effects of global and local context can signal aspect words*, which have never been studied before in previous work.

3 Our Neural Model Coupling Global and Local Context

This section describes our neural model coupling the force of global and local context for aspect extraction. Figure 1 shows our overall architecture. There are two modules composed, one for local context modeling and the other for global.

In the following, we first describe the formulation of input and output in Section 3.1. Then the local and global context modeling process will be in turn given in Section 3.2 and 3.3.

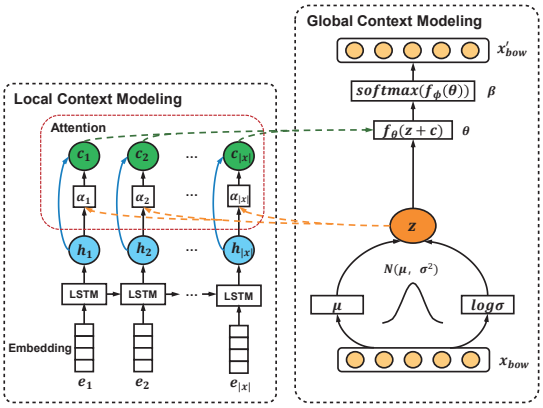

Figure 1: Our overall architecture with one module for local context modeling (on the left) and the other for global (on the right).

3.1 Input and Output

Before touching details to reveal how our model works, we first describe our input and output.

Formally, given a corpus $\mathcal{C}$ with $|C|$ sentences, $\{\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_{|C|}\}$, we process each sentence $\mathbf{x}$ into two forms: word sequence form $\mathbf{x}_{seq}$ and bag-of-words (BoW) form $\mathbf{x}_{bow}$. $\mathbf{x}_{seq} = \langle w_1, w_2, ..., w_{|\mathbf{x}|} \rangle$, where w_n indicates word index of the n-th word and $|\mathbf{x}|$ denotes the number of words. $\mathbf{x}_{bow}$ is the BoW term vector over the vocabulary V. Here $\mathbf{x}_{seq}$ (considering word order) is fed for modeling local context and learning how words co-occur with their neighbors, while $\mathbf{x}_{bow}$ (following the bag-of-words assumption in most topic models (Blei et al., 2003; Miao et al., 2017)) serves as the input for global context modeling and capture sentence-level word co-occurrence.

Our goal is to output distributional clusters of aspect words. Then following Qiu et al. (2011)'s practice, the top N nouns (N as a hyperparameter) from each cluster (ranked by likelihood) are selected as the extracted aspect words, considering most aspects are nouns.

3.2 Local Context Modeling

As mentioned above, local context modeling module takes word sequence form, $\mathbf{x}_{seq}$, as its input. In this module, each word $w_n \in \mathbf{x}_{seq}$ is first processed with an embedding layer and converted into an embedding vector $\mathbf{e}_n$. Then we employ long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) network to explore local context. Word embeddings $\mathbf{e}_1, \mathbf{e}_2, ..., \mathbf{e}_{|\mathbf{x}|}$ are processed into hidden states via recurrently exploring word co-occurrence with left neighbors. Specifically, for word w_n, its hidden states $\mathbf{h}_n$ is:

$$\mathbf{h}_n = f_{LSTM}(\mathbf{e}_n, \mathbf{h}_{n-1}) \quad (1)$$

where $f_{LSTM}(\cdot)$ refers to an LSTM unit. The hidden states $\langle \mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_{|\mathbf{x}|} \rangle$ are considered as the local representation, further leveraged in global context modeling and described later.

3.3 Global Context Modeling

Our global context modeling module is inspired by previous practice that discovers aspect words with LDA-fashion Bayesian graphical models (Lin and He, 2009). We assume there are K latent aspect factors embedded in the the given corpus $\mathcal{C}$. Each factor ϕ_k ($k = 1, 2, ..., K$) is represented with a distributional word cluster over the vocabulary V.

Also Inspired by neural topic models (Miao et al., 2017), we adopt a variational auto-encoder (VAE) (Kingma and Welling, 2013), with an encoder and a decoder, to resemble the topic model-style data generation process. In doing so, we enable latent aspects, capturing word co-occurrence in both global and local context, to be learned in neural architecture. There are two main steps involved: First, the input sentence $\mathbf{x}$ (in BoW form $\mathbf{x}_{bow}$) is encoded to global representation $\mathbf{z}$. Conditioned on $\mathbf{z}$, together with local representation $\mathbf{h}_n$ (defined in Section 3.2 and $n = 1, 2, ..., |\mathbf{x}|$), decoder further generates $\mathbf{x}'_{bow}$, the BoW-form reconstruction of $\mathbf{x}_{bow}$. In the rest of this section, we first introduce how global representation $\mathbf{z}$ is learned by encoder from global context. Then we introduce how global and local representations are coupled to work together for data generation.

Global Representation Encoding. The encoder is employed to learn global representation, $\mathbf{z}$, from $\mathbf{x}_{bow}$. Following Miao et al. (2017), words in global context are assumed to satisfy Gaussian distribution, prior on mean μ and standard deviation σ. Their estimation formula are defined as:

$$\mu = f_\mu(f_e(\mathbf{x}_{bow})), \log \sigma = f_\sigma(f_e(\mathbf{x}_{bow})) \quad (2)$$

where $f_*(\cdot)$ is a neural perceptron performing a linear transformation operation followed by a non-linear ReLU activation (Nair and Hinton, 2010).

Coupling Global and Local Context. Recall we obtain the hidden states $\mathbf{h}_n$ ($n = 1, 2, ..., |\mathbf{x}|$) from local context modeling, and here we describe how we couple them with global representation $\mathbf{z}$.

Concretely, we employ attention mechanism (Bahdanau et al., 2015) over the hidden states in local representation, which, in aware

of global information, aims to identify words in $\mathbf{x}$ that can usefully indicate its aspect factors. We design attention weight α_n to measure the similarity between the semantic meaning of word w_n and $\mathbf{x}$'s global representation $\mathbf{z}$:

$$\alpha_n = \mathbf{z}^T f_h(\mathbf{h}_n) \tag{3}$$

where $f_h(\cdot)$ is a ReLU activation function. The context vector of this attention, namely **globally-scoped local representation**, is defined as:

$$\mathbf{c} = \sum_n^{|\mathbf{x}|} \alpha_n \mathbf{h}_n \tag{4}$$

In the next step, the decoder will use $\mathbf{c}$ for learning corpus-level aspect factors and reproducing $\mathbf{x}_{bow}$. Below comes more details.

Decoding Process. Given the global representation $\mathbf{z}$ and the globally-scoped local representation $\mathbf{c}$, the decoder carries out the data generation process conditioned on both of them. For each input sentence $\mathbf{x}$, we assume each word $w_n \in \mathbf{x}_{bow}$ is sampled conditioned on its aspect mixture, θ, a K-dim distribution reflecting $\mathbf{x}$'s composition of aspect factors. θ is then estimated with both $\mathbf{z}$ and $\mathbf{c}$, conveying global and local context of $\mathbf{x}$'s words. The story describing $\mathbf{x}$'s generation process is:

- Draw global representation $\mathbf{z} \sim \mathcal{N}(\mu, \sigma^2)$.
- Obtain globally-scoped local representation $\mathbf{c}$ with Eq. 4.
- Aspect mixture $\theta = softmax(f_\theta(\mathbf{z} + \mathbf{c}))$.
- For the n-th word in $\mathbf{x}$:
  - $\beta_n = softmax(f_\phi(\theta))$.
  - Draw the word $w_n \sim Multi(\beta_n)$.

Here $f_*(\cdot)$ is a ReLU-activated neural perceptron described above. Particularly, the weight matrix of $f_\phi(\cdot)$ (with the softmax normalization) are employed as the aspect-word distributions (distributional word clusters), ϕ, used to represent the latent aspect factors and serves as our main output.

Learning Objective. We design the learning objective of our entire framework as:

$$\mathcal{L} = D_{KL}(p(\mathbf{z})||q(\mathbf{z}\,|\,\mathbf{x})) - \mathbb{E}_{p(\mathbf{z})}[p(\mathbf{x}\,|\,\mathbf{z})] \tag{5}$$

where $p(\mathbf{z})$ is a standard Gaussian prior. The first term reflects encoding loss while the second estimation likelihood (for decoding). We refer the readers to Miao et al. (2017) for more details.

4 Experimental Setup

Datasets. We conduct experiments on two benchmark datasets constructed for the SemEval aspect-based sentiment analysis (ABSA) challenge (Pontiki et al., 2014, 2015, 2016) with human annotated aspects — one gathers restaurant reviews (henceforth **restaurant**) and the other consists of laptop reviews (henceforth **laptop**). For model training and evaluation, we combine the training and test datasets for 2014-2016 ABSA (except for 2015 without laptop data released). Following common practice (Wagner et al., 2014), a review sentence is considered as a data sentence for input. The statistics of our datasets are displayed in Table 2. We can see that aspect words take around 25.0% of the vocabulary, yet less than 19.1% of the words per sentence. It is indicated the sparsity and diversity of aspect words, further suggesting the challenging of our task.

	# of sen	|Voc|	Avg len per sen	|Apt|	# of apt per sen
Laptop					
Train	6,355	3,374	14.51	837	2.35
Test	800	1,866	13.17	430	2.52
Rest					
Train	6,359	5,166	13.20	1,404	2.36
Test	2,161	3,800	13.51	948	2.41

Table 2: Statistics of laptop and restaurant (rest) datasets. |Voc|: the vocabulary size (including stop words). Avg len: average number of tokens. |Apt|: the number of distinct aspects. # of apt per sen: average number of aspects in a sentence.

Preprocessing. Here are our preprocessing steps. First, we adopted NLTK toolkit for text tokenization.[1] Then, we normalized all letters into their lower cases. Next, we removed words appearing less than five times. Finally, for BoW-form input, we removed all stop words and punctuation following common practice in topic models (Blei et al., 2003).

Parameter Setting. We applied pre-trained GloVe embedding (Pennington et al., 2014) for initialization in local context modeling.[2] The embedding dimension is set to 300, and batch size to 128. For the number of latent aspect factors, K, we tuned it on training data with five-fold validation and set it to 40. As for N, the number of nouns to be selected from each aspect word cluster, we set it to 30 following Qiu et al. (2011). In model training, we employ Adam optimizer (Kingma and Ba, 2015), with learning rate set to

[1] https://www.nltk.org

[2] https://nlp.stanford.edu/projects/glove/

$1e-3$, and run 20 epochs with early stop strategy adopted. Dropout strategy (Srivastava et al., 2014) is also adopted to avoid overfitting.

Evaluation Metrics. To ensure comparable performance, for clustering-based approaches, we select the top 30 nouns from 40 aspect clusters, same as our set up. For the rest, the top $1,200$ nouns are extracted. Here we adopt two sets of evaluation metrics. First, we follow Qiu et al. (2011) to test sentence-level aspect extraction, where the intersection of our selection and the words appear in a review sentence are considered as the extracted aspects. In this evaluation, we report precision, recall, and F1 scores. Second, we evaluate our ability to build aspect lexicon (a.k.a. corpus-level extraction) following Hamilton et al. (2016). We consider all the annotated aspects as gold standard lexicon and adopt accuracy for evaluation.

Comparisons. We first consider a simple baseline that randomly selects nouns as aspect words (henceforth RANDOM). We also compare with extracting- and clustering-based baselines — TF-IDF (Bahdanau et al., 2015), K-MEANS (Lloyd, 1982) (implemented with sklearn toolkit[3] and taking Glove embedding for similarity measure), and BTM[4] (Yan et al., 2013), state-of-the-art in short text topic modeling and well-performed in aspect extraction (He et al., 2017).

In addition, we consider the following recently proposed *unsupervised* models in comparison: LF-LDA (Nguyen et al., 2015), LDA topic model incorporating word embeddings (GloVe is applied here), and ABAE (He et al., 2017), the state-of-the-art attention-based model for unsupervised aspect extraction. Besides the existing models, we also compare with our variant that only models global context with neural topic model (henceforth GBC ONLY). The full model coupling global and local context is hence referred to as LCC+GBC.

5 Experimental Result

In this section, we first discuss comparison results with unsupervised aspect extraction models in Section 5.1. Section 5.2 shows what our model learns and interprets why it can discover aspect words. Next, in Section 5.3, we carry out an empirical study over how global and local context indicate aspect words. Last, we further discuss our parameter effects and main error in Section 5.4.

Table 3: Precision (pre), Recall (rec), F1, and Accuracy (Acc) produced by various unsupervised models. Acc measures corpus-level extraction while others sentence-level. Our model significantly outperform others in F1 and Acc measure (paired t-test, $p < 0.05$).

5.1 Aspect Extraction Results

Main Comparison Results. In Table 3, we report the aspect extraction results on two datasets. Several interesting observations can be drawn:

• *All models tend to yield better F1 on restaurant yet better Acc on laptop.* We find that restaurant exhibits generally worse model performance on corpus-level extraction than that on sentence level. The opposite findings is whereas drawn on laptop. It might be because restaurant contains more distinct aspects (shown with the larger |Apt| in Table 2). It is possibly due to the prominence of rare aspects, which is challenging to be discovered.

• *Simple baselines do not work well.* Both RANDOM and TF-IDF perform poorly, indicating the challenge of unsupervised aspect extraction.

• *Global context can well indicate aspects.* We observe that approaches based on topic models (BTM, LF-LDA, and our models) perform better than others. The results indicate that aspect words do vary from other words in global context distributions. Topic model-based approaches, via exploiting sentence-level word co-occurrence, can thus effectively identify aspect words.

• *Coupling global and local context is effective.* By combining topic models (global context) with word embeddings (local context), LF-LDA produces the second best F1. Also, our full model LCC+GBC outperforms its variant GBC ONLY in F1. These observations indicate the benefit of joint modeling of global and local context to discover aspect words.

Besides, by comparing model performance over the two datasets, we observe that all models perform worse on laptop. An intuitive explanation is that laptop reviews generally concern wide

GBC ONLY	LCC+GBC

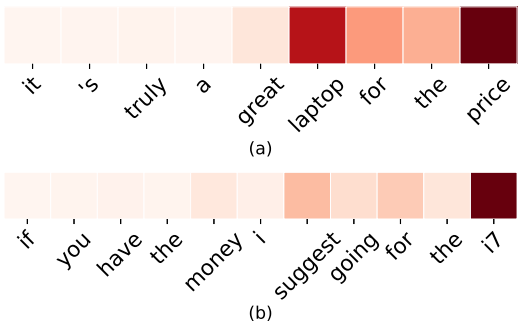
range of aspects (e.g., screens, battery, etc.), while restaurant reviews tend to be centered around general aspects (e.g., food and service). Aspect words thus exhibit sparse occurrence patterns in laptop reviews, rendering generally worse model performance. Section 5.3, we will discuss more. For the same reason, local context helps LCC+GBC obtain larger margin on laptop, compared with models relying on global word co-occurrence.

5.2 Model Interpretation

Here we probe into our output and study why LCC+GBC model works.

Topic Coherence. We first analyze the coherence of our latent aspects, where C_V metrics, a widely-applied automatic topic coherence measure (Röder et al., 2015) is adopted. LCC+GBC's latent aspects achieves C_V coherence scores of 0.401 and 0.393 on restaurant and laptop dataset, respectively, compared to 0.382 and 0.377 produced by GBC ONLY. It hence suggests the joint effects of global and local context also helps produce coherent aspects.

Sample Latent Aspects. We further conduct a qualitative analysis on the produced latent aspects. Table 4 shows the top 30 words (ranked by likelihood) of the sample latent aspects. LCC+GBC's output aspects look more coherent, with words



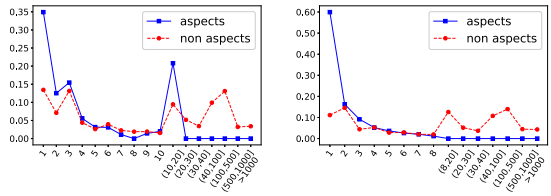


Figure 2: The globally-scoped local attention weights learned by our LCC+GBC model for the sample sentences in Table 1. Darker colors indicate higher values.

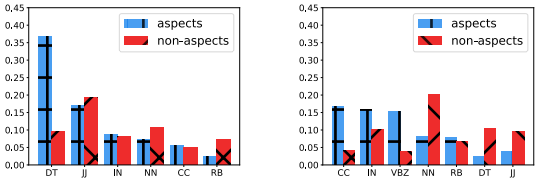
having similar semantics clustered together, such as "*course*", "*romantic*", and "*date*" learned from restaurant dataset, and "*skype*", "*remote*", and "*internet*" from laptop. The possible reason is that words conveying similar semantic meanings tend to appear in similar local context. LCC+GBC, via coupling local context with global one, is thus able to capture such semantic representations.

We also notice that LCC+GBC discovers more rare aspects, such as "*pastrami*" (from restaurant) and "*gui*" (from laptop). These words, though may exhibit sparse occurrence and unable to be discovered purely with global context, might be effectively indicated by their local context. This reveals the benefit of combining the effects of global and local context for aspect extraction.



In addition, we notice that our output aspect clusters include some sentiment words. It is possibly because aspect words tend to co-occur with sentiment ones in both global and local context. Thus without supervision, it is likely our models discover them together. These findings suggest our potential benefit on extracting sentiment words — which can be easily separated from aspects by their POS tags (Qiu et al., 2011)). Such extension is beyond the scope of this paper but worth exploring in future work.

Case Study. To understand what LCC+GBC learns resulting its superiority in aspect extraction. We take the two samples in Table 1 as input. Figure 2 visualizes their globally-scoped attention weights (defined in Eq. 3). We observe that LCC+GBC assigns high attention weights for aspect words "*laptop*", "*price*", and "*i7*". Also highlighted are the neighboring words "*for the*" in both attentions, usefully signaling their next word to be aspect. The results indicate LCC+GBC learns meaningful information via exploring inter-

actions between global and local representation.

5.3 Analysis of Global and Local Context

To extensively understand the effects of global and local context on aspect identification, we carry out an empirical study on our datasets.

Aspects vs. Non-aspects. We first compare the global and local word occurrence statistics in context of aspect and non-aspect words. This is to empirically analyze why LCC+GBC can effectively distinguish aspect and non-aspect words.

To examine global context, Figure 3 presents distributions of word pair co-occurrence in sentences, with two lines corresponding to aspect and non-aspect pairs. It is seen different distribution are exhibited by aspect and non-aspect pairs, with non-aspect ones flatly distributed over varying frequency while the aspect pairs are more sparse. This indicates global context, capturing how words co-appear in sentences, can indeed help distinguish aspect and non-aspect words.

We also notice that aspect pair distributions are slightly different on two datasets. On restaurant dataset, we observe a pulse on pairs occurring $10-20$ times, while the distribution on laptop is a long tail. This demonstrates the sparse aspect occurrence patterns in laptop dataset (probably owing to the broad range of aspects discussed there), also explains the general worse performance on it (compared to restaurant and shown in Table 3).

We then analyze local context and show the distribution of POS tags (predicted with NLTK toolkit) in left and right neighbors. We take laptop dataset as an example to discuss, and similar observations are drawn from restaurant. For better displays, from 34 POS tags in total, we pick up the top 5 tags in aspects' and non-aspects' neighbors respectively. Distributions are shown over their union set in Figure 4. In both left and right context, we observe aspects and non-aspects exhibit different distributions for their neighboring POS tags. For example, aspect words are likely to have "*DT*" (e.g., *an*, *this*) appearing as left while "*RB*" (e.g., *highly*, *barely*) frequently acting as non-aspects' left neighbors while rarely in aspects'.

In addition, we display in Table 5 the top 10 neighboring bigrams in left context. Although it is merely a qualitative human judgement at this point, we can draw some interesting observations from the results. For example, some opinioned bigrams, such as "a great" and "love the", are likely to appear on the left local context of aspects (opinion targets). Such patterns may usefully indicate aspect words and help distinguish them from non-aspect ones. As for right bigram neighbors, they exhibit sparse occurrence patterns, hence might provide less useful clues. We will analyze the effects of left and right local context next.

Aspects	Non-aspects
easy to, and the, of the, for the, with the, a great, that the, it 's, all the, love the	of the, it is, and the, is a, battery life, to use, it 's, with the, i have, for the

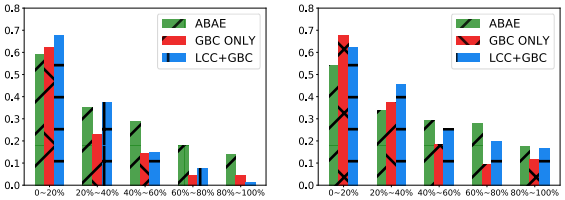

Table 5: Top 10 neighboring bigrams in left context of aspects and non-aspects (laptop dataset).

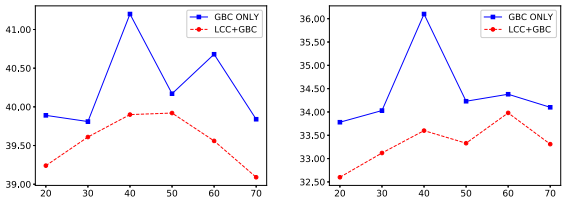
Local Context Modeling. We then compare and discuss the effectiveness of varying modules to capture local representation. The performance of our variants combined with varying local encoders are shown in Table 6. It is observed that all variants with attention, in aware of global context and put over local representation, yield better performance. This shows that attention mechanism is able to capture interactions between global and local representations, which are useful in discovering aspect words. We also notice that LSTM encoder performs better than CNN and Bi-LSTM.

	Restaurant	Laptop
W/O LCC	39.9	33.6
AVG EMB	40.0	33.9
LSTM *(w/o att)*	40.1	34.4
CNN *(w/ att)*	40.4	34.0
BI-LSTM *(w/ att)*	40.6	34.8
LSTM *(w/ att)*	**41.2**	**36.1**

Table 6: F1 score of our variants with varying encoders for local context modeling. Here *att* refers to the attention to capture globally-scoped local representation (shown in Eq. 3 and 4). In the first column, W/O LCC refers to GBC ONLY variant. AVG EMB means average embedding. LSTM (*w/ att*) is our LCC+GBC model.



It is possibly because, in local context, left neighbors convey more useful clues for indicating aspect words, compared with right ones. As a result, CNN and BI-LSTM, equally considering left and right context, might be somehow affected by the noise in right context. They are thus outperformed by LSTM, which only models local context in left-to-right direction.

(a) Restaurant (b) Laptop

Figure 5: Recall scores for discovering varying quintiles (20%) of aspects (ranked by frequency). X-axis: quintiles of aspect frequency. Y-axis: recall scores.

Varying Aspect Frequency. Recall that the sample aspects in Table 4 suggest more rare aspects discovered by LCC+GBC compared with GBC ONLY. We conduct an analysis on model performance to discover aspects with varying frequency. Figure 5 compares the recall scores produced by ABAE, GBC ONLY, and LCC+GBC when retrieving varying aspect quintiles (5-quantile) (ranked by frequency). It shows ABAE performs better in discovering low-frequency aspects while GBC ONLY better at recognizing frequent ones. It suggests global context is more useful to indicate common aspects while local context better at signaling rare ones. LCC+GBC, capturing the coupled effects of global and local context, can identify both common and rare aspects, and thus yield superior performance.

(a) Restaurant (b) Laptop

Figure 6: F1 scores of our models (in y-axis) given varying aspect number K (in x-axis). LCC+GBC performs consistently better than GBC ONLY .

5.4 Further Discussion

Parameter Analysis In main results, we fix the number of latent aspects to $K = 40$. In Figure 6, we further examine how our models (GBC ONLY and LCC+GBC) perform given varying number of K. Here to ensure comparable performance, we set $N = 1200/K$. It is seen that LCC+GBC yields consistently better F1 than GBC ONLY. We also observe that both models do not exhibit monotomic curves, where LCC+GBC obtains the best performance given $K = 40$, consistent with the validation results.

Error Analysis. Here we analyze our main errors types. One major type is caused by wrongly identifying aspect phrases, such as "*windows 7*", where "*7*" is missed possibly ascribed to its sparse occurrence. We have such errors owning to modeling context in word level and sometimes fail to capture semantics in coarser grain. One possible solution is to extend our global context modeling module to learn phrase-level semantics (He, 2016). Another main errors occur when processing context-sensitive aspect words. For example, "*hard*" indicates aspect in "*The hard drive is fast.*", rather than "*It is hard to use that laptop.*". Our model, failing to distinguish "*hard*" in varying context, considers it as aspect for both sentences. To deal with such error, we can adopt context-aware decoders, such as Hu et al. (2017), to distinguish word semantics in different context.

6 Conclusion

We have presented a study of unsupervised aspect extraction via exploring the coupled effects of global and local context. A neural model has been proposed to learn the interactions between global and local representations indicative of aspect words. Experiment results on two benchmark datasets show our model outperform comparison approaches modeling local or global context only.

We find out three interesting points in empirical analysis over global and local context: First, aspects and non-aspects exhibit distinguishing distributions in either global and local context; Second, in local context, left neighbors can better indicate aspect words compared with the right; Third, local context can better indicate rare aspects while global signals common aspects better.

Abstract

Joint extraction of aspects and sentiments can be effectively formulated as a sequence labeling problem. However, such formulation hinders the effectiveness of supervised methods due to the lack of annotated sequence data in many domains. To address this issue, we firstly explore an unsupervised domain adaptation setting for this task. Prior work can only use common syntactic relations between aspect and opinion words to bridge the domain gaps, which highly relies on external linguistic resources. To resolve it, we propose a novel Selective Adversarial Learning (SAL) method to align the inferred correlation vectors that automatically capture their latent relations. The SAL method can dynamically learn an alignment weight for each word such that more important words can possess higher alignment weights to achieve fine-grained (word-level) adaptation. Empirically, extensive experiments[1] demonstrate the effectiveness of the proposed SAL method.

1 Introduction

End-to-End Aspect-Based Sentiment Analysis (E2E-ABSA) aims to jointly detect the aspect terms explicitly mentioned in sentences and predict the sentiment polarities over them (Liu, 2012; Pontiki et al., 2014). For example, in the sentence "*The **AMD Turin Processor** seems to always perform much better than **Intel***", the user mentions two aspect terms, i.e., "***AMD Turin Processor***" and "***Intel***", and expresses positive and negative sentiments over them, respectively.

Typically, prior work formulates E2E-ABSA as a sequence labeling problem over a unified tagging scheme (Mitchell et al., 2013; Zhang et al., 2015; Li et al., 2019a). The unified tagging scheme connects a set of *aspect boundary tags* (e.g., {`B`, `I`, `E`, `S`, `O`} denotes the beginning of, inside of, end of, single-word, and no aspect term), and *sentiment tags* (e.g. {`POS`, `NEG`, `NEU`} denotes positive, negative or neutral sentiment) together to constitute a joint label space for each word. As such, "***AMD Turin Processor***" and "***Intel***" should be tagged with {`B-POS`, `I-POS`, `E-POS`} and {`S-NEG`}, respectively, while the remaining words are tagged with `O`. This formulation makes two sub-tasks joint modeling easier, and meanwhile, tend to be low-resource. There usually exist few annotated data for each new domain, where labeling each word with a unified tag could be more time-consuming and expensive.

To alleviate the dependence on domain supervisions, we explore an unsupervised domain adaptation setting for E2E-ABSA, which aims to leverage knowledge from a labeled source domain to improve the sequence learning in an unlabeled target domain. The challenges in fulfillment of this setting are two-fold: (1) there exists a large feature distribution shift between domains since aspect terms in different domains are usually disjoint. For example, users usually mention "***pizza***" in the *Restaurant* domain while "***camera***" is often discussed in the *Laptop* domain; (2) Unlike domain adaptation in traditional sentiment classification (Blitzer et al., 2007) that learns shared sentence or document representations, we need to learn fine-grained (word-level) representations to be domain-invariant for sequence prediction.

Consider the first problem, i.e., what to transfer? Even though aspect terms from different domains behave distinctly, some association patterns between aspect and opinion words are common across domains; e.g., "*The **pizza** is great.*" from the *Restaurant* domain and "*The **camera** is excellent.*" from the *Laptop* domain. Both of them share the same syntactic pattern (*as-*

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4590–4600, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

pect words→nsubj→opinion words). Inspired by this, existing studies use general syntactic relations as the pivot to bridge the domain gaps for cross-domain aspect extraction (Jakob and Gurevych, 2010; Ding et al., 2017), or aspect and opinion co-extraction (Li et al., 2012; Wang and Pan, 2018). Unfortunately, these methods highly rely on prior knowledge (e.g., manually-designed rules) or external linguistic resources (e.g., dependency parsers), which are inflexible and prone to bringing in knowledge errors. Instead, we introduce a multi-hop Dual Memory Interaction (DMI) mechanism to automatically capture the latent relations among aspect and opinion words. The DMI iteratively infers the correlation vectors of each word by interacting its local memory (LSTM hidden state) with both the global aspect and opinion memories, such that the inter-correlations between aspects and opinions, and the intra-correlations in aspects or opinions can be derived.

Second, how to transfer for this sequence prediction task? One straightforward way is to apply domain adaption methods to align all words within the sentence, however, it is observed that it will not yield significant improvements. Actually, not all the words contribute equally to the domain-invariant feature space though fine-grained adaptation is required. Thus, we propose a novel Selective Adversarial Learning (SAL) method to dynamically learn an alignment weight for each word, where more important words can possess higher alignment weights to achieve a local semantic alignment based on adversarial training. Empirically, the proposed model outperforms the state-of-the-art fine-grained adaptation methods by a large margin on four benchmark datasets. We also conduct extensive ablation studies to quantitatively and qualitatively demonstrate the effectiveness of the selectivity of adversarial learning.

Overall, our main contributions are summarized as: (1) to the best of our knowledge, an unsupervised domain adaptation setting is firstly explored for E2E-ABSA; (2) an effective SAL method is proposed to conduct a local semantic alignment for fine-grained domain adaptation; (3) extensive experiments verify the effectiveness of the proposed SAL method.

2 Task Definition

Single-domain: E2E-ABSA involves both aspect detection (**AD**) and aspect sentiment (**AS**) classification tasks, which are formulated as a unified sequence labeling problem. Given an input sequence of words $\mathbf{x}=\{w_1, w_2, ..., w_T\}$ and its word embeddings $\mathbf{e}=\{e_1, e_2, ..., e_T\}$, the goal is to predict a tag sequence $\mathbf{y}=\{y_1, y_2, ..., y_T\}$ over the *unified tags*, with $y_i \in \mathcal{Y}^{\mathcal{U}} = \{$`B-POS`, `I-POS`, `E-POS`, `S-POS`, `B-NEG`, `I-NEG`, `E-NEG`, `S-NEG`, `B-NEU`, `I-NEU`, `E-NEU`, `S-NEU`, `O`$\}$. **Cross-domain:** Here we are performing in a more challenging unsupervised domain adaptation setting. Given a set of labeled data $D_s = \{(\mathbf{x}_s^i, \mathbf{y}_s^i)\}_{i=1}^{N_s}$ from a source domain and a set of unlabeled data $D_t = \{(\mathbf{x}_t^j)\}_{j=1}^{N_t}$ from a target domain, we aim to transfer the knowledge of D_s to improve the sequence learning in D_t.

3 Model Description

Overview: As shown in Figure 1, we adopt two stacked bi-directional LSTMs as the base model (Li et al., 2019a) for E2E-ABSA. The upper LSTM$^{\mathcal{U}}$ is for the high-level **ADS** (AD+AS) task and it predicts the *unified tags* as output, while the lower LSTM$^{\mathcal{B}}$ is for the low-level **AD** task and predicts the *aspect boundary tags* as the guidance. To adapt the base model, we design different components in terms of the two problems, i.e., what to transfer and how to transfer, respectively.

(1) To automatically capture the latent relations between aspect and opinion words as transferable knowledge across domains, we introduce a multi-hop Dual Memory Interaction (DMI) mechanism between the two LSTMs. At each hop, e.g., the 1st hop, each local memory $\mathbf{h}_i^{\mathcal{B}}$ will interact with both the global aspect and opinion memories, i.e., $\mathbf{m}_a^1$ and $\mathbf{m}_o^1$ based on the DMI, to produce two correlation vectors for aspect and opinion words co-detection, where the opinion detection is used as an auxiliary task for the AD task. The "local" memory denotes the hidden representation (LSTM$^{\mathcal{B}}$ hidden state) of each word within the sentence. Whereas the two "global" memories are globally shared by all input sentences, which are commonly used in memory networks (Sukhbaatar et al., 2015; Kumar et al., 2016) and can be seen as high-level representations for aspect and opinion words, respectively. The A-attention and O-attention then aggregate most relevant aspect or opinion words information to refine the two global memories for the next hop.

(2) To adapt these relations across domains, we propose a Selective Adversarial Learning (SAL)

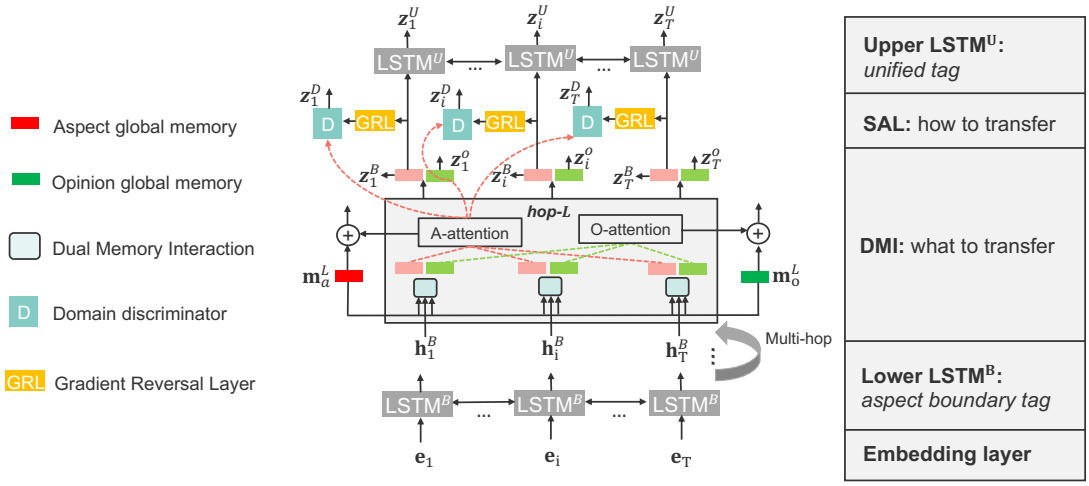

Figure 1: The framework of the proposed model.

method to dynamically focus on aligning the aspect words between domains. This is because the informative aspect words contribute more to the shared feature space than the unmeaning words tagged with O in the sentence (Zhou et al., 2019b). As such, an aspect tagger trained on a source domain can work well when applied to a target domain. Specifically, at the final hop, we adopt a domain discriminator for each word with a gradient reversal layer (Ganin et al., 2016) to perform domain adversarial learning over its correlation vector (alignment). While the A-attention module provides an aspect attention distribution as a selector to control a learnable alignment weight for each word (selectivity). Finally, each aligned correlation vector will be used to predict *aspect boundary tags* (AD task) and fed to the LSTM$^{\mathcal{U}}$ for the *unified tags* prediction (ADS task). In the following sections, we detail each component.

3.1 Base Model

We adopt two stacked bi-directional LSTMs as the base model. We link these two LSTM layers so that the hidden representations generated by the LSTM$^{\mathcal{B}}$ can be fed to LSTM$^{\mathcal{U}}$ as the guidance information. Specifically, their hidden representations $\mathbf{h}_i^{\mathcal{B}} \in \mathbb{R}^{\dim_h^{\mathcal{B}}}$ and $\mathbf{h}_i^{\mathcal{U}} \in \mathbb{R}^{\dim_h^{\mathcal{U}}}$ at the i-th time step ($i \in [1, T]$) are calculated as follows:

$$\mathbf{h}_i^{\mathcal{B}} = [\overrightarrow{\text{LSTM}}^{\mathcal{B}}(\mathbf{e}_i); \overleftarrow{\text{LSTM}}^{\mathcal{B}}(\mathbf{e}_i)],$$
$$\mathbf{h}_i^{\mathcal{U}} = [\overrightarrow{\text{LSTM}}^{\mathcal{U}}(\mathbf{h}_i^{\mathcal{B}}); \overleftarrow{\text{LSTM}}^{\mathcal{U}}(\mathbf{h}_i^{\mathcal{B}})].$$

The probability scores $\mathbf{z}_i^{\mathcal{B}} \in \mathbb{R}^{|\mathcal{Y}^{\mathcal{B}}|}$ over the *aspect boundary tags* $\mathcal{Y}^{\mathcal{B}} = \{\texttt{B}, \texttt{I}, \texttt{E}, \texttt{S}, \texttt{O}\}$ are calculated by a fully-connected softmax layer:

$$\mathbf{z}_i^{\mathcal{B}} = \mathbf{p}(\mathbf{y}_i^{\mathcal{B}}|\mathbf{h}_i^{\mathcal{B}}) = \text{Softmax}(\mathbf{W}_{\mathcal{B}}\mathbf{h}_i^{\mathcal{B}} + \mathbf{b}_{\mathcal{B}}).$$

Similarly, the scores $\mathbf{z}_i^{\mathcal{U}} \in \mathbb{R}^{|\mathcal{Y}^{\mathcal{U}}|}$ over the *unified tags* $\mathcal{Y}^{\mathcal{U}}$ defined in Section 2 are obtained as:

$$\mathbf{z}_i^{\mathcal{U}} = \mathbf{p}(\mathbf{y}_i^{\mathcal{U}}|\mathbf{h}_i^{\mathcal{U}}) = \text{Softmax}(\mathbf{W}_{\mathcal{U}}\mathbf{h}_i^{\mathcal{U}} + \mathbf{b}_{\mathcal{U}}).$$

3.2 Global-Local Memory Interaction

Before detailing the DMI module, we firstly introduce Global-Local Memory Interaction (GLMI) that describes the interaction between a local memory $\mathbf{h}_i \in \mathbb{R}^{\dim_h}$ and a global memory $\mathbf{m} \in \mathbb{R}^{\dim_h}$. Formally, we parameterize the GLMI $f(\mathbf{h}_i, \mathbf{m}; \mathbf{\Theta}, \mathbf{G})$, with $\mathbf{\Theta} = \{\mathbf{W}, \mathbf{b}\}$ and $\mathbf{G}$, which consists of a residual transformation and a tensor product operation. Specifically, we firstly incorporate the global memory information $\mathbf{m}$ into each local position with a residual transformation as $\tilde{\mathbf{h}}_i = \mathbf{h}_i + \text{ReLU}(\mathbf{W}[\mathbf{h_i}:\mathbf{m}] + \mathbf{b})$, where $[:]$ denotes the vector concatenation. As such, the global memory can distill more correlated local information and they are mapped into the same space. Then we compute a correlation vector $\mathbf{r}_i \in \mathbb{R}^K$ that encodes the strength of correlations between the global memory $\mathbf{m}$ and the transformed local memory $\tilde{\mathbf{h}}_i$ through a tensor product operation as:

$$\mathbf{r}_i = \mathbf{m}^T \mathbf{G} \tilde{\mathbf{h}}_i^{\mathcal{B}},$$

where the tensor $\mathbf{G} \in \mathbb{R}^{\dim_h \times \dim_h \times K}$ can be seen as multiple bilinear matrice that model K kinds of latent relations between two objects. The k-th slice of the $\mathbf{G}$, i.e., $\mathbf{G}_k \in \mathbb{R}^{\dim_h \times \dim_h}$ denotes one type of latent relation that interacts with 2 vectors to constitute one type of composition.

3.3 Dual Memory Interaction

Following the notations in Section 3.2, we further define a global aspect memory $\mathbf{m}_a \in \mathbb{R}^{\dim_h^{\mathcal{B}}}$, a

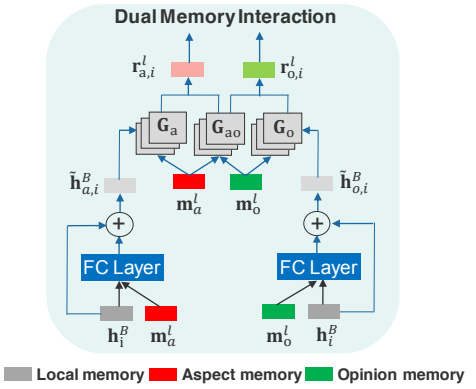

Figure 2: The Dual Memory Interaction (DMI).

global opinion memory $\mathbf{m}_o \in \mathbb{R}^{\dim_h^{\mathcal{B}}}$, and LSTM$^{\mathcal{B}}$ hidden states $\mathbf{H}^{\mathcal{B}} = \{\mathbf{h}_i^{\mathcal{B}}\}_{i=1}^{T}$ as the local memories. The global aspect and opinion memories are able to capture highly correlated aspect or opinion words from the local memories, respectively. Based on the observation that aspect words are often collocated with opinion words across domains, thus their associations can act as the pivot information to bridge the domain gaps. To automatically capture their latent relations within the sentences, at the l-th hop, each local memory $\mathbf{h}_i^{\mathcal{B}}$ will interact with the global memories $\mathbf{m}_a^l$ and $\mathbf{m}_o^l$ by the Dual Memory Interaction (DMI) shown in Figure 2, to produce two correlation vectors for aspect and opinion co-detection:

$$\mathbf{r}_{a,i}^l = [f(\mathbf{h}_i^{\mathcal{B}}, \mathbf{m}_a^l; \mathbf{\Theta}_a, \mathbf{G}_a) : f(\mathbf{h}_i^{\mathcal{B}}, \mathbf{m}_o^l; \mathbf{\Theta}_o, \mathbf{G}_{ao})],$$
$$\mathbf{r}_{o,i}^l = [f(\mathbf{h}_i^{\mathcal{B}}, \mathbf{m}_o^l; \mathbf{\Theta}_o, \mathbf{G}_o) : f(\mathbf{h}_i^{\mathcal{B}}, \mathbf{m}_a^l; \mathbf{\Theta}_a, \mathbf{G}_{ao}^{\top})],$$

where $\mathbf{G}_a, \mathbf{G}_o$ and $\mathbf{G}_{ao}$ denote the composition tensors of modeling the latent relations between aspect and aspect, opinion and opinion, and aspect and opinion, respectively.

The correlation vector measures the association strength between local and global memories; e.g., If $\mathbf{h}_i^{\mathcal{B}}$ for the word w_i is both highly intra-correlated with the aspect memory $\mathbf{m}_a$ and inter-correlated with the opinion memory $\mathbf{m}_o$, w_i is more likely to be an aspect term. Then the two correlation vectors can be transformed to a scalar **a**spect attention (**A**-attention) and **o**pinion attention (**O**-attention) weight $\alpha_{p,i}^l$, respectively, with $p \in \{a, o\}$ denoting the aspect or opinion, which indicates the possibility of each word in the sentence being an aspect word or an opinion word as:

$$\alpha_{p,i}^l = \frac{\exp(\mathbf{W}_p \mathbf{r}_{p,i}^l)}{\sum_{j=1}^{T} \exp(\mathbf{W}_p \mathbf{r}_{p,j}^l)},$$

where $\mathbf{W}_p$ is the weight of the attention module. The aspect or opinion attention weight $\alpha_{p,i}^l$ will summarize the local memories to update the global aspect and opinion memories, respectively, for the next hop, i.e., $\mathbf{m}_p^{l+1} = \mathbf{m}_p^l + \sum_{i=1}^{T} \alpha_{p,i}^l \mathbf{h}_i^{\mathcal{B}}$. The updates gradually refine the global memories to incorporate more relevant candidates based on the attention mechanism. In the DMI, all parameters are shared in different hops and domains.

At the final L-th hop, we use $\mathbf{r}_{a,i}^L$ for the AD task and feed it to the LSTM$^{\mathcal{U}}$ for the ADS task. For the auxiliary opinion detection task, we feed $\mathbf{r}_{o,i}^L$ into a softmax layer for predicting the probability scores $\mathbf{z}_i^{\mathcal{O}} \in \mathbb{R}^{|\mathcal{Y}^{\mathcal{O}}|}$ over the opinion labels[2] $\mathcal{Y}^{\mathcal{O}}$, i.e., a word is an opinion word or not, as:

$$\mathbf{z}_i^{\mathcal{O}} = \mathbf{p}(\mathbf{y}_i^{\mathcal{O}} | \mathbf{r}_{o,i}^L) = \mathrm{Softmax}(\mathbf{W}_{\mathcal{O}} \mathbf{r}_{o,i}^L + \mathbf{b}_{\mathcal{O}}).$$

3.4 Selective Adversarial Learning

To adapt the captured relations to be domain-invariant, we propose a Selective Adversarial Learning (SAL) method to dynamically align the words with high probability to fall into the aspect boundaries, i.e., being an aspect word. Specifically, we introduce a domain discriminator for each word, which aims to identify the domain label $\mathbf{y}_i^{\mathcal{D}} \in \mathbb{R}^{|\mathcal{Y}^{\mathcal{D}}|}$ of the input word, i.e., the word in the sentence is from the source or the target domain. While the feature extractor is to produce the domain-invariant correlation vector $\mathbf{r}_{a,i}^L$ that cannot be distinguished by the domain discriminator via a Gradient Reversal Layer (GRL) (Ganin et al., 2016). Mathematically, we formulate the GRL as a 'pseudo-function' $R_\lambda(\mathbf{x}) = \mathbf{x}$ with a reversal gradient $\frac{\partial R_\lambda(\mathbf{x})}{\partial \mathbf{x}} = -\lambda I$, where λ is the adaptation rate. The correlation vector $\mathbf{r}_{a,i}^L$ will be fed to the GRL before the domain discriminator, which is used to predict the probability scores $\mathbf{z}_i^{\mathcal{D}} \in \mathbb{R}^{|\mathcal{Y}^{\mathcal{D}}|}$ over the domain labels $\mathcal{Y}^{\mathcal{D}}$ as:

$$\mathbf{z}_i^{\mathcal{D}} = \mathbf{p}(\mathbf{y}_i^{\mathcal{D}} | \mathbf{r}_{a,i}^L) = \mathrm{Softmax}(\mathbf{W}_{\mathcal{D}} R_\lambda(\mathbf{r}_{a,i}^L) + \mathbf{b}_{\mathcal{D}}).$$

And meanwhile, the aspect attention weight $\alpha_{a,i}^L$ at the final hop serves as a selector to be a learnable alignment weight for each word. Thus, the selective domain adversarial loss is a weighted cross-entropy loss ℓ for all the words from the labeled source data D_s and unlabeled target data D_t:

$$\mathcal{L}_{\mathcal{D}} = \sum_{D_s \cup D_t} \sum_{i=1}^{T} \alpha_{a,i}^L \ell(\mathbf{z}_i^{\mathcal{D}}, \mathbf{y}_i^{\mathcal{D}}). \quad (1)$$

[2]The opinion lexicon (http://mpqa.cs.pitt.edu/) is used to provide opinion labels for both domains.

Existing studies (Yosinski et al., 2014; Mou et al., 2016) have already shown some evidence that low-level neural layer features (i.e., low-level task) are more easily transferred to different tasks or domains. Thus, we choose the $\mathbf{r}_{a,i}^{L}$ from the low-level AD task to be aligned instead of the feature $\mathbf{h}_i^{\mathcal{U}}$ from the high-level ADS task to transfer. Our ablation studies also confirm this assumption.

3.5 Alternating Training

The primary task loss consists of the cross-entropy losses ℓ for both the guided AD and main ADS tasks for the labeled source data D_s:

$$\mathcal{L}_{\mathcal{M}} = \sum_{D_s} \sum_{\mathcal{Q}\in\{\mathcal{B},\mathcal{U}\}} \sum_{i=1}^{T} \ell(\mathbf{z}_i^{\mathcal{Q}}, \mathbf{y}_i^{\mathcal{Q}}). \quad (2)$$

The auxiliary opinion detection loss is the cross-entropy loss for the labeled source data D_s and unlabeled target data D_t as follows:

$$\mathcal{L}_{\mathcal{O}} = \sum_{D_s \cup D_t} \sum_{i=1}^{T} \ell(\mathbf{z}_i^{\mathcal{O}}, \mathbf{y}_i^{\mathcal{O}}). \quad (3)$$

Traditionally, we can directly optimize the joint loss of Eqs. (1)-(3), i.e., $E = \mathcal{L}_{\mathcal{M}} + \rho\mathcal{L}_{\mathcal{O}} + \gamma\mathcal{L}_{\mathcal{D}}$ to obtain both discriminative and domain-invariant word representations, where ρ and γ are the trade-off factors. However, we found the optimization process tends to be unstable since it may be hard to jointly optimize many objectives. Thus, we propose an empirically alternating strategy to train the $\mathcal{L}_{\mathcal{M}} + \rho\mathcal{L}_{\mathcal{O}}$ and $\mathcal{L}_{\mathcal{D}}$ iteratively, which separates the whole word representation learning into a *discriminative* stage and a *domain-invariant* stage. Let $\boldsymbol{\theta}_f$, $\boldsymbol{\theta}_w$, $\boldsymbol{\theta}_d$ denote the parameters for feature learning of each word, word predictors for AD, ADS and opinion detection tasks, and domain discriminators, respectively. Based on our strategy, we are seeking the parameters $(\hat{\boldsymbol{\theta}}_f^{(1)}, \hat{\boldsymbol{\theta}}_f^{(2)}, \hat{\boldsymbol{\theta}}_w, \hat{\boldsymbol{\theta}}_d)$ that deliver a saddle point of E among two stages:

$$(\hat{\boldsymbol{\theta}}_f^{(1)}, \hat{\boldsymbol{\theta}}_w) = \arg\min_{\boldsymbol{\theta}_f, \boldsymbol{\theta}_w} \mathcal{L}_{\mathcal{M}} + \rho\mathcal{L}_{\mathcal{O}}$$

$$(\hat{\boldsymbol{\theta}}_f^{(2)}, \hat{\boldsymbol{\theta}}_d) = \arg\min_{\boldsymbol{\theta}_d} \max_{\boldsymbol{\theta}_f} \mathcal{L}_{\mathcal{D}}.$$

At the saddle point, the feature learning parameters $\boldsymbol{\theta}_f$ minimize the word prediction losses (i.e., the features are discriminative) for the first stage. For the second stage, the domain classification loss is minimized by the domain discriminator parameters $\boldsymbol{\theta}_d$ while maximized by the feature learning parameters $\boldsymbol{\theta}_f$ via GRL (i.e., the features are domain-invariant). As such, we can achieve easier and more stable optimization for feature learning.

Dataset	Domain	Sentences	Training	Testing
$\mathbb{L}$	Laptop	1,869	1,458	411
$\mathbb{R}$	Restaurant	3,900	2,481	1,419
$\mathbb{D}$	Device	1,437	954	483
$\mathbb{S}$	Service	2,153	1,433	720

Table 1: Statistics of the datasets.

4 Experiments

4.1 Experimental Setup

Datasets: Our experiments are conducted on four benchmark datasets: Laptop ($\mathbb{L}$), Restaurant ($\mathbb{R}$), Device ($\mathbb{D}$), and Service ($\mathbb{S}$). $\mathbb{L}$ contains reviews from the laptop domain in SemEval ABSA challenge 2014 (Pontiki et al., 2014). Following the setup in (Li et al., 2019a), $\mathbb{R}$ is the union set of the restaurant datasets from SemEval ABSA challenge 2014, 2015, and 2016 (Pontiki et al., 2014, 2015, 2016). $\mathbb{D}$ is a combination of device reviews from 5 different digital products provided by (Hu and Liu, 2004). $\mathbb{S}$ is introduced by (Toprak et al., 2010) and contains reviews from web services. Detailed statistics are shown in Table 1.

Settings: We construct 10 transfer pairs like $D_s \rightarrow D_t$ with the four domains mentioned above, and we do not use the pairs $\mathbb{L}\rightarrow\mathbb{D}$ and $\mathbb{D}\rightarrow\mathbb{L}$ as these two domains are very similar. Note that for the unsupervised domain adaptation setting, no labels are available for the target domain. Therefore, for each transfer pair, its training dataset is the combination of the labeled training data of the source domain and the unlabeled training data of the target domain. Meanwhile, it employs the testing data of the source domain with labels as the validation set and the testing data of the target domain as the evaluation set. We report the results for both AD and ADS tasks. The evaluation metric is the Micro-F1 score under the **exact** match, which means that an output segment is considered to be correct only if it exactly matches with the gold standard span of the aspect term for the AD task or the aspect term and its sentiment for the ADS task. All experiments are repeated 5 times and we report the average results over 5 runs.

4.2 Implementation details

The word embeddings are 100-dimensional *word2vec* (Mikolov et al., 2013) vectors pre-trained on the combination of the Yelp Challenge

dataset[3] and the electronics dataset from Amazon reviews[4]. For out-of-vocabulary words, we randomly initialized them with a uniform distribution $U(-0.25, 0.25)$. The dimensions of two LSTM layers $\dim_h^{\mathcal{B}}$ and $\dim_h^{\mathcal{U}}$ are all set to 100. The number of hops L is set to 2. The number of bilinear interactions K is set to 50. The weight matrices are initialized with a uniform distribution $U(-0.2, 0.2)$. The adaptation rate λ is 0.1 and the trade-off factor ρ is 1.0. For training, the model is optimized by the Adam algorithm (Kingma and Ba, 2014) with the initial learning rate 0.001. The batch size is 64, with a half coming from the source and target domains, respectively. Gradients with the ℓ_2 norm larger than 40 are normalized to be 40. To alleviate the overfitting, we apply the dropout on the word embeddings $\mathbf{e}_i$ and the learned word representations $\mathbf{r}_{a,i}^l$, $\mathbf{r}_{o,i}^l$, and $\mathbf{h}_i^{\mathcal{U}}$ with dropout rate 0.5. We use the same hyper-parameters, which are tuned on 10% randomly held-out training data of the source domain in $\mathbb{R}\rightarrow\mathbb{L}$, for all transfer pairs.

4.3 Baselines

We compare with several state-of-the-art fine-grained adaptation methods.

- **TCRF** (Jakob and Gurevych, 2010): Transferable CRF that uses a linear-chain CRF for sequence prediction based on shared non-lexical features across domains, e.g., POS tags and dependency relations.
- **RAP** (Li et al., 2012): A cross-domain Relational Adaptive Bootstrapping method that iteratively expands target aspect and opinion lexicons according to common opinion words and syntactic relations.
- **Hier-Joint** (Ding et al., 2017): A recurrent neural network (RNN) with manually designed rule-based auxiliary tasks based on common syntactic relations among aspect and opinion words.
- **RNSCN** (Wang and Pan, 2018): a recursive neural structural correspondence network that incorporates syntactic structures and exploits an auto-encoder to denoise relation labels generated from the parser.

As the first to address cross-domain E2E-ABSA, we have to adapt all the baselines which are originally proposed for cross-domain aspect detection, or aspect and opinion co-detection to return the ADS results by replacing their *aspect boundary tags* with the *unified tags*. Absent of the proposed stacking architecture, all the baselines fail to accomplish the auxiliary AD task meantime. Thus, we only report their ADS results. Besides, E2E-ABSA aims to simultaneously learn aspect terms along with their sentiments. Thus, the ADS is exactly our main task while the AD is only an auxiliary task used for the guidance.

To be more convincing, we extend neural models (i.e., Hier-Joint and RNSCN) to more powerful baselines named **Hier-Joint**$^+$ and **RNSCN**$^+$ with the proposed stacking architecture, respectively. Both of them stack an additional RNN layer on top of the original framework to produce the *unified tags* while the lower layer is to predict the *aspect boundary tags* as the guidance. The validity of such extensions is guaranteed by the fact that the extended versions achieve even better AD performances than the original versions. We use the source code of the baselines for experiments. For

fair comparison, all baselines use the same pre-trained word embeddings and the baselines that require opinion labels use the same opinion lexicon.

4.4 Main Results

Based on the results in Table 2, we have the following observations:

- Our model consistently and significantly achieves the best results on almost all transfer pairs, outperforming the strongest baseline RNSCN^{+} by 3.07% and 7.62% Micro-F1 on average for the AD and ADS tasks, respectively. Our model can automatically model complicated relations among aspect and opinion words via the DMI as transferable knowledge. Besides, the proposed SAL method can dynamically learn an alignment weight for each word to achieve a local semantic alignment, which distills a better shared feature space and further improves the performances.

- Traditional non-neural methods like TCRF and RAP perform very poorly due to the reliance on hand-crafted features. Our model outperforms Hier-Joint and RNSCN, which are neural models, by 10.92% and 8.72% Micro-F1 on average for the ADS task, respectively. Both of them rely on the dependency parser to exploit syntactic relations, which are inflexible due to the no end-to-end manner and may bring in external errors.

- The extended version Hier-Joint^{+} and RNSCN^{+} can further improve the performances, which shows the benefits of the guidance from the low-level AD task. However, our model can still outperform them by a large margin, which demonstrates the effectiveness of the proposed methods.

4.5 Ablation Study

To investigate the effectiveness of each component, we conduct the ablation study to compare our full model with different ablation variants:

- **Base Model (SO / TO)**: it uses two stacked Bi-LSTMs as the Base Model. SO (Source Only) and TO (Target Only) denote that the base model is only trained on the labeled data from the source and target domain, respectively. We usually refer to them as a lower bound and a upper bound, respectively.

- **Base Model+DMI**: it uses two stacked Bi-LSTMs with a multi-hop dual memory interaction (DMI) between them.

- **AD-AL**: it performs pure adversarial learning (removing the selective weight $\alpha^{L}_{a,i}$ from the Eq. (1)) on each correlation vector $\mathbf{r}^{L}_{a,i}$ for the low-level AD task.

- **AD-SAL**: it advances the AD-AL by conducting selective adversarial learning.

- **ADS-SAL**: it conducts selective adversarial learning on each word representation $\mathbf{h}^{\mathcal{U}}_{i}$ for the high-level ADS task.

Note that, the AD-AL, AD-SAL (**Full model**) and ADS-SAL all use the same architecture as the Base Model+DMI. Based on the Table 3, we have the following observations to give us evidences:

- **No DMI** v.s. **DMI**: Base Model+DMI outperforms the Base Model (SO) by 9.80% and 9.70% Micro-F1 on average for the AD and ADS tasks, respectively. This demonstrates

Table 4: Case analysis for the $\mathbb{R}\rightarrow\mathbb{L}$ pair. Note that we only show the sentiment part of the unified labels (i.e., POS, NEG, and NEU) and use brackets to indicate the boundary. The marker ✗ denotes an incorrect prediction.

that the original word hidden representations (LSTM$^{\mathcal{B}}$ hidden states) are not suitable for transfer. Thus, we need to resort to the correlation vectors inferred by the DMI that models the transferable latent relations between aspect and opinion words.

- **No SAL** v.s. **SAL**: AD-SAL significantly and consistently exceeds Base Model+DMI by 6.46% and 4.92% Micro-F1 on average for the AD and ADS tasks, respectively. Without any adaptation, the captured relations by the DMI may not work well across domains, while the proposed SAL method can effectively align these latent relations to be domain-invariant.

- **No Selectivity** v.s. **Selectivity**: AD-SAL outperforms AD-AL by 5.18% and 4.11% Micro-F1 on average for the AD and ADS tasks, respectively. This proves the necessity to conduct the selective alignment. The SAL method can dynamically learn to control an alignment weight for each word to achieve a local semantic alignment, which captures a better domain-invariant feature space than pure adversarial learning that treats all words equally for the fine-grained adaptation.

- **Low-level** v.s. **High-level**: AD-SAL exceeds ADS-SAL by 2.31% and 1.94% Micro-F1 on average for the AD and ADS tasks, respectively. The label space of the *unified tags* for the high-level ADS task is more complicated than that of the *aspect boundary tag* for the low-level AD task. This gives the evidence that low-level neural features are more easily to transfer than high-level features.

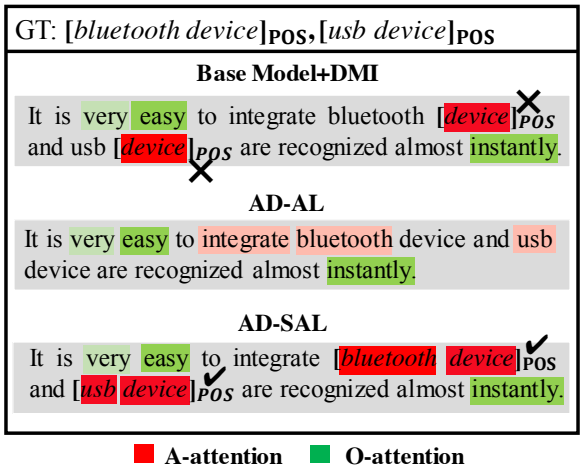

Figure 3: Visualization of attention for the $\mathbb{R}\rightarrow\mathbb{L}$ pair.

4.6 Case Analysis

As illustrated in Table 4, we perform case analysis of the $\mathbb{R}\rightarrow\mathbb{L}$ pair for the Base model+DMI, AD-AL, and the full model AD-SAL to demonstrate the necessity to conduct selective alignment for the fine-grained adaptation. The Base model+DMI can identify some domain-specific aspect words (e.g., *battery*, *ports*) without any supervision from the target domain. This is because the DMI can infer relational representations that capture some common latent relations between aspect and opinion words. However, it still cannot completely capture the multi-word aspect terms (e.g. *bluetooth device*, *battery life*) and sometimes it totally ignores them (e.g. *window 7*). The AD-AL performs pure adversarial learning for aligning all words in a sentence. Even though the domain adaptation method is adopted, it does not yield significant improvements and sometimes it becomes worse. For example, the AD-AL cannot even identify aspect words that can be captured

by the Base Model+DMI (e.g., *ports*, *devices*), or wrongly identifies some non-aspect words (e.g., *pc*). The reason is that pure adversarial learning treats all the words equally for the alignment, which may bring in noises of uninformative words into the shared feature space. To solve that, the full model AD-SAL performs a local semantic alignment to dynamically focus on aligning aspect words that contribute more to the domain-invariant feature space. Hence, AD-SAL model can precisely and completely identity all the aspect terms and make correct unified tag predictions.

Moreover, in Figure 3, we visualize the attentions from these models, where deeper colors denote larger weights. Compared with the Base model+DMI, the full model AD-SAL can precisely attend the complete aspect words from the target domain (A-attention), i.e., *bluetooth device* and *usb device*, and make correct predictions, while the AD-AL cannot achieve that. The AD-AL can only align all the words equally, which hinders the model to attend the aspect words, while the A-attention of the AD-SAL model can be used for both discriminative word tags predictions and acting as a learnable alignment weight for each word. This shows that the proposed SAL method can learn to align important aspect words to improve the transferability of the model for the fine-grained adaptation.

5 Related Works

E2E-ABSA can be broken into two sub-tasks, namely, aspect detection and aspect sentiment classification. The aspect detection aims to extract the aspect terms mentioned in the text and it has been actively studied (Qiu et al., 2011; Liu et al., 2015; Poria et al., 2016; Wang et al., 2016a; He et al., 2017; Wang et al., 2017; Majumder et al., 2018; Li et al., 2018b; Xu et al., 2018). The aspect sentiment classification is to predict the sentiment polarities of the given aspect terms and has also received a lot of attention recently (Dong et al., 2014; Tang et al., 2016; Wang et al., 2016b; Ma et al., 2017; Chen et al., 2017; Ma et al., 2018; He et al., 2018b; Li et al., 2018a, 2019b). For practical applications, a typical way is to pipeline these two sub-tasks together, which becomes ineffective due to the accumulated errors across tasks. These two sub-tasks have strong couplings and thus a unified formulation (Mitchell et al., 2013; Zhang et al., 2015; Li et al., 2019a) to handle them together in an end-to-end manner becomes a more promising direction. Despite its importance, existing studies are only exploring the performance in a single domain, while ignoring the transferability across domains. To address this problem, unsupervised domain adaptation methods can be applied. While existing methods focus on traditional cross-domain sentiment classification to learn shared representations for sentences or documents, including pivot-based methods (Blitzer et al., 2007; Pan et al., 2010; Bollegala et al., 2013; Yu and Jiang, 2016), auto-encoders (Glorot et al., 2011; Chen et al., 2012; Zhou et al., 2016), domain adversarial networks (Ganin et al., 2016; Li et al., 2017, 2018c), or semi-supervised methods (He et al., 2018a). Due to the difficulties in fine-grained adaptation, there exist very few methods for cross-domain aspect extraction (Jakob and Gurevych, 2010; Ding et al., 2017), which acts as a sub-task of E2E-ABSA, or aspect and opinion co-extraction (Li et al., 2012; Wang and Pan, 2018) that focuses on detecting aspect and opinion words, while E2E-ABSA needs to analyze more complicated correspondences between them. Besides, those methods can only rely on general syntactic relations between aspect and opinion words to bridge the domains. Different from them, our method leverages the attention mechanism (Bahdanau et al., 2014; Sukhbaatar et al., 2015; Shen et al., 2018, 2019) as a dynamic selector to automatically achieve the selective alignment.

6 Conclusion

The effectiveness of supervised methods for E2E-ABSA is limited due to the data scarcity. Our wok is the first attempt to resolve cross-domain E2E-ABSA by leveraging knowledge from other related domains to enhance the sequence learning of the target domain. Extensive experiments show the effectiveness of the proposed SAL method. Ablation studies also prove the necessity to perform selective alignment. In the future, the proposed SAL method can be potentially extended to other domain adaptation methods and applied to more general sequence labeling tasks including named entity recognition (Zhou et al., 2019c), part-of-speech tagging (Zhou et al., 2019a), etc.

Abstract

Aspect level sentiment classification is a fine-grained sentiment analysis task. To detect the sentiment towards a particular aspect in a sentence, previous studies have developed various attention-based methods for generating aspect-specific sentence representations. However, the attention may inherently introduce noise and downgrade the performance. In this paper, we propose constrained attention networks (CAN), a simple yet effective solution, to regularize the attention for multi-aspect sentiment analysis, which alleviates the drawback of the attention mechanism. Specifically, we introduce orthogonal regularization on multiple aspects and sparse regularization on each single aspect. Experimental results on two public datasets demonstrate the effectiveness of our approach. We further extend our approach to multi-task settings and outperform the state-of-the-art methods.

1 Introduction

Sentiment analysis (Nasukawa and Yi, 2003; Liu, 2012), an important task in natural language understanding, receives much attention in recent years. Aspect level sentiment classification (ALSC) is a fine-grained sentiment analysis task, which aims at detecting the sentiment towards a particular aspect in a sentence. ALSC is especially critical for multi-aspect sentences which contain multiple aspects. A multi-aspect sentence can be categorized as *overlapping* or *non-overlapping*. A sentence is annotated as non-overlapping if any two of its aspects have no overlap. Our study found that around 85% of the multi-aspect sentences are non-overlapping in the two public datasets. Figure 1 shows a simple example. The non-overlapping sentence contains two aspects. The aspect *food* is on the left side of the aspect *service*. Their distributions on words are **orthogonal** to each other. Another observation is that only a few words relate to the opinion expression in each aspect. As shown in Figure 1, only the word *"good"* is relevant to the aspect *food* and *"ok"* to *service*. The distribution of the opinion expression of each aspect is **sparse**.

Figure 1: Example of a non-overlapping sentence. The attention weights of the aspect *food* are from the model ATAE-LSTM (Wang et al., 2016).

To detect the sentiment towards a particular aspect, previous studies (Wang et al., 2016; Ma et al., 2017; Cheng et al., 2017; Ma et al., 2018; Huang et al., 2018) have developed various attention-based methods for generating aspect-specific sentence representations. In these works, the attention may inherently introduce noise and downgrade the performance (Li et al., 2018) since the attention scatters across the whole sentence and is prone to attend on noisy words, or the opinion words from other aspects. Take Figure 1 as an example, for the aspect *food*, we visualize the attention weights from the model (Wang et al., 2016). Much of the attention focuses on the noisy word *"sometimes"*, and the opinion word *"ok"* which is relevant to the aspect *service* rather than *food*.

To alleviate the above issue, we propose a model for multi-aspect sentiment analysis, which regularizes the attention by handling multiple aspects of a sentence simultaneously. Specifically, we introduce orthogonal regularization for attention weights among multiple non-overlapping as-

pects. The orthogonal regularization tends to make the attention weights of multiple aspects concentrate on different parts of the sentence with less overlap. We also introduce the sparse regularization, which tends to make the attention weights of each aspect concentrate only on a few words. We call our networks with such regularizations *constrained attention networks* (CAN). There have been some works on introducing sparsity in attention weights in machine translation (Malaviya et al., 2018) and orthogonal constraints in domain adaptation (Bousmalis et al., 2016). In this paper, we add both sparse and orthogonal regularizations in a unified form inspired by the work (Lin et al., 2017). The details will be introduced in Section 3.

In addition to aspect level sentiment classification (ALSC), aspect category detection (ACD) is another task of aspect based sentiment analysis. ACD (Zhou et al., 2015; Schouten et al., 2018) aims to identify the aspect categories discussed in a given sentence from a predefined set of aspect categories (e.g., price, food, service). Take Figure 1 as an example, aspect categories *food* and *service* are mentioned. We introduce ACD as an auxiliary task to assist the ALSC task, benefiting from the shared context of the two tasks. We also apply our attention constraints to the ACD task. By applying attention weight constraints to both ALSC and ACD tasks in an end-to-end network, we can further evaluate the effectiveness of CAN in multi-task settings.

In summary, the main contributions of our work are as follows:

- We propose CAN for multi-aspect sentiment analysis. Specifically, we introduce orthogonal and sparse regularizations to constrain the attention weight allocation, helping learn better aspect-specific sentence representations.
- We extend CAN to multi-task settings by introducing ACD as an auxiliary task, and applying CAN on both ALSC and ACD tasks.
- Extensive experiments are conducted on public datasets. Results demonstrate the effectiveness of our approach for aspect level sentiment classification.

2 Related Work

Aspect level sentiment analysis is a fine-grained sentiment analysis task. Earlier methods are usually based on explicit features (Liu et al., 2010; Vo and Zhang, 2015). With the development of deep learning technologies, various neural attention mechanisms have been proposed to solve this fine-grained task (Wang et al., 2016; Ruder et al., 2016; Ma et al., 2017; Tay et al., 2017; Cheng et al., 2017; Chen et al., 2017; Tay et al., 2018; Ma et al., 2018; Wang and Lu, 2018; Wang et al., 2018). To name a few, Wang et al. (2016) propose an attention-based LSTM network for aspect level sentiment classification. Ma et al. (2017) use the interactive attention networks to generate the representations for targets and contexts separately. Cheng et al. (2017); Ruder et al. (2016) both propose hierarchical neural network models for aspect level sentiment classification. Wang and Lu (2018) employ a segmentation attention based LSTM model for aspect level sentiment classification. All these works can be categorized as single-aspect sentiment analysis, which deals with aspects in a sentence separately, without considering the relationship between aspects.

More recently, a few works have been proposed to take the relationship among multiple aspects into consideration. Hazarika et al. (2018) make simultaneous classification of all aspects in a sentence using recurrent networks. Majumder et al. (2018) employ memory network to model the dependency of the target aspect with the other aspects in the sentence. Fan et al. (2018) design an aspect alignment loss to enhance the difference of the attention weights towards the aspects which have the same context and different sentiment polarities. In this paper, we introduce orthogonal regularization to constrain the attention weights of multiple non-overlapping aspects, as well as sparse regularization on each single aspect.

Multi-task learning Caruana (1997) solves multiple learning tasks at the same time, achieving improved performance by exploiting commonalities and differences across tasks. Multi-task learning has been used successfully in many machine learning applications. Huang and Zhong (2018) learn both main task and auxiliary task jointly with shared representations, achieving improved performance in question answering. Toshniwal et al. (2017) use low-level auxiliary tasks for encoder-decoder based speech recognition, which suggests that the addition of auxiliary tasks can help in either optimization or generalization. Yu and Jiang (2016) use two auxiliary tasks to help induce a

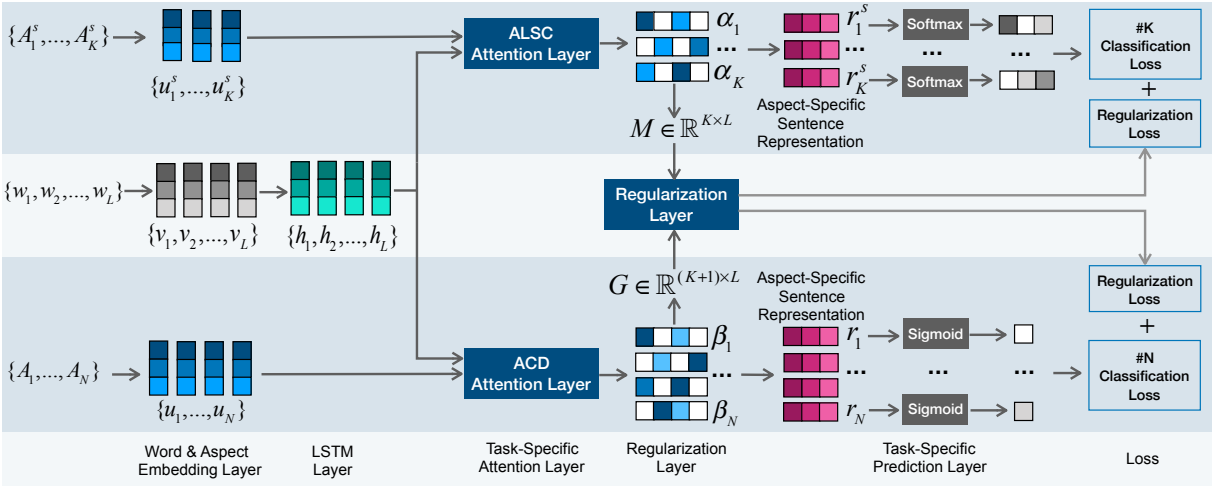

Figure 2: Network Architecture. The aspect categories are embedded as vectors. The model encodes the sentence using LSTM. Based on its hidden states, aspect-specific sentence representations for ALSC and ACD tasks are learned via constrained attention. Then aspect level sentiment prediction and aspect category detection are made.

sentence embedding that works well across domains for sentiment classification. In this paper, we adopt the multi-task learning approach by using ACD as the auxiliary task to help the ALSC task.

3 Model

We first formulate the problem. There are totally N predefined aspect categories in the dataset, $A = \{A_1, ..., A_N\}$. Given a sentence $S = \{w_1, w_2, ..., w_L\}$, which contains K aspects $A^s = \{A^s_1, ..., A^s_K\}$, $A^s \subseteq A$, the multi-task learning is to simultaneously solve the ALSC and ACD tasks, namely, the ALSC task predicts the sentiment polarity of each aspect $A^s_k \in A^s$, and the auxiliary ACD task checks each aspect $A_n \in A$ to see whether the sentence S mentions it. Note that we only focus on aspect-category instead of aspect-term (Xue and Li, 2018) in this paper.

We propose CAN for multi-aspect sentiment analysis, supporting both ALSC and ACD tasks by a multi-task learning framework. The network architecture is shown in Figure 2. We will introduce all components sequentially from left to right.

3.1 Embedding and LSTM Layers

Traditional single-aspect sentiment analysis handles each aspect separately, one at a time. In such settings, a sentence S with K aspects will be copied to form K instances. For example, a sentence S contains two aspects: A^s_1 with polarity p_1 and A^s_2 with polarity p_2. Two instances, $\langle S, A^s_1, p_1\rangle$ and $\langle S, A^s_2, p_2\rangle$, will be constructed. Our multi-aspect sentiment analysis method handles multiple aspects together and takes the single instance $\langle S, [A^s_1, A^s_2], [p_1, p_2]\rangle$ as input.

The input sentence $\{w_1, w_2, ..., w_L\}$ is first converted to a sequence of vectors $\{v_1, v_2, ..., v_L\}$, and the K aspects of the sentence are transformed to vectors $\{u^s_1, ..., u^s_K\}$, which is a subset of $\{u_1, ..., u_N\}$, the vectors of all aspect categories. The word embeddings of the sentence are then fed into an LSTM network (Hochreiter and Schmidhuber, 1997), which outputs hidden states $H = \{h_1, h_2, ..., h_L\}$. The sizes of the embedding and the hidden state are both set to be d.

3.2 Task-Specific Attention Layer

The ALSC and ACD tasks share the hidden states from the LSTM layer, while compute their own attention weights separately. The attention weights are then used to compute aspect-specific sentence representations.

ALSC Attention Layer The key idea of aspect level sentiment classification is to learn different attention weights for different aspects, so that different aspects can concentrate on different parts of the sentence. We follow the approach in the work (Bahdanau et al., 2015) to compute the attention. Particularly, given the sentence S with K aspects, $A^s = \{A^s_1, ..., A^s_K\}$, for each aspect A^s_k, its attention weights are calculated by:

$$\alpha_k = softmax(z^{a\mathrm{T}} tanh(W^a_1 H + W^a_2 (u^s_k \otimes e_L))) \quad (1)$$

where u^s_k is the embedding of the aspect A^s_k, $e_L \in \mathbb{R}^L$ is a vector of 1s, $u^s_k \otimes e_L$ is the op-

eration repeatedly concatenating u_k^s for L times. $W_1^a \in \mathbb{R}^{d\times d}$, $W_2^a \in \mathbb{R}^{d\times d}$ and $z^a \in \mathbb{R}^d$ are the weight matrices.

ACD Attention Layer We treat the ACD task as multi-label classification problem for the set of N aspect categories. For each aspect $A_n \in A$, its attention weights are calculated by:

$$\beta_n = softmax({z^b}^{\mathrm{T}} tanh(W_1^b H + W_2^b(u_n \otimes e_L))) \quad (2)$$

where u_n is the embedding of the aspect A_n. $W_1^b \in \mathbb{R}^{d\times d}$, $W_2^b \in \mathbb{R}^{d\times d}$ and $z^b \in \mathbb{R}^d$ are the weight matrices.

The ALSC and ACD tasks use the same attention mechanism, but they do not share parameters. The reason to use separated parameters is that, for the same aspect, the attention of ALSC concentrates more on opinion words, while ACD focuses more on aspect target terms (see the attention visualizations in Section 4.6).

3.3 Regularization Layer

We simultaneously handles multiple aspects by adding constraints to their attention weights. **Note that this layer is only available in the training stage**, in which the ground-truth aspects are known for calculating the regularization loss, and then influence parameter updating in back propagation. While in the testing/inference stage, the true aspects are unknown and the regularization loss is not calculated so that this layer is omitted from the architecture.

In this paper, we introduce two types of regularizations: the sparse regularization on each single aspect; the orthogonal regularization on multiple non-overlapping aspects.

Sparse Regularization For each aspect, the sparse regularization constrains the distribution of the attention weights (α_k or β_n) to concentrate on less words. For simplicity, we use α_k as an example, $\alpha_k = \{\alpha_{k1}, \alpha_{k2}, ..., \alpha_{kL}\}$. To make α_k sparse, the sparse regularization term is defined as:

$$R_s = \mid \sum_{l=1}^{L} \alpha_{kl}^2 - 1 \mid \quad (3)$$

where $\sum_{l=1}^{L} \alpha_{kl} = 1$ and $\alpha_{kl} > 0$. Since α_k is normalized as a probability distribution, L_1 norm is always equal to 1 (the sum of the probabilities) and does not work as sparse regularization as usual. Minimizing Equation 3 will force the sparsity of α_k. It has the similar effect as minimizing the entropy of α_k, which leads to placing more probabilities on less words.

Orthogonal Regularization This regularization term forces orthogonality among attention weight vectors of multiple aspects, so that different aspects attend on different parts of the sentence with less overlap. Note that we only apply this regularization to non-overlapping multi-aspect sentences. Assume that the sentence S contains K non-overlapping aspects $\{A_1^s, ..., A_K^s\}$ and their attention weight vectors are $\{\alpha_1, ..., \alpha_K\}$. We pack them together as a two-dimensional attention matrix $M \in \mathbb{R}^{K\times L}$ to calculate the orthogonal regularization term.

$$R_o = \parallel M^{\mathrm{T}} M - I \parallel_2 \quad (4)$$

where I is an identity matrix. In the resulted matrix of $M^{\mathrm{T}}M$, each non-diagonal element is the dot product between two attention weight vectors, minimizing the non-diagonal elements will force orthogonality between corresponding attention weight vectors. The diagonal elements of $M^{\mathrm{T}}M$ are subtracted by 1, which are the same as R_s defined in Equation 3. As a whole, R_o includes both sparse and orthogonal regularization terms.

Note that in the ACD task, we do not pack all the N attention vectors $\{\beta_1, ..., \beta_N\}$ as a matrix. The sentence S contains K aspects. For simplicity, let $\{\beta_1, ..., \beta_K\}$ be the attention vectors of the K aspects mentioned, while $\{\beta_{K+1}, ..., \beta_N\}$ be the attention vectors of the $N - K$ aspects not mentioned. We compute the average of the $N - K$ attention vectors, denoted by β_{avg}. We then construct the attention matrix $G = \{\beta_1, ..., \beta_K, \beta_{avg}\}$, $G \in \mathbb{R}^{(K+1)\times L}$. The reason why we calculate β_{avg} is that if an aspect is not mentioned in the sentence, its attention weights often attend to meaningless stop words, such as *"to"*, *"the"*, *"was"*, etc. We do not need to distinguish among the $N - K$ aspects not mentioned, therefore they can share stop words in the sentence by being averaged as a whole, which keeps the K aspects mentioned away from such stop words.

3.4 Task-Specific Prediction Layer

Given the attention weights of each aspect, we can generate aspect-specific sentence representation, and then make prediction for the ALSC and ACD tasks respectively.

ALSC Prediction The weighted hidden state is combined with the last hidden state to generate the

final aspect-specific sentence representation.

$$r_k^s = tanh(W_1^r \bar{h}_k + W_2^r h_L) \quad (5)$$

where $W_1^r \in \mathbb{R}^{d\times d}$ and $W_2^r \in \mathbb{R}^{d\times d}$. $\bar{h}_k = \sum_{l=1}^{L} \alpha_{kl} h_l$ is the weighted hidden state for aspect k. r_k^s is then used to make sentiment polarity prediction.

$$\hat{y_k} = softmax(W_p^a r_k^s + b_p^a) \quad (6)$$

where $W_p^a \in \mathbb{R}^{d\times c}$ and $b_p^a \in \mathbb{R}^c$ are the parameters of the projection layer, and c is the number of classes.

For the sentence S with K aspects mentioned, we make K predictions simultaneously. That is why we call our approach multi-aspect sentiment analysis.

ACD Prediction We directly use the weighted hidden state as the sentence representation for ACD prediction.

$$r_n = \bar{h}_n = \sum_{l=1}^{L} \beta_{nl} h_l \quad (7)$$

We do not combine with the last hidden state h_L since the aspect may not be mentioned by the sentence. We make N predictions for all predefined aspect categories.

$$\hat{y_n} = sigmoid(W_p^b r_n + b_p^b) \quad (8)$$

where $W_p^b \in \mathbb{R}^{d\times 1}$ and b_p^b is a scalar.

3.5 Loss

For the task ALSC, the loss function for the K aspects of the sentence S is defined by:

$$L_a = -\sum_{k=1}^{K}\sum_{c} y_{kc} \log \hat{y_{kc}}$$

where c is the number of classes. For the task ACD, as each prediction is binary classification problem, the loss function for the N aspects of the sentence S is defined by:

$$L_b = -\sum_{n=1}^{N}[y_n \log \hat{y_n} + (1-y_n)\log(1-\hat{y_n})]$$

We jointly train our model for the two tasks. The parameters in our model are then trained by minimizing the combined loss function:

$$L = L_a + \frac{1}{N} L_b + \lambda R \quad (9)$$

Dataset	#Single	#Multi			#Total
		OL	*NOL*	*Total*

Table 1: The numbers of single- and multi-aspect sentences. *OL* and *NOL* denote the overlapping and non-overlapping multi-aspect sentences, respectively.

where R is the regularization term mentioned previously, which can be R_s or R_o. λ is the hyper-parameter used for tuning the impact from regularization loss to the overall loss. To avoid L_b overwhelming the overall loss, we divide it by the number of aspect categories.

4 Experiments

4.1 Datasets

We conduct experiments on two public datasets from SemEval 2014 task 4 (Pontiki et al., 2014) and SemEval 2015 task 12 (Pontiki et al., 2015) (denoted by Rest14 and Rest15 respectively). These two datasets consist of restaurant customer reviews with annotations identifying the mentioned aspects and the sentiment polarity of each aspect. To apply orthogonal regularization, we manually annotate the multi-aspect sentences with overlapping or non-overlapping[1]. We randomly split the original training set into training, validation sets in the ratio 5:1, where the validation set is used to select the best model. We count the sentences of single-aspect and multi-aspect separately. Detailed statistics are summarized in Table 1. Particularly, 85.23% and 83.73% of the multi-aspect sentences are non-overlapping in Rest14 and Rest15, respectively.

4.2 Comparison Methods

Since we focus on aspect-category sentiment analysis, many works (Ma et al., 2017; Li et al., 2018; Fan et al., 2018) which focus on aspect-term sentiment analysis are excluded.

- **LSTM**: We implement the vanilla LSTM to model the sentence and use the average of all

[1]We will release the annotated dataset later.

Table 2: Results of the ALSC task in single-task settings in terms of accuracy (%) and Macro-F1 (%).

hidden states as the sentence representation. In this model, aspect information is not used.

- **AT-LSTM** (Wang et al., 2016): It adopts the attention mechanism in LSTM to generate a weighted representation of a sentence. The aspect embedding is used to compute the attention weights as in Equation 1. We do not concatenate the aspect embedding to the hidden state as in the work (Wang et al., 2016) and gain small performance improvement. We use this modified version in all experiments.

- **ATAE-LSTM** (Wang et al., 2016): This method is an extension of AT-LSTM. In this model, the aspect embedding is concatenated to each word embedding of the sentence as the input to the LSTM layer.

- **GCAE** (Xue and Li, 2018): This state-of-the-art method is based on the convolutional neural network with gating mechanisms, which is for both aspect-category and aspect-term sentiment analysis. We compare with its aspect-category sentiment analysis task.

4.3 Our Methods

To verify the performance gain of introducing constraints on attention weights, we first create several variants of our model for single-task settings.

- **AT-CAN-R_s**: Add sparse regularization R_s to AT-LSTM to constrain the attention weights of each single aspect.

- **AT-CAN-R_o**: Add orthogonal regularization R_o to AT-CAN-R_s to constrain the attention weights of multiple non-overlapping aspects.

- **ATAE-CAN-R_s**: Add R_s to ATAE-LSTM.

- **ATAE-CAN-R_o**: Add R_o to ATAE-CAN-R_s.

We then extend attention constraints to multi-task settings, creating variants by different options: 1) no constraints, 2) adding regularizations only to the ALSC task, 3) adding regularizations to both tasks.

- **M-AT-LSTM**: This is the basic multi-task model without regularizations.

- **M-CAN-R_s**: Add R_s to the ALSC task in M-AT-LSTM.

- **M-CAN-R_o**: Add R_o to the ALSC task in M-CAN-R_s.

- **M-CAN-2R_s**: Add R_s to both tasks in M-AT-LSTM.

- **M-CAN-2R_o**: Add R_o to both tasks in M-CAN-2R_s.

4.4 Implementation Details

We set $\lambda = 0.1$ with the help of the validation set. All models are optimized by the Adagrad optimizer (Duchi et al., 2011) with learning rate 0.01. Batch size is 25. We apply a dropout of $p = 0.7$ after the embedding and LSTM layers. All words in the sentences are initialized with 300 dimension Glove Embeddings (Pennington et al., 2014). The aspect embedding matrix and parameters are initialized by sampling from a uniform distribution $U(-\varepsilon, \varepsilon)$, $\varepsilon = 0.01$. d is set as 300. The models are trained for 100 epochs, during which the model with the best performance on the validation set is saved. We also apply early stopping in training, which means that the training will stop if the performance on validation set does not improve in 10 epochs.

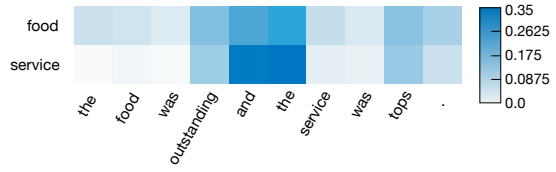
4.5 Results

Table 2 and 3 show our experimental results on the two public datasets for single-task and multi-task settings respectively. In both tables, "3-way" stands for 3-class classification (positive, neutral, and negative), and "Binary" for binary classification (positive and negative). The best scores are marked in bold.



Single-task Settings Table 2 shows our experimental results of ALSC in single-task settings. Firstly, we observe that by introducing attention regularizations (either R_s or R_o), most of our proposed methods outperform their counterparts. Particularly, AT-CAN-R_s and AT-CAN-R_o outperform AT-LSTM in all results; ATAE-CAN-R_s and ATAE-CAN-R_o also outperform ATAE-LSTM in 15 of 16 results. For example, in the Rest15 dataset, ATAE-CAN-R_o outperforms ATAE-LSTM by up to 5.39% of accuracy and 6.46% of the F1 score in the 3-way classification. Secondly, regularization R_o achieves better performance improvement than R_s in all results. This is because R_o includes both orthogonal and sparse regularizations for non-overlapping multi-aspect sentences. Thirdly, our approaches, especially ATAE-CAN-R_o, outperform the state-of-the-art baseline model GCAE. Finally, the LSTM method outputs the worst results in all cases, because it can not distinguish different aspects.

Multi-task Settings Table 3 shows experimental results of ALSC in multi-task settings. We first observe that the overall results in multi-task settings outperform the ones in single-task settings, which demonstrates the effectiveness of multi-task learning by introducing the auxiliary ACD task to help the ALSC task. Second, in almost all cases, applying attention regularizations to both tasks gains more performance improvement than only to the ALSC task, which shows that our attention regularization approach can be extended to different tasks which involving aspect level attention weights, and works well in multi-task settings. For example, for the Binary classification in the Rest15 dataset, M-AT-LASTM outperforms AT-LSTM by 3.57% of accuracy and 4.96% of the F1 score, and M-CAN-2R_o further outperforms M-AT-LSTM by 3.28% of accuracy and 4.0% of the F1 score.

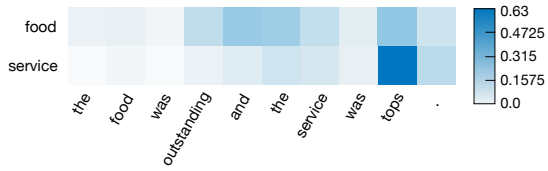


Table 4 shows the results of the ACD task in multi-task settings. Our proposed regularization terms can also improve the performance of ACD. Regularization R_o achieves the best performance in almost all metrics.

4.6 Attention Visualizations

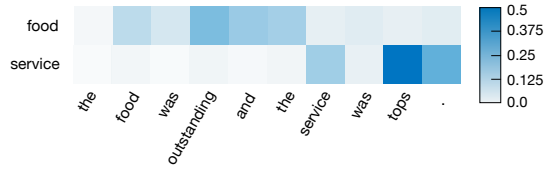

Figure 3 depicts the attention weights from AT-LSTM, M-AT-LSTM and M-CAN-2R_o methods, which are used to predict the sentiment polarity in the ALSC task. The subfigure (a), (b) and (c) show the attention weights of the same sentence, for the aspect *food* and *service* respectively. We observe that the attention weights of each word associated with each aspect are quite different for different methods. For AT-LSTM method in sub-

(a) AT-LSTM

(b) M-AT-LSTM

(c) M-CAN-2R_o

Figure 3: Visualization of attention weights of different aspects in the ALSC task. Three different models are compared.

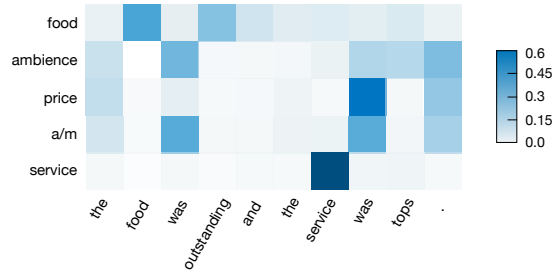

Figure 4: Visualization of attention weights of different aspects in the ACD task from M-CAN-2R_o. The a/m is short for anecdotes/miscellaneous.

figure (a), the attention weights of aspect *food* and *service* are both high in words *"outstanding"*, *"and"*, and *"the"*, but actually, the word *"outstanding"* is used to describe the aspect *food* rather than *service*. The same situation occurs with the word *"tops"*, which should associate with *service* rather than *food*. The attention mechanism alone is not good enough to locate aspect-specific opinion words and generate aspect-specific sentence representations in the ALSC task.

As shown in subfigure (b), the issue is mitigated in M-AT-LSTM. Multi-task learning can learn better hidden states of the sentence, and better aspect embeddings. However, it is still not good enough. For instance, the attention weights of the word

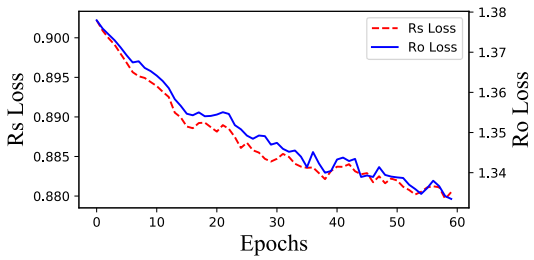

Figure 5: The regularization loss curves of R_s and R_o during the training of AT-CAN-R_o.

"tops" are both high for the two aspects, and the weights are overlapped in the middle part of the sentence.

As shown in subfigure (c), M-CAN+2R_o generates the best attention weights. The attention weights of the aspect *food* are almost orthogonal to the weights of *service*. The aspect *food* concentrates on the first part of the sentence while *service* on the second part. Meanwhile, the key opinion words *"outstanding"* and *"tops"* get highest attention weights in the corresponding aspects.

We also visualize the attention for the auxiliary task ACD. Figure 4 depicts the attention weights from the method M-CAN-2R_o. There are five predefined aspect categories (*food, ambience, price, anecdotes/miscellaneous, service*) in the dataset, two of which are mentioned in the sentence. In the ACD task, we need to calculate the attention weights for all the five aspect categories, and then generate aspect-specific sentence representations to determine whether the sentence contains each aspect. As shown in Figure 4, attention weights for aspects *food* and *service* are pretty good. The aspect *food* concentrates on words *"food"* and *"outstanding"*, and the aspect *service* focuses on the word *"service"*. It is interesting that for aspects which are not mentioned in the sentence, their attention weights often attend to meaningless stop words, such as *"the"*, *"was"*, etc. We do not distinguish these aspects and just treat them as a whole.

We plot the regularization loss curves in Figure 5, which shows that both R_s and R_o decrease during the training of AT-CAN-R_o.

4.7 Case Studies

Overlapping Case We only add sparse regularization to overlapping sentences in which multiple aspects share the same opinion snippet. As shown in Figure 6, the sentence contains two aspects *food*

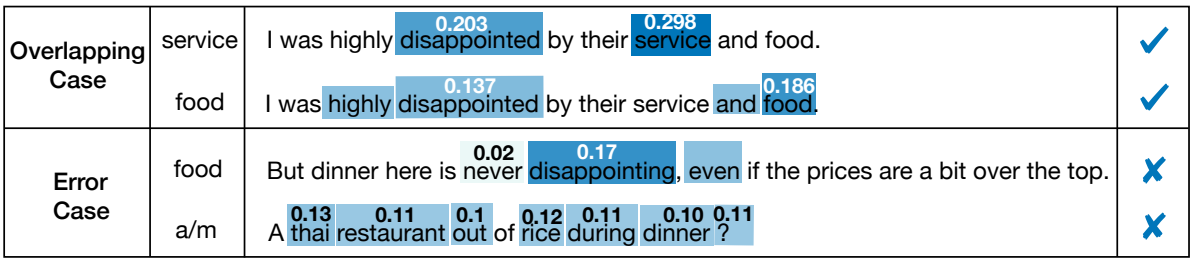

Figure 6: Examples of overlapping case and error case. The a/m is short for anecdotes/miscellaneous.

and *service*, both described by the opinion snippet *"highly disappointed"*. Our method can locate the aspect terms and shared opinion words for both aspects, and then classify the sentiment correctly.

Error Case With the help of attention visualization, we can conduct error analysis of our model conveniently. As shown in Figure 6, for the first sentence in error case, the aspect *food* attends on the right word *"disappointing"*, but fails to include the negation word *"never"*. This may be caused by the inaccurate sentence representation or aspect embedding. We can not rebuild the connection between the aspect and the word by our regularizations. The second sentence is negative but classified as neutral. The attention weights distribute evenly since the sentence does not contain any explicit opinion words. Since there is no tendency which words to concentrate, our model can not adjust the attention weights and help on such cases.

5 Conclusions

We propose constrained attention networks for multi-aspect sentiment analysis, which handles multiple aspects of a sentence simultaneously. Specifically, we introduce orthogonal and sparse regularizations on attention weights. Furthermore, we introduce an auxiliary task ACD for promoting the ALSC task, and apply CAN on both tasks. Experimental results demonstrate that our approach outperforms the state-of-the-art methods.

Leveraging Just a Few Keywords for Fine-Grained Aspect Detection Through Weakly Supervised Co-Training

Giannis Karamanolakis, Daniel Hsu, Luis Gravano
Columbia University, New York, NY 10027, USA
{gkaraman, djhsu, gravano}@cs.columbia.edu

Abstract

User-generated reviews can be decomposed into fine-grained segments (e.g., sentences, clauses), each evaluating a different aspect of the principal entity (e.g., price, quality, appearance). Automatically detecting these aspects can be useful for both users and downstream opinion mining applications. Current supervised approaches for learning aspect classifiers require many fine-grained aspect labels, which are labor-intensive to obtain. And, unfortunately, unsupervised topic models often fail to capture the aspects of interest. In this work, we consider weakly supervised approaches for training aspect classifiers that only require the user to provide a small set of seed words (i.e., weakly positive indicators) for the aspects of interest. First, we show that current weakly supervised approaches do not effectively leverage the predictive power of seed words for aspect detection. Next, we propose a student-teacher approach that effectively leverages seed words in a bag-of-words classifier (teacher); in turn, we use the teacher to train a second model (student) that is potentially more powerful (e.g., a neural network that uses pre-trained word embeddings). Finally, we show that iterative co-training can be used to cope with noisy seed words, leading to both improved teacher and student models. Our proposed approach consistently outperforms previous weakly supervised approaches (by 14.1 absolute F1 points on average) in six different domains of product reviews and six multilingual datasets of restaurant reviews.

1 Introduction

A typical review of an entity on platforms such as Yelp and Amazon discusses multiple aspects of the entity (e.g., price, quality) in individual review segments (e.g., sentences, clauses). Consider for example the Amazon product review in Figure 1. The text discusses various aspects of the TV such as price, ease of use, and sound quality. Given the vast number of online reviews, both sellers and customers would benefit from automatic methods for detecting fine-grained segments that discuss particular aspects of interest. Fine-grained aspect detection is also a key task in downstream applications such as aspect-based sentiment analysis and multi-document summarization (Hu and Liu, 2004; Liu, 2012; Pontiki et al., 2016; Angelidis and Lapata, 2018).

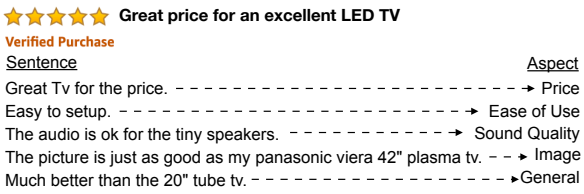

Figure 1: Example of product review with aspect annotations: each individual sentence of the review discusses a different aspect (e.g., price) of the TV.

In this work, we consider the problem of classifying individual segments of reviews to predefined aspect classes when ground truth aspect labels are not available. Indeed, reviews are often entered as unstructured, free-form text and do not come with aspect labels. Also, it is infeasible to manually obtain segment annotations for retail stores like Amazon with millions of different products. Unfortunately, fully supervised neural networks cannot be applied without aspect labels. Moreover, the topics learned by unsupervised neural topic models are not perfectly aligned with the users' aspects of interest, so substantial human effort is required for interpreting and mapping the learned topics to meaningful aspects.

Here, we investigate whether neural networks can be effectively trained under this challenging setting when only a small number of descriptive keywords, or *seed words*, are available for each

Table 1: Examples of aspects and five of their corresponding seed words in various domains (electronic products, restaurants) and languages ("EN" for English, "FR" for French, "SP" for Spanish).

aspect class. Table 1 shows examples of aspects and five of their corresponding seed words from our experimental datasets (described later in more detail). In contrast to a classification label, which is only relevant for a single segment, a seed word can implicitly provide aspect supervision to potentially many segments. We assume that the seed words have already been collected either manually or automatically. Indeed, collecting a small[1] set of seed words per aspect is typically easier than manually annotating thousands of segments for training neural networks. As we will see, even noisy seed words that are only weakly predictive of the aspect will be useful for aspect detection.

Training neural networks for segment-level aspect detection using just a few seed words is a challenging task. Indeed, as a contribution of this paper, we observe that current weakly supervised networks do not effectively leverage the predictive power of the available seed words. To address the shortcomings of previous seed word-based approaches, we propose a novel *weakly supervised* approach, which uses the available seed words in a more effective way. In particular, we consider a *student-teacher* framework, according to which a bag-of-seed-words classifier (teacher) is applied on unlabeled segments to supervise a second model (student), which can be any supervised model, including neural networks.

Our approach introduces several important contributions. First, our teacher model considers each individual seed word as a (noisy) aspect indicator, which as we will show, is more effective than previously proposed weakly supervised approaches. Second, by using only the teacher's aspect probabilities, our student generalizes better than the teacher and, as a result, the student outperforms both the teacher and previously proposed weakly supervised models. Finally, we show how iterative co-training can be used to cope with noisy seed words: the teacher effectively estimates the predictive quality of the noisy seed words in an unsupervised manner using the associated predictions by the student. Iterative co-training then leads to both improved teacher and student models. Overall, our approach consistently outperforms existing weakly supervised approaches, as we show with an experimental evaluation over six domains of product reviews and six multilingual datasets of restaurant reviews.

The rest of this paper is organized as follows. In Section 2 we review relevant work. In Section 3 we describe our proposed weakly supervised approach. In Section 4 we present our experimental setup and findings. Finally, in Section 5 we conclude and suggest future work. A preliminary version of this work was presented at the Second Learning from Limited Labeled Data Workshop (Karamanolakis et al., 2019).

2 Related Work and Problem Definition

We now review relevant work on aspect detection (Section 2.1), co-training (Section 2.2), and knowledge distillation (Section 2.3). We also define our problem of focus (Section 2.4).

2.1 Segment-Level Aspect Detection

The goal of segment-level aspect detection is to classify a segment s to K aspects of interest.

Supervised Approaches. Rule-based or traditional learning models for aspect detection have been outperformed by supervised neural networks (Liu et al., 2015; Poria et al., 2016; Zhang et al., 2018). Supervised neural networks first use an embedding function[2] (EMB) to compute a low dimensional segment representation $h = \text{EMB}(s) \in \mathbb{R}^d$ and then feed h to a classification layer[3] (CLF) to predict probabilities for the K aspect classes of interest: $p = \langle p^1, \ldots, p^K \rangle = \text{CLF}(h)$. For simplicity, we write $p = f(s)$. The parameters of the embedding function and the classification layer are learned using ground truth,

[1] In our experiments, we only consider around 30 seed words per aspect. For comparison, the vocabulary of the datasets has more than 10,000 terms.

[2] Examples of segment embedding functions are the average of word embeddings (Wieting et al., 2015; Arora et al., 2017), Recurrent Neural Networks (RNNs) (Yang et al., 2016; Wieting and Gimpel, 2017), Convolutional Neural Networks (CNNs) (Kim, 2014), self-attention blocks (Devlin et al., 2019; Radford et al., 2018), etc.

[3] The classification layer is usually a hidden layer followed by the softmax function.

segment-level aspect labels. However, aspect labels are not available in our setting, which hinders the application of supervised learning approaches.

Unsupervised Approaches. Topic models have been used to train aspect detection with unannotated documents. Recently, neural topic models (Iyyer et al., 2016; Srivastava and Sutton, 2071; He et al., 2017) have been shown to produce more coherent topics than earlier models such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003). In their Aspect Based Autoencoder (ABAE), He et al. (2017) first use segment s to predict aspect probabilities $p = f(s)$ and then use p to reconstruct an embedding h' for s as a convex combination of K aspect embeddings: $h' = \sum_{k=1}^{K} p^k A_k$, where $A_k \in \mathbb{R}^d$ is the embedding of the k-th aspect. The aspect embeddings A_k are initialized by clustering the vocabulary embeddings using k-means with K clusters. ABAE is trained by minimizing the segment reconstruction error.[4]

Unfortunately, unsupervised topic models are not effective when used directly for aspect detection. In particular, in ABAE, the K topics learned to reconstruct the segments are not necessarily aligned with the K aspects of interest. A possible fix is to first learn $K' >> K$ topics and do a K'-to-K mapping as a post-hoc step. However, this mapping requires either aspect labels or substantial human effort for interpreting topics and associating them with aspects. This mapping is nevertheless not possible if the learned topics are not aligned with the aspects.

Weakly Supervised Approaches. Weakly supervised approaches use minimal domain knowledge (instead of ground truth labels) to model meaningful aspects. In our setting, domain knowledge is given as a set of seed words for each aspect of interest (Lu et al., 2011; Lund et al., 2017; Angelidis and Lapata, 2018). Lu et al. (2011) use seed words as asymmetric priors in probabilistic topic models (including LDA). Lund et al. (2017) use LDA with fixed topic-word distributions, which are learned using seed words as "anchors" for topic inference (Arora et al., 2013). Neither of these two approaches can be directly applied into more recent neural networks for aspect detection. Angelidis and Lapata (2018) recently proposed a weakly supervised extension of the unsupervised ABAE. Their model, named Multi-seed Aspect Extractor, or MATE, initializes the aspect embedding A_k using the weighted average of the corresponding seed word embeddings (instead of the k-means centroids). To guarantee that the aspect embeddings will still be aligned with the K aspects of interest after training, Angelidis and Lapata (2018) keep the aspect and word embeddings fixed throughout training. In this work, we will show that the predictive power of seed words can be leveraged more effectively by considering each individual seed word as a more direct source of supervision during training.

[4]The reconstruction error can be efficiently estimated using contrastive max-margin objectives (Weston et al., 2011; Pennington et al., 2014).

2.2 Co-training

Co-training (Blum and Mitchell, 1998) is a classic multi-view learning method for semi-supervised learning. In co-training, classifiers over different feature spaces are encouraged to agree in their predictions on a large pool of unlabeled examples. Blum and Mitchell (1998) justify co-training in a setting where the different views are conditionally independent given the label. Several subsequent works have relaxed this assumption and shown co-training to be effective in much more general settings (Balcan et al., 2005; Chen et al., 2011; Collins and Singer, 1999; Clark et al., 2018). Co-training is also related to self-training (or bootstrapping) (Yarowsky, 1995), which trains a classifier using its own predictions and has been successfully applied for various NLP tasks (Collins and Singer, 1999; McClosky et al., 2006).

Recent research has successfully revisited these general ideas to solve NLP problems with modern deep learning methods. Clark et al. (2018) propose "cross-view training" for sequence modeling tasks by modifying Bi-LSTMs for *semi-supervised* learning. Ruder and Plank (2018) show that classic bootstrapping approaches such as tri-training (Zhou and Li, 2005) can be effectively integrated in neural networks for semi-supervised learning under domain shift. Our work provides further evidence that co-training can be effectively integrated into neural networks and combined with recent transfer learning approaches for NLP (Dai and Le, 2015; Howard and Ruder, 2018; Devlin et al., 2019; Radford et al., 2018), in a substantially different, *weakly supervised* setting where no ground-truth labels but only a few seed words are available for training.

Variable	Description
s	Segment (e.g., sentence) of a text review
K	Number of aspects of interest
D	Total number of seed words
$G_i \quad (i = 1, \ldots, K)$	Set of seed words for the i-th aspect
$h \in \mathbb{R}^d$	Segment embedding (student)
$c \in \mathbb{N}^D$	Bag-of-seed-words representation of s
$p = \langle p^1, \ldots, p^K \rangle$	Student's aspect predictions
$q = \langle q^1, \ldots, q^K \rangle$	Teacher's aspect predictions

Table 2: Notation.

2.3 Knowledge Distillation

Our approach is also related to the "knowledge distillation" framework (Buciluǎ et al., 2006; Ba and Caruana, 2014; Hinton et al., 2015), which has received considerable attention recently (Lopez-Paz et al., 2016; Kim and Rush, 2016; Furlanello et al., 2018; Wang, 2019). Traditional knowledge distillation aims at compressing a cumbersome model (teacher) to a simpler model (student) by training the student using both ground truth labels and the soft predictions of the teacher in a distillation objective. Our work also considers a student-teacher architecture and the distillation objective but under a considerably different, weakly supervised setting: (1) we do not use any labels for training and (2) we create conditions that allow the student to outperform the teacher; in turn, (3) we can use the student's predictions to learn a better teacher under co-training.

2.4 Problem Definition

Consider a corpus of text reviews from an entity domain (e.g., televisions, restaurants). Each review is split into segments (e.g., sentences, clauses). We also consider K pre-defined aspects of interest $(1, \ldots, K)$, including the "General" aspect, which we assume is the K-th aspect for simplicity. Different segments of the same review may be associated with different aspects but ground-truth aspect labels are *not* available for training. Instead, a small number of seed words G_k are provided for each aspect $k \in [K]$. Our goal is to use the corpus of training reviews and the available seed words $G = (G_1, \ldots, G_K)$ to train a classifier, which, given an unseen test segment s, predicts K aspect probabilities $p = \langle p^1, \ldots, p^K \rangle$.

3 Our Student-Teacher Approach

We now describe our weakly supervised framework for aspect detection. We consider a student-teacher architecture (Figure 2), where the teacher

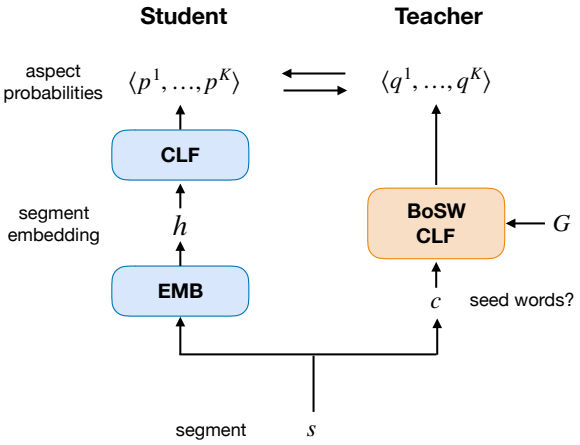

Figure 2: Our student-teacher approach for segment-level aspect detection using seed words.

is a bag-of-words classifier based solely on the provided seed words (i.e., a "bag-of-seed-words" classifier), and the student is an embedding-based neural network trained on data "softly" labeled by the teacher (as in the distillation objective). In the rest of this section, we describe the individual components of our student-teacher architecture and our proposed algorithm for performing updates.

3.1 Teacher: A Bag-of-Seed-Words Classifier

Our teacher model leverages the available seed words G that are predictive of the K aspects. Let D denote the total number of seed words in G. We can represent a segment s_i using a bag-of-seed-words representation $c_i \in \mathbb{N}^D$, where c_i^j encodes the number of times the j-th seed word occurs in s_i. (Note that c_i ignores the non-seed words.) The teacher's prediction for the k-th aspect is:

$$q_i^k = \frac{\exp(\sum_{j=1}^{D} \mathbb{1}\{j \in G_k\} \cdot c_i^j)}{\sum_{k'} \exp(\sum_{j=1}^{D} \mathbb{1}\{j \in G_{k'}\} \cdot c_i^j)}. \quad (1)$$

If no seed word appears in s, then the teacher predicts the "General" aspect by setting $q_i^K = 1$. Under this configuration the teacher uses seed words in a direct and intuitive way: it predicts aspect probabilities for the k-th aspect, which are proportional to the counts of the seed words under G_k, while if no seed word occurs in s, it predicts the "General" aspect. The classifier receives c_i as input and predicts $q_i = \langle q_i^1, \ldots, q_i^K \rangle$.

Although the teacher only uses seed words to predict the aspect of a segment, we also expect

non-seed words to carry predictive power. Next, we describe the student network that learns to associate non-seed words with aspects.

3.2 Student: An Embedding-Based Network

Our student model is an embedding-based neural network: a segment is first embedded ($h_i = \text{EMB}(s_i) \in \mathbb{R}^d$) and then classified to the K aspects ($p_i = \text{CLF}(h_i)$) (see Section 2.1). The student does not use ground-truth aspect labels for training. Instead, it is trained by optimizing the distillation objective, i.e., the cross entropy between the teacher's (soft) predictions and the student's predictions:

$$H(q_i, p_i) = -\sum_k q_i^k \log p_i^k \quad (2)$$

While the teacher only uses the seed words in s_i to form its prediction q_i, the student uses all the words in s_i. Thus, using the distillation loss for training, the student learns to use both seed words and non-seed words to predict aspects. As a result, the student is able to generalize better than the teacher and *predict aspects even in segments that do not contain any seed words*. To regularize the student model, we apply L2 regularization to the classifier's weights and dropout regularization to the word embeddings (Srivastava et al., 2014). As we will show in Section 4, our student with this configuration outperforms the teacher in aspect prediction.

3.3 Iterative Co-Training

In this section, we describe our iterative co-training algorithm to cope with noisy seed words. The teacher in Section 3.1 considers each seed word equally, which can be problematic because not all seed words are equally good for predicting an aspect. In this work, we propose to estimate the predictive quality of each seed word in an unsupervised way. Our approach is inspired in the Model Bootstrapped Expectation Maximization (MBEM) algorithm of Khetan et al. (2018). MBEM is guaranteed to converge (under mild conditions) when the number of training data is sufficiently large and the worker quality is sufficiently high. Here, we treat seed words as "noisy annotators" and adopt an iterative estimation procedure similar to MBEM, as we describe next.

We model the predictive quality of the j-th seed word as a weight vector $z_j = \langle z_j^1, \ldots, z_j^K \rangle$, where

Algorithm 1 Iterative Seed Word Distillation

Input: $\{s_i\}_{i\in[N]}$, D seed words grouped into K disjoint sets $G = (G_1, \ldots, G_K)$
Output: $\hat{f}$: predictor function for segment-level aspect detection

Predict $\{q_i\}_{i\in[N]}$ (Eq. (1)) ▷ *Apply teacher*
Repeat until convergence criterion
  Learn $\hat{f}$ (Eq. (2)) ▷ *Train student*
  Predict $\{p_i = \hat{f}(s_i)\}_{i\in[N]}$ ▷ *Apply student*
  Update $\{z_j\}_{j\in[D]}$ (Eq. (4)) ▷ *Update teacher*
  Predict $\{q_i\}_{i\in[N]}$ (Eq. (3)) ▷ *Apply teacher*

z_j^k measures the strength of the association with the k-th aspect. We thus change the teacher to consider seed word quality. In particular, we replace Equation (1) by:

$$q_i^k = \frac{\exp \sum_{j=1}^{D} \mathbb{1}\{j \in G_k\} \cdot \hat{z}_j^k \cdot c_i^j}{\sum_{k'} \exp \sum_{j=1}^{D} \mathbb{1}\{j \in G_{k'}\} \cdot \hat{z}_j^{k'} \cdot c_i^j}, \quad (3)$$

where $\hat{z}_j$ is the current estimate of z_j. As no ground-truth labels are available, we follow Khetan et al. (2018) and estimate z_j via Maximum Likelihood Estimation using the student's predictions as the current estimate of the ground truth labels. In particular, we assume that the prediction of the student for a training segment s_i is $t_i = \text{argmax}_k\, p_i^k$. Then, for each seed word we compute the quality estimate for the k-th aspect using the student's predictions for N segments:

$$\hat{z}_j^k = \frac{\sum_{i=1}^{N} \mathbb{1}\{c_i^j > 0\} \mathbb{1}\{t_i = k\}}{\sum_{k'} \sum_{i=1}^{N} \mathbb{1}\{c_i^j > 0\} \mathbb{1}\{t_i = k'\}}. \quad (4)$$

According to Equation (4), the quality of the j-th seed word is estimated according to the student-teacher agreement on segments where the seed word appears.

Building upon the previous ideas, we present our Iterative Seed Word Distillation (ISWD) algorithm for effectively leveraging the seed words for fine-grained aspect detection. Each round of ISWD consists of the following steps (Algorithm 1): (1) we apply the teacher on unlabeled training segments to get predictions q_i (without considering seed word qualities); (2) we train the student using the teacher's predictions in the distillation objective of Equation (2);[5] (3) we apply the student in the training data to get predictions p_i; and

[5] Note that the quality-aware loss function proposed

(4) we update the seed word quality parameters using the student's predictions in Equation (4).

In contrast to MATE, which uses the validation set (with aspect labels) to estimate seed weights in an initialization step, our proposed method is an unsupervised approach to modeling and adapting the seed word quality during training. We stop this iterative procedure after the disagreement between the student's and teacher's hard predictions in the training data stops decreasing. We empirically observe that 2-3 rounds are sufficient to satisfy this criterion. This observation also agrees with Khetan et al. (2018), who only run their algorithm for two rounds.

4 Experiments

We evaluate our approach to aspect detection on several datasets of product and restaurant reviews.

4.1 Experimental Settings

Datasets. We train and evaluate our models on Amazon product reviews for six domains (Laptop Bags, Keyboards, Boots, Bluetooth Headsets, Televisions, and Vacuums) from the OPOSUM dataset (Angelidis and Lapata, 2018), and on restaurant reviews in six languages (English, Spanish, French, Russian, Dutch, Turkish) from the SemEval-2016 Aspect-based Sentiment Analysis task (Pontiki et al., 2016). Aspect labels (9-class for product reviews and 12-class for restaurant reviews) are available for each segment[6] of the validation and test sets. The restaurant reviews also come with training aspect labels, which we only use for training the fully supervised models. For a fair comparison, we use exactly the same 30 seed words (per aspect and domain) used in Angelidis and Lapata (2018) for the product reviews and use the same extraction method described in Angelidis and Lapata (2018) to extract 30 seed words for the restaurant reviews. See the supplementary material for more dataset details.

Experimental Procedure. For a fair comparison, we use exactly the same pre-processing (tokenization, stemming, and word embedding) and evaluation procedure as in Angelidis and Lapata (2018). For each domain, we train our model on the training set without using any aspect labels, and only use the seed words G via the teacher. For each model, we report the average test performance over 5 different runs with the parameter configuration that achieves best validation performance. As evaluation metric, we use the micro-averaged F1.

Model Configuration. For the student network, we experiment with various modeling choices for segment representations: bag-of-words (BOW) classifiers, the unweighted average of word2vec embeddings (W2V), the weighted average of word2vec embeddings using bilinear attention (Luong et al., 2015) (same setting as He et al. (2017); Angelidis and Lapata (2018)), and the average of contextualized word representations obtained from the second-to-last layer of the pre-trained (self-attention based) BERT model (Devlin et al., 2019), which uses multiple self-attention layers (Vaswani et al., 2017) and has been shown to achieve state-of-the-art performance in many downstream NLP applications. For the English product reviews, we use the base uncased BERT model. For the multilingual restaurant reviews, we use the multilingual cased BERT model.[7]

In iterative co-training, we train the student network to convergence in each iteration (which may require more than one epoch over the training data). Moreover, we observed that the iterative process is more stable when we interpolate between weights of the previous iteration and the estimated updates instead of directly applying the estimated seed weight updates (according to Equation (3)).

Model Comparison. For a robust evaluation of our approach, we compare the following models and baselines:

- **LDA-Anchors:** The topic model of Lund et al. (2017) using seed words as "anchors."
- **ABAE:** The unsupervised autoencoder of He et al. (2017), where the learned topics were manually mapped to aspects.
- **MATE-*:** The MATE model of Angelidis and Lapata (2018) with various configurations: initialization of the aspect embeddings

in Khetan et al. (2018), which is an alternative form of noise-aware loss functions (Natarajan et al., 2013), is equivalent to our distillation loss: using the log loss as $l(.)$ in Equation (4) of Khetan et al. (2018) yields the cross entropy loss.

[6] In product reviews, elementary discourse units (EDUs) are used as segments. In restaurant reviews, sentences are used as segments.

[7] Both models can be found in https://github.com/google-research/bert/blob/master/multilingual.md. The multilingual cased BERT model is recommended by the authors instead of the multilingual uncased BERT model.

4.2 Experimental Results

Tables 3 and 4 show the results for aspect detection on product and restaurant reviews, respectively. The rightmost column of each table reports the average performance across the 6 domains/languages.

[8]The multi-task training objective in MATE requires datasets from different domains but same language, thus it cannot be applied in our datasets of restaurant reviews.

MATE-* models outperform ABAE. Using the seed words to initialize aspect embeddings leads to more accurate aspect predictions than mapping the learned (unsupervised) topics to aspects.

LDA-Anchors performs worse than MATE-* models. Although averages of seed words were used as "anchors" in the "Tandem Anchoring" algorithm, we observed that the learned topics did not correspond to our aspects of interest.

The teacher effectively leverages seed words. By leveraging the seed words in a more direct way, Teacher is able to outperform the MATE-* models. Thus, we can use Teacher's predictions as supervision for the student, as we describe next.

The student outperforms the teacher. Student-BoW outperforms Teacher: the two models have the same architecture but Teacher only considers seed words; regularizing Student's weights encourages Student to mimic the noisy aspect predictions of Teacher by also considering non-seed words for aspect detection. The benefits of our dis-

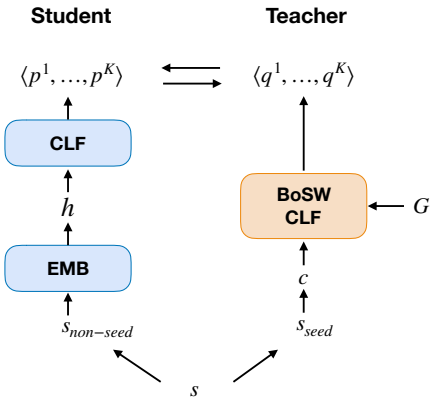

Figure 3: Our weakly supervised co-training approach when seed words are removed from the student's input (RSW baseline). Segment $s_{non-seed}$ is an edited version of s, where we replace each seed word in s by an "UNK" special token (like out-of-vocabulary words).

tillation approach are highlighted using neural networks with word embeddings. Student-W2V outperforms both Teacher and Student-BoW, showing that obtaining segment representations as the average of word embeddings is more effective than using bag-of-words representations for this task.

The student outperforms previous weakly supervised models even in one co-training round. Student-ATT outperforms MATE-unweighted (by 36.3% in product reviews and by 52.2% in restaurant reviews) even in a single co-training round: although the two models use exactly the same seed words (without weights), pre-trained word embeddings, EMB function, and CLF function, our student-teacher approach leverages the available seed words more effectively as noisy supervision than just for initialization. Also, using our approach, we can explore more powerful methods for segment embedding without the constraint of a fixed word embedding space. Indeed, using contextualized word representations in Student-BERT leads to the best performance over all models.

As expected, our weakly supervised approach does not outperform the fully supervised (*-Gold) models. However, our approach substantially reduces the performance gap between weakly supervised approaches and fully supervised approaches by 62%. The benefits of our student-teacher approach are consistent across all datasets, highlighting the predictive power of seed words across different domains and languages.

The student leverages non-seed words. To better understand the extent to which non-seed words can predict the aspects of interest, we experiment with completely removing the seed words from Student-W2V's input during training (Student-W2V-RSW method; see Figure 3). Thus, in this setting, Student-W2V-RSW is forced to only use non-seed words to detect aspects. Note that the co-training assumption of conditionally independent views (Blum and Mitchell, 1998) is satisfied in this setting, where Teacher is only using seed words and Student-W2V is only using non-seed words. Student-W2V-RSW effectively learns to use non-seed words to predict aspects and performs better than Teacher (but worse than Student-W2V, which considers both seed and non-seed words). For additional ablation experiments, see the supplementary material.

Method	Initial	Iterative

Table 5: Micro-averaged F1 scores during the first round (middle column) and after iterative co-training (right column) in product reviews (top) and restaurant reviews (bottom).

Iterative co-training copes with noisy words. Further performance improvement in Teacher and Student-* can be observed with the iterative co-training procedure of Section 3.3. Table 5 reports the performance of Teacher and Student-* after co-training for both product reviews (top) and English restaurant reviews (bottom). (For more detailed, per-domain results, see the supplementary material.) Compared to the initial version of Teacher that does not model the quality of the seed words, iterative co-training leads to estimates of seed word quality that improve Teacher's performance up to 12.3% (in product reviews using Student-BERT).

A better teacher leads to a better student. Co-training leads to improved student performance in both datasets (Table 5). Compared to MATE, which uses the validation set to estimate the seed weights as a pre-processing step, we estimate and iteratively adapt the seed weights using the

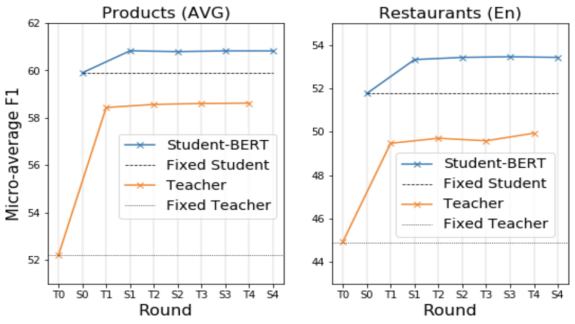

Figure 4: Co-training performance for each round reported for product reviews (left) and restaurant reviews (right). T<i>and S<i>correspond to the teacher's and student's performance, respectively, at the i-th round.

student-teacher disagreement, which substantially improves performance. Across the 12 datasets, Student-BERT leads to an average absolute increase of 14.1 F1 points.

Figure 4 plots Teacher's and Student-BERT's performance after each round of co-training. Most of the improvement for both Teacher and Student-BERT is gained in the first two rounds of co-training: "T0" (in Figure 4) is the initial teacher, while "T1" is the teacher with estimates of seed word qualities, which leads to more accurate predictions, e.g., in segments with multiple seed words from different aspects.

5 Conclusions and Future Work

We presented a weakly supervised approach for leveraging a small number of seed words (instead of ground truth aspect labels) for segment-level aspect detection. Our student-teacher approach leverages seed words more directly and effectively than previous weakly supervised approaches. The teacher model provides weak supervision to a student model, which generalizes better than the teacher by also considering non-seed words and by using pre-trained word embeddings. We further show that iterative co-training lets us estimate the quality of the (possibly noisy) seed words. This leads to a better teacher and, in turn, a better student. Our proposed method consistently outperforms previous weakly supervised methods in 12 datasets, allowing for seed words from various domains and languages to be leveraged for aspect detection. Our student-teacher approach could be applied for any classification task for which a small set of seed words describe each class. In future work, we plan to extend our framework to multi-task settings, and to incorporate interaction to learn better seed words.

Integrating Text and Image: Determining Multimodal Document Intent in Instagram Posts

Abstract

Computing author intent from multimodal data like Instagram posts requires modeling a complex relationship between text and image. For example, a caption might evoke an ironic contrast with the image, so neither caption nor image is a mere transcript of the other. Instead they combine—via what has been called *meaning multiplication* Bateman (2014)—to create a new meaning that has a more complex relation to the literal meanings of text and image. Here we introduce a multimodal dataset of 1299 Instagram posts labeled for three orthogonal taxonomies: the authorial intent behind the image-caption pair, the contextual relationship between the literal meanings of the image and caption, and the semiotic relationship between the signified meanings of the image and caption. We build a baseline deep multimodal classifier to validate the taxonomy, showing that employing both text and image improves intent detection by 9.6% compared to using only the image modality, demonstrating the commonality of non-intersective meaning multiplication. The gain with multimodality is greatest when the image and caption diverge semiotically. Our dataset offers a new resource for the study of the rich meanings that result from pairing text and image.

1 Introduction

Multimodal social platforms such as Instagram let content creators combine visual and textual modalities. The resulting widespread use of text+image makes interpreting author intent in multimodal messages an important task for NLP for document understanding.

There are many recent language processing studies of images accompanied by basic text labels or captions (Chen et al., 2015; Faghri et al., 2018, inter alia). But prior work on image–text pairs has generally been asymmetric, regarding either image or text as the primary content, and the other as mere complement. Scholars from semiotics as well as computer science have pointed out that this is insufficient; often text and image are not combined by a simple addition or intersection of the component meanings (Bateman, 2014; Marsh and Domas White, 2003; Zhang et al., 2018).

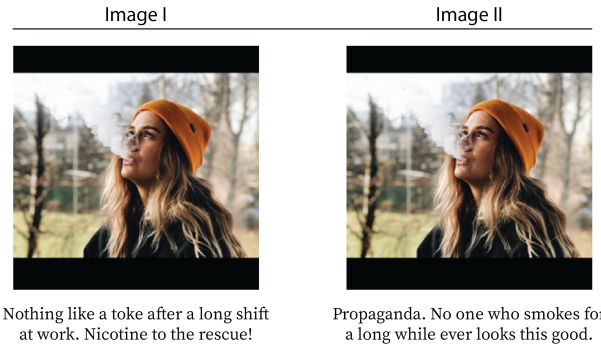

Figure 1: Image-Caption meaning multiplication: A change in the caption completely changes the overall meaning of the image-caption pair.

Rather, determining author intent with text+image content requires a richer kind of meaning composition that has been called *meaning multiplication* (Bateman, 2014): the creation of new meaning through integrating image and text. Meaning multiplication includes simple meaning intersection or concatenation (a picture of a dog with the label "dog", or the label "Rufus"). But it also includes more sophisticated kinds of composition, such as irony or indirection, where the text+image integration requires inference that creates a new meaning. For example in Figure 1, a picture of a young woman smoking is given two different hypothetical captions that result in different composed meanings. In Pairing I, the image and text are parallel, with the picture

used to highlight relaxation through smoking. Pairing II uses the tension between her image and the implications of her actions to highlight the dangers of smoking.

Computational models that detect complex relationships between text and image and how they cue author intent could be significant for many areas, including the computational study of advertising, the detection and study of propaganda, and our deeper understanding of many other kinds of persuasive text, as well as allowing NLP applications to news media to move beyond pure text.

To better understand author intent given such meaning multiplication, we create three novel taxonomies related to the relationship between text and image and their combination/multiplication in Instagram posts, designed by modifying existing taxonomies (Bateman, 2014; Marsh and Domas White, 2003) from semiotics, rhetoric, and media studies. Our taxonomies measure the **authorial intent** behind the image-caption pair and two kinds of text-image relations: the **contextual relationship** between the literal meanings of the image and caption, and the **semiotic relationship** between the signified meanings of the image and caption. We then introduce a new dataset, MDID (Multimodal Document Intent Dataset), with 1299 Instagram posts covering a variety of topics, annotated with labels from our three taxonomies.

Finally, we build a deep neural network model for annotating Instagram posts with the labels from each taxonomy, and show that combining text and image leads to better classification, especially when the caption and the image diverge. While our goal here is to establish a computational framework for investigating multimodal meaning multiplication, in other pilot work we have begun to consider some applications, such as using intent for social media event detection and for user engagement prediction. Both these directions highlight the importance of the intent and semiotic structure of a social media posting in determining its influence on the social network as a whole.

2 Prior Work

A wide variety of work in multiple fields has explored the relationship between text and image and extracting meaning, although often assigning a subordinate role to either text or images, rather than the symmetric relationship in media such as Instagram posts. The earliest work in the Barthesian tradition focuses on advertisements, in which the text serves as merely another connotative aspect to be incorporated into a larger connotative meaning (Heath et al., 1977). Marsh and Domas White (2003) offer a taxonomy of the relationship between image and text by considering image/illustration pairs found in textbooks or manuals. We draw on their taxonomy, although as we will see, the connotational aspects of Instagram posts require some additions.

For our model of speaker intent, we draw on the classic concept of illocutionary acts (Austin, 1962) to develop a new taxonomy of illocutionary acts focused on the kinds of intentions that tend to occur on social media. For example, we rarely see commissive posts on Instagram and Facebook because of the focus on information sharing and constructions of self-image.

Computational approaches to multi-modal document understanding have focused on key problems such as image captioning (Chen et al., 2015; Faghri et al., 2018), visual question answering (Goyal et al., 2017; Zellers et al., 2018; Hudson and Manning, 2019), or extracting the literal or connotative meaning of a post (Soleymani et al., 2017). More recent work has explored the role of image as context for interaction and pragmatics, either in dialog (Mostafazadeh et al., 2016, 2017), or as a prompt for users to generate descriptions (Bisk et al., 2019). Another important direction has looked at an image's *perlocutionary force* (how it is perceived by its audience), including aspects such as memorability (Khosla et al., 2015), saliency (Bylinskii et al., 2018), popularity (Khosla et al., 2014) and virality (Deza and Parikh, 2015; Alameda-Pineda et al., 2017).

Some prior work has focused on intention. Joo et al. (2014) and Huang and Kovashka (2016) study prediction of intent behind politician portraits in the news. Hussain et al. (2017) study the understanding of image and video advertisements, predicting topic, sentiment, and intent. Alikhani et al. (2019) introduce a corpus of the coherence relationships between recipe text and images. Our work builds on Siddiquie et al. (2015), who focused on a single type of intent (detecting politically persuasive video on the internet) and even more closely on Zhang et al. (2018), who study visual rhetoric as interaction between the image and the text slogan in advertisements. They categorize image-text relationships into par-

allel equivalent (image-text deliver same point at equal strength), parallel non-equivalent (image-text deliver the same point at different levels) and non-parallel (text or image alone is insufficient in point delivery). They also identify the novel issue of understanding the complex, non-literal ways in which text and image interacts. Weiland et al. (2018) study the non-literal meaning conveyed by image-caption pairs and draw on a knowledge-base to generate the gist of the image-caption pair.

3 Taxonomies

As Berger (1972) points out in discussing the relationship between one image and its caption:

> It is hard to define exactly how the words have changed the image but undoubtedly they have. (p. 28).

We propose three taxonomies in an attempt to answer Berger's implicit question, two (contextual and semiotic) to capture different aspects of the relationship between the image and the caption, and one to capture speaker intent.

3.1 Intent Taxonomy

The proposed intent taxonomy is a generalization and elaboration of existing rhetorical categories pertaining to illocution, that targets multimodal social networks like Instagram. We developed a set of eight illocutionary intents from our examination and clustering of a large body of representative Instagram content, informed by previous studies of intent in Instagram posts. There is some overlap between categories; to bound the burden on the annotators, however, we asked them to identify intent for the image-caption pairing as a whole and not for the individual components

For example drawing on Goffman's idea of the presentation of self (Goffman, 1978), Mahoney et al. (2016) in their study of Scottish political Instagram posts define acts like Presentation of Self, which, following Hogan (2010) we refer to as *exhibition*, or Personal Political Expression, which we generalize to *advocative*. Following are our final eight labels; Figure 2 shows some examples.

1. **advocative**: advocate for a figure, idea, movement, etc.
2. **promotive**: promote events, products, organizations etc.

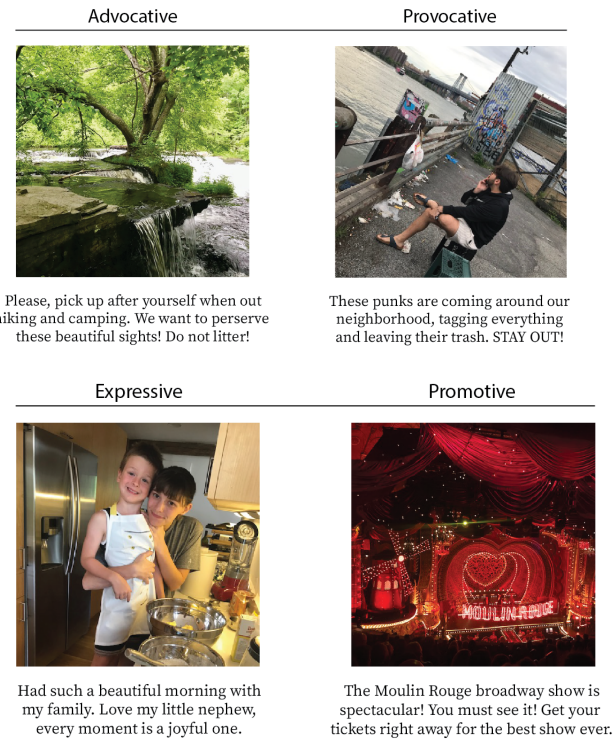

Figure 2: Examples of multimodal document intent: advocative, provocative, expressive and promotive content

3. **exhibitionist**: create a self-image reflecting the person, state etc. for the user using selfies, pictures of belongings (e.g. pets, clothes) etc.
4. **expressive**: express emotion, attachment, or admiration at an external entity or group.
5. **informative**: relay information regarding a subject or event using factual language.
6. **entertainment**: entertain using art, humor, memes, etc.
7. **provocative/discrimination**: directly attack an individual or group.
8. **provocative/controversial**: be shocking.

3.2 The Contextual Taxonomy

The contextual relationship taxonomy captures the relationship between the literal meanings of the image and text. We draw on the three top-level categories of the Marsh and Domas White (2003) taxonomy, which distinguished images that are minimally related to the text, highly related to the text, and related but going beyond it. These three classes— reflecting Marsh et al.'s primary interest in illustration—frame the image only as subordinate to the text. We slightly generalize the three

Intent	
Category	*# Samples*
Provocative	84
Informative	119
Advocative	97
Entertainment	310
Expositive	237
Expressive	95
Promotive	162

Semiotic	
Category	*# Samples*
Divergent	115
Additive	277
Parallel	712

Contextual Relationship	
Category	*# Samples*
Minimal	372
Close	585
Transcendent	147

Table 1: Counts of different labels in the Multimodal Document Intent Dataset (MDID).

top-level categories taxonomy of Marsh and Domas White (2003) to make them symmetric for the Instagram domain:

Minimal Relationship: The literal meanings of the caption and image overlap very little. For example, a selfie of a person at a waterfall with the caption "selfie". While such a terse caption does nevertheless convey a lot of information, it still leaves out details such as the location, description of the scene, etc. that are found in typical loquacious Instagram captions.

Close Relationship: The literal meanings of the caption and the image overlap considerably. For example, a selfie of a person at a crowded waterfall, with the caption "Selfie at Hemlock falls on a crowded sunny day".

Transcendent Relationship: The literal meaning of one modality picks up and expands on the literal meaning of the other. For example, a selfie of a person at a crowded waterfall with the caption "Selfie at Hemlock Falls on a sunny and crowded day. Hemlock falls is a popular picnic spot. There are hiking and biking trails, and a great restaurant 3 miles down the road ...".

Note that while the labels "minimal" and "close" could be thought of as lying on a continuous scale indicating semantic overlap, the label "transcendent" indicates an expansion of the meaning that cannot be captured by such a continuous scale.

3.3 The Semiotic Taxonomy

The contextual taxonomy described above does not deal with the more complex forms of "meaning multiplication" illustrated in Figure 1. For example, an image of three frolicking puppies with the caption "My happy family," sends a message of pride in one's pets that is not directly reflected in either modality taken by itself. First, it forces the reader to step back and consider what is being signified by the image and the caption, in effect offering a meta-comment on the text-image relation. Second, there is a tension between what is signified (a family and a litter of young animals respectively) that results in a richer idiomatic meaning.

Our third taxonomy therefore captures the relationship between what is *signified* by the respective modalities, their *semiotics*. We draw on the earlier 3-way distinction of Kloepfer (1977) as modeled by Bateman (2014) and the two-way (parallel vs. non-parallel) distinction of Zhang et al. (2018) to classify the semiotic relationship of image/text pairs as divergent, parallel and additive. A *divergent* relationship occurs when the image and text semiotics pull in opposite directions, creating a gap between the meanings suggested by the image and text. A *parallel* relationship occurs when the image and text independently contribute to the same meaning. An *additive* relationship occurs when the image and text semiotics amplify or modify each other.

The semiotic classification is not always homologous to the contextual. For example, an image of a mother feeding her baby with a caption "My new small business needs a lot of tender loving care", would have a minimal contextual relationship. Yet because both signify loving care and the image intensifies the caption's sentiment, the semiotic relationship is additive. Or a lavish formal farewell scene at an airport with the caption "Parting is such sweet sorrow", has a close contextual relationship because of the high overlap in literal meaning, but the semiotics would be additive, not parallel, since the image shows only the leave-taking, while the caption suggests love (or ironic lack thereof) for the person leaving.

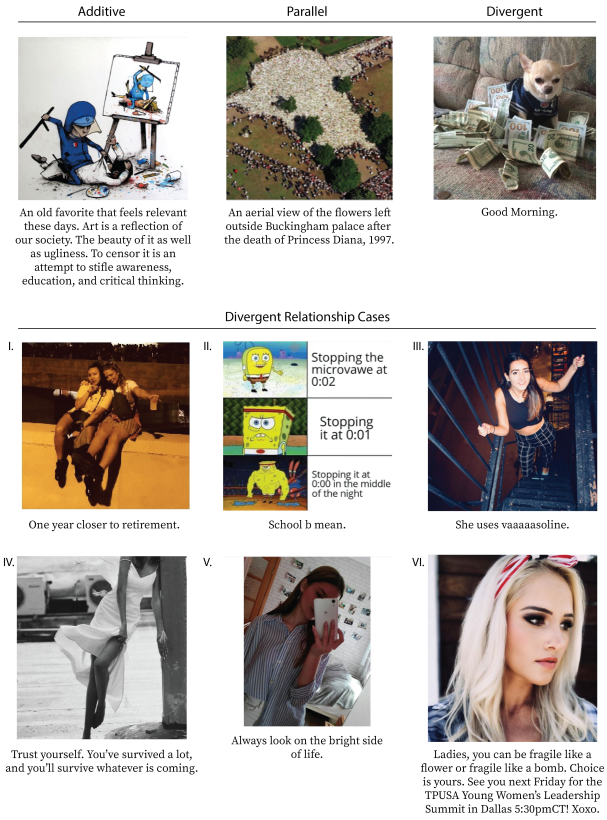

Figure 3: The top three images exemplify the semiotic categories. Images I-VI show instances of divergent semiotic relationships.

Figure 3 further illustrates the proposed semiotic classification. The first three image-caption pairs (ICP's) exemplify the three semiotic relationships. To give further insights into the rich complexity of the divergent category, the six ICP's below showcase the kinds of divergent relationships we observed most frequently on Instagram.

ICP I exploits the tension between the reference to retirement expressed in the caption and the youth projected by the two young women in the image to convey irony and thus humor in what is perhaps a birthday greeting or announcement. Many ironic and humorous posts exhibit divergent semiotic relationships. ICP II has the structure of a classic Instagram meme, where the focus is on the image, and the caption is completely unrelated to the image. This is also exhibited in the divergent "Good Morning" caption in the top row. ICP III is an example of a divergent semiotic relationship within an exhibitionist post. A popular communicative practice on Instagram is to combine selfies with a caption that is some sort of inside joke. The inside joke in ICP III is a lyric from a song a group of friends found funny and discussed the night this photo was taken. ICP IV is an aesthetic photo of a young woman, paired with a caption that has no semantic elements in common with the photo. The caption may be a prose excerpt, the author's reflection on what the image made them think or feel, or perhaps just a pairing of pleasant visual stimulus with pleasant literary material. This divergent relationship is often found in photography, artistic and other entertainment posts. ICP V uses one of the most common divergent relationships, in which exhibitionist visual material is paired with reflections or motivational captions. ICP V is thus similar to ICP III, but without the inside jokes/hidden meanings common to ICP III. ICP VI is an exhibitionist post that seems to be common recently among public figures on Instagram. The image appears to be a classic selfie or often a professionally taken image of the individual, but the caption refers to that person's opinions or agenda(s). This relationship is divergent—there are no common semantic elements in the image and caption—but the pair paints a picture of the individual's current state or future plans.

4 The MDID Dataset

Our dataset, MDID (the *Multimodal Document Intent Dataset*) consists of 1299 public Instagram posts that we collected with the goal of developing a rich and diverse set of posts for each of the eight illocutionary types in our intent taxonomy. For each intent we collected at least 16 hashtags or users likely to yield a high proportion of posts that could be labeled by that heading.

For the *advocative* intent, we selected mostly hashtags advocating and spanning political or social ideology such as #pride and #maga. For the *promotive* intent we relied on the #ad tag that Instagram has recently begun requiring for sponsored posts. For *exhibitionist* intent we used tags that focused on the self as the most important aspect of the post such as #selfie and #ootd (outfit of the day). The *expressive* posts were retrieved via tags that actively expressed a stance or an affective intent, such as #lovehim or #merrychristmas. Informative posts were taken from informative accounts such as news websites. Entertainment posts drew on an eclectic group of tags such as #meme, #earthporn, #fatalframes. Finally, provocative posts were extracted via tags that either expressed a controversial or provocative message or that would draw people into being influ-

enced or provoked by the post (#redpill, #antifa, #eattherich, #snowflake).

Data Labeling: Data was pre-processed (for example to convert all albums to single image-caption pairs). We developed a simple annotation toolkit that displayed an image–caption pair and asked the annotator to confirm whether the pair was relevant (contains both an image and text in English) and if so to identify the post's intent (advocative, promotive, exhibitionist, expressive, informative, entertainment, provocative), contextual relationship (minimal, close, transcendent), and semiotic relationship (divergent, parallel, additive). Two of the authors collaborated on the labelers manual and then labeled the data by consensus, and any label on which the authors disagreed after discussion was removed. Dataset statistics are shown in Table 1; see https://www.ksikka.com/document_intent.html for the data.

5 Computational Model

We train and test a deep convolutional neural network (DCNN) model on the dataset, both to offer a baseline model for users of the dataset, and to further explore our hypothesis about meaning multiplication.

Our model can take as input either image (Img), text (Txt) or both (Img + Txt), and consists of modality specific encoders, a fusion layer, and a class prediction layer. We use the ResNet-18 network pre-trained on ImageNet as the image encoder (He et al., 2016). For encoding captions, we use a standard pipeline that employs a RNN model on word embeddings. We experiment with both word2vec type (word token-based) embeddings trained from scratch (Mikolov et al., 2013) and pre-trained character-based contextual embeddings (ELMo) (Peters et al., 2018). For our purpose ELMo character embeddings are more useful since they increase robustness to noisy and often misspelled Instagram captions. For the combined model, we implement a simple fusion strategy that first linearly projects encoded vectors from both the modalities in the same embedding space and then adds the two vectors. Although naive, this strategy has been shown to be effective at a variety of tasks such as Visual Question Answering (Nguyen and Okatani, 2018) and image-caption matching (Ahuja et al., 2018). We then use the fused vector to predict class-wise scores using a fully connected layer.

6 Experiments

We evaluate our models on predicting intent, semiotic relationships, and image-text relationships from Instagram posts, using image only, text only, and both modalities.

6.1 Dataset, Evaluation and Implementation

We use the 1299-sample MDID dataset (section 4). We only use corresponding image and text information for each post and do not use other meta-data to preserve the focus on image-caption joint meaning. We perform basic pre-processing on the captions such as removing stopwords and non-alphanumeric characters. We do not perform any pre-processing for images.

Due to the small dataset, we perform 5-fold cross-validation for our experiments reporting average performance across all splits. We report classification accuracy (ACC) and also area under the ROC curve (AUC) (since AUC is more robust to class-skew), using macro-average across all classes (Jeni et al., 2013; Stager et al., 2006).

We use a pre-trained ResNet-18 model as the image encoder. For word token based embeddings we use 300 dimensional vectors trained from scratch. For ELMo we use a publicly available API [1] and use a pre-trained model with two layers resulting in a 2048 dimensional input. We use a bi-directional GRU as the RNN model with 256 dimensional hidden layers. We set the dimensionality of the common embedding space in the fusion layer to 128. In case there is a single modality, the fusion layer only projects features from that modality. We train with the Adam optimizer with a learning rate of 0.00005, which is decayed by 0.1 after every 15 epochs. We report results with the best model selected based on performance on a mini validation set.

6.2 Quantitative Results

We show results in Table 2. For the intent taxonomy images are more informative than (word2vec) text (76% for Img vs 72.7% for Txt-emb) but with ELMo text outperforms just using images (82.6% for Txt-ELMo, 76.0% for Img). ELMo similarly improves performance on the contextual taxonomy but not the semiotic taxonomy.

For the semiotic taxonomy, ELMo and word2vec embeddings perform similarly, (67.8%

[1] https://github.com/allenai/allennlp/blob/master/tutorials/how_to/elmo.md

Method	Intent		Semiotic		Contextual

Table 2: Table showing results with various DCNN models– image-only (Img), text-only (Txt-emb and Txt-ELMo), and combined model (Img + Txt-emb and Img + Txt-ELMo). Here *emb* is the model using standard word (token) based embeddings, while *ELMo* is the pre-trained ELMo based word embeddings (Peters et al., 2018). The numbers in Table2 are standard deviations across 5 folds.

for Txt-emb vs. 66.5% for Txt-ELMo), suggesting that individual words are sufficient for the semiotic labeling task, and the presence of the sentence context (as in ELMo) is not needed.

Combining visual and textual modalities helps across the board. For example, for intent taxonomy the joint model Img + Txt-ELMo achieves 85.6% compared to 82.6% for Txt-ELMo. Images seem to help even more when using a word embedding based text model (80.8% for Img + Txt-emb vs. 72.7% for Txt-emb). Joint models also improve over single-modality on labeling the image-text relationship and the semiotic taxonomy. We show class-wise performances with the single- and multi-modality models in Table 3. It is particularly interesting that in the semiotic taxonomy, multi-modality helps the most with divergent semiotics (gain of 4.4% compared to the image-only model).

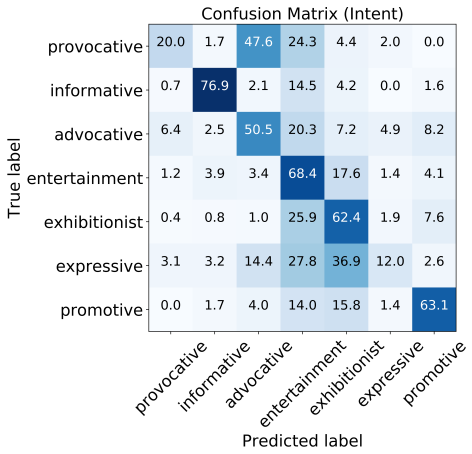

Figure 4: Confusion between intent classes for the intent classification task. The confusion matrix was obtained using the Img + Txt-ELMo model and the results are averaged over the 5 splits.

6.3 Discussion

In general, using both text and image is helpful, a fact that is unsurprising since combinations of text and image are known to increase performance on tasks such as predicting post popularity or user personality (Hessel et al., 2017; Wendlandt et al., 2017). Most telling, however, were the differences in this helpfulness across items. In the semiotic category the greatest gain came when the text-image semiotics were "divergent". By contrast, multimodal models help less when the image and text are additive, and help the least when the image and text are parallel and provide less novel information. Similarly, with contextual relationships, multimodal analysis helps the most with the "minimal" category (1.6%). This further supports the idea that on social media such as Instagram, the relation between image and text can be richly divergent and thereby form new meanings.

The category confusion matrix in Figure 4 provides further insights. The least confused category is informative. Informative posts are least similar to the rest of Instagram, since they consist of detached, objective posts, with little use of first person pronouns like "I" or "me." Promotive posts are also relatively easy to detect, since they are formally informative, telling the viewer the advantages and logistics of an item or event, with the addition of a persuasive intent reflecting the poster's personal opinions ("I love this watch".). We found that the *entertainment* label is often misapplied; perhaps to some extent all posts have a goal of entertaining, and any analysis must account for this filter of entertainment. The *Exhibitionist* intent tends to be predicted well, likely due to its visual and textual signifiers of individuality (e.g. selfies are almost always exhibitionist, as are captions

Intent			
Class	Img	Txt-ELMo	Img+ Txt-ELMo
Provocative	85.5	84.1	90.0
Informative	77.0	93.9	92.8
Advocative	84.8	82.4	87.4
Entertainment	69.0	78.6	80.5
Exhibitionist	81.7	78.7	84.9
Expressive	57.9	72.0	73.2
Promotive	76.3	88.5	90.1
Mean	76.0	82.6	85.6

Semiotic			
Class	Img	Txt-emb	Img+ Txt-ELMo
Divergent	69.8	72.7	77.1
Additive	55.0	66.7	68.2
Parallel	54.5	64.3	64.0
Mean	59.8	67.8	69.7

Contextual			
Class	Img	Txt-ELMo	Img+ Txt-ELMo
Minimal	60.9	79.7	81.3
Close	60.5	73.8	74.6
Transcendent	66.1	82.0	81.2
Mean	62.5	78.5	79.0

Table 3: Class-wise results (AUC) for the three taxonomies with different DCNN models on the MDID dataset. Except for the semiotic taxonomy we used ELMo text representations (based on the performance in Table 2).

like "I love my new hair"). There is a great deal of confusion, however, between the expressive and exhibitionist categories, since the only distinction lies in whether the post is about a general topic or about the poster, and between the provocative and advocative categories, perhaps because both often seek to prove points in a similar way.

With the contextual and semiotic taxonomies, some good results are obtained with text alone. In the "transcendent" contextual case, it is not necessarily surprising that using text alone enables 82% AUC because whenever a caption is really long or has many adverbs, adjectives or abstract concepts, it is highly likely to be transcendent. In the "divergent" semiotics case, we were surprised that text alone would predict divergence with 72.7% AUC. Examining these cases showed that many of them had lexical cues suggesting irony or sarcasm, allowing the system to infer that the image will diverge in keeping with the irony. There is, however, a consistent improvement when both modalities are used for both taxonomies.

6.4 Sample Outputs

We show some sample successful outputs of the (multimodal) model in Figure 5, in which the highest probability class in each of the three dimension corresponds to our gold labels. The top-left Image-caption pair (Image I) is classified as exhibitionist, closely followed by expressive; it is a picture of someone's home with a caption describing a domestic experience. The semiotic relationship is classified as additive; the image and caption together signify the concept of spending winter at home with pets before the fireplace. The contextual relationship is classified as transcendental; the caption indeed goes well beyond the image.

The top-right image-caption pair (Image II) is classified as entertainment; the image caption pair works as an ironic reference to dancing ("yeet") grandparents, who are actually reading, in language used usually by young people that a typical grandparent would never use. The semiotic relationship is classified as divergent and the contextual relationship is classified as minimal; there is semantic and semiotic divergence of the image-caption pair caused by the juxtaposition of youthful references with older people.

To further understand the role of meaning multiplication, we consider the change in intent and semiotic relationships when the same image of the British Royal Family is matched with two different captions in the bottom row of Figure 5 (Image IV). In both cases the semiotic relationship is parallel, perhaps due to the match between the multi-figure portrait setting and the word *family*. But the other two dimensions show differences. When the caption is "the royal family" our system classifies the intent as entertainment; presumably such pictures and caption pairs often appear on Instagram intending to entertain. But when the caption is "my happy family" the intent is classified as expressive, perhaps due to the family pride expressed in the caption.

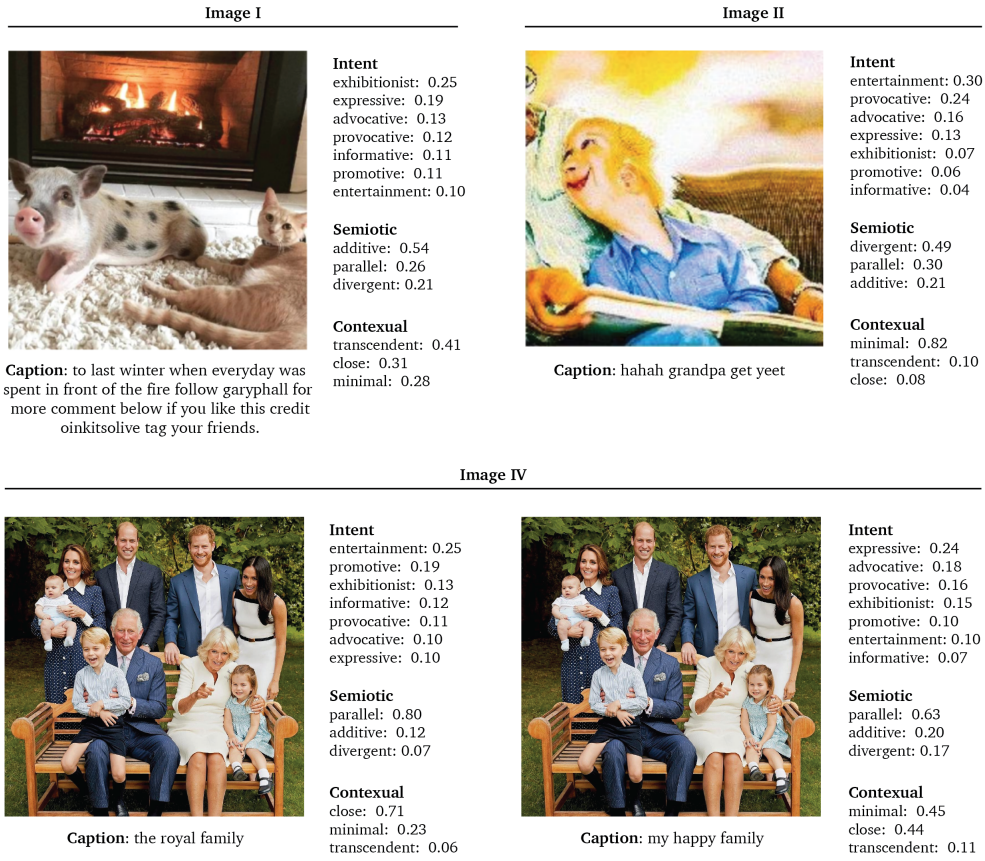

Figure 5: Sample successful output predictions for the three taxonomies, showing ranked classes and predicted probabilities. In images IV the same image when paired with a different caption gives rise to a different intent.

7 Conclusion

We have proposed a model to capture the complex *meaning multiplication* relationship between image and text in multimodal Instagram posts. Our three new taxonomies, adapted from the media and semiotic literature, allow the literal, semiotic, and illocutionary relationship between text and image to be coded. Of course our new dataset and the baseline classifier models are just a preliminary effort, and future work will need to examine larger datasets, consider additional data such as hashtags, richer classification schemes, and more sophisticated classifiers. Some of these may be domain-specific. For example, Alikhani et al. (2019) show how to develop rich coherence relations that model the contextual relationship between recipe text and accompanying images (specific versions of Elaboration or Exemplification such as "Shows a tool used in the step but not mentioned in the text"). Expanding our taxonomies with richer sets like these is an important goal. Nonetheless, the fact that we found multimodal classification to be most helpful in cases where the image and text diverged semiotically points out the importance of these complex relations, and our taxonomies, dataset, and tools should provide impetus for the community to further develop more complex models of this important relationship.

Abstract

The prevalent use of social media leads to a vast amount of online conversations being produced on a daily basis. It presents a concrete challenge for individuals to better discover and engage in social media discussions. In this paper, we present a novel framework to automatically recommend conversations to users based on their prior conversation behaviors. Built on neural collaborative filtering, our model explores deep semantic features that measure how a user's preferences match an ongoing conversation's context. Furthermore, to identify salient characteristics from interleaving user interactions, our model incorporates graph-structured networks, where both replying relations and temporal features are encoded as conversation context. Experimental results on two large-scale datasets collected from Twitter and Reddit show that our model yields better performance than previous state-of-the-art models, which only utilize lexical features and ignore past user interactions in the conversations.

1 Introduction

Social media has profoundly revolutionized people's social interactions, as many individuals now turn to online platforms to voice opinions and exchange ideas. Meanwhile, the abundance of information brings the problem of information explosion — the huge volume of online discussions produced every day has far outpaced any individual's capability of digesting them. It is hence difficult for one to discover online discussions that are potentially of interest. To address this issue, we study the problem of online conversation recommendation, with the goal of identifying conversations that fit a user's preferences, hence likely to result in the user's future engagement.

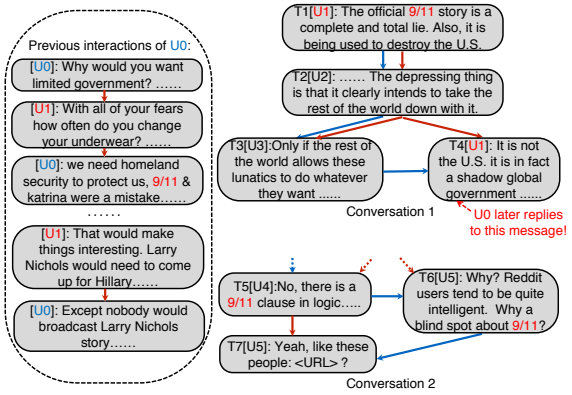

Figure 1: Two Reddit conversation snippets on the right. User U_0, whose historical interactions with another user U_1 shown on the left, only engages in Conversation 1 (which is initialized by U_1), but not Conversation 2 (U_1 does not participate in). Red arrows indicate in-reply-to relations, and blue arrows depict chronological orders.

In previous studies, it has been shown that effective online conversation recommendation has the potential to produce more positive online social interaction experience (Chen et al., 2011; Zeng et al., 2018). Prior work on this subject has focused on post-level recommendation (Yan et al., 2012; Chen et al., 2012), or conversation-level suggestion with handcrafted features (Chen et al., 2011) and word co-occurrence patterns (Zeng et al., 2018). Nevertheless, they ignore the useful information embedded in replying relations, where the conversation structure is formed via messages sent among users. In this work, we examine conversation context, and model the participants' interactions therein. This approach enables deep representation learning that reflects personal interests and conversation preferences, together signaling what conversations a user is likely to be involved in.

To illustrate how online interactions could indicate users' future conversation behavior, Figure 1

*This work was mainly conducted when Jing Li was affiliated with Tencent AI Lab, Shenzhen, China.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4633–4643, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

shows two conversation snippets on Reddit, both centering around the September 11 attack (9/11). As can be seen, user U_0, who had discussed the event according to the chat history, later engaged in Conversation 1 (C_1) instead of Conversation 2 (C_2). One explanation is that C_1 was initialized by user U_1, whose discussion topics overlap with U_0's, and more importantly, used to interact with U_0 in many prior discussions.

To model user preferences from their prior interactions, we propose to employ graph-structured neural networks to explicitly encode *who replies to whom at when* in the conversation history. In this way, temporal features of conversations are also exploited to capture messages' chronological orders (shown in Figure 1 with blue arrows). We then incorporate the interaction representations into a novel neural collaborative filtering framework (He et al., 2017), which further aligns user's preferences with the conversation context. Compared with existing methods that are based on handcrafted features (Chen et al., 2011) or Bayesian models (Zeng et al., 2018), our end-to-end trained neural model learns to automatically recommend conversations as well as to encode user interests embedded in their conversation interactions. To the best of our knowledge, this is the first work to explore neural conversation recommendation with online interactions explicitly encoded for user preference modeling.

To evaluate our model, we conduct extensive experiments on two large-scale datasets with online conversations from Twitter and Reddit[1]. Experimental results show that our method significantly outperforms state-of-the-art models that do not capture user interactions. For example, our model obtains an MAP (Mean Average Precision) of 0.625 on Twitter, compared with 0.591 by Zeng et al. (2018). We further find that our model still exhibits superior performance when the sparsity levels of user history and conversation context are varied, demonstrating our model's potential ability to handle sparse conversation records. Additional experiments on an ablation study confirms the effectiveness of different components in our framework. A case study further reveals important interaction features captured by our model, which indicate their conversation entries and hence explain our model's advanced performance. Finally, we investigate the challenging task of first time replies prediction, where our model again produces significantly better results than existing popular recommendation models.

2 Related Work

Our work is in line with conversation behavior analysis, where studies explore user interactions in ongoing conversations (Ritter et al., 2010) and how they signal the conversations' future trajectory, such as continued activity (Backstrom et al., 2013; Jiao et al., 2018; Zeng et al., 2019) and the risk of going awry (Zhang et al., 2018). Different from these proposals which do not model personal interests, we study conversation recommendation for a specific user, where we measure how a user's preferences match a conversation's context.

This work is also related to user response prediction (Artzi et al., 2012; Zhang et al., 2015) and post recommendation (Duan et al., 2010; Chen et al., 2012; Yan et al., 2012; Hong et al., 2013). While most of these studies focus on post modeling, we examine conversation context to predict user engagements, which goes beyond the post-level prediction task. Other prior work examining conversation-level recommendation relies on either manual features (Chen et al., 2011) or shallow word occurrence patterns (Zeng et al., 2018), largely ignoring the useful features from historical user interactions. On the contrary, we utilize online user interactions in the conversation history, to allow the inclusion of richer information of modeling personal interests. In addition, our neural network-based model enables automatic learning for a deeper representation of user interests, whereas existing methods require significant manual efforts for model customization (Chen et al., 2011; Zeng et al., 2018).

Furthermore, our user interaction module is inspired by prior work on conversation structure modeling. Compared with popular sequential conversation models that focus on messages' temporal features (Cheng et al., 2017; Jiao et al., 2018; Zeng et al., 2019), our module explicitly encodes the replying relationships to exploit the user conversation structure (Miura et al., 2018; Zayats and Ostendorf, 2018). It is shown that such structure indicates salient messages and can benefit various compelling applications, e.g., conversation summarization (Chang et al., 2013; Li et al., 2015) and discussion topic extraction (Li et al., 2016, 2018).

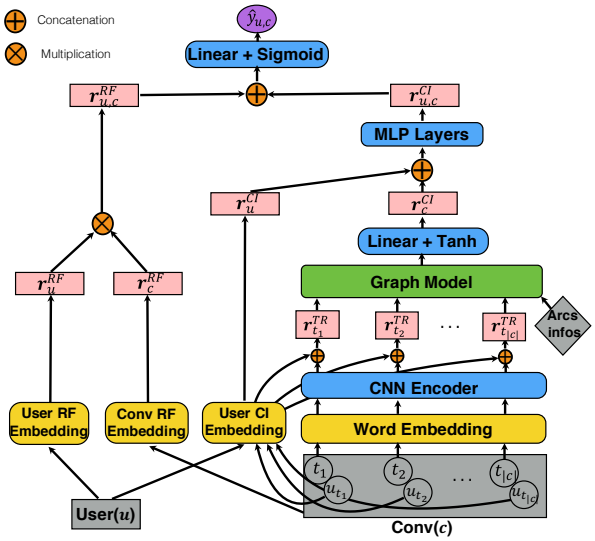

Figure 2: The architecture of our neural conversation recommendation framework, which models replying preferences and conversation interactions to predict a user's future engagement in given conversations. RF: replying factors modeling. CI: conversation interaction modeling.

However, its effect on conversation recommendation has not been explored yet, and our work aims to fill the gap.

3 Neural Conversation Recommendation

This section describes our neural recommendation model with interaction modeling. Figure 2 shows the overall architecture of our framework based on neural collaborative filtering (NCF) (He et al., 2017). Section 3.1 will present an overview showing how our model works, where both users' replying history and conversations' interaction structure will be encoded for recommendation. Their modeling details will be given in Section 3.2 and 3.3 in turn. At last, Section 3.4 shows the overall model training process.

3.1 Model Overview

Here we first describe the input and output. For training, our model is fed with a conversation dataset $\mathcal{C}$. Each conversation $c \in \mathcal{C}$ is formed with a sequence of turns $\langle t_1, t_2, ..., t_{|c|} \rangle$, where $|c|$ denotes the number of turns. Each turn t is in form of a word sequence $\langle w_1, w_2, ..., w_{|t|} \rangle$ with $|t|$ being t's word number. Its author is represented by user id u_t. We also record each turn's parent turn in replying relations (i.e. which turn it replies to) and chronological order (i.e. which turn posted before it), so that the interaction patterns within a conversation can be captured. We will talk more about it in Section 3.3.

For recommendation, our model is taken a user u and a conversation c as input, and then predict how likely u will engage in c, conditioned on u's previous behavior and c's context history.

Our goal is to predict $\hat{y}_{u,c} \in [0, 1]$, which measures how likely user u will engage in conversation c. Here to estimate $\hat{y}_{u,c}$, two types of information are encoded: replying history of users and interaction structure of conversations. The former is captured from what conversations a user previously replied to, where we learn $\boldsymbol{r}^{RF}_{u,c}$ to encode u's replying preference on c. However, such learned representation captures user replying preferences without diving into turn-level features and interaction structure in conversations. So we utilize the latter to explore how users interact with each other in conversation context, which encodes words in turns and turn interactions to produce conversation interaction representation $\boldsymbol{r}^{CI}_{u,c}$, reflecting a denser preference of a user. In Section 3.2, we will present how to learn $\boldsymbol{r}^{RF}_{u,c}$, and in Section 3.3 we learn about $\boldsymbol{r}^{CI}_{u,c}$.

Coupling the $\boldsymbol{r}^{RF}_{u,c}$ and $\boldsymbol{r}^{CI}_{u,c}$, we predict $\hat{y}_{u,c}$ via the formula below:

$$\hat{y}_{u,c} = \sigma(\boldsymbol{h}_O^T[\boldsymbol{r}^{RF}_{u,c}; \boldsymbol{r}^{CI}_{u,c}]) \quad (1)$$

where $\sigma(\cdot)$ denotes sigmoid activation, $[;]$ indicates concatenation operation, and $\boldsymbol{h}_O$ is a learnable parameter. In recommendation for user u, we rank the conversations with $\hat{y}_{u,c}$ and the top N results will serve as our final output.

3.2 Replying Factors Modeling

As mentioned in Section 3.1, we first model users' replying preferences with what conversations they entered before. We follow the practice in He et al. (2017) to use two embedding layers, $I^{RF}_U(\cdot)$ and $I^{RF}_C(\cdot)$, to capture the latent factors for users and conversations that result in user's previous replying history. For user u, we can obtain its user embedding $\boldsymbol{r}^{RF}_u$ by looking up u in $I^{RF}_U(\cdot)$. A conversation embedding $\boldsymbol{r}^{RF}_c$ can be similarly obtained from $I^{RF}_C(\cdot)$. Then we measure user u's replying preference over conversation c with the similarity between $\boldsymbol{r}^{RF}_u$ and $\boldsymbol{r}^{RF}_c$:

$$\boldsymbol{r}^{RF}_{u,c} = \boldsymbol{r}^{RF}_u \odot \boldsymbol{r}^{RF}_c \quad (2)$$

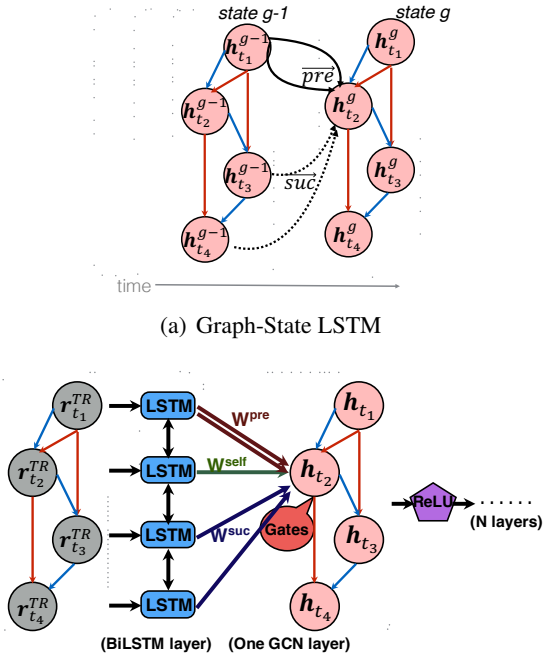
where $\odot$ denotes element-wise product. As can be seen, $\boldsymbol{r}^{RF}_{u,c}$ is able to encode what conversations

a user engages in and analyze the factors of why it happen, simply with general replying history. More features will be explored via conversation interaction modeling presented in Section 3.3.

3.3 Conversation Interaction Modeling

We first explore users' prior interaction behavior in conversations. A user embedding layer $I_U^{CI}(\cdot)$ is hence employed, where the embedding $\boldsymbol{r}_u^{CI}$ for user u reflects u's interaction patterns, such as what they used to say and whom they usually interacted with. For the conversation modeling, we adopt graph-structured networks to model the interaction structure therein and yield a representation $\boldsymbol{r}_c^{CI}$ for conversation c. The effects of user- and conversation-specific interaction features are combined with Multilayer Perceptron (MLP):

$$\boldsymbol{r}_{u,c}^{CI} = \alpha(W_M^T(...\alpha(W_1^T[\boldsymbol{r}_u^{CI}; \boldsymbol{r}_c^{CI}] + b_1)...) + b_M) \quad (3)$$



where $\alpha(\cdot)$ is ReLU-activated function (Rectified Linear Unit) and M is the number of layers in MLP. In the following, we will introduce how we obtain $\boldsymbol{r}_c^{CI}$ via modeling of intra-turn features and inter-turn interactions.

Turn-level Modeling. Here we describe how we model turn-level representations, which combine what content it conveys and who its author is.

Content representation is to reflect how words appear therein, where we employ a Convolutional Neural Network (CNN) (Kim, 2014) encoder to model a turn's word sequence. Specifically, given a turn t in conversation c, we first map each word in t into a word embedding layer (initialized with pre-trained word vectors) to explore deep word semantics. And then, to capture how a word appears in local context with its neighbors, a CNN encoder is exploited to generate the turn-level content representation $\boldsymbol{z}_t$.

Next, we concatenate $\boldsymbol{z}_t$, conveying content features, and $\boldsymbol{r}_{u_t}^{CI}$, embedded with the interaction patterns of t's author u_t, to produce a turn representation $\boldsymbol{r}_t^{TR}$. It couples turn t's word occurrence patterns and its author's history interactions with other conversation turns. Afterwards, $\boldsymbol{r}_t^{TR}$ is delivered to model t's interaction with the other turns in c. We will describe how it is processed next.

Turn Interaction Modeling. To encode conversation interaction structure, we first organize the turns in a conversation c as a reply tree to formulate who replies to whom. Each node therein represents a turn and the edges reflect replying relations (directed from turns to replies such as the red arrows in Figure 1). Moreover, to exploit temporal information, we add another kind of edges to indicate chronological order (such as the blue arrows in Figure 1). In doing so, a reply tree is extended to a directed graph (such as the one in Figure 1), with both replying and temporal interactions encoded and therefore named as an interaction graph. For each turn t on the graph, we distinguish its neighbors into predecessors, denoted by $E^p(t)$, and successors, $E^s(t)$.

(a) Graph-State LSTM

(b) Graph Convolutional Networks

Figure 3: Two variants of our proposed graph-structured networks.

Then, we employ graph-structured networks to model the interaction structure. There are two modeling methods discussed here: **Graph-State LSTM** (Long Short-Term Memory) (henceforth GLSTM) (Beck et al., 2018; Song et al., 2018) and **Graph Convolutional Networks** (henceforth GCN) (Kipf and Welling, 2017; Marcheggiani and Titov, 2017), whose empirical effectiveness will be compared in Section 5.1. Here we present their architecture in Figure 3 and describe how they model conversation interactions below.

Graph-State LSTM. We start with GLSTM and show its architecture in Figure 3(a). It is an extension of LSTM from sequence to graph structure, where a turn's hidden states are updated conditioned on both the turn-level representation $\boldsymbol{r}_t^{TR}$

and the states of all its neighbors on the graph. The update strategy is the same as standard LSTM (Hochreiter and Schmidhuber, 1997), except for the following formula, which can be used in the update of input gate, output gate, forget gate, and content recorder:

$$\boldsymbol{g}_t^{GLSTM} = \sigma(W^p \boldsymbol{x}_t^p + W^s \boldsymbol{x}_t^s + U^p \boldsymbol{h}_t^p + U^s \boldsymbol{h}_t^s + b) \quad (4)$$

The first two terms explore the turn-level representations ($\boldsymbol{r}_t^{TR}$) from the neighbors. The third and forth terms capture turn interactions on the graph. b denotes the bias. The superscripts p and s indicate the neighbor being a predecessor or successor. $\boldsymbol{x}_t^p$ takes the sum of predecessor k's turn representations $\boldsymbol{r}_k^{TR}$ and so does $\boldsymbol{x}_t^s$ for successors. $\boldsymbol{h}_t^*$ means the neighbors' hidden states in their last updates. W^* and U^* are learnable parameter weights and $\sigma(\cdot)$ means sigmoid activation. Moreover, in GLSTM, we define the state number g to reflect the maximum order of GLSTM state transitions, where the larger g indicates longer turn dependency on graph paths encoded. Here due to the space limitation, we leave out the details of GLSTM and refer the readers to Song et al. (2018).

Afterwards, to produce conversation representation $\boldsymbol{r}_c^{CI}$ with turn interactions, we combine all turns' hidden states with average pooling and map them into the same dimension (with Tanh activation) as $\boldsymbol{r}_u^{CI}$ to measure user and conversation similarity.

Graph Convolutional Networks. Figure 3(b) shows the architecture of GCN, which can be considered as CNN on graph. Here following previous practice (Marcheggiani and Titov, 2017), before using GCN to model turn interactions, we first feed the turn representations $\boldsymbol{r}_t^{TR}$ into a sequential Bidirectional LSTM (BiLSTM) layer to capture the chronological turn interactions. Then, we take the t-th hidden states of BiLSTM $\boldsymbol{h}_t^{LSTM}$ to further capture turn t's interaction with its neighbors on interaction graph. The formula describing this process is given as:

$$\begin{aligned}\boldsymbol{h}_t^{GCN} = &\sum_{i \in E^p(t)} \omega_{i,t}(W^{pre}\boldsymbol{h}_i^{LSTM} + b^{pre}) + \\ &\sum_{j \in E^s(t)} \omega_{j,t}(W^{suc}\boldsymbol{h}_j^{LSTM} + b^{suc}) + \\ &\omega_{t,t}(W^{self}\boldsymbol{h}_t^{LSTM} + b^{self})\end{aligned} \quad (5)$$

Here following Marcheggiani and Titov (2017), we use different sets of parameters to fit varying types of interactions: self interactions (self), interaction from predecessors to successors (pre), and that from the other way around (suc). $\omega_{i,j}$ is a scalar gate controlling weights defined below:

$$\omega_{i,j} = \sigma(\boldsymbol{h}_i^{LSTM} \cdot V^{dir(i,j)} + d^{dir(i,j)}) \quad (6)$$

It is to identify the neighbors affecting more to t than others. $dir(i,j)$ indicates the type of i-j direction (pre, suc, or self).

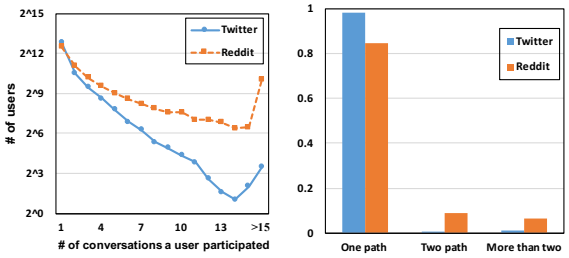
Furthermore, to allow deep interactions to be learned, we can stack multiple GCN layers to form a multi-layer GCNs, where we apply a ReLU activated function between two layers. After that, we take the similar operations as for GLSTM yield conversation representation $\boldsymbol{r}_c^{CI}$ as c's conversation interaction representation.

3.4 Model Training

Here we describe how we formulate our learning objective and train our model. As mentioned above, our goal is to predict a score $\hat{y}_{u,c} \in [0,1]$ indicating how likely user u will reply to conversation c. In training, we adopt binary cross-entropy as our learning loss with penalty given to negative feedback (u does not engage in c). It is because negative feedback may happen for many unpredictable reasons, such as users being too busy to go online. Thus for conversation recommendation, we rely more on the positive feedback and design the *weighted binary cross-entropy loss* below:

$$\mathcal{L} = -\sum_{(u,c)\in\mathcal{T}} \left[\lambda \cdot y_{u,c}\log(\hat{y}_{u,c}) + (1-y_{u,c})\log(1-\hat{y}_{u,c})\right] \quad (7)$$

where $\mathcal{T}$ is a set of training instances. $y_{u,c}$ is a binary label indicating whether u replied to c, and $\hat{y}_{u,c}$ is our predicted score. λ ($\lambda > 1$) is a predefined parameter to trade off the weights of positive and negative instances.



In model training, the negative sampling strategy is adopted (He et al., 2017), whose sampling ratio (the number of negative samples for each positive instance) is set to 5. Also, we pre-train the embedding layers for both the replying factors and conversation interaction modeling with the parameters from He et al. (2017). We will discuss the effects of pre-training in Section 5.3.

4 Experimental Setup

Data Collection and Preprocessing. In our experiments, we use datasets from two different platforms: the first one is released by Zeng et al. (2018) containing **Twitter** conversations formed by tweets from the TREC 2011 microblog track

	Twitter	Reddit
# of users	10,122	13,134
# of conversations	7,500	29,477
# of turns	38,999	109,774
Avg. # of conversations per user	1.7	5.9
Avg. # of turns per conversation	5.2	3.7
Avg. # of users per conversation	2.3	2.6

Table 1: Dataset statistics.

(a) User conversation dist. (b) Ratio of diff. structure

Figure 4: Distribution of number of conversations per user (left) and proportion of different conversation structures (right) for both datasets.

data[2] covering a diverse set of topics; the other is from Zeng et al. (2019), which is comprised of discussion threads about political issues on **Reddit**, a popular discussion website.

The tweets in Twitter dataset were mainly posted from Jan 23 to Feb 8, 2011, and discussion threads in Reddit dataset were posted from Jan to Dec, 2008. To discover the whole conversations, we retrieved all messages with replying relations (indicated by "*parent_id*" property in Reddit corpus, for example), and recorded their authors and parent messages. Finally, conversations with only one message were removed.

We applied the Glove tweet preprocessing toolkit (Pennington et al., 2014)[3] on the Twitter dataset. As for the Reddit dataset, we performed tokenization using open source natural language toolkit (NLTK) (Loper and Bird, 2002), with links replaced to a generic tag "URL" and all number tokens removed. We maintained a vocabulary with all the rest characters appearing in the corpus for both datasets, including punctuation and emoticons.

Data Statistics and Analysis. The statistics of two datasets are shown in Table 1, with more information in Figure 4. We can observe that Reddit dataset contains more conversations, with a higher average number of conversations per user. On the other hand, Twitter conversations are longer, with fewer participants. Figure 4(a) shows that most users participate in very few conversations in both datasets, indicating a potential sparsity problem. In terms of conversation structure (Figure 4(b)), most conversations only contain one path where the replying relations precisely follow the chronological order; whereas the Reddit dataset contains more tree-structured conversations with rich and complex interactions.

To further illustrate the effect of a conversation's structure on its future development, we calculate the likelihoods of (1) new users joining the discussion, and (2) current participants continuing the conversation, grouped by different conversation structures (Table 2). In general (especially on Reddit), conversations with only one path tend to continue within the current participants, and keep newcomers out, whereas conversations with complex structures are more likely to attract new users.

	Twitter			Reddit		
Paths amount	1	2	> 2	1	2	> 2
New comers rate	0.18	0.20	0.16	0.30	0.45	0.50
Continue rate	0.70	0.64	0.74	0.51	0.31	0.38

Table 2: Different structures and the future trend of conversations.

Model Setting. We follow the experimental settings employed in previous work (Zeng et al., 2018). For each conversation, we take first 75% of the context as observation for training purpose. The rest is equally divided into a testing set and a development set. For negative instances, we also split the unobserved user-conversation pairs into three parts: 80%, 10%, and 10% for training, testing, and development, respectively. Furthermore, due to the large amount of conversations in Reddit dataset, we only sample 100 negative instances uniformly from them for testing and development.

For parameters setups, we initialize the word embedding layer with 200-dimensional Glove embedding (Pennington et al., 2014), where the Twitter version is used for our Twitter dataset, and the Common Crawl version is applied on the Reddit dataset[4]. Factor dimension for the RF part is set to 20, while for the CI part it is 100. For the CNN

[2] https://trec.nist.gov/data/tweets/

[3] https://nlp.stanford.edu/projects/glove/preprocess-twitter.rb

[4] https://nlp.stanford.edu/projects/glove/

encoders, we use filter windows of 2, 3, and 4, each with 100 feature maps. For the size of hidden states of our graph models, we set 200 (100 for each direction for BiLSTM). The number of MLP layers is 3. During training, the batch size is set to 512 and Adam optimizer (Kingma and Ba, 2014) is adopted with an initial learning rate of 0.01. We set the trade off weight in learning loss $\lambda = 100$.

Evaluation and Comparisons. Following Zeng et al. (2018)'s work, we adopt mean average precision (MAP), precision at 1 (P@1), and normalized Discounted Cumulative Gain at 5 (nDCG@5) for evaluation (we also try other metrics including P@5 and nDCG@10, and find similar trends). The metrics are first computed for users in the datasets, then averaged over all users.

For comparison, we first search for the best model among different interaction modeling (Section 5.1). We then consider two baselines: 1) ranking conversations randomly (RANDOM), 2) conversations with more participants ranked higher (POPULARITY). Previous work compared includes[5]:

• RSVM: Ranks conversations for each user with features described in Duan et al. (2010) by ranking SVM (Joachims, 2002).

• NCF: The neural CF model (He et al., 2017), not utilizing any context information.

• CONVMF: A CNN-based model for recommendation with reviews (Kim et al., 2016), where we adapt to use a hierarchical two-layer CNN to model words in turns and turn sequences.

• CR_JTD: The state-of-the-art method for our task (Zeng et al., 2018), with a Bayesian model jointly modeling topics and discourse.

5 Experimental Results

In this section, we first evaluate the effectiveness of varying modules for conversation interaction modeling in Section 5.1. Then our model with the best module is further compared with the baselines and previous recommendation systems in Section 5.2. There we also discuss the model performance given varying conversation context length and user interaction sparsity. We further discuss our model with an ablation study and a case study in Section 5.3. Finally in Section 5.4, we analyze the results of first time replies prediction.

[5]We did not compare with Chen et al. (2011) since that method mainly requires information about social relationship, which is unavailable in our datasets.

Models	Train Time	MAP	
		Twitter	Reddit
BiLSTM	0.94	0.617	0.498
GLSTM	1.25	0.617	0.528
GCN (W/O BiLSTM)	1.03	0.619	0.530
GCN (With BiLSTM)	1.00	**0.620**	**0.533**

Table 3: Results of our model variants on development set. The best MAP results are in **bold**. "Train Time": training time per epoch divided by that of model GCN (With BiLSTM).

5.1 Interaction Modeling Comparison

We first compare the effects of varying interaction modeling methods (see Section 3.3) on conversation recommendation. Table 3 displays their results on development set. In comparison, we consider BiLSTM over turn sequence (only chronological order encoded and henceforth BiLSTM), GLSTM (state number $g = 6$), GCN (layer number set to 3) without BiLSTM-encoded temporal representations (henceforth GCN (W/O BiLSTM)), and the full GCN described in Section 3.3 (henceforth GCN (With BiLSTM) and layer number set to 1). The above hyper-parameters are tuned based on the training loss.

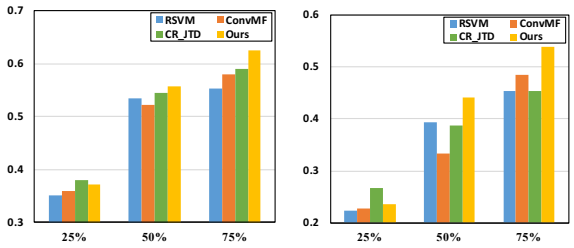
From the results, we find that BiLSTM exhibits the worst results for not encoding replying relations. Its difference from others are larger on Reddit attributed to the rich replying structure therein (as shown in Figure 4(b)). The best performance is achieved for GCN (With BiLSTM), with relatively less training time. This shows the effectiveness and efficiency to explore the order of turns with BiLSTM and the user interactions with GCN. In the later analysis, we will only discuss our model that exploits GCN (With BiLSTM) for interaction modeling.

5.2 Comparisons with Previous Work

Main Results. Table 4 shows the conversation recommendation results with baselines and state of the arts. Our model exhibits the best results on both datasets, significantly outperforming all the comparison models. It indicates the usefulness to encode user interactions for conversation recommendation. Particularly, CONVMF is able to encode turns' temporal orders yet ignores how they reply with each other in conversation history. It is outperformed by our model, showing the benefit to capture users' replying patterns for predicting what conversations will draw their engagement.

Models	Twitter			Reddit		
	MAP	P@1	nDCG	MAP	P@1	nDCG
Baselines						
RANDOM	0.006	0.001	0.002	0.040	0.010	0.022
POPULARITY	0.023	0.005	0.010	0.082	0.033	0.063
Comparisons						
RSVM	0.554	0.575	0.559	0.453	0.457	0.466
NCF	0.573	0.593	0.576	0.412	0.544	0.461
CONVMF	0.579	0.596	0.583	0.485	0.532	0.520
CR_JTD	0.591	0.591	0.600	0.453	0.559	0.485
OURS	**0.625**	**0.632**	**0.626**	**0.538**	**0.674**	**0.590**

Table 4: Main results on conversation recommendation. "nDCG" stands for "nDCG@5". The best result for each column is in **bold**. Our model significantly outperforms all the comparisons ($p < 0.01$, paired t-test).



We also observe that both baseline models work poorly. It is because conversation recommendation is challenging, not possible to be well tackled with simple ranking strategies.

In addition, we notice that CR_JTD outperforms CONVMF on Twitter, with opposite observation made on Reddit. It is possibly because Twitter exhibits more informal language style. Thus CR_JTD, taken bag-of-words input, can better fit the data than CONVMF, taking word orders into account. Nevertheless, our model outperforms them both, showing that prior interactions among users can better signal their future reply behavior compared with the words they said.

The final observation is that, all comparing methods (except for the naive baselines) perform better on Twitter than Reddit. One reason is that the Twitter dataset is smaller and contains fewer users and conversations. Another possible reason might be that the topics in the Reddit dataset are mostly about politics, while the Twitter conversations are of diverse topics, which makes the model easier to distinguish user interests.

Training with Varying Conversation History. The main results are reported given the first 75% turns as conversation history. Here we investigate how the length of conversation history affects reply preference prediction. The models are hence trained with the first 25%, 50%, and 75% turns as conversation history and their MAP scores are shown in Figure 5.

As can be seen, all models exhibit better results when trained with longer history. This shows that users' future conversation preference can be better predicted with richer history data. We also observe

(a) Twitter (b) Reddit

Figure 5: MAP scores (in Y-axis) of models trained with the first 25%, 50%, and 75% turns as history.

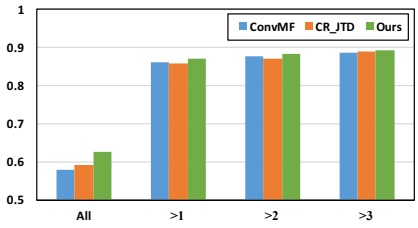


Figure 6: MAP scores (in Y-axis) for users with varying degrees of interaction history. X-axis indicates the number of conversations users previously engage in. *"All"* means recommendation for all users.

that our model obtains the best MAP on both the 50% and 75% setting, while for 25%, it is outperformed by CR_JTD. It might be ascribed to the sparse user interactions exhibited in 25% context, where there are only 1 or 2 turns on average according to Table 1.

Results for Varying User Interaction Sparsity. Figure 4(a) has shown that most users only engage in very few conversations. This results in severe data sparsity in user interaction history, especially on Twitter. We are hence interested in how models perform on varying degree of sparsity.

Figure 6 shows the MAP scores in recommendation to users engaged in varying number of conversations before on Twitter. As can be seen, user interaction sparsity can largely affect recommendation performance, where all models perform poorly for users exhibiting less than one conversation entry. We also observe that our model performs consistently better in varying degrees of sparsity. It may because our model is able to learn rich interactions from conversation context, which helps alleviate the sparsity in user history.

5.3 Further Discussion

Here we further discuss what our model learns leading to its superiority.

Ablation Study. We start with an ablation study to discuss the relative contributions of our different components. The MAP scores of their ablations are compared in Table 5. Our full model performs the best, showing that all components are useful. It is also seen that RF modeling contribute the most, meanwhile better contributions can be made with its parameters pre-trained. It indicates the crucial role RF modeling plays for neural conversation recommendation.

Models	Twitter	Reddit
W/O RF modeling (Sec. 3.2)	0.509	0.239
W/O pre-training (Sec. 3.4)	0.593	0.525
W/O MLP layers (Eq. 3)	0.600	0.537
W/O gate control weights (Eq. 6)	0.608	0.530
Our full model	**0.625**	**0.538**

Table 5: MAP scores obtained by our ablations. The best MAP results are highlighted in **bold**.

Case Study. To further understand how our model predicts users' conversation preferences, we take the example in Figure 1 and analyze what our model learns for it. Recall that user U_0 used to discuss a lot on 9/11 with U_1, who starts C_1. U_0 later engages in C_1 instead of C_2, though it also concerns 9/11.

	U_1	U_2	U_4	U_5
$\boldsymbol{r}_u^{RF}$	**0.761**	0.731	0.681	0.659
$\boldsymbol{r}_u^{CI}$	**0.763**	0.453	0.287	0.737

Table 6: Cosine similarity between U_0's user embeddings in RF and CI modeling with others'.

Table 6 shows the similarity of user factors learned by our RF (replying factor modeling in Section 3.2) and CI (conversation interaction modeling in Section 3.3) modules. As can be seen, both modules learn that U_0 and U_1 are similar (probably referred from their frequent interactions). Their joint effects result in our successful prediction of U_0 to engage in C_1 rather than C_2. For the same reason, our model can further predict that U_0 is more likely to reply to T_4 (in C_1), which is posted by U_1, based on the similarity between user factors and turn representations.

5.4 First Time Replies Prediction

In some scenarios, users may be more interested in seeing new conversations, which they haven't seen before but potentially match their preferences. We hence examine model performance to predict only first time replies and show their MAP scores in Table 7. It is observed that all models perform poorly, which implies that recommending unseen conversations to users is extremely difficult. This finding is consistent with Zeng et al. (2018). However, our model still outperforms others by a large margin. It again demonstrates the effectiveness of modeling user interactions for recommendation.

Models	Twitter	Reddit
RSVM	0.002	0.049
NCF	0.033	0.038
ConvMF	0.049	0.210
CR_JTD	0.090	0.075
Ours	**0.160**	**0.212**

Table 7: MAP scores for first time replies prediction.

6 Conclusion

We study neural conversation recommendation with graph-structured networks to encode user interactions. Experimental results on Twitter and Reddit show our model significantly outperforms the state of the arts. We also observe that competitive results can still be obtained on varying conversation history length and user interaction sparsity. Further discussions analyze the contributions of different components of our model and the useful features we learn leading to our superiority. At last, we study a challenging task of first time replies prediction, where our model still exhibits its effectiveness.

Abstract

Recently, neural networks based on multi-task learning have achieved promising performance on fake news detection, which focus on learning shared features among tasks as complementary features to serve different tasks. However, in most of the existing approaches, the shared features are completely assigned to different tasks without selection, which may lead to some useless and even adverse features integrated into specific tasks. In this paper, we design a sifted multi-task learning method with a selected sharing layer for fake news detection. The selected sharing layer adopts gate mechanism and attention mechanism to filter and select shared feature flows between tasks. Experiments on two public and widely used competition datasets, i.e. RumourEval and PHEME, demonstrate that our proposed method achieves the state-of-the-art performance and boosts the F1-score by more than 0.87%, 1.31%, respectively.

1 Introduction

In recent years, the proliferation of fake news with various content, high-speed spreading, and extensive influence has become an increasingly alarming issue. A concrete instance[1] was cited by Time Magazine in 2013 when a false announcement of Barack Obama's injury in a White House explosion "wiped off 130 Billion US Dollars in stock value in a matter of seconds". Other examples, an analysis of the US Presidential Election in 2016 (Allcott and Gentzkow, 2017) revealed that fake news was widely shared during the three months prior to the election with 30 million total Facebook shares of 115 known pro-Trump fake stories and 7.6 million of 41 known pro-Clinton fake stories. Therefore, automatically detecting fake news has attracted significant research attention in both industries and academia.

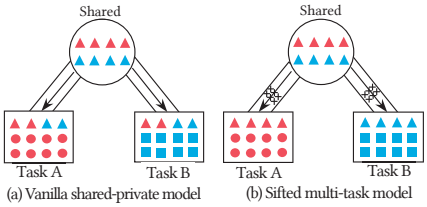

Figure 1: Two schemes for sharing features among tasks. Red circles and blue boxes represent the task-specific features, while the red and blue triangles mean shared features that benefit Task A and Task B, respectively.

Most existing methods devise deep neural networks to capture credibility features for fake news detection. Some methods provide in-depth analysis of text features, e.g., linguistic (Conroy et al., 2015), semantic (Yang et al., 2012), emotional (Wang et al., 2015), stylistic (Potthast et al., 2017), etc. On this basis, some work additionally extracts social context features (a.k.a. meta-data features) as credibility features, including source-based (Castillo et al., 2011), user-centered (Long et al., 2017), post-based (Wang, 2017) and network-based (Ruchansky et al., 2017), etc. These methods have attained a certain level of success. Additionally, recent researches (Thorne et al., 2017; Dungs et al., 2018) find that doubtful and opposing voices against fake news are always triggered along with its propagation. Fake news tends to provoke controversies compared to real news (Mendoza et al., 2010; Zubiaga et al., 2016b). Therefore, stance analysis of these controversies can serve as valuable credibility features for fake news detection.

There is an effective and novel way to improve the performance of fake news detection combined with stance analysis, which is to build multi-task learning models to jointly train both tasks (Ma

et al., 2018a; Kochkina et al., 2018; Li et al., 2018). These approaches model information sharing and representation reinforcement between the two tasks, which expands valuable features for their respective tasks. However, prominent drawback to these methods and even typical multi-task learning methods, like the shared-private model, is that the shared features in the shared layer are equally sent to their respective tasks without filtering, which causes that some useless and even adverse features are mixed in different tasks, as shown in Figure 1(a). By that the network would be confused by these features, interfering effective sharing, and even mislead the predictions.

To address the above problems, we design a sifted multi-task learning model with filtering mechanism (Figure 1(b)) to detect fake news by joining stance detection task. Specifically, we introduce a selected sharing layer into each task after the shared layer of the model for filtering shared features. The selected sharing layer composes of two cells: gated sharing cell for discarding useless features and attention sharing cell for focusing on features that are conducive to their respective tasks. Besides, to better capture long-range dependencies and improve the parallelism of the model, we apply transformer encoder module (Vaswani et al., 2017) to our model for encoding input representations of both tasks. Experimental results reveal that the proposed model outperforms the compared methods and gains new benchmarks.

In summary, the contributions of this paper are as follows:

- We explore a selected sharing layer relying on gate mechanism and attention mechanism, which can selectively capture valuable shared features between tasks of fake news detection and stance detection for respective tasks.
- The transformer encoder is introduced into our model for encoding inputs of both tasks, which enhances the performance of our method by taking advantages of its long-range dependencies and parallelism.
- Experiments on two public, widely used fake news datasets demonstrate that our method significantly outperforms previous state-of-the-art methods.

2 Related Work

Fake News Detection Exist studies for fake news detection can be roughly summarized into two categories. The first category is to extract or construct comprehensive and complex features with manual ways (Castillo et al., 2011; Ruchansky et al., 2017; Flintham et al., 2018). The second category is to automatically capture deep features based on neural networks. There are two ways in this category. One is to capture linguistic features from text content, such as semantic (Wang, 2017; Wu et al., 2018), writing styles (Potthast et al., 2017), and textual entailments (Oshikawa et al., 2018). The other is to focus on gaining effective features from the organic integration of text and user interactions (Qian et al., 2018; Wu et al., 2019). User interactions include users' behaviours, profiles, and networks between users. In this work, following the second way, we automatically learn representations of text and stance information from response and forwarding (users' behaviour) based on multi-task learning for fake news detection.

Stance Detection The researches (Lukasik et al., 2016; Zubiaga et al., 2016a) demonstrate that the stance detected from fake news can serve as an effective credibility indicator to improve the performance of fake news detection. The common way of stance detection in rumors is to catch deep semantics from text content based on neural networks(Mohtarami et al., 2018). For instance, Kochkina et al.(Kochkina et al., 2017) project branch-nested LSTM model to encode text of each tweet considering the features and labels of the predicted tweets for stance detection, which reflects the best performance in RumourEval dataset. In this work, we utilize transformer encoder to acquire semantics from responses and forwarding of fake news for stance detection.

Multi-task Learning A collection of improved models (Chen and Cardie, 2018; Chen et al., 2018; Liu et al., 2019) are developed based on multi-task learning. Especially, shared-private model, as a popular multi-task learning model, divides the features of different tasks into private and shared spaces, where shared features, i.e., task-irrelevant features in shared space, as supplementary features are used for different tasks. Nevertheless, the shared space usually mixes some task-relevant features, which makes the learning of different tasks introduce noise. To address this issue, Liu et al. (Liu et al., 2017) explore an adversarial shared-

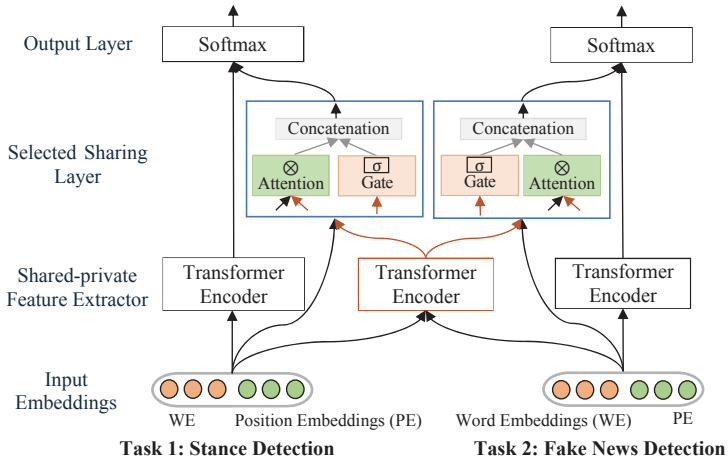

Figure 2: The architecture of the sifted multi-task learning method based on shared-private model. In particular, the two blue boxes represent selected sharing layers of stance detection and fake news detection and the red box denotes shared layer between tasks.

private model to alleviate the shared and private latent feature spaces from interfering with each other. However, these models transmit all shared features in the shared layer to related tasks without distillation, which disturb specific tasks due to some useless and even harmful shared features. How to solve this drawback is the main challenge of this work.

3 Method

We propose a novel sifted multi-task learning method on the ground of shared-private model to jointly train the tasks of stance detection and fake news detection, filter original outputs of shared layer by a selected sharing layer. Our model consists of a 4-level hierarchical structure, as shown in Figure 2. Next, we will describe each level of our proposed model in detail.

3.1 Input Embeddings

In our notation, a sentence of length l tokens is indicated as $\mathbf{X} = \{x_1, x_2, ..., x_l\}$. Each token is concatenated by word embeddings and position embeddings. Word embeddings w_i of token x_i are a d_w-dimensional vector obtained by pre-trained Word2Vec model (Mikolov et al., 2013), i.e., $w_i \in \mathbb{R}^{d_w}$. Position embeddings refer to vectorization representations of position information of words in a sentence. We employ one-hot encoding to represent position embeddings p_i of token x_i, where $p_i \in \mathbb{R}^{d_p}$, d_p is the positional embedding dimension. Therefore, the embeddings of a sentence are represented as $\mathbf{E} = \{[w_1; p_1], [w_2; p_2], ..., [w_l; p_l]\}, \mathbf{E} \in \mathbb{R}^{l \times (d_p + d_w)}$. In particular, we adopt one-hot encoding to embed positions of tokens, rather than sinusoidal position encoding recommended in BERT model (Devlin et al., 2018). The reason is that our experiments show that compared with one-hot encoding, sinusoidal position encoding not only increases the complexity of models but also performs poorly on relatively small datasets.

3.2 Shared-private Feature Extractor

Shared-private feature extractor is mainly used for extracting shared features and private features among different tasks. In this paper, we apply the encoder module of transformer (Vaswani et al., 2017) (henceforth, transformer encoder) to the shared-private extractor of our model. Specially, we employ two transformer encoders to encode the input embeddings of the two tasks as their respective private features. A transformer encoder is used to encode simultaneously the input embeddings of the two tasks as shared features of both tasks. This process is illustrated by the shared-private layer of Figure 2. The red box in the middle denotes the extraction of shared features and the left and right boxes represent the extraction of private features of two tasks. Next, we take the extraction of the private feature of fake news detection as an example to elaborate on the process of transformer encoder.

The kernel of transformer encoder is the scaled dot-product attention, which is a special case of attention mechanism. It can be precisely described as follows:

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{\mathbf{d}}})\mathbf{V} \quad (1)$$

where $\mathbf{Q} \in \mathbb{R}^{l\times(d_p+d_w)}$, $\mathbf{K} \in \mathbb{R}^{l\times(d_p+d_w)}$, and $\mathbf{V} \in \mathbb{R}^{l\times(d_p+d_w)}$ are query matrix, key matrix, and value matrix, respectively. In our setting, the query $\mathbf{Q}$ stems from the inputs itself, i.e., $\mathbf{Q} = \mathbf{K} = \mathbf{V} = \mathbf{E}$.

To explore the high parallelizability of attention, transformer encoder designs a multi-head attention mechanism based on the scaled dot-product attention. More concretely, multi-head attention first linearly projects the queries, keys and values h times by using different linear projections. Then h projections perform the scaled dot-product attention in parallel. Finally, these results of attention are concatenated and once again projected to get the new representation. Formally, the multi-head attention can be formulated as follows:

$$head_i = \text{Attention}(\mathbf{Q}\mathbf{W}_i^Q, \mathbf{K}\mathbf{W}_i^K, \mathbf{V}\mathbf{W}_i^V) \quad (2)$$

$$\begin{aligned}\mathbf{H} &= \text{MultiHead}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) \\ &= \text{Concat}(head_1, head_2, ..., head_h)\mathbf{W}^o\end{aligned} \quad (3)$$

where $\mathbf{W}_i^Q \in \mathbb{R}^{(d_p+d_w)\times d_k}$, $\mathbf{W}_i^K \in \mathbb{R}^{(d_p+d_w)\times d_k}$, $\mathbf{W}_i^V \in \mathbb{R}^{(d_p+d_w)\times d_k}$ are trainable projection parameters. d_k is $(d_p + d_w)/h$, h is the number of heads. In Eq.(3), $\mathbf{W}^o \in \mathbb{R}^{(d_p+d_w)\times(d_p+d_w)}$ is also trainable parameter.

3.3 Selected Sharing Layer

In order to select valuable and appropriate shared features for different tasks, we design a selected sharing layer following the shared layer. The selected sharing layer consists of two cells: gated sharing cell for filtering useless features and attention sharing cell for focusing on valuable shared features for specific tasks. The description of this layer is depicted in Figure 2 and Figure 3. In the following, we introduce two cells in details.

Gated Sharing Cell Inspired by forgotten gate mechanism of LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Chung et al., 2014), we design a single gated cell to filter useless shared features from shared layer. There are two reasons why we adopt single-gate mechanism. One is that transformer encoder in shared layer can efficiently capture the features of long-range dependencies. The features do not need to capture repeatedly by multiple complex gate mechanisms of LSTM and GRU. The other is that single-gate mechanism is more convenient for training (Srivastava et al., 2015). Formally, the gated sharing cell can be expressed as follows:

$$\mathbf{g}_{fake} = \sigma(\mathbf{W}_{fake} \cdot \mathbf{H}_{shared} + \mathbf{b}_{fake}) \quad (4)$$

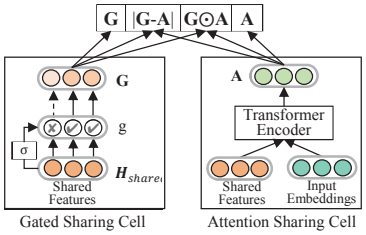

Figure 3: The details of selected sharing layer.

where $\mathbf{H}_{shared} \in \mathbb{R}^{1\times l(d_p+d_w)}$ denotes the outputs of shared layer upstream, $\mathbf{W}_{fake} \in \mathbb{R}^{l(d_p+d_w)\times l(d_p+d_w)}$ and $\mathbf{b}_{fake} \in \mathbb{R}^{1\times l(d_p+d_w)}$ are trainable parameters. σ is a non-linear activation - sigmoid, which makes final choices for retaining and discarding features in shared layer.

Then the shared features after filtering via gated sharing cell $\mathbf{g}_{fake}$ for the task of fake news detection are represented as:

$$\mathbf{G}_{fake} = \mathbf{g}_{fake} \odot \mathbf{H}_{shared} \quad (5)$$

where $\odot$ denotes element-wise multiplication.

Similarly, for the auxiliary task - the task of stance detection, filtering process in the gated sharing cell is the same as the task of fake news detection, so we do not reiterate them here.

Attention Sharing Cell To focus on helpful shared features that are beneficial to specific tasks from upstream shared layer, we devise an attention sharing cell based on attention mechanism. Specifically, this cell utilizes input embeddings of the specific task to weight shared features for paying more attention to helpful features. The inputs of this cell include two matrixes: the input embeddings of the specific task and the shared features of both tasks. The basic attention architecture of this cell, the same as shared-private feature extractor, also adopts transformer encoder (the details in subsection 3.2). However, in this architecture, query matrix and key matrix are not projections of the same matrix, i.e., query matrix $\mathbf{E}_{fake}$ is the input embeddings of fake news detection task, and key matrix $\mathbf{K}_{shared}$ and value matrix $\mathbf{V}_{shared}$ are the projections of shared features $\mathbf{H}_{shared}$. Formally, the attention sharing cell can be formalized as follows:

$$\begin{aligned}head_i = \text{Attention}(&\\ &\mathbf{E}_{fake}\mathbf{W}_i^Q, \mathbf{K}_{shared}\mathbf{W}_i^K, \mathbf{V}_{shared}\mathbf{W}_i^V)\end{aligned} \quad (6)$$

$$\begin{aligned}\mathbf{A}_{fake} &= \text{MultiHead}(\mathbf{H}_{fake}, \mathbf{K}_{shared}, \mathbf{V}_{shared}) \\ &= \text{Concat}(head_1, head_2, ..., head_h)\mathbf{W}^o\end{aligned} \quad (7)$$

where the dimensions of $\mathbf{E}_{fake}$, $\mathbf{K}_{shared}$, and $\mathbf{V}_{shared}$ are all $\mathbb{R}^{l\times(d_p+d_w)}$. The dimensions of remaining parameters in Eqs.(6, 7) are the same as in Eqs.(2, 3). Moreover, in order to guarantee the diversity of focused shared features, the number of heads h should not be set too large. Experiments show that our method performs the best performance when h is equal to 2.

Integration of the Two Cells We first convert the output of the two cells to vectors **G** and **A**, respectively, and then integrate the vectors in full by the absolute difference and element-wise product (Mou et al., 2016).

$$\mathbf{SSL} = [\mathbf{G}; |\mathbf{G} - \mathbf{A}|; \mathbf{G} \odot \mathbf{A}; \mathbf{A}] \quad (8)$$

where $\odot$ denotes element-wise multiplication and ; denotes concatenation.

3.4 The Output Layer

As the last layer, softmax functions are applied to achieve the classification of different tasks, which emits the prediction of probability distribution for the specific task i.

$$\hat{\mathbf{y}}_i = \text{softmax}(\mathbf{W}_i\mathbf{F}_i + \mathbf{b}_i) \quad (9)$$

$$\mathbf{F}_i = [\mathbf{H}_i; \mathbf{SSL}_i] \quad (10)$$

where $\hat{\mathbf{y}}_i$ is the predictive result, $\mathbf{F}_i$ is the concatenation of private features $\mathbf{H}_i$ of task i and the outputs $\mathbf{SSL}_i$ of selected sharing layer for task i. $\mathbf{W}_i$ and $\mathbf{b}_i$ are trainable parameters.

Given the prediction of all tasks, a global loss function forces the model to minimize the cross-entropy of prediction and true distribution for all the tasks:

$$\mathcal{L} = \sum_{i=1}^{N} \lambda_i L(\hat{\mathbf{y}}_i, \mathbf{y}_i) \quad (11)$$

$$L(\hat{\mathbf{y}}_i, \mathbf{y}_i) = \mathbf{y}_i log\hat{\mathbf{y}}_i + (1 - \mathbf{y}_i)log(1 - \hat{\mathbf{y}}_i) \quad (12)$$

where λ_i is the weight for the task i, and N is the number of tasks. In this paper, $N = 2$, and we give more weight λ to the task of fake news detection.

4 Experiments

4.1 Datasets and Evaluation Metrics

We use two public datasets for fake news detection and stance detection, i.e., RumourEval (Derczynski et al., 2017) and PHEME (Zubiaga et al., 2016b). We introduce both the datasets in details from three aspects: content, labels, and distribution.

Content. Both datasets contain Twitter conversation threads associated with different newsworthy events including the Ferguson unrest, the shooting at Charlie Hebdo, etc. A conversation thread consists of a tweet making a true and false claim, and a series of replies. **Labels.** Both datasets have the same labels on fake news detection and stance detection. Fake news is labeled as true, false, and unverified. Because we focus on classifying true and false tweets, we filter the unverified tweets. Stance of tweets is annotated as support, deny, query, and comment. **Distribution.** RumourEval contains 325 Twitter threads discussing rumours and PHEME includes 6,425 Twitter threads. Threads, tweets, and class distribution of the two datasets are shown in Table 1.

In consideration of the imbalance label distributions, in addition to accuracy (A) metric, we add Precision (P), Recall (R) and F1-score (F1) as complementary evaluation metrics for tasks. We hold out 10% of the instances in each dataset for model tuning, and the rest of the instances are performed 5-fold cross-validation throughout all experiments.

4.2 Settings

Pre-processing - Processing useless and inappropriate information in text: (1) removing nonalphabetic characters; (2) removing website links of text content; (3) converting all words to lower case and tokenize texts.

Parameters - hyper-parameters configurations of our model: for each task, we strictly turn all the hyper-parameters on the validation dataset, and we achieve the best performance via a small grid search. The sizes of word embeddings and position embeddings are set to 200 and 100. In transformer encoder, attention heads and blocks are set to 6 and 2 respectively, and the dropout of multi-head attention is set to 0.7. Moreover, the minibatch size is 64; the initial learning rate is set to 0.001, the dropout rate to 0.3, and λ to 0.6 for fake news detection.

4.3 Performance Evaluation

4.3.1 Baselines

SVM A Support Vector Machines model in (Derczynski et al., 2017) detects misinformation relying on manually extracted features.

CNN A Convolutional Neural Network model (Chen et al., 2017) employs pre-trained word embeddings based on Word2Vec as input embeddings

Datasets	Threads	Tweets	True	False	Unverified	Support	Deny	Query	Comment
RumourEval	325	5,568	145	74	106	1,004	415	464	3,685
PHEME	6,425	105,354	1,067	638	697	891	335	353	2,855

Table 1: Statistics of the two datasets.

Dataset	Measure	SVM	CNN	TE	DeClarE	MTL-LSTM	TRNN	Bayesian-DL	Ours
RumourEval	A(%)	71.42	61.90	66.67	66.67	66.67	76.19	80.95	**81.48**
	P(%)	66.67	54.54	60.00	58.33	57.14	70.00	**77.78**	72.24
	R(%)	66.67	66.67	66.67	77.78	**88.89**	77.78	77.78	86.31
	F1(%)	66.67	59.88	63.15	66.67	69.57	73.68	77.78	**78.65**
PHEME	A(%)	72.18	59.23	65.22	67.87	74.94	78.65	80.33	**81.27**
	P(%)	**78.80**	56.14	63.05	64.68	68.77	77.11	78.29	73.41
	R(%)	75.75	64.64	64.64	71.21	87.87	78.28	79.29	**88.10**
	F1(%)	72.10	60.09	63.83	67.89	77.15	77.69	78.78	**80.09**

Table 2: Performance comparison of our sifted multi-task learning method against the baselines.

to capture features similar to n-grams.

TE Tensor Embeddings (Guacho et al., 2018) leverages tensor decomposition to derive concise claim embeddings, which are used to create a claim-by-claim graph for label propagation.

DeClarE Evidence-Aware Deep Learning (Popat et al., 2018) encodes claims and articles by Bi-LSTM and focuses on each other based on attention mechanism, and then concatenates claim source and article source information.

MTL-LSTM A multi-task learning model based on LSTM networks (Kochkina et al., 2018) trains jointly the tasks of veracity classification, rumor detection, and stance detection.

TRNN Tree-structured RNN (Ma et al., 2018b) is a bottom-up and a top-down tree-structured model based on recursive neural networks.

Bayesian-DL Bayesian Deep Learning model (Zhang et al., 2019) first adopts Bayesian to represent both the prediction and uncertainty of claim and then encodes replies based on LSTM to update and generate a posterior representations.

4.3.2 Compared with State-of-the-art Methods

We perform experiments on RumourEval and PHEME datasets to evaluate the performance of our method and the baselines. The experimental results are shown in Table 2. We gain the following observations:

- On the whole, most well-designed deep learning methods, such as ours, Bayesian-DL, and TRNN, outperform feature engineering-based methods, like SVM. This illustrates that deep learning methods can represent better intrinsic semantics of claims and replies.
- In terms of recall (R), our method and MTL-LSTM, both based on multi-task learning, achieve more competitive performances than other baselines, which presents that sufficient features are shared for each other among multiple tasks. Furthermore, our method reflects a more noticeable performance boost than MTL-LSTM on both datasets, which extrapolates that our method earns more valuable shared features.
- Although our method shows relatively low performance in terms of precision (P) and recall (R) compared with some specific models, our method achieves the state-of-the-art performance in terms of accuracy (A) and F1-score (F1) on both datasets. Taking into account the tradeoff among different performance measures, this reveals the effectiveness of our method in the task of fake news detection.

4.4 Discussions

4.4.1 Model Ablation

To evaluate the effectiveness of different components in our method, we ablate our method into several simplified models and compare their performance against related methods. The details of these methods are described as follows:

Single-task Single-task is a model with transformer encoder as the encoder layer of the model for fake news detection.

MT-lstm The tasks of fake news detection and stance detection are integrated into a shared-private model and the encoder of the model is achieved by LSTM.

	RumourEval				PHEME			
	A(%)	P(%)	R(%)	F1(%)	A(%)	P(%)	R(%)	F1(%)
Single-task	62.86	54.21	65.43	59.29	60.94	55.56	64.53	58.57
MT-lstm	65.90	56.61	85.60	68.15	71.61	66.24	85.31	75.29
MT-trans	71.67	58.43	78.78	67.10	75.57	65.73	78.94	71.73
MT-trans-G	74.89	64.32	81.68	71.97	76.24	67.32	83.56	74.57
MT-trans-A	79.22	68.97	84.86	76.10	79.54	70.90	86.71	78.01
MT-trans-G-A	82.10	72.24	86.31	78.65	81.27	73.41	88.10	80.09

Table 3: Ablation analysis of the sifted multi-task learning method.

SL:	what	why	wrong	scary	like	fact			great	probably
SSL-FND:	what		wrong	scary		fact	few		false	real
SSL-SD:		why	wrong		like			hold	confirm	misleading
PL-FND:	what			scary		few	really		no	notice
PL-SD:		why			like		really	hold	sure	doubt

Figure 4: Typical tokens obtained by different layers of the sifted multi-task learning method. In our proposed method, typical tokens are captured by shared layer (SL), selected sharing layer for fake news detection (SSL-FND), selected sharing layer for stance detection (SSL-SD), private layer for fake news detection (PL-FND), and private layer for stance detection (PL-SD) respectively. A column of the same color represents the distribution of one token in different layers, while the last two columns denote unique tokens captured by different layers.

MT-trans The only difference between MT-trans and MT-lstm is that encoder of MT-trans is composed of transformer encoder.

MT-trans-G On the basis of MT-trans, MT-trans-G adds gated sharing cell behind the shared layer of MT-trans to filter shared features.

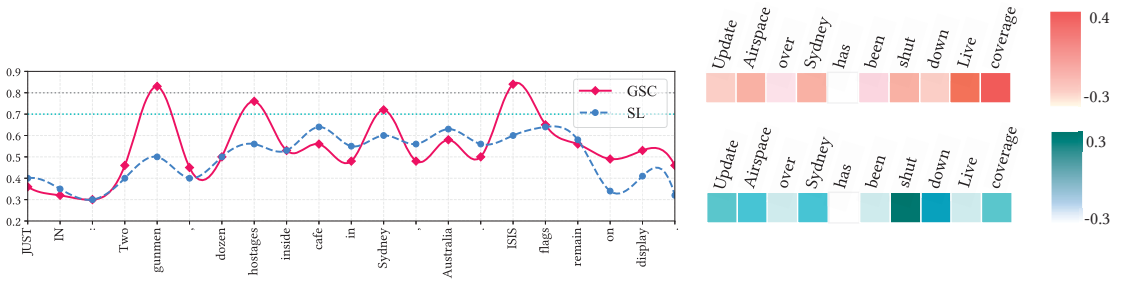
MT-trans-A Unlike MT-trans-G, MT-trans-A replaces gated sharing cell with attention sharing cell for selecting shared features.

MT-trans-G-A Gated sharing cell and attention sharing cell are organically combined as selected sharing layer behind the shared layer of MT-trans, called MT-trans-G-A.

Table 3 provides the experimental results of these methods on RumourEval and PHEME datasets. We have the following observations:

- Effectiveness of multi-task learning. MT-trans boosts about 9% and 15% performance improvements in accuracy on both datasets compared with Single-task, which indicates that the multi-task learning method is effective to detect fake news.

- Effectiveness of transformer encoder. Compared with MT-lstm, MT-trans obtains more excellent performance, which explains that transformer encoder has better encoding ability than LSTM for news text on social media.



- Effectiveness of the selected sharing layer. Analysis of the results of the comparison with MT-trans, MT-trans-G, MT-Trans-A, and MT-trans-G-A shows that MT-trans-G-A ensures optimal performance with the help of the selected sharing layer of the model, which confirms the reasonability of selectively sharing different features for different tasks.

4.4.2 Error Analysis

Although the sifted multi-task learning method outperforms previous state-of-the-art methods on two datasets (From Table 2), we observe that the proposed method achieves more remarkable performance boosts on PHEME than on RumourEval. There are two reasons for our analysis according to Table 1 and Table 2. One is that the number of training examples in RumourEval (including 5,568 tweets) is relatively limited as compared with PHEME (including 105,354 tweets), which is not enough to train deep neural networks. Another is that PHEME includes more threads (6,425 threads) than RumourEval (325 threads) so that PHEME can offer more rich credibility features to our proposed method.

4.5 Case Study

In order to obtain deeper insights and detailed interpretability about the effectiveness of the selected shared layer of the sifted multi-task learning method, we devise experiments to explore some ideas in depth: 1) Aiming at different tasks, what effective features can the selected sharing layer in our method obtain? 2) In the selected sharing layer, what features are learned from different cells?

(a) Obtained weights of tokens by two models

(b) Neuron behaviours of $\mathbf{A}_{fake}$ and $\mathbf{A}_{stance}$

Figure 5: (a) In fake news detection task, the GSC line denotes the weight values $\mathbf{g}_{fake}$ of gated sharing cell, while the SL line represents feature weights of $\mathbf{H}_{shared}$ in the shared layer. Two horizontal lines give two different borders to determine the importance of tokens. (b) The red and green heatmaps describe the neuron behaviours of attention sharing cell $\mathbf{A}_{fake}$ in fake news detection task and $\mathbf{A}_{stance}$ in stance detection task, respectively.

4.5.1 The Visualization of Shared Features Learned from Two Tasks

We visualize shared features learned from the tasks of fake news detection and stance detection. Specifically, we first look up these elements with the largest values from the outputs of the shared layer and the selected shared layer respectively. Then, these elements are mapped into the corresponding values in input embeddings so that we can find out specific tokens. The experimental results are shown in Figure 4. We draw the following observations:

- Comparing PL-FND and PL-SD, private features in private layer from different tasks are different. From PL-FND, PL-SD, and SLT, the combination of the private features and shared features from shared layer increase the diversity of features and help to promote the performance of both fake news detection and stance detection.

- By compared SL, SSL-FND, and SSL-SD, selected sharing layers from different tasks can not only filter tokens from shared layer (for instance, 'what', 'scary', and 'fact' present in SL but not in SSL-SD), but also capture helpful tokens for its own task (like 'false' and 'real' in SSL-FND, and 'confirm' and 'misleading' in SSL-SD).

4.5.2 The Visualization of Different Features Learned from Different Cells

To answer the second question, we examine the neuron behaviours of gated sharing cell and attention sharing cell in the selected sharing layer, respectively. More concretely, taking the task of fake news detection as an example, we visualize feature weights of $\mathbf{H}_{shared}$ in the shared layer and show the weight values $\mathbf{g}_{fake}$ in gated sharing cell. By that we can find what kinds of features are discarded as interference, as shown in Figure 5(a). In addition, for attention sharing cell, we visualize which tokens are concerned in attention sharing cell, as shown in Figure 5(b). From Figure 5(a) and 5(b), we obtain the following observations:

- In Figure 5(a), only the tokens "gunmen, hostages, Sydney, ISIS" give more attention compared with vanilla shared-private model (SP-M). In more details, 'gunmen' and 'ISIS' obtain the highest weights. These illustrate that gated sharing cell can effectively capture key tokens.

- In Figure 5(b), "live coverage", as a prominent credibility indicator, wins more concerns in the task of fake news detection than other tokens. By contrast, when the sentence of Figure 5(b) is applied to the task of stance detection, the tokens "shut down" obtain the maximum weight, instead of "live coverage". These may reveal that attention sharing cell focuses on different helpful features from the shared layer for different tasks.

5 Conclusion

In this paper, we explored a sifted multi-task learning method with a novel selected sharing structure for fake news detection. The selected sharing structure fused single gate mechanism for filtering useless shared features and attention mechanism for paying close attention to features that were helpful to target tasks. We demonstrated the effectiveness of the proposed method on two public, challenging

datasets and further illustrated by visualization experiments. There are several important directions remain for future research: (1) the fusion mechanism of private and shared features; (2) How to represent meta-data of fake news better to integrate into inputs.

Abstract

We present a text-based framework for investigating moral sentiment change of the public via longitudinal corpora. Our framework is based on the premise that language use can inform people's moral perception toward right or wrong, and we build our methodology by exploring moral biases learned from diachronic word embeddings. We demonstrate how a parameter-free model supports inference of historical shifts in moral sentiment toward concepts such as slavery and democracy over centuries at three incremental levels: moral relevance, moral polarity, and fine-grained moral dimensions. We apply this methodology to visualizing moral time courses of individual concepts and analyzing the relations between psycholinguistic variables and rates of moral sentiment change at scale. Our work offers opportunities for applying natural language processing toward characterizing moral sentiment change in society.

1 Moral sentiment change and language

People's moral sentiment—our feelings toward right or wrong—can change over time. For instance, the public's views toward *slavery* have shifted substantially over the past centuries (Oldfield, 2012). How society's moral views evolve has been a long-standing issue and a constant source of controversy subject to interpretations from social scientists, historians, philosophers, among others. Here we ask whether natural language processing has the potential to inform moral sentiment change in society at scale, involving minimal human labour or intervention.

The topic of moral sentiment has been thus far considered a traditional inquiry in philosophy (Hume, 1739; Smith, 1759; Kant, 1785), with contemporary development of this topic represented in social psychology (Piaget, 1932; Kohlberg, 1969; Stigler et al., 1990; Fiske and Taylor, 1991; Pizarro and Bloom, 2003), cognitive linguistics (Lakoff, 1996), and more recently, the advent of Moral Foundations Theory (Haidt and Joseph, 2004; Haidt et al., 2007; Graham et al., 2013). Despite the fundamental importance and interdisciplinarity of this topic, large-scale formal treatment of moral sentiment, particularly its evolution, is still in infancy from the natural language processing (NLP) community (see overview in Section 2).

We believe that there is a tremendous potential to bring NLP methodologies to bear on the problem of moral sentiment change. We build on extensive recent work showing that word embeddings reveal implicit human biases (Bolukbasi et al., 2016; Caliskan et al., 2017) and social stereotypes (Garg et al., 2018). Differing from this existing work, we demonstrate that moral sentiment change can be revealed by moral biases implicitly learned from diachronic text corpora. Accordingly, we present to our knowledge the first text-based framework for probing moral sentiment change at a large scale with support for different levels of analysis concerning *moral relevance*, *moral polarity*, and *fine-grained moral dimensions*. As such, for any query item such as *slavery*, our goal is to automatically infer its moral trajectories from sentiments at each of these levels over a long period of time.

Our approach is based on the premise that people's moral sentiments are reflected in natural language, and more specifically, in text (Bloom, 2010). In particular, we know that books are highly effective tools for conveying moral views to the public. For example, *Uncle Tom's Cabin* (Stowe, 1852) was central to the anti-slavery movement in the United States. The framework that we develop builds on this premise to explore

*Equal contribution.

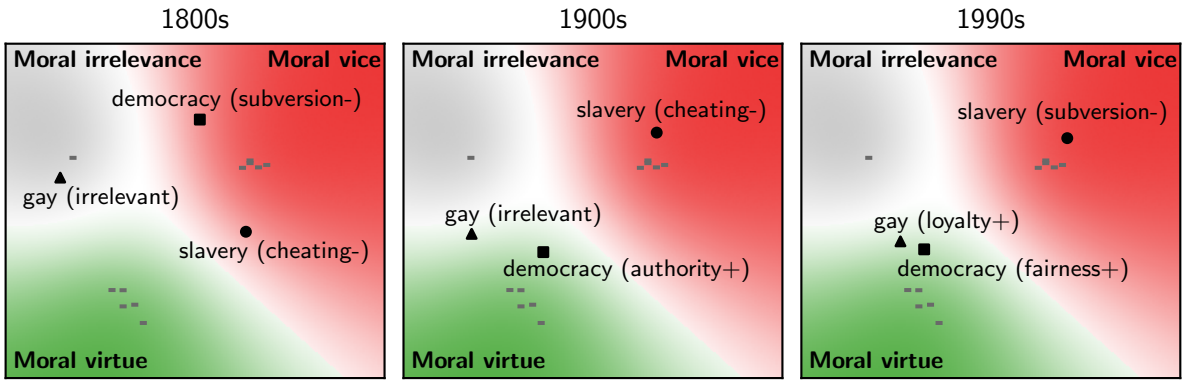

Figure 1: Illustration of moral sentiment change over the past two centuries. Moral sentiment trajectories of three probe concepts, *slavery*, *democracy*, and *gay*, are shown in moral sentiment embedding space through 2D projection from Fisher's discriminant analysis with respect to seed words from the classes of *moral virtue*, *moral vice*, and *moral irrelevance*. Parenthesized items represent moral categories predicted to be most strongly associated with the probe concepts. Gray markers represent the fine-grained centroids (or anchors) of these moral classes.

changes in moral sentiment reflected in longitudinal or historical text.

Figure 1 offers a preview of our framework by visualizing the evolution trajectories of the public's moral sentiment toward concepts signified by the probe words *slavery*, *democracy*, and *gay*. Each of these concepts illustrates a piece of "moral history" tracked through a period of 200 years (1800 to 2000), and our framework is able to capture nuanced moral changes. For instance, *slavery* initially lies at the border of moral virtue (positive sentiment) and vice (negative sentiment) in the 1800s yet gradually moves toward the center of moral vice over the 200-year period; in contrast, *democracy* considered morally negative (e.g., subversion and anti-authority under monarchy) in the 1800s is now perceived as morally positive, as a mechanism for fairness; *gay*, which came to denote homosexuality only in the 1930s (Kay et al., 2019), is inferred to be morally irrelevant until the modern day. We will describe systematic evaluations and applications of our framework that extend beyond these anecdotal cases of moral sentiment change.

The general text-based framework that we propose consists of a parameter-free approach that facilitates the prediction of public moral sentiment toward individual concepts, automated retrieval of morally changing concepts, and broad-scale psycholinguistic analyses of historical rates of moral sentiment change. We provide a description of the probabilistic models and data used, followed by comprehensive evaluations of our methodology.

2 Emerging NLP research on morality

An emerging body of work in natural language processing and computational social science has investigated how NLP systems can detect moral sentiment in online text. For example, moral rhetoric in social media and political discourse (Garten et al., 2016; Johnson and Goldwasser, 2018; Lin et al., 2018), the relation between moralization in social media and violent protests (Mooijman et al., 2018), and bias toward refugees in talk radio shows (Gillani and Levy, 2019) have been some of the topics explored in this line of inquiry. In contrast to this line of research, the development of a formal framework for moral sentiment change is still under-explored, with no existing systematic and formal treatment of this topic (Bloom, 2010).

While there is emerging awareness of ethical issues in NLP (Hovy et al., 2017; Alfano et al., 2018), work exploiting NLP techniques to study principles of moral sentiment change is scarce. Moreover, since morality is variable across cultures and time (Graham et al., 2013; Bloom, 2010), developing systems that capture the diachronic nature of moral sentiment will be a pivotal research direction. Our work leverages and complements existing research that finds implicit human biases from word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017; Garten et al., 2016) by developing a novel perspective on using NLP methodology to discover principles of moral sentiment change in human society.

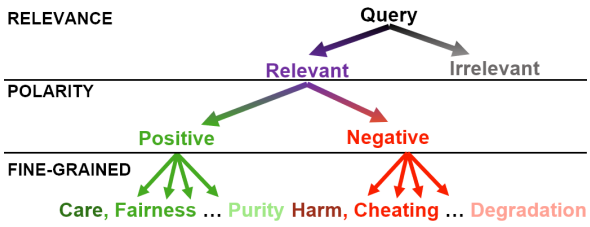

Figure 2: Illustration of the three-tier framework that supports moral sentiment inference at different levels.

3 A three-tier modelling framework

Our framework treats the moral sentiment toward a concept at three incremental levels, as illustrated in Figure 2. First, we consider moral relevance, distinguishing between morally irrelevant and morally relevant concepts. At the second tier, moral polarity, we further split morally relevant concepts into those that are positively or negatively perceived in the moral domain. Finally, a third tier classifies these concepts into fine-grained categories of human morality.

We draw from research in social psychology to inform our methodology, most prominently Moral Foundations Theory (MFT; Graham et al., 2013). MFT seeks to explain the structure and variation of human morality across cultures, and proposes five moral foundations: Care / Harm, Fairness / Cheating, Loyalty / Betrayal, Authority / Subversion, and Sanctity / Degradation. Each foundation is summarized by a positive and a negative pole, resulting in ten fine-grained moral categories.

3.1 Lexical data for moral sentiment

To ground moral sentiment in text, we leverage the Moral Foundations Dictionary (MFD; Graham et al., 2009). The MFD is a psycholinguistic resource that associates each MFT category with a set of *seed words*, which are words that provide evidence for the corresponding moral category in text. We use the MFD for moral polarity classification by dividing seed words into positive and negative sets, and for fine-grained categorization by splitting them into the 10 MFT categories.

To implement the first tier of our framework and detect moral relevance, we complement our morally relevant seed words with a corresponding set of seed words approximating moral irrelevance based on the notion of valence, i.e., the degree of pleasantness or unpleasantness of a stimulus. We refer to the emotional valence ratings collected by Warriner et al. (2013) for approximately 14,000 English words, and choose the words with most neutral valence rating that do not occur in the MFD as our set of morally irrelevant seed words, for an equal total number of morally relevant and morally irrelevant words.

3.2 Models

We propose and evaluate a set of probabilistic models to classify concepts in the three tiers of morality specified above. Our models exploit the semantic structure of word embeddings (Mikolov et al., 2013) to perform tiered moral classification of query concepts. In each tier, the model receives a query word embedding vector $\mathbf{q}$ and a set of seed words for each class in that tier, and infers the posterior probabilities over the set of classes c to which the query concept is associated with.

The seed words function as "labelled examples" that guide the moral classification of novel concepts, and are organized per classification tier as follows. In moral relevance classification, sets $\mathbf{S}_0$ and $\mathbf{S}_1$ contain the morally irrelevant and morally relevant seed words, respectively; for moral polarity, $\mathbf{S}_+$ and $\mathbf{S}_-$ contain the positive and negative seed words; and for fine-grained moral categories, $\mathbf{S}_1, \ldots, \mathbf{S}_{10}$ contain the seed words for the 10 categories of MFT. Then our general problem is to estimate $p(c \mid \mathbf{q})$, where $\mathbf{q}$ is a query vector and c is a moral category in the desired tier.

We evaluate the following four models:

- A Centroid model summarizes each set of seed words by its expected vector in embedding space, and classifies concepts into the class of closest expected embedding in Euclidean distance following a softmax rule;
- A Naïve Bayes model considers both mean and variance, under the assumption of independence among embedding dimensions, by fitting a normal distribution with mean vector and diagonal covariance matrix to the set of seed words of each class;
- A k-Nearest Neighbors (kNN) model exploits local density estimation and classifies concepts according to the majority vote of the k seed words closest to the query vector;
- A Kernel Density Estimation (KDE) model performs density estimation at a broader scale by considering the contribution of each seed word toward the total likelihood of each

Model	Parameter	Posterior Inference
Centroid	–	$p(c \mid \mathbf{q}) \propto \exp\left(-\left\|\mathbf{q} - \mathrm{E}\left[\mathbf{S}_c\right]\right\|\right)$
Naïve Bayes	–	$p(c \mid \mathbf{q}) \propto \prod_{j=1}^{d} f_N\left(\mathbf{q}_j; \mu = \mathrm{E}\left[\mathbf{S}_{c,j}\right], \sigma^2 = \mathrm{Var}\left[\mathbf{S}_{c,j}\right]\right)$
k-Nearest Neighbors (kNN)	k	$p(c \mid \mathbf{q}) \propto \left\lvert \{k \text{ nearest seed words to } \mathbf{q}\} \cap \mathbf{S}_c \right\rvert$
Kernel Density Estimation (KDE)	h	$p(c \mid \mathbf{q}) \propto \frac{1}{\lvert\mathbf{S}_c\rvert} \sum_{\mathbf{w} \in \mathbf{S}_c} f_{MN}\left(\mathbf{q}; \mu = \mathbf{w}, \Sigma = \mathrm{diag}(h)\right)$

Table 1: Summary of models for moral sentiment classification. Each model infers moral sentiment of a query word vector $\mathbf{q}$ based on moral classes c (at any of the three levels) represented by moral seed words $\mathbf{S}_c$. $\mathrm{E}\left[\mathbf{S}_c\right]$ is the mean vector of $\mathbf{S}_c$; $\mathrm{E}\left[\mathbf{S}_{c,j}\right], \mathrm{Var}\left[\mathbf{S}_{c,j}\right]$ refer to the mean and variance of $\mathbf{S}_c$ along the j-th dimension in embedding space. d is the number of embedding dimensions; and f_N, f_{MN} refer to the density functions of univariate and multivariate normal distributions, respectively.

class, regulated by a bandwidth parameter h that controls the sensitivity of the model to distance in embedding space.

Table 1 specifies the formulation of each model. Note that we adopt a parsimonious design principle in our modelling: both Centroid and Naïve Bayes are parameter-free models, kNN only depends on the choice of k, and KDE uses a single bandwidth parameter h.

4 Historical corpus data

To apply our models diachronically, we require a word embedding space that captures the meanings of words at different points in time and reflects changes pertaining to a particular word as diachronic shifts in a common embedding space.

Following Hamilton et al. (2016), we combine skip-gram word embeddings (Mikolov et al., 2013) trained on longitudinal corpora of English with rotational alignments of embedding spaces to obtain diachronic word embeddings that are aligned through time.

We divide historical time into decade-long bins, and use two sets of embeddings provided by Hamilton et al. (2016), each trained on a different historical corpus of English:

- Google N-grams (Lin et al., 2012): a corpus of 8.5×10^{11} tokens collected from the English literature (Google Books, all-genres) spanning the period 1800–1999.
- COHA (Davies, 2010): a smaller corpus of 4.1×10^{8} tokens from works selected so as to be genre-balanced and representative of American English in the period 1810–2009.

5 Model evaluations

We evaluated our models in two ways: classification of moral seed words on all three tiers (moral relevance, polarity, and fine-grained categories), and correlation of model predictions with human judgments.

5.1 Moral sentiment inference of seed words

In this evaluation, we assessed the ability of our models to classify the seed words that compose our moral environment in a leave-one-out classification task. We performed the evaluation for all three classification tiers: 1) moral relevance, where seed words are split into morally relevant and morally irrelevant; 2) moral polarity, where moral seed words are split into positive and negative; 3) fine-grained categories, where moral seed words are split into the 10 MFT categories. In each test, we removed one seed word from the training set at a time to obtain cross-validated model predictions.

Table 2 shows classification accuracy for all models and corpora on each tier for the 1990–1999 period.[1] We observe that all models perform substantially better than chance, confirming the efficacy of our methodology in capturing moral dimensions of words. We also observe that models using word embeddings trained on Google N-grams perform better than those trained on COHA, which could be expected given the larger corpus size of the former.

In the remaining analyses, we employ the Centroid model, which offers competitive accuracy and a simple, parameter-free specification.

5.2 Alignment with human valence ratings

We evaluated the approximate agreement between our methodology and human judgments using valence ratings, i.e., the degree of pleasantness or un-

[1] We also computed average accuracy over all decades using Google N-grams, the only corpus covering all moral categories through time. See Supplementary Material.

	Google N-grams			COHA		
Model	**Relevance**	**Polarity**	**Category**	**Relevance**	**Polarity**	**Category**

Table 2: Classification accuracy of moral seed words for moral relevance, moral polarity, and fine-grained moral categories based on 1990–1999 word embeddings for two independent corpora, Google N-grams and COHA.

Corpus	**Correlation**
Google N-grams	0.43 ($n = 12293; p < 0.0001$)
COHA	0.38 ($n = 7141; p < 0.0001$)

Table 3: Pearson correlations between model predicted moral sentiment polarities and human valence ratings.

pleasantness of a stimulus. Our assumption is that the valence of a concept should correlate with its perceived moral polarity, e.g., morally repulsive ideas should evoke an unpleasant feeling. However, we do not expect this correspondence to be perfect; for example, the concept of *dessert* evokes a pleasant reaction without being morally relevant.

In this analysis, we took the valence ratings for the nearly 14,000 English nouns collected by Warriner et al. (2013) and, for each query word q, we generated a corresponding prediction of positive moral polarity from our model, $P(c_+ \mid \mathbf{q})$. Table 3 shows the correlations between human valence ratings and predictions of positive moral polarity generated by models trained on each of our corpora. We observe that the correlations are significant, suggesting the ability of our methodology to capture relevant features of moral sentiment from text.

In the remaining applications, we use the diachronic embeddings trained on the Google N-grams corpus, which enabled superior model performance throughout our evaluations.

6 Applications to diachronic morality

We applied our framework in three ways: 1) evaluation of selected concepts in historical time courses and prediction of human judgments; 2) automatic detection of moral sentiment change; and 3) broad-scale study of the relations between psycholinguistic variables and historical change of moral sentiment toward concepts.

6.1 Moral change in individual concepts

Historical time courses. We applied our models diachronically to predict time courses of moral relevance, moral polarity, and fine-grained moral categories toward two historically relevant topics: slavery and democracy. By grounding our model in word embeddings for each decade and querying concepts at the three tiers of classification, we obtained the time courses shown in Figure 3.

We note that these trajectories illustrate actual historical trends. Predictions for democracy show a trend toward morally positive sentiment, consistent with the adoption of democratic regimes in Western societies. On the other hand, predictions for slavery trend down and suggest a drop around the 1860s, coinciding with the American Civil War. We also observe changes in the dominant fine-grained moral categories, such as the perception of democracy as a fair concept, suggesting potential mechanisms behind the polarity changes and providing further insight into the public sentiment toward these concepts as evidenced by text.

Prediction of human judgments. We explored the predictive potential of our framework by comparing model predictions with human judgments of moral relevance and acceptability. We used data from the Pew Research Center's 2013 Global Attitudes survey (Pew Research Center, 2013), in which participants from 40 countries judged 8 topics such as *abortion* and *homosexuality* as one of "acceptable", "unacceptable", and "not a moral issue".

We compared human ratings with model predictions at two tiers: for moral relevance, we paired the proportion of "not a moral issue" human responses with irrelevance predictions $p(c_0 \mid \mathbf{q})$ for

Concept	Rate (e−03/decade)	Relevant Moral Category	Switching Period

Table 5: Top 10 changing words towards moral positive (upper panel) and negative (lower panel) polarities, with model-inferred most representative moral categories during historical and modern periods and the switching periods. *, **, and *** denote $p < 0.05$, $p < 0.001$, and $p < 0.0001$, all Bonferroni-corrected for multiple tests.

each topic, and for moral acceptability, we paired the proportion of "acceptable" responses with positive predictions $p(c_+ \mid \mathbf{q})$. We used 1990s word embeddings, and obtained predictions for two-word topics by querying the model with their averaged embeddings.

Figure 4 shows plots of relevance and polarity predictions against survey proportions, and we observe a visible correspondence between model predictions and human judgments despite the difficulty of this task and limited number of topics.

6.2 Retrieval of morally changing concepts

Beyond analyzing selected concepts, we applied our framework predictively on a large repertoire of words to automatically discover the concepts that have exhibited the greatest change in moral sentiment at two tiers, moral relevance and moral polarity.

We selected the 10,000 nouns with highest total frequency in the 1800–1999 period according to data from Hamilton et al. (2016), restricted to words labelled as nouns in WordNet (Miller,

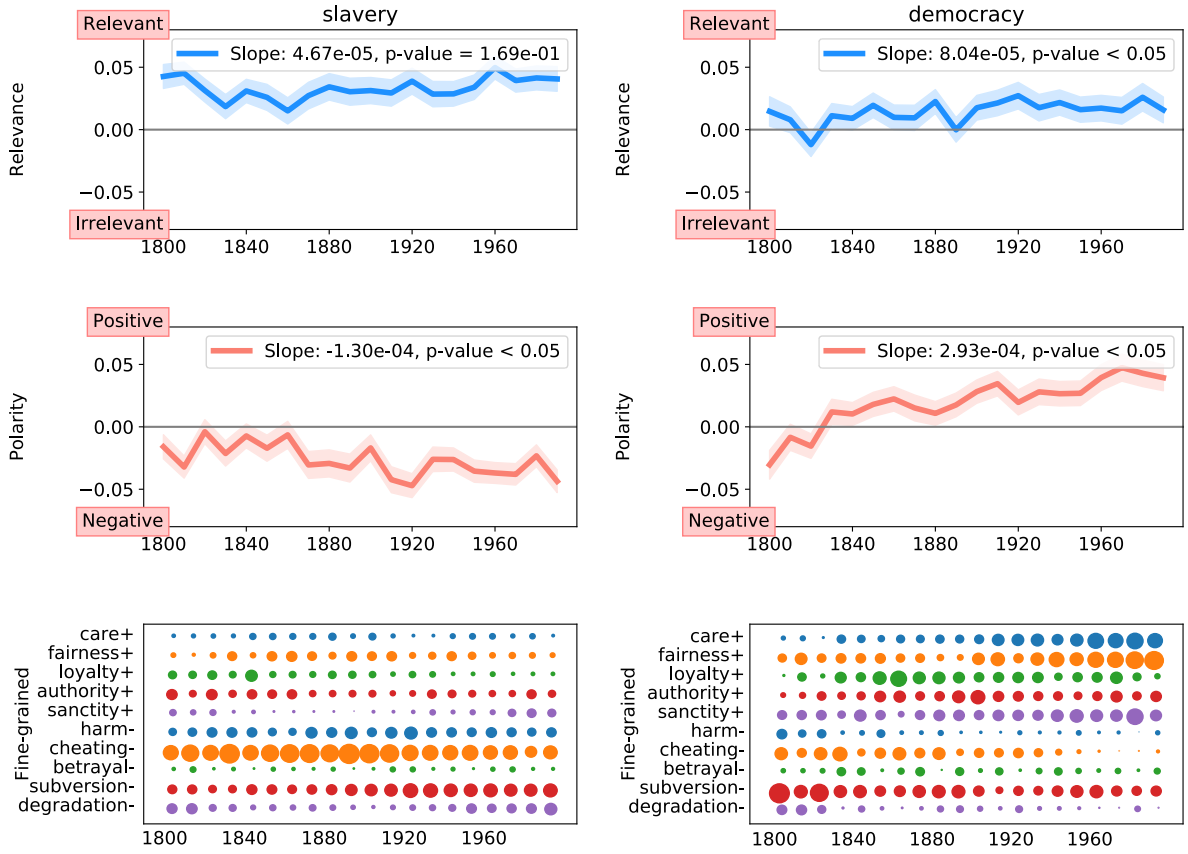

Figure 3: Moral sentiment time courses of *slavery* (left) and *democracy* (right) at each of the three levels, inferred by the Centroid model. Time courses at the moral relevance and polarity levels are in log odds ratios, and those for the fine-grained moral categories are represented by circles with sizes proportional to category probabilities.

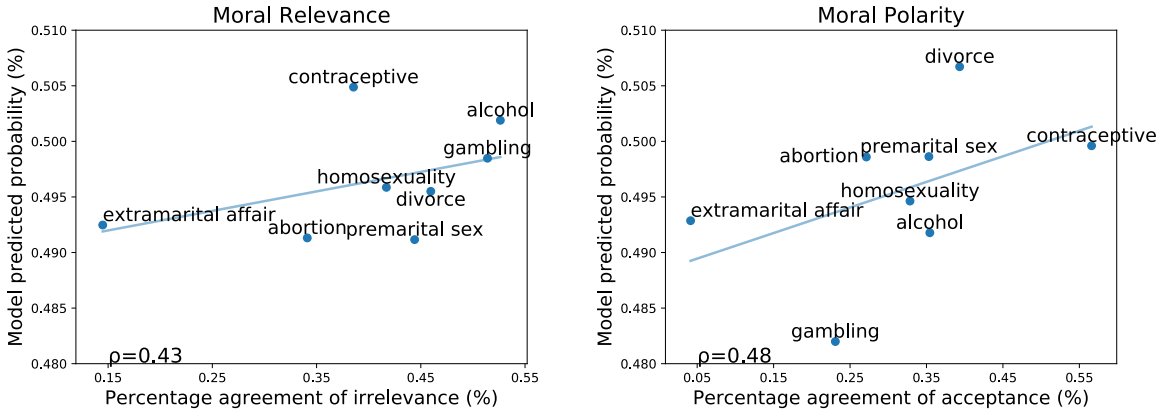

Figure 4: Model predictions against percentage of Pew respondents who selected "Not a moral concern" (left) or "Acceptable" (right), with lines of best fit and Pearson correlation coefficients ρ shown in the background.

1995) for validation. For each such word $\mathbf{q}$, we computed diachronic moral relevance scores $R_i = p(c_1 \mid \mathbf{q}), i = 1,\ldots,20$ for the 20 decades in our time span. Then, we performed a linear regression of R on $T = 1,\ldots,n$ and took the fitted slope as a measure of moral relevance change. We repeated the same procedure for moral polarity. Finally, we removed words with average relevance score below 0.5 to focus on morally relevant retrievals.

Table 4 shows the words with steepest predicted change toward moral relevance, along with their predicted fine-grained moral categories in mod-

ern times (i.e., 1900–1999). Table 5 shows the words with steepest predicted change toward the positive and negative moral poles. To further investigate the moral sentiment that may have led to such polarity shifts, we also show the predicted fine-grained moral categories of each word at its earliest time of predicted moral relevance and in modern times. Although we do not have access to ground truth for this application, these results offer initial insight into the historical moral landscape of the English language at scale.

6.3 Broad-scale investigation of moral change

In this application, we investigated the hypothesis that concept concreteness is inversely related to change in moral relevance, i.e., that concepts considered more abstract might become morally relevant at a higher rate than concepts considered more concrete. To test this hypothesis, we performed a multiple linear regression analysis on rate of change toward moral relevance of a large repertoire of words against concept concreteness ratings, word frequency (a correlate of semantic change; see Hamilton et al., 2016), and word length (as a proxy for concept complexity; see Lewis and Frank, 2016).

We obtained norms of concreteness ratings from Warriner et al. (2013). We collected the same set of high-frequency nouns as in the previous analysis, along with their fitted slopes of moral relevance change. Since we were interested in moral relevance change within this large set of words, we restricted our analysis to those words whose model predictions indicate change in moral relevance, in either direction, from the 1800s to the 1990s.

We performed a multiple linear regression under the following model:

$$\tilde{\rho}(w) = \beta_f \log(f(w)) + \beta_l l(w) + \beta_c c(w) + \beta_0 + \tilde{\varepsilon} \quad (1)$$

Here $\rho(w)$ is the slope of moral relevance change for word w; $f(w)$ is its average frequency; $l(w)$ is its character length; $c(w)$ is its concreteness rating; β_f, β_l, β_c, and β_0 are the corresponding factor weights and intercept, respectively; and $\varepsilon \sim \mathcal{N}(0, \sigma)$ is the regression error term.

Table 6 shows the results of multiple linear regression. We observe that concreteness is a significant negative predictor of change toward moral relevance, suggesting that abstract concepts are more strongly associated with increasing moral relevance over time than concrete concepts. This

Factor	Coeff. (e-03)	Significance
Frequency	0.1	$p < 0.001$
Length	-0.03	n.s. ($\alpha = 0.05$)
Concreteness	-0.2	$p < 0.002$

Table 6: Results from multiple regression that regresses rate of change in moral relevance against the factors of word frequency, length, and concreteness ($n = 606$).

significance persists under partial correlation test against the control factors ($p < 0.01$).

We further verified the diachronic component of this effect in a random permutation analysis. We generated 1,000 control time courses by randomly shuffling the 20 decades in our data, and repeated the regression analysis to obtain a control distribution for each regression coefficient. All effects became non-significant under the shuffled condition, suggesting the relevance of concept concreteness for diachronic change in moral sentiment (see Supplementary Material).

7 Discussion and conclusion

We presented a text-based framework for exploring the socio-scientific problem of moral sentiment change. Our methodology uses minimal parameters and exploits implicit moral biases learned from diachronic word embeddings to reveal the public's moral perception toward a large concept repertoire over a long historical period.

Differing from existing work in NLP that treats moral sentiment as a flat classification problem (Garten et al., 2016; Johnson and Goldwasser, 2018), our framework probes moral sentiment change at multiple levels and captures moral dynamics concerning relevance, polarity, and fine-grained categories informed by Moral Foundations Theory (Graham et al., 2013). We applied our methodology to the automated analyses of moral change both in individual concepts and at a broad scale, thus providing insights into psycholinguistic variables that associate with rates of moral change in the public.

Our current work focuses on exploring moral sentiment change in English-speaking cultures. Future research should evaluate the appropriateness of the framework to probing moral change from a diverse range of cultures and linguistic backgrounds, and the extent to which moral sentiment change interacts and crisscrosses with linguistic meaning change and lexical coinage. Our

work creates opportunities for applying natural language processing toward characterizing moral sentiment change in society.

Detecting Causal Language Use in Science Findings

Bei Yu[1], Yingya Li[1], and Jun Wang[2]

[1]School of Information Studies, Syracuse University

Abstract

Causal interpretation of correlational findings from observational studies has been a major type of misinformation in science communication. Prior studies on identifying inappropriate use of causal language relied on manual content analysis, which is not scalable for examining a large volume of science publications. In this study, we first annotated a corpus of over 3,000 PubMed research conclusion sentences, then developed a BERT-based prediction model that classifies conclusion sentences into "no relationship", "correlational", "conditional causal", and "direct causal" categories, achieving an accuracy of 0.90 and a macro-F1 of 0.88. We then applied the prediction model to measure the causal language use in the research conclusions of about 38,000 observational studies in PubMed. The prediction result shows that 21.7% studies used direct causal language exclusively in their conclusions, and 32.4% used some direct causal language. We also found that the ratio of causal language use differs among authors from different countries, challenging the notion of a shared consensus on causal language use in the global science community. Our prediction model could also be used to help identify the inappropriate use of causal language in science publications.

1 Introduction

Establishing causality is one of the most important goals and concerns of science. Therefore, the language that describes causal relationships plays a crucial role in communicating science findings among scientists and with the general public (Kleinberg and Hripcsak, 2011). However, scientists and journalists have been found to inappropriately use causal language in research publications and news articles. Specifically, causal interpretation of correlational findings from observational studies has been a major type of misinformation in science communication (Cofield et al., 2010; Sumner et al., 2014; Chiu et al., 2017; Boutron and Ravaud, 2018). In scientific research, observational studies (non-intervention) are designed for testing association/correlation between variables, while intervention studies, such as clinical trials, are for testing causal relations (Buhse et al., 2018). Misinterpreting correlations as causations can lead to serious consequences, such as wrong medical decisions (Buhse et al., 2018) or harmful misperception of certain groups of people in society (Richardson et al., 2014).

The misinterpretations are often attributed to humans' inherent tendency to conflate correlation and causation (Bleske-Rechek et al., 2015), and journalists' lack of scientific training or their pursuit of sensational effect (Fahnestock, 1998; Sumner et al., 2014). However, misinterpreting correlational findings as causal claims has been found not only in news stories and press releases written by journalists (Sumner et al., 2014), but also in research papers published by scientists. For example, Robinson et al. (2007) manually examined the methodologies of educational studies and found an increasing number of nonintervention studies using causal statements, from 34% in 1994 to 43% in 2004. Cofield et al. (2010), also through manual content analysis, found 31% of observational studies in obesity and nutrition inappropriately used causal language.

Scientists' inappropriate use of causal language may also be attributed to the pursuit of exaggeration in research contribution, or the lack of training in science writing, especially for non-English speaking researchers. For example, a number of linguistic studies have found that expressing and interpreting epistemic modality is not an easy task for learners of English as a second language (Holmes, 1982). There is also a lack of consistent

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4664–4674, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

teaching of strategies for thinking about probability and causality (Stanovich, 2010). With English as the most popular language for scientific writing, non-native English-speaking authors' native languages may also affect their choice of causal expressions (Hyland and Milton, 1997; Hyland, 1998; McEnery and Kifle, 2002; Kranich, 2009), adding to the challenge of establishing a shared standard of causal language use in the global science community.

In this study, we developed a prediction model to automatically identify correlational and causal statements in research conclusions. We then applied this model to the observational studies in PubMed to answer three research questions regarding causal language use. First, what is the overall ratio of causal lanugage use in observational studies? Second, what is the trend of causal language use? Third, do authors from different countries and language backgrounds use causal language at different levels? This study contributes to the field of computational social science by providing a new prediction model to identify causal language use in research findings, and by providing new evidence from large-scale analysis for answering research questions regarding causal language use in global science communication.

2 Related Work

2.1 Challenge in Describing Causal Relations

Making valid causal inferences from observational data is a challenging and risky process (Hernán and Robins, 2006). Linguistic expressions of causal relations vary greatly (Dunietz et al., 2017). Commonly used causal markers can be domain- and genre-dependent (Mulkar-Mehta et al., 2011). Therefore, choosing the appropriate linguistic cues to describe different causal levels has been identified as one of the main difficulties that student writers experience in managing epistemic meaning (Holmes, 1982). Though such difficulty is reflected in a number of best-practice guides for science writers (Zweig and DeVoto, 2018), suggestions in those guides are generally based on the judgment of only a few individuals (Adams et al., 2017), and there lacks consistent teaching of strategies for thinking about probability and causality (Stanovich, 1992). As a result, authors of observational studies sometimes wrongly extrapolate their results for clinical practice recommendations rather than suggesting follow-up randomized controlled trials (RCTs) (Prasad et al., 2013). Inappropriate use of causal language was then observed by researchers in different science reporting venues, such as leading research journals (e.g. Cofield et al., 2010; Brown et al., 2013; Lazarus et al., 2015), and press releases (e.g. Yavchitz et al., 2012).

2.2 Definition of Causal Relations

Detecting causal language use is closely related to the work of cause-effect relation extraction. NLP tasks such as SemEval-2007 (Girju et al., 2007) and SemEval-2010 (Hendrickx et al., 2009) included extracting cause-effect relations as a subtask of semantic relation extraction. Overall, the cause-effect relation could broadly refer to relations between events and entities (Bethard and Martin, 2008; Mirza and Tonelli, 2014; Chambers et al., 2014), clauses (Grivaz, 2010), and discourse arguments (Prasad et al., 2008).

Contrarily, some studies specifically focused on the causal relations expressed between independent variables and dependent variables. They normally formulate the task as a binary classification problem to distinguish causation from correlation (e.g. Cofield et al., 2010). To capture the different levels of certainty in research findings, Sumner et al. (2014) proposed a more fine-grained categorization with seven levels: *no mentioned relationship*, *statement of no relationship*, *statement of correlation*, *ambiguous statement of relationship*, *conditional statement of causation*, *statement of can*, and *statement of causation*.

In comparison, some defined patterns by the broader definition are not applicable to the narrower definition. For example, relations such as "purpose" and "motivation" (Dunietz et al., 2015) between news events are hard to be generalized to describe relations between variables in research findings. Meanwhile, discourse markers such as reporting verbs (Mihăilă et al., 2013) and conjunctions like "because" are commonly used indicators for causal relations at clause or discourse levels, but are rarely used to describe relations between variables. In this study, we adopted the narrow definition and focused on the causal relations expressed between dependent variable and independent variables.

2.3 Corpora for Causal Relation Analysis

Texts from different domains have been used for causal relation analysis, such as news articles (e.g.

Khoo et al., 1998; Girju et al., 2002; Girju, 2003; Prasad et al., 2008; Sumner et al., 2014), health and biomedical publications (e.g. Cofield et al., 2010; Khoo et al., 2000; Mihăilă et al., 2013; Sumner et al., 2014; Sharma et al., 2018), expository texts (Kaplan and Berry-Rogghe, 1991), and technical texts (Garcia et al., 1997). Mulkar-Mehta et al. (2011) compared the causal markers from different domains, some of which are domain-specific. Dunietz et al. (2017) also found that biomedical texts and other specialized fields may have context-specific language constructs about causality. A review of these prior studies showed that to date there is no existing corpus particularly focusing on research findings in the health domain.

2.4 Methods for Identifying Causal Relations

Both manual and machine learning approaches have been used to extract causal relations. Manual approaches often applied domain-specific, knowledge-based inferences (e.g. Kaplan and Berry-Rogghe, 1991) and hand-coded rules to encode the causal language cues (e.g. Garcia et al., 1997; Cofield et al., 2010; Lazarus et al., 2015; Chiu et al., 2017). However, such manual approaches often require an exhaustive list of linguistic cues, which costs a significant amount of human effort and its generalizability may be limited by the small sample size.

Meanwhile, machine learning algorithms, such as Logistic Regression (Bui et al., 2010), Naive Bayes (Chang and Choi, 2004), Decision Trees (Blanco et al., 2008), Conditional Random Fields (CRF) (Mihăilă and Ananiadou, 2013) and SVM, have also been used to extract causal relations. SVM was among the most frequently applied algorithms (e.g. Sarker and Gonzalez, 2015; Mirza and Tonelli, 2016).

Most recently, deep learning approaches have also been used to extract causal relations. For example, Miwa and Bansal (2016) proposed a LSTM-RNN model incorporated with rich linguistic structures to extract relations in nominal relation extraction in SemEval-2010 (Hendrickx et al., 2009), which outperformed the CNN-based models. Dasgupta et al. (2018) proposed a bidirectional LSTM model to extract causal relations from drug effect data and news articles, with better performance than the rule-based approaches and CRF.

Despite the progress on machine learning approaches for causal relation detection, due to the different definition of causal relations and the dataset, experimental results may not be necessarily comparable to each other. Their generalizability remains an open question for tasks focusing on research conclusions. To this end, Li et al. (2017) adopted a simplified taxonomy from (Sumner et al., 2014) for causal relations in research findings, and used SVM to develop a four-category classifier with a 0.718 F1-score, suggesting room for further performance improvement. In this study we will investigate traditional and deep learning methods for building causal language prediction model with a new, human-annotated corpus dedicated to research conclusions.

3 Corpus Construction

To perform automatic detection of causal language use in research findings, a data set consisting of both causal and non-causal statements is needed. We chose PubMed as the data source to construct the corpus. We focused on health because it is a research topic of high social impact, and inappropriate use of causal language in health literature has been reported in prior manual studies. PubMed provides convenient access to a large number of health research publications with rich metadata particularly useful for this study.

In this study we chose to analyze the abstracts instead of full-text articles because the PubMed abstracts are openly available to the public while many full-text articles are behind a paywall. The research papers in PubMed may include an unstructured abstract, or a structured abstract which usually has a conclusion subsection to present the major findings. For the convenience of locating research findings, we used the structured abstracts only.

We selected a sample of structured abstracts based on a three-dimensional stratified sampling strategy. First, to account for the vocabulary variation among different health issues, five common health topics —nutrition, diabetes, obesity, breast cancer, and cholesterol— were selected. Second, because different study designs can affect the strength of the research findings, and thus affect the language choice for correlational or causal relations, we sampled both observational studies and randomized controlled trials (RCTs) using PubMed's metadata property "Publication Type".

For observational studies, we also used an advanced keyword search query[1] to further identify four different types of observational studies (case-control, cross-sectional, retrospective cohort, and prospective cohort). Third, the abstracts were selected based on the length of the conclusion subsection. The XML files from PubMed contain occasional parsing errors, resulting in extremely long conclusions which actually included paragraphs in the following sections. For quality control purpose, we used the Stanford CoreNLP tool (Manning et al., 2014) to split the conclusion subsections into sentences and removed the articles with conclusions longer than four sentences. Eventually, articles were sampled with the conclusion length as 1, 2, 3, or 4 sentences.

We then constructed a coding schema to define the relation categories for research findings. Drawing on prior studies of factuality (Kilicoglu et al., 2015) and causal strength (Sumner et al., 2014), we defined a causal level taxonomy as a simplified combination of the taxonomies in the two studies: *correlational*, *conditional causal*, *direct causal*, and *no relationship*. Table 1 lists the category definitions and some common language cues used to identify the relation type for each category. Table 2 shows the examples of sentences with different relation types. Sometimes a sentence may contain language cues indicating a causal relationship, such as "a reliable way to determine"; however, if the sentence describes the function of certain tools or diagnoses rather than the explicit relations between independent variable and dependent variables, it should be labelled as "no relationship" (as shown in Example 6 of Table 2). Meanwhile, sentences that discuss study limitations, as shown in Example 7 of Table 2, should be labelled as "no relationship".

A sample of 30 abstracts were randomly selected for the inter-coder reliability test. Specifically, two annotators labelled the relation type for each sentence from the 30 conclusion subsections, and also highlighted the linguistic indicators. The overall Cohen's Kappa agreement (Cohen, 1960) was 0.98, indicating a near-perfect inter-coder agreement (McHugh, 2012). Disagreements in the annotation were later resolved by the two annotators through discussion.

One of the annotators, who has linguistics background, then annotated the rest of the data. The annotator also marked unsure cases and brought to team discussion before finalizing the annotations. The corpus contains 3,126 annotated sentences, of which 3,061 sentences contained only one type of relations, and the remaining 65 sentences had more than one type of relations. Table 3 shows the relation type distribution of single-class sentences in the corpus.

4 Experiments and Evaluation

We trained and evaluated four machine learning approaches for classifying causal language use in conclusion sentences. The learning approaches are bag-of-words based Linear SVM, Bidirectional Recurrent Neural Network, BERT (Devlin et al., 2018), and BioBERT (Lee et al., 2019).

4.1 Experimental Setup

Linear SVM. We used the Scikit Learn vectorizer with unigrams and bigrams as feature set to convert texts to sparse vectors. Adding tri-grams did not improve model performance. Performance on *count* and *tf-idf* vectorizations were similar. The parameter C in LinearSVM was set to 0.1 after tuning.

BiRNN. Different from the traditional bag-of-words methods that convert a text to a sparse vector, BiRNN and BERT are deep learning approaches designed to transform a text to a dense vector that can better represent the meaning of the text. In our implementation, we used the combination of two word embeddings: the PMC embedding based on full-text research publications from PubMed Central (PMC) [2], and the universal GloVe embedding. We found that the PMC embedding did better than GloVe, and their combination performed the best. In addition, we used GRU recurrent network units, which are generally simpler and faster than LSTM units.

BERT. BERT is the latest method for pre-training language representations, which has achieved the state-of-the-art results on a wide array of NLP tasks, including sentence classification. We used the Pytorch version of BERT with its pre-trained model (Cased BERT-Base, which performs better than the Uncased one) [3]. Because the distribution of sentence relationships in our corpus is unbalanced, we revised the loss function in the original

[1] Public Health: Search Strategies by Study Type (University of Adelaide)

[2] http://bio.nlplab.org/

[3] https://github.com/huggingface/pytorch-pretrained-BERT

Relation Type	Description	Language Cue
Correlational	The statement describes the association between variables, but causation cannot be explicitly stated.	association, associated with, predictor, at high risk of
Conditional Causal	The statement shows that one variable directly changes the other. However, the relation carries an element of doubt in it, which is normally via hedges or modalities.	increase, decrease, lead to, effect on, contribute to, result in *Cues indicating doubt:* may, might, appear to, probably
Direct Causal	The statement says that the independent variable directly alters the dependent variable.	increase, decrease, lead to, effective in, contribute to, reduce
No Relationship	No correlation or causation relationship is mentioned in the statement.	

Table 1: A taxonomy of relation types and examples of commonly used language cues.

Annotation	Example Sentence
Correlational	1 The findings from this large prospective study show that men who are taller and who have greater adiposity have an elevated risk of high-grade prostate cancer and prostate cancer death. 2 The association of high PCT and CRP was no more predictive of mortality than high CRP.
Conditional Causal	3 MTHFR A1298C polymorphism might contribute to an increased risk of breast cancer and/or ovarian cancer susceptibility.
Direct Causal	4 Participatory community-based nutrition education for caregivers improved child dietary diversity even in a food insecure area. 5 The adoption of a comprehensive preoperative multidisciplinary approach led to significant improvements in the postoperative outcomes and also in the compliance to the postoperative follow-up.
No Relationship	6 A quick foot-of-the-bed clinical assessment is not a reliable way to determine frailty. 7 This approach may, however, be difficult to implement on a large scale.

Table 2: Examples of sentences and annotated relation types.

Label	Count	Ratio
Correlational	998	32.6%
Conditional Causal	213	7.0%
Direct Causal	494	16.1%
No Relationship	1356	44.3%
Total	3061	100.0%

Table 3: Distribution of sentence types in the corpus.

code to ensure that the penalty on misclassifying rare classes was high.

BioBERT. BioBERT is a domain specific language representation model that is based on BERT and further pre-trained on large-scale biomedical corpora. BioBERT has shown to outperform BERT on three representative biomedical text mining tasks (Lee et al., 2019). In our experiment, we used the same BERT code as described above, and replaced the Cased BERT-Base pre-trained model with the BioBERT model.

4.2 Evaluation

To compare the performance of the above four learning approaches, we evaluated them on our annotated corpus via 5-fold stratified cross-validation. The result in Table 4 shows that BioBERT performed the best by all measures, followed by BERT, BiRNN and then LinearSVM. BioBERT achieved 0.881 macro-averaged F1 score with fairly balanced performance on each category except the conditional causal one, which only covers 7% data in the training set. See the performance scores per category in Table 5 and the confusion matrix in Fig. 1.

	Precision	Recall	Accuracy	F1
LinearSVM	0.739	0.711	0.772	0.722
BiRNN	0.801	0.825	0.836	0.811
BERT	0.867	0.883	0.889	0.874
BioBERT	0.878	0.886	0.901	0.881

Table 4: Model performance: BioBERT$>$ BERT $>$ BiRNN $>$ LinearSVM. (F1 represents macro-F1.)

4.3 Error Analysis

Error analysis of misclassified cases shows the most common disagreement between machine prediction and human annotation is between the categories of *direct causal* and *no relationship*, even though the two categories are not semanti-

	Precision	Recall	F1
Correlational	0.917	0.924	0.921
Conditional Causal	0.791	0.854	0.822
Direct Causal	0.878	0.858	0.868
No Relationship	0.915	0.906	0.911

Table 5: Detailed performance of BioBERT on each category of sentence relationship.

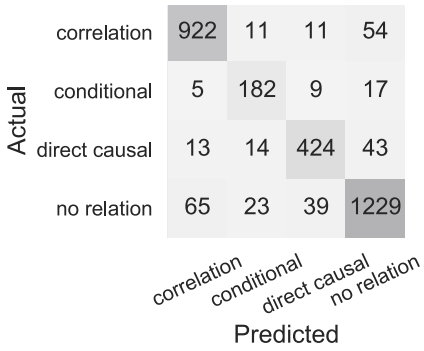

Figure 1: Confusion matrix. The prediction results on each test fold from 5-fold cross-validation were assembled together.

cally close in our dataset. This is largely caused by the confounding language cues in the *no relationship* examples. Specifically, a *no relationship* sentence that describes implications for future studies or functions of certain assessments may contain causal markers, such as "is critical to achieving", and "improved" in the following Examples 1 and 2, and thus mislead the prediction model. In addition, causal markers sometimes appeared in subordinate clauses instead of in the main clauses, which could also confuse the prediction model (see "the impact of" in Example 3). The prediction model also has some difficultly in recognizing the less commonly used causal markers, especially when nouns were used to describe causal relations, such as "cause" and "the key role of" in Examples 4 and 5.

Sentence examples:

1. However, training and experience of nurses in aromatherapy massage is critical to achieving positive results.
2. These findings pose the question: why has not the nutritional status of children improved, although the living conditions of their families have significantly improved?
3. Some studies that have assessed the impact of monitoring guidelines on clinical practice show only limited impact.
4. However, body mass index greater than 25 and smoking history are cause for caution.
5. Findings reinforce the key role of mvpa for childrens health.

4.4 Learning Curve

Our training dataset contains 3,061 sentences. To test whether the dataset size is sufficient to build a strong prediction model, we ran a learning curve test by setting aside 20% of the dataset for testing (i.e., about 600 examples), and then trained the BioBERT model with the 10%, 20%, ..., 100% of the remaining data (i.e., about 2500). We ran the experiment 5 times. As shown in Fig. 2, the average performance levels off around 60% of training data (i.e., about 1500), indicating that the training dataset is sufficient, although a larger dataset might help build a stronger model.

Figure 2: Learning curve. The average performance levels off around 60% of the training data, which is about 1500 examples.

5 Application to Observational Studies

In this section, we aim to investigate the causal language use in observational studies at a large scale. In 2014, the PubMed staff introduced *observational study* to their list of publication types[4]. To date 61,830 PubMed publications have been manually assigned to the observational study category. However, some complicated studies were assigned to multiple study design categories, such as both observational study and randomized controlled trial. After removing those with multiple study design types, we obtained 51,274 publications. Among them, 38,191 studies have structured abstracts with a conclusion subsection. For the reason mentioned in section 3, we do not consider those publications with more than 4 sentences in their conclusion subsections, since those with more than 4 sentences are often the result

[4]https://www.ncbi.nlm.nih.gov/mesh/68064888

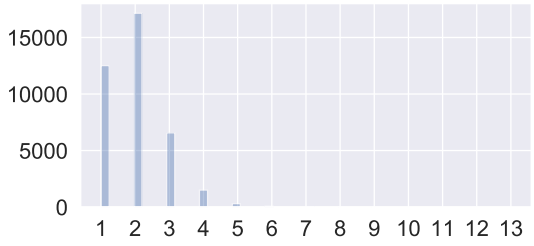

Figure 3: Distribution of number of sentences in the abstract conclusion subsections of the 38,191 observational studies. 98.8% of the publications have 4 or less sentences.

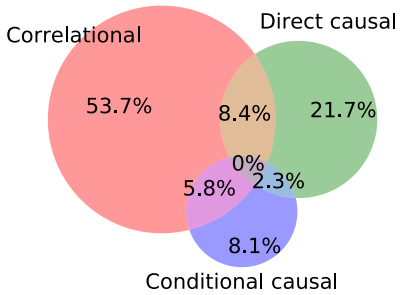

Figure 4: The constitution of the three relationships.

of PubMed metadata concatenating the conclusion subsection with the following paragraphs. Among the 38,191 publications, 98.8% have 4 or less sentences. (Fig. 3 shows the distribution of number of sentences included in the conclusion subsections.) The final data set of observational studies includes 37,746 publications, which in total contains 72,565 conclusion sentences.

We then applied the sentence classification model, as described in the previous section, to these conclusion sentences. The prediction results from the model are used to answer three research questions regarding causal language use in observational studies.

5.1 Results and Discussion

We aim to investigate the following questions:

RQ1. What is the overall ratio of causal lanugage use in observational studies?

The prediction result shows that among the 37,746 observational studies, 22% did not mention either correlation or causal relations. Because we would like to focus on distinguishing correlation vs. causal statements, the publications without mentioning relations were excluded, and the remaining 78% or 29,410 studies were used in further analyses.

Since PubMed also includes a small number of non-English publications with an English abstract, we used the PubMed metadata "language" to separate the 29,410 studies into the English subset (28,217 publications) and the non-English subset (1,193 publications).

The predictions were made on individual sentences. A conclusion subsection may contain multiple sentences; only 33% of the publications consist of one conclusion sentence.

Using the result from the 28,217 English publications, a Venn diagram (Fig. 4) was generated to show the proportion of studies mentioning one or more types of relations. It shows that 83.5% of studies contained only one type of relation in the conclusion: 53.7% correlational, 8.1% conditional causal, and 21.7% direct causal. Most of these studies contain only one sentence in the conclusion subsection. A manual examination of examples in the mixed categories found two main types of cases. The first type usually includes findings for multiple research questions. The second type uses multiple sentences to describe one finding; for example, the first sentence describes a correlation, and the second generalizes the correlation to a conditional or direct causal relation.

In this study we focus on the inappropriate use of direct causal language in observational studies. Therefore, we calculated the percentage of studies that used direct causal language in at least one finding sentence, and the percentage of studies that exclusively used direct causal language in their findings. Our result shows that 21.7% studies used direct causal exclusively in their conclusions, and 32.4% used some direct causal language. This result is close to the manual estimation reported in (Cofield et al., 2010), which is 31%.

RQ2. What is the trend of causal language use?

From now on, in the following figures and tables, for simplicity, we use word *causal* for the studies that used some direct causal language, and phrase *causal only* for those that used direct causal exclusively. Fig. 5 illustrates the ratios of causal language use and causal only from year 2013 to 2019. The two ratios follow the same pattern. Different from (Robinson et al., 2007), no obvious increase of causal language use was observed in our study.

One limitation of our study is that the PubMed labels of observational studies were introduced in 2014 (although some 2013 publications were an-

notated too); therefore, our dataset covers only seven years with partial data from 2013 and 2019. In the future we will design a classifier to automatically label observational studies, and then will be able to analyze the trend with more longitudinal data.

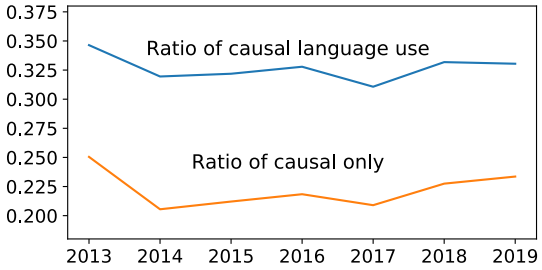

Figure 5: Causal language use over recent years.

RQ3. Do authors from different countries and language backgrounds use causal language at different levels? Prior studies in linguistics, as described in sections 1 and 2, have found that German, French, and Dutch translations tend to use stronger claims than the original English science publications. In this study, we will be able to compare causal language use in English and non-English publications, all with English abstracts. We hypothesize that if authors' native languages did affect their causal language use in English, the effect would be more pronounced in the English abstracts of the non-English publications, because these authors mainly used their native languages for science communication.

Language	Papers	Causal	Causal only
German	34	0.706	0.500
French	145	0.490	0.393
Chinese	80	0.487	0.388
Italian	32	0.469	0.375
Spanish	715	0.394	0.297
English	28217	0.323	0.217
Portugese	124	0.266	0.194

Table 6: Ratios of causal language use in studies published in English and other languages (sorted by *causal only*, reversely). Languages with fewer than 30 publications were excluded.

Table 6 shows the ratios of causal language use in the non-English subset. The result shows that publications in some languages, such as German, used much more causal language than those in English and Portugese.

Country	Papers	Causal	Causal only
Germany	909	0.421	0.295
Italy	1314	0.390	0.287
France	992	0.342	0.247
Spain	1621	0.365	0.239
UK	1071	0.331	0.222
Brazil	750	0.316	0.219
Japan	1299	0.296	0.216
China	919	0.301	0.215
Netherlands	797	0.359	0.213
Korea	772	0.284	0.201
US	4771	0.277	0.174

Table 7: Ratios of causal language use in different countries (sorted by *causal only*, reversely). Countries with fewer than 750 publications were excluded.

Table 7 shows the ratios in the English subset, broken down by the authors' countries. For each publication, each author's country was extracted from the PubMed affiliation metadata. Publications with authors from more than one country were excluded. The result shows that Germany has the highest ratio of causal language use (42.1%). In comparison, the US has the lowest ratio.

Because some languages are used in multiple countries and some countries did not publish many papers, not all results in Table 6 and Table 7 are comparable. However, we were able to identify four country-language pairs that correspond well to each other: Germany-German, Italy-Italian, France-French, and China-Chinese. In the case of other non-English languages, Portugese is majorly used by Brazil and Portugal, and Spanish is majorly used in Spain and Mexico. In the above four pairs, the ratios of causal language use in the non-English subsets were all higher than those in the English subset.

These results provide supportive evidence to the claim that causal language use varies across countries and languages, and thus challenge the notion of a shared consensus on causal language use in global science community.

6 Conclusion and Future Work

In this study we developed a manually-annotated corpus for causal statements in science publications, and used the corpus to train a prediction model to identify correlational, conditional causal, and direct causal statements in research conclu-

sions, achieving an accuracy of 0.90 and a macro-F1 score of 0.88. This prediction model provides an automated approach for identifying potential misuse of causal language in science writing. When applying the model to investigating association between causal language use and authors' countries or native languages, the result lends support to the claim that causal language use varies across countries and languages, and thus challenges the notion of a shared consensus of causal language use in the global science community. The result is also important for raising awareness towards recognizing disparities in causal language use in science communication.

In the future we will further our investigation by developing prediction models to automatically identify study designs in more fine-grained categories, such as cross-sectional, case-control, retrospective cohort, and prospective cohort. We will then be able to accurately identify inappropriate causal language use in weaker study design types, and also to compare among countries and languages in each specific study design types.

We also plan to extend our work to other domains in the future. In our current work we chose the biomedical domain as the starting point not only for the problem significance but also for the high-quality and rich metadata provided by PubMed that can help identify study types. By contrast, no such data are available in other domains yet. Toward this new goal, we also plan to develop a classification method to identify study types in other domains such as psychology and education.

The corpus and the code are available at https://github.com/junwang4/causal-language-use-in-science.

Abstract

Current research on hate speech analysis is typically oriented towards monolingual and single classification tasks. In this paper, we present a new multilingual multi-aspect hate speech analysis dataset and use it to test the current state-of-the-art multilingual multitask learning approaches. We evaluate our dataset in various classification settings, then we discuss how to leverage our annotations in order to improve hate speech detection and classification in general.

1 Introduction

With the expanding amount of text data generated on different social media platforms, current filters are insufficient to prevent the spread of hate speech. Most internet users involved in a study conducted by the Pew Research Center report having been subjected to offensive name calling online or witnessed someone being physically threatened or harassed online.[1] Additionally, Amnesty International within Element AI have lately reported that many women politicians and journalists are assaulted every 30 seconds on Twitter.[2] This is despite the Twitter policy condemning the promotion of violence against people on the basis of race, ethnicity, national origin, sexual orientation, gender identity, religious affiliation, age, disability, or serious disease.[3] Hate speech may not represent the general opinion, yet it promotes the dehumanization of people who are typically from minority groups (Soral et al., 2017; Martin et al., 2012) and can incite hate crime (Ross et al., 2017).

Moreover, although people of various linguistic backgrounds are exposed to hate speech (Waseem et al., 2017; Ross et al., 2017), English is still at the center of existing work on toxic language analysis. Recently, some research studies have been conducted on languages such as German (Kratzke, 2017), Arabic (Albadi et al., 2018), and Italian (Sanguinetti et al., 2018). However, such studies usually use monolingual corpora and do not contrast, or examine the correlations between online hate speech in different languages. On the other hand, tasks involving more than one language such as the hatEval task[4], which covers English and Spanish, include only separate classification tasks, namely (a) women and immigrants as target groups, (b) individual or generic hate and, (c) aggressive or non-aggressive hate speech.

Treating hate speech classification as a binary task may not be enough to inspect the motivation and the behavior of the users promoting it and, how people would react to it. For instance, the hateful tweets presented in Figure 1 show toxicity directed towards different targets, with or without using slurs, and generating several types of reactions. We believe that, in order to balance between truth and subjectivity, there are at least five important aspects in hate speech analysis. Hence, our annotations indicate (a) whether the text is direct or indirect; (b) if it is offensive, disrespectful, hateful, fearful out of ignorance, abusive, or normal; (c) the attribute based on which it discriminates against an individual or a group of people; (d) the name of this group; and (e) how the annotators feel about its content within a range of negative to neutral sentiments. To the best of our knowledge there are no other hate speech datasets that attempt to capture fear out of ignorance in hateful tweets or examine how people react to hate speech. We claim that our multi-aspect annotation schema would provide a valuable insight into sev-

eral linguistic and cultural differences and bias in hate speech.

We use Amazon Mechanical Turk to label around 13,000 potentially derogatory tweets in English, French, and Arabic based on the above mentioned aspects and, regard each aspect as a prediction task. Since in natural language processing, there is a peculiar interest in multitask learning, where different tasks can be used to help each other (Collobert et al., 2011; Ruder et al., 2017; Hashimoto et al., 2017), we use a unified model to handle the annotated data in all three languages and five tasks. We adopt (Ruder et al., 2017) as a learning algorithm adapted to loosely related tasks such as our five annotated aspects and, use the Babylon cross-lingual embeddings (Smith et al., 2017) to align the three languages. We compare the multilingual multitask learning settings with monolingual multitask, multilingual single-task, and monolingual single-task learning settings respectively. Then, we report the performance results of the different settings and discuss how each task affects the remaining ones. We release our dataset and code to the community to extend research work on multilingual hate speech detection and classification.[5]

2 Related Work

There is little consensus on the difference between profanity and hate speech and, how to define the latter (Schmidt and Wiegand, 2017). As shown in Figure 2, slurs are not an unequivocal indicator of hate speech and can be part of a non-aggressive conversation, while some of the most offensive comments may come in the form of subtle metaphors or sarcasm (Malmasi and Zampieri, 2018). Consequently, there is no existing human annotated vocabulary that explicitly reveals the presence of hate speech, which makes the available hate speech corpora sparse and noisy (Nobata et al., 2016).

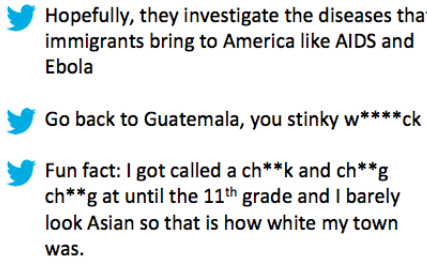

Figure 2: Three tweets in which (1) the first one accuses immigrants of harming society without using any direct insult; (2) the second insults a Hispanic person using a slur; and (3) the third one uses slurs to give a personal account. This shows that profanity is not a clear indicator of the presence of hate speech.

Given the subjectivity and the complexity of such data, annotation schemes have rarely been made fine-grained. Table 1 compares different labelsets that exist in the literature. For instance, Waseem and Hovy (2016) use racist, sexist, and normal as labels; Davidson et al. (2017) label their data as hateful, offensive (but not hateful), and neither, while ElSherief et al. (2018) present an English dataset that records the target category based on which hate speech discriminates against people, such as ethnicity, gender, or sexual orientation and ask human annotators to classify the tweets as hate and non hate. Founta et al. (2018) label their data as offensive, abusive, hateful, aggressive, cyberbullying, spam, and normal. On the other hand, Qian et al. (2018) have chosen to detect ideologies of hate speech counting 40 different hate ideologies among 13 extremist hate groups.

The detection of hate speech targets is yet another challenging aspect of the annotation. Park et al. (2018) report the bias that exists in the current datasets towards identity words, such as *women*, which may later cause false predictions. They propose to debias gender identity word em-

Ours	13,000	Labels for five different aspects	5

Table 1: Comparative table of some of the available hate speech and abusive language corpora in terms of labels and sizes.

beddings with additional data for training and tuning their binary classifier. We address this false positive bias problem and the common ambiguity of target detection by asking the annotators to label target attributes such as origin, gender, or religious affiliation within 16 named target groups such as refugees, or immigrants.

Furthermore, Klubička and Fernandez (2018) have reproduced the experiment of Waseem and Hovy (2016) in order to study how hate speech affects the popularity of a tweet, but discovered that some tweets have been deleted. For replication purposes, we provide the community with anonymized[6] tweet texts rather than IDs.

Non-English hate speech datasets include Italian, German, Dutch, and Arabic corpora. Sanguinetti et al. (2018) present a dataset of Italian tweets, in which the annotations capture the degree of intensity of offensive and aggressive tweets, in addition to whether the tweets are ironic and contain stereotypes or not. Ross et al. (2017) have collected more than 500 German tweets against refugees, and annotated them as hateful and not hateful. Hee et al. (2015) detect bullies and victims among youngsters in Dutch comments on AskFM, and classify cyberbullying comments as insults or threats. Moreover, Albadi et al. (2018) provide a corpus of Arabic sectarian speech.

Another predominant phenomenon in hate speech corpora is code switching. Bohra et al. (2018) present a dataset of code mixed Hindi-English tweets, while Galery et al. (2018) report the presence of Hindi tokens in English data and use multilingual word embeddings to deal with this issue when detecting toxicity. Similarly, we use such embeddings to take advantage of the multilinguality and comparability of our corpora during the classification.

Our dataset is the first trilingual dataset comprising English, French, and Arabic tweets that encompasses various targets and hostility types. Additionally, to the best of our knowledge, this is the first work that examines how annotators react to hate speech comments.

To fully exploit the collected annotations, we tested multitask learning on our dataset. Multitask learning (Collobert et al., 2011) allows neural networks to share parameters with one another and, thus, learn from related tasks. It has been used in different NLP tasks such as parsing (Hashimoto et al., 2017), dependency parsing (Peng et al., 2017), neural machine translation (Luong et al., 2016), sentiment analysis (Augenstein et al., 2018), and other tasks. Multitask learning architectures tackle challenges that include sharing the label space and the question of private and shared space for loosely related tasks (Ruder et al., 2017), for which techniques may involve a massive space of potential parameter sharing architectures.

3 Dataset

In this section, we present our data collection methodology and annotation process.

3.1 Data Collection

Considering the cultural differences and commonly debated topics in the main geographic regions where English, French, and Arabic are spoken, searching for equivalent terms in the three languages led to different results at first. Therefore, after looking for 1,000 tweets per 15 more or less equivalent phrases in the three languages, we revised our search words three times by ques-

[6] In conformity with Twitter terms and conditions.

tioning the results, adding phrases, and taking off unlikely ones in each of the languages. In fact, we started our data collection by searching for common slurs and demeaning expressions such as *"go back to where you come from"*. Then, we observed that discussions about controversial topics, such as *feminism* in general, *illegal immigrants* in English, *Islamo-gauchisme* ("Islamic leftism") in French, or *Iran* in Arabic were more likely to provoke disputes, comments filled with toxicity and thus, notable insult patterns that we looked for in subsequent search rounds.

3.2 Linguistic Challenges

All of the annotated tweets include original tweets only, whose content has been processed by (1) deleting unarguably detectable spam tweets, (2) removing unreadable characters and emojis, and (3) masking the names of mentioned users using *@user* and potentially enclosed URLs using *@url*. As a result, annotators had to face the lack of context generated by this normalization process.

Furthermore, we perceived code-switching in English where Hindi, Spanish, and French tokens appear in the tweets. Some French tweets also contain Romanized dialectal Arabic tokens generated by, most likely, bilingual North African Twitter users. Hence, although we eliminated most of these tweets in order to avoid misleading the annotators, the possibly remaining ones still added noise to the data.

One more challenge that the annotators and ourselves had to tackle, consisted of Arabic diglossia and switching between different Arabic dialects and Modern Standard Arabic (MSA). While MSA represents the standardized and literary variety of Arabic, there are several Arabic dialects spoken in North Africa and the Middle East in use on Twitter. Therefore, we searched for derogatory terms adapted to different circumstances, and acquired an Arabic corpus that combines tweets written in MSA and Arabic dialects. For instance, the tweet shown in Figure 1 contains a dialectal slur that means "maiden."

3.3 Annotation Process

We rely on the general public opinion and common linguistic knowledge to assess how people view and react to hate speech.[7] Given the subjectivity and difficulty of the task, we reminded the annotators not to let their personal opinions about the topics being discussed in the tweets influence their annotation decisions.

Our annotation guidelines explained the fact that offensive comments and hate do not necessarily come in the form of profanity. Since different degrees of discrimination work on the dehumanization of individuals or groups of people in distinct ways, we chose not to annotate the tweets within two or three classes. For instance, a sexist comment can be disrespectful, hateful, or offensive towards women. Our initial labelset was established in conformity with the prevalent antisocial behaviors people tend to deal with. We also chose to address the problem of false positives caused by the misleading use of identity words by asking the annotators to label both the target attributes and groups.

Avoiding scams To prevent scams, we also prepared three annotation guideline forms and three aligned labelsets written in English, French, and Modern Standard Arabic with respect to the language of the tweets to be annotated.

We requested native speakers to annotate the data and chose annotators with good reputation scores (more than 0.90). We informed the annotator in the guidelines, that in case of noticeable patterns of random labeling on a substantial number of tweets, their work will be rejected and we may have to block them. Since the rejection affects the reputation of the annotators and their chances to get new tasks on Amazon Mechanical Turk, well-reputed annotators are usually reliable. We have divided our corpora into smaller batches on Amazon Mechanical Turk in order to facilitate the analysis of the annotations of the workers and, fairly identify any incoherence patterns possibly caused by the use of an automatic translation system on the tweets, or the repetition of the same annotation schema. If we reject the work of a scam, we notify them, then reassign the tasks to other annotators.

3.4 Pilot Dataset

We initially put samples of 100 tweets in each of the three languages on Amazon Mechanical Turk. We showed the annotators the tweet along with lists of labels describing (a) whether it is direct or indirect hate speech; (b) if the tweet is dangerous, offensive, hateful, disrespectful, confident or supported by some URL, fearful out of ignorance,

[7] We have also provided the annotators with the Urban Dictionary definitions of some slang English words they may not be aware of.

or other; (c) the target attribute based on which it discriminates against people, specifically, race, ethnicity, nationality, gender, gender identity, sexual orientation, religious affiliation, disability, and other ("other" could refer to political ideologies or social classes.); (d) the name of its target group, and (e) whether the annotators feel anger, sadness, fear or nothing about the tweets.

Each tweet has been labeled by three annotators. We have provided them with additional text fields to fill in with labels or adjectives that would (1) better describe the tweet, (2) describe how they feel about it more accurately, and (3) name the group of people the tweet shows bias against. We kept the most commonly used labels from our initial labelset, took off some of the initial class names and added frequently introduced labels, especially the emotions of the annotators when reading the tweets and the names of the target groups. For instance, after this step, we have ended up merging *race, ethnicity, nationality* into one label *origin* given common confusions we noticed and; added *disgust* and *shock* to the emotion labelset; and introduced *socialists* as a target group label since many annotators have suggested these labels.

3.5 Final Dataset

The final dataset is composed of a pilot corpus of 100 tweets per language, and comparable corpora of 5,647 English tweets, 4,014 French tweets, and 3,353 Arabic tweets. Each of the annotated aspects represents a classification task of its own, that could either be evaluated independently, or, as intended in this paper, tested on how it impacts other tasks. The different labels are designed to facilitate the study of the correlations between the explicitness of the tweet, the type of hostility it conveys, its target attribute, the group it dehumanizes, how different people react to it, and the performance of multitask learning on the five tasks. We assigned each tweet to five annotators, then applied majority voting to each of the labeling tasks. Given the numbers of annotators and labels in each annotation sub-task, we allowed multilabel annotations in the most subjective classification tasks, namely the hostility type and the annotator's sentiment labels, in order to keep the right human-like approximations. If there are two annotators agreeing on two labels respectively, we add both labels to the annotation.

The average Krippendorff scores for inter-annotator agreement (IAA) are 0.153, 0.244, and 0.202 for English, French, and Arabic respectively, which are comparable to existing complex annotations (Sanguinetti et al., 2018) given the nature of the labeling tasks and the number of labels.

Attribute	Label	En	Fr	Ar
Directness	Direct	530	2,198	1,684

	Indifference	2,878	2,035	1,825
Total number of tweets		5,647	4,014	3,353

Table 2: The label distributions of each task. The counts of direct and indirect hate speech include all tweets except those that are single labeled as "normal". Tweet and annotator's sentiment (Annotator) are multi-label classification tasks, while target attribute (Target) and target group (Group) are not.

We present the labelset the annotators refer to, and statistics of our annotated data in the following.

Directness label Annotators determine the explicitness of the tweet by labeling it as *direct* or *indirect* speech. This should be based on whether the target is explicitly named, or less easily discernible, especially if the tweet contains humor, metaphor, or figurative speech. Table 2 shows that even when partly using equivalent keywords to search for candidate tweets, there are still significant differences in the resulting data.

Hostility type To identify the hostility type of the tweet, we stick to the following conventions: (1) if the tweet sounds dangerous, it should be la-

beled as *abusive*; (2) according to the degree to which it spreads hate and the tone its author uses, it can be *hateful*, *offensive* or *disrespectful*; (3) if the tweet expresses or spreads fear out of ignorance against a group of individuals, it should be labeled as *fearful*; (4) otherwise it should be annotated as *normal*. We define this task to be multilabel. Table 2 shows that hostility types are relatively consistent across different languages and offensive is the most frequent label.

Target attribute After annotating the pilot dataset, we noticed common misconceptions regarding race, ethnicity, and nationality, therefore we merged these attributes into one label *origin*. Then, we asked the annotators to determine whether the tweet insults or discriminates against people based on their (1) *origin*, (2) *religious affiliation*, (3) *gender*, (4) *sexual orientation*, (5) *special needs* or (6) *other*. Table 2 shows there are fewer tweets targeting disability in Arabic compared to English and French and no tweets insulting people based on their sexual orientation which may be due to the fact that the labels of gender, gender identity, and sexual orientation use almost the same wording. On the other hand, French contains a small number of tweets targeting people based on their *gender* in comparison to English and Arabic. We have observed significant differences in terms of target attributes in the three languages. More data may help us examine the problems affecting targets of different linguistic backgrounds.

Target group We determined 16 common target groups tagged by the annotators after the first annotation step. The annotators had to decide on whether the tweet is aimed at *women, people of African descent, Hispanics, gay people, Asians, Arabs, immigrants in general, refugees*; people of different religious affiliations such as *Hindu, Christian, Jewish people, and Muslims*; or from political ideologies *socialists, and others*. We also provided the annotators with a category to cover hate directed towards one *individual*, which cannot be generalized. In case the tweet targets more than one group of people, the annotators should choose the group which would be the most affected by it according to them. Table 1 shows the counts of the five categories out of 16 that commonly occur in the three languages. In fact, most of the tweets target individuals or fall into the "other" category. In the latter case, they may target people with different political views such as liberals or conservatives in English and French, or specific ethnic groups such as Kurdish people in Arabic. English tweets tend to have more tweets targeting people with special needs, due to common language-specific demeaning terms used in conversations where people insult one another. Arabic tweets contain more hateful comments towards women for the same reason. On the other hand, the French corpus contains more tweets that are offensive towards African people, due to hateful comments generated by debates about immigrants.

Sentiment of the annotator We claim that the choice of a suitable emotion representation model is key to this sub-task, given the subjective nature and social ground of the annotator's sentiment analysis. After collecting the annotation results of the pilot dataset regarding how people feel about the tweets, and observing the added categories, we adopted a range of sentiments that are in the negative and neutral scales of the hourglass of emotions introduced by Cambria et al. (2011). This model includes sentiments that are connected to objectively assessed natural language opinions, and excludes what is known as self-conscious or moral emotions such as shame and guilt. Our labels include *shock*, *sadness*, *disgust*, *anger*, *fear*, *confusion* in case of ambivalence, and *indifference*. This is the second multilabel task of our model.

Table 2 shows more tweets making the annotators feel disgusted and angry in English, while annotators show more indifference in both French and Arabic. A relatively more frequent label in both French and Arabic is shock, therefore reflecting what some of the annotators were feeling during the labeling process.

4 Experiments

We report and discuss the results of five classification tasks: (1) the directness of the speech, (2) the hostility type of the tweet, (3) the discriminating target attribute, (4) the target group, and (5) the annotator's sentiment.

4.1 Models

We compare both traditional baselines using bag-of-words (BOW) as features on Logistic regression (LR), and deep learning based methods.

For deep learning based models, we run bidirectional LSTM (biLSTM) models with one hidden

layer on each of the classification tasks. Deeper BiLSTM models performed poorly due to the size of the tweets. We chose to use Sluice networks (Ruder et al., 2017) since they are suitable for loosely related tasks such as the annotated aspects of our corpora.

We test different models, namely single task single language (STSL), single task multilingual (STML), and multitask multilingual models (MTML) on our dataset. In multilingual settings, we tested Babylon multilingual word embeddings (Smith et al., 2017) and MUSE (Lample et al., 2017) on the different tasks. We use Babylon embeddings since they appear to outperform MUSE on our data.

Sluice networks (Ruder et al., 2017) learn the weights of the neural networks sharing parameters (sluices) jointly with the rest of the model and share an embedding layer, Babylon embeddings in our case, that associates the elements of an input sequence. We use a standard 1-layer BiLSTM partitioned into two subspaces, a shared subspace and a private one, forced to be orthogonal through a regularization penalty term in the loss function in order to enable the multitask network to learn both task-specific and shared representations. The hidden layer has a dimension of 200, the learning rate is initially set to 0.1 with a learning rate decay, and we use the DyNet (Neubig et al., 2017) automatic minibatch function to speed-up the computation. We initialize the cross-stitch unit to imbalanced, set the standard deviation of the Gaussian noise to 2, and use simple stochastic gradient descent (SGD) as the optimizer.

All compared methods use the same split as train:dev:test=8:1:1 and the reported results are based on the test set. We use the dev set to tune the threshold for each binary classification problem in the multilabel classification settings of each task.

4.2 Results and Analysis

We report both the micro and macro-F1 scores of the different classification tasks in Tables 3 and 4. *Majority* refers to labeling based on the majority label, *LR* to logistic regression, *STSL* to single task single language models, *STML* to single task multilingual models, and *MTML* to multitask multilingual models.

STSL STSL performs the best among all models on the directness classification, and it is also consistent in both micro and macro-F1 scores. This is due to the fact that the directness has only two labels and multilabeling is not allowed in this task. Tasks involving imbalanced data, multiclass and multilabel annotations harm the performance of the directness in multitask settings.

Since macro-F1 is the average of all F1 scores of individual labels, all deep learning models have high macro-F1 scores in English which indicates that they are particularly good at classifying the *direct* class. STSL is also comparable or better than traditional BOW feature-based classifiers when performed on other tasks in terms of micro-F1 and for most of the macro-F1 scores. This shows the power of the deep learning approach.

MTSL Except for the directness, MTSL usually outperforms STSL or is comparable to it. When we jointly train each task on the three languages, the performance decreases in most cases, other than the target group classification tasks. This may be due to the difference in label distributions across languages. Yet, multilingual training of the target group classification task improves in all languages. Since the target group classification task involves 16 labels, the amount of data annotated for each label is lower than in other tasks. Hence, when aggregating annotated data in different languages, the size of the training data also increases, due to the relative regularity of identification words of different groups in all three languages in comparison to other tasks.

MTML MTML settings do not lead to a big improvement which may be due to the class imbalance, multilabel tasks, and the difference in the nature of the tasks. In order to inspect which tasks hurt or help one another, we trained multilingual models for pairwise tasks such as (group, target), (hostility, annotator's sentiment), (hostility, target), (hostility, group), (annotator's sentiment, target) and (annotator's sentiment, group). We noticed that when trained jointly, the target attribute slightly improves the performance of the tweet's hostility type classification by 0.03,0.05 and 0.01 better than the best reported scores in English, French, and Arabic, respectively. When target groups and attributes are trained jointly, the macro F-score of the target group classification in Arabic improves by 0.25 and when we train the tweet's hostility type within the annotator's sentiment, we improve the macro F-score of Arabic by 0.02. We believe that we can take advantage of the

Table 4: Full evaluation of tasks where multilingual and multitask models outperform on average single task single language model on four different tasks.

correlations between target attributes and groups along with other tasks, to set logic rules and develop better multilingual and multitask settings.

5 Conclusion

In this paper, we presented a multilingual hate speech dataset of English, French, and Arabic tweets. We analyzed in details the difficulties related to the collection and annotation of this dataset. We performed multilingual and multitask learning on our corpora and showed that deep learning models perform better than traditional BOW-based models in most of the multilabel classification tasks. Multilingual multitask learning also helped tasks where each label had less annotated data associated with it.

Better tuned deep learning settings in our multilingual and multitask models would be expected to outperform the existing state-of-the-art embeddings and algorithms applied to our data. The different annotation labels and comparable corpora would help us perform transfer learning and investigate how multimodal information on the tweets, additional unlabeled data, label transformation, and label information sharing may boost the classification performance in the future.

Abstract

We contribute the largest publicly available dataset of naturally occurring factual claims for the purpose of automatic claim verification. It is collected from 26 fact checking websites in English, paired with textual sources and rich metadata, and labelled for veracity by human expert journalists. We present an in-depth analysis of the dataset, highlighting characteristics and challenges. Further, we present results for automatic veracity prediction, both with established baselines and with a novel method for joint ranking of evidence pages and predicting veracity that outperforms all baselines. Significant performance increases are achieved by encoding evidence, and by modelling metadata. Our best-performing model achieves a Macro F1 of 49.2%, showing that this is a challenging testbed for claim veracity prediction.

1 Introduction

Misinformation and disinformation are two of the most pertinent and difficult challenges of the information age, exacerbated by the popularity of social media. In an effort to counter this, a significant amount of manual labour has been invested in fact checking claims, often collecting the results of these manual checks on fact checking portals or websites such as politifact.com or snopes.com. In a parallel development, researchers have recently started to view fact checking as a task that can be partially automated, using machine learning and NLP to automatically predict the *veracity* of claims. However, existing efforts either use small datasets consisting of naturally occurring claims (e.g. Mihalcea and Strapparava (2009); Zubiaga et al. (2016)), or datasets consisting of artificially constructed claims such as FEVER (Thorne et al., 2018). While the latter offer valuable contributions to further automatic claim verification work, they cannot replace real-world datasets.

Table 1: An example of a claim instance. Entities are obtained via entity linking. Article and outlink texts, evidence search snippets and pages are not shown.

Contributions. We introduce the currently largest claim verification dataset of naturally occurring claims.[1] It consists of 34,918 claims, collected from 26 fact checking websites in English; evidence pages to verify the claims; the context in which they occurred; and rich metadata (see Table 1 for an example). We perform a thorough analysis to identify characteristics of the dataset such as entities mentioned in claims. We demonstrate the utility of the dataset by training state of the art veracity prediction models, and find that evidence pages as well as metadata significantly contribute to model performance. Finally, we propose a novel model that jointly ranks evidence pages and performs veracity prediction. The best-performing model achieves a Macro F1 of 49.2%, showing that this is a non-trivial dataset with remaining challenges for future work.

2 Related Work

2.1 Datasets

Over the past few years, a variety of mostly small datasets related to fact checking have been released. An overview over core datasets is given in Table 2. The datasets can be grouped into four categories (I–IV). Category I contains datasets aimed at testing how well the veracity[3] of a claim can be predicted using the claim alone, without context or evidence documents. Category II contains datasets bundled with documents related to each claim – either topically related to provide context, or serving as evidence. Those documents are, however, not annotated. Category III is for predicting veracity; they encourage retrieving evidence documents as part of their task description, but do not distribute them. Finally, category IV comprises datasets annotated for both veracity and stance. Thus, every document is annotated with a label indicating whether the document supports or denies the claim, or is unrelated to it. Additional labels can then be added to the datasets to better predict veracity, for instance by jointly training stance and veracity prediction models.

Methods not shown in the table, but related to fact checking, are stance detection for claims (Ferreira and Vlachos, 2016; Pomerleau and Rao, 2017; Augenstein et al., 2016a; Kochkina et al., 2017; Augenstein et al., 2016b; Zubiaga et al., 2018; Riedel et al., 2017), satire detection (Rubin et al., 2016), clickbait detection (Karadzhov et al., 2017), conspiracy news detection (Tacchini et al., 2017), rumour cascade detection (Vosoughi et al., 2018) and claim perspectives detection (Chen et al., 2019).

Claims are obtained from a variety of sources, including Wikipedia, Twitter, criminal reports and fact checking websites such as politifact.com and snopes.com. The same goes for documents – these are often websites obtained through Web search queries, or Wikipedia documents, tweets or Facebook posts. Most datasets contain a fairly small number of claims, and those that do not, often lack evidence documents. An exception is Thorne et al. (2018), who create a Wikipedia-based fact checking dataset. While a good testbed for developing deep neural architectures, their dataset is artificially constructed and can thus not take metadata about claims into account.

Contributions: We provide a dataset that, uniquely among extant datasets, contains a large number of *naturally occurring* claims and rich additional meta-information.

2.2 Methods

Fact checking methods partly depend on the type of dataset used. Methods only taking into account claims typically encode those with CNNs or RNNs (Wang, 2017; Pérez-Rosas et al., 2018), and potentially encode metadata (Wang, 2017) in a similar way. Methods for small datasets often use handcrafted features that are a mix of bag of word and other lexical features, e.g. LIWC, and then use those as input to a SVM or MLP (Mihalcea and Strapparava, 2009; Pérez-Rosas et al., 2018; Baly et al., 2018). Some use additional Twitter-specific features (Enayet and El-Beltagy, 2017). More involved methods taking into account evidence documents, often trained on larger datasets, consist of evidence identification and ranking following a neural model that measures the compatibility between claim and evidence (Thorne et al., 2018; Mihaylova et al., 2018; Yin and Roth, 2018).

Contributions: The latter category above is the most related to our paper as we consider evidence documents. However, existing models are not trained jointly for evidence identification, or for stance and veracity prediction, but rather employ a pipeline approach. Here, we show that a joint approach that learns to weigh evidence pages by their importance for veracity prediction can improve downstream veracity prediction performance.

3 Dataset Construction

We crawled a total of 43,837 claims with their metadata (see details in Table 11). We present the data collection in terms of selecting sources, crawling claims and associated metadata (Section 3.1); retrieving evidence pages; and linking entities in the crawled claims (Section 3.3).

3.1 Selection of sources

We crawled all active fact checking websites in English listed by Duke Reporters' Lab[4] and on the Fact Checking Wikipedia page.[5] This resulted in

[3] We use *veracity*, *claim credibility*, and *fake news* prediction interchangeably here – these terms are often conflated in the literature and meant to have the same meaning.

V: Veracity + evidence relevancy				
MultiFC	36,534	2-40	Yes	Fact Checking Websites

Table 2: Comparison of fact checking datasets. † indicates claims are not 'naturally occuring': Mitra and Gilbert (2015) use events as claims; Ciampaglia et al. (2015) use DBPedia tiples as claims; Shu et al. (2018) use tweets as claims; and Thorne et al. (2018) rewrite sentences in Wikipedia as claims.

38 websites in total (shown in Table 11). Out of these, ten websites could not be crawled, as further detailed in Table 9. In the later experimental descriptions, we refer to the part of the dataset crawled from a specific fact checking website as a *domain*, and we refer to each website as *source*.

From each source, we crawled the ID, claim, label, URL, reason for label, categories, person making the claim (speaker), person fact checking the claim (checker), tags, article title, publication date, claim date, as well as the full text that appears when the claim is clicked. Lastly, the above full text contains hyperlinks, so we further crawled the full text that appears when each of those hyperlinks are clicked (outlinks).

There were a number of crawling issues, e.g. security protection of websites with SSL/TLS protocols, time out, URLs that pointed to pdf files instead of HTML content, or unresolvable encoding. In all of these cases, the content could not be retrieved. For some websites, no veracity labels were available, in which case, they were not selected as domains for training a veracity prediction model. Moreover, not all types of metadata (category, speaker, checker, tags, claim date, publish date) were available for all websites; and availability of articles and full texts differs as well.

We performed semi-automatic cleansing of the dataset as follows. First, we double-checked that the veracity labels would not appear in claims. For some domains, the first or last sentence of the claim would sometimes contain the veracity label, in which case we would discard either the full sentence or part of the sentence. Next, we checked the dataset for duplicate claims. We found 202 such instances, 69 of them with different labels. Upon manual inspection, this was mainly due to them appearing on different websites, with labels not differing much in practice (e.g. 'Not true', vs. 'Mostly False'). We made sure that all such duplicate claims would be in the training split of the dataset, so that the models would not have an unfair advantage. Finally, we performed some minor manual merging of label types for the same domain where it was clear that they were supposed to denote the same level of veracity (e.g. 'distorts', 'distorts the facts').

This resulted in a total of 36,534 claims with their metadata. For the purposes of fact verification, we discarded instances with labels that occur fewer than 5 times, resulting in 34,918 claims. The number of instances, as well as labels per domain, are shown in Table 6 and label names in Table 10 in the appendix. The dataset is split into a training part (80%) and a development and testing part (10% each) in a label-stratified manner. Note that

the domains vary in the number of labels, ranging from 2 to 27. Labels include both straight-forward ratings of veracity ('correct', 'incorrect'), but also labels that would be more difficult to map onto a veracity scale (e.g. 'grass roots movement!', 'misattributed', 'not the whole story'). We therefore do not postprocess label types across domains to map them onto the same scale, and rather treat them as is. In the methodology section (Section 4), we show how a model can be trained on this dataset regardless by framing this multi-domain veracity prediction task as a multi-task learning (MTL) one.

3.2 Retrieving Evidence Pages

The text of each claim is submitted verbatim as a query to the Google Search API (without quotes). The 10 most highly ranked search results are retrieved, for each of which we save the title; Google search rank; URL; time stamp of last update; search snippet; as well as the full Web page. We acknowledge that search results change over time, which might have an effect on veracity prediction. However, studying such temporal effects is outside the scope of this paper. Similar to Web crawling claims, as described in Section 3.1, the corresponding Web pages can in some cases not be retrieved, in which case fewer than 10 evidence pages are available. The resulting evidence pages are from a wide variety of URL domains, though with a predictable skew towards popular websites, such as Wikipedia or The Guardian (see Table 3 for detailed statistics).

3.3 Entity Detection and Linking

To better understand what claims are about, we conduct entity linking for all claims. Specifically, mentions of people, places, organisations, and other named entities within a claim are recognised and linked to their respective Wikipedia pages, if available. Where there are different entities with the same name, they are disambiguated. For this, we apply the state-of-the-art neural entity linking model by Kolitsas et al. (2018). This results in a total of 25,763 entities detected and linked to Wikipedia, with a total of 15,351 claims involved, meaning that 42% of all claims contain entities that can be linked to Wikipedia. Later on, we use entities as additional metadata (see Section 4.3). The distribution of claim numbers according to the number of entities they contain is shown in Figure 1. We observe that the majority of claims have one to four entities, and the maximum number of 35 entities occurs in one claim only. Out of the 25,763 entities, 2,767 are unique entities. The top 30 most frequent entities are listed in Table 4. This clearly shows that most of the claims involve entities related to the United States, which is to be expected, as most of the fact checking websites are US-based.

Table 4: Top 30 most frequent entities listed by their Wikipedia URL with prefix omitted

only consider the claims themselves, and those that encode evidence pages as well. In addition, claim metadata (speaker, checker, linked entities) is optionally encoded for both categories of models, and ablation studies with and without that metadata are shown. We first describe the base model used in Section 4.1, followed by introducing our novel evidence ranking and veracity prediction model in Section 4.2, and lastly the metadata encoding model in Section 4.3.

4.1 Multi-Domain Claim Veracity Prediction with Disparate Label Spaces

Since not all fact checking websites use the same claim labels (see Table 6, and Table 10 in the appendix), training a claim veracity prediction model is not entirely straight-forward. One option would be to manually map those labels onto one another. However, since the sheer number of labels is rather large (165), and it is not always clear from the guidelines on fact checking websites how they can be mapped onto one another, we opt to learn how these labels relate to one another as part of the veracity prediction model. To do so, we employ the multi-task learning (MTL) approach inspired by collaborative filtering presented in Augenstein et al. (2018) (*MTL with LEL*–multitask learning with label embedding layer) that excels on pairwise sequence classification tasks with disparate label spaces. More concretely, each domain is modelled as its own task in a MTL architecture, and labels are projected into a fixed-length label embedding space. Predictions are then made by taking the dot product between the claim-evidence embeddings and the label embeddings. By doing so, the model implicitly learns how semantically close the labels are to one another, and can benefit from this knowledge when making predictions for individual tasks, which on their own might only have a small number of instances. When making predictions for individual domains/tasks, both at training and at test time, as well as when calculating the loss, a mask is applied such that the valid and invalid labels for that task are restricted to the set of known task labels.

Note that the setting here slightly differs from Augenstein et al. (2018). There, tasks are less strongly related to one another; for example, they consider stance detection, aspect-based sentiment analysis and natural language inference. Here, we have different domains, as opposed to conceptually different tasks, but use their framework, as we have the same underlying problem of disparate label spaces. A more formal problem definition follows next, as our evidence ranking and veracity prediction model in Section 4.2 then builds on it.

4.1.1 Problem Definition

We frame our problem as a multi-task learning one, where access to labelled datasets for T tasks $\mathcal{T}_1, \ldots, \mathcal{T}_T$ is given at training time with a target task $\mathcal{T}_T$ that is of particular interest. The training dataset for task $\mathcal{T}_i$ consists of N examples $X_{\mathcal{T}_i} = \{x_1^{\mathcal{T}_i}, \ldots, x_N^{\mathcal{T}_i}\}$ and their labels $Y_{\mathcal{T}_i} = \{\mathbf{y}_1^{\mathcal{T}_i}, \ldots, \mathbf{y}_N^{\mathcal{T}_i}\}$. The base model is a classic deep neural network MTL model (Caruana, 1993) that shares its parameters across tasks and has task-specific softmax output layers that output a probability distribution $\mathbf{p}^{\mathcal{T}_i}$ for task $\mathcal{T}_i$:

$$\mathbf{p}^{\mathcal{T}_i} = \text{softmax}(\mathbf{W}^{\mathcal{T}_i}\mathbf{h} + \mathbf{b}^{\mathcal{T}_i}) \quad (1)$$

where $\text{softmax}(\mathbf{x}) = e^{\mathbf{x}} / \sum_{i=1}^{\|\mathbf{x}\|} e^{\mathbf{x}_i}$, $\mathbf{W}^{\mathcal{T}_i} \in \mathbb{R}^{L_i \times h}$, $\mathbf{b}^{\mathcal{T}_i} \in \mathbb{R}^{L_i}$ is the weight matrix and bias term of the output layer of task $\mathcal{T}_i$ respectively, $\mathbf{h} \in \mathbb{R}^h$ is the jointly learned hidden rep-

resentation, L_i is the number of labels for task $\mathcal{T}_i$, and h is the dimensionality of $\mathbf{h}$. The MTL model is trained to minimise the sum of individual task losses $\mathcal{L}_1 + \ldots + \mathcal{L}_T$ using a negative log-likelihood objective.

Label Embedding Layer. To learn the relationships between labels, a Label Embedding Layer (LEL) embeds labels of all tasks in a joint Euclidian space. Instead of training separate softmax output layers as above, a label compatibility function $c(\cdot, \cdot)$ measures how similar a label with embedding $\mathbf{l}$ is to the hidden representation $\mathbf{h}$:

$$c(\mathbf{l}, \mathbf{h}) = \mathbf{l} \cdot \mathbf{h} \tag{2}$$

where $\cdot$ is the dot product. Padding is applied such that l and h have the same dimensionality. Matrix multiplication and softmax are used for making predictions:

$$\mathbf{p} = \text{softmax}(\mathbf{Lh}) \tag{3}$$

where $\mathbf{L} \in \mathbb{R}^{(\sum_i L_i) \times l}$ is the label embedding matrix for all tasks and l is the dimensionality of the label embeddings. We apply a task-specific mask to $\mathbf{L}$ in order to obtain a task-specific probability distribution $\mathbf{p}^{\mathcal{T}_i}$. The LEL is shared across all tasks, which allows the model to learn the relationships between labels in the joint embedding space.

4.2 Joint Evidence Ranking and Claim Veracity Prediction

So far, we have ignored the issue of how to obtain claim representation, as the base model described in the previous section is agnostic to how instances are encoded. A very simple approach, which we report as a baseline, is to encode claim texts only. Such a model ignores evidence for and against a claim, and ends up guessing the veracity based on surface patterns observed in the claim texts.

We next introduce two variants of evidence-based veracity prediction models that encode 10 pieces of evidence in addition to the claim. Here, we opt to encode search snippets as opposed to whole retrieved pages. While the latter would also be possible, it comes with a number of additional challenges, such as encoding large documents, parsing tables or PDF files, and encoding images or videos on these pages, which we leave to future work. Search snippets also have the benefit that they already contain summaries of the part of the page content that is most related to the claim.

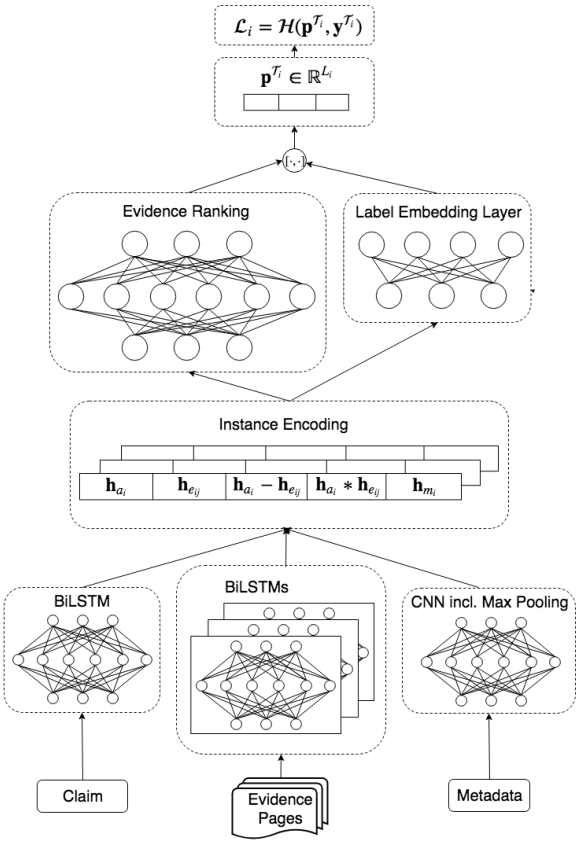

Figure 2: The Joint Veracity Prediction and Evidence Ranking model, shown for one task.

4.2.1 Problem Definition

Our problem is to obtain encodings for N examples $X_{\mathcal{T}_i} = \{x_1^{\mathcal{T}_i}, \ldots, x_N^{\mathcal{T}_i}\}$. For simplicity, we will henceforth drop the task superscript and refer to instances as $X = \{x_1, \ldots, x_N\}$, as instance encodings are learned in a task-agnostic fashion. Each example further consists of a claim a_i and $k = 10$ evidence pages $E_k = \{e_{1_0}, \ldots, e_{N_{10}}\}$.

Each claim and evidence page is encoded with a BiLSTM to obtain a sentence embedding, which is the concatenation of the last state of the forward and backward reading of the sentence, i.e. $\mathbf{h} = BiLSTM(\cdot)$, where $\mathbf{h}$ is the sentence embedding.

Next, we want to combine claims and evidence sentence embeddings into joint instance representations. In the simplest case, referred to as model variant *crawled_avg*, we mean average the BiLSTM sentence embeddings of all evidence pages (signified by the overline) and concatenate those with the claim embeddings, i.e.

$$\mathbf{s}_{g_i} = [\mathbf{h}_{a_i}; \overline{\mathbf{h}_{E_i}}] \tag{4}$$

where s_{g_i} is the resulting encoding for training example i and $[\cdot;\cdot]$ denotes vector concatenation.

However, this has the disadvantage that all evidence pages are considered equal.

Evidence Ranking The here proposed alternative instance encoding model, *crawled_ranked*, which achieves the highest overall performance as discussed in Section 5, learns the compatibility between an instance's claim and each evidence page. It ranks evidence pages by their utility for the veracity prediction task, and then uses the resulting ranking to obtain a weighted combination of all claim-evidence pairs. No direct labels are available to learn the ranking of individual documents, only for the veracity of the associated claim, so the model has to learn evidence ranks implicitly.

To combine claim and evidence representations, we use the matching model proposed for the task of natural language inference by Mou et al. (2016) and adapt it to combine an instance's claim representation with each evidence representation, i.e.

$$s_{r_{i_j}} = [\mathbf{h}_{a_i}; \mathbf{h}_{e_{i_j}}; \mathbf{h}_{a_i} - \mathbf{h}_{e_{i_j}}; \mathbf{h}_{a_i} \cdot \mathbf{h}_{e_{i_j}}] \quad (5)$$

where $s_{r_{i_j}}$ is the resulting encoding for training example i and evidence page j , $[\cdot;\cdot]$ denotes vector concatenation, and $\cdot$ denotes the dot product.

All joint claim-evidence representations $\mathbf{s}_{r_{i_0}}, \ldots, \mathbf{s}_{r_{i_{10}}}$ are then projected into the binary space via a fully connected layer FC, followed by a non-linear activation function f, to obtain a soft ranking of claim-evidence pairs, in practice a 10-dimensional vector,

$$\mathbf{o}_i = [f(\mathrm{FC}(s_{r_{i_0}})); \ldots; f(\mathrm{FC}(s_{r_{i_{10}}}))] \quad (6)$$

where $[\cdot;\cdot]$ denotes concatenation.

Scores for all labels are obtained as per (6) above, with the same input instance embeddings as for the evidence ranker, i.e. $s_{r_{i_j}}$. Final predictions for all claim-evidence pairs are then obtained by taking the dot product between the label scores and binary evidence ranking scores, i.e.

$$\mathbf{p}_i = \mathrm{softmax}(c(\mathbf{l}, \mathbf{s}_{\mathbf{r_i}}) \cdot \mathbf{o}_i) \quad (7)$$

Note that the novelty here is that, unlike for the model described in Mou et al. (2016), we have no direct labels for learning weights for this matching model. Rather, our model has to implicitly learn these weights for each claim-evidence pair in an end-to-end fashion given the veracity labels.

Model	Micro F1	Macro F1
claim-only	0.469	0.253
claim-only_embavg	0.384	0.302
crawled-docavg	0.438	0.248
crawled_ranked	0.613	0.441
claim-only + meta	0.494	0.324
claim-only_embavg + meta	0.418	0.333
crawled-docavg + meta	0.483	0.286
crawled_ranked + meta	**0.625**	**0.492**

Table 5: Results with different model variants on the test set, 'meta' means all metadata is used.

4.3 Metadata

We experiment with how useful claim metadata is, and encode the following as one-hot vectors: speaker, category, tags and linked entities. We do not encode 'Reason' as it gives away the label, and do not include 'Checker' as there are too many unique checkers for this information to be relevant. The claim publication date is potentially relevant, but it does not make sense to merely model this as a one-hot feature, so we leave incorporating temporal information to future work. Since all metadata consists of individual words and phrases, a sequence encoder is not necessary, and we opt for a CNN followed by a max pooling operation as used in Wang (2017) to encode metadata for fact checking. The max-pooled metadata representations, denoted h_m, are then concatenated with the instance representations, e.g. for the most elaborate model, *crawled_ranked*, these would be concatenated with $s_{cr_{i_j}}$.

5 Experiments

5.1 Experimental Setup

The base sentence embedding model is a BiLSTM over all words in the respective sequences with randomly initialised word embeddings, following Augenstein et al. (2018). We opt for this strong baseline sentence encoding model, as opposed to engineering sentence embeddings that work particularly well for this dataset, to showcase the dataset. We would expect pre-trained contextual encoding models, e.g. ELMO (Peters et al., 2018), ULMFit (Howard and Ruder, 2018), BERT (Devlin et al., 2018), to offer complementary performance gains, as has been shown for a few recent papers (Wang et al., 2018; Rajpurkar et al., 2018).

For claim veracity prediction without evidence documents with the MTL with LEL model, we use the following sentence encoding variants: *claim-*

only, which uses a BiLSTM-based sentence embedding as input, and *claim-only_embavg*, which uses a sentence embedding based on mean averaged word embeddings as input.

We train one multi-task model per task (i.e., one model per domain). We perform a grid search over the following hyperparameters, tuned on the respective dev set, and evaluate on the correspoding test set (final settings are underlined): word embedding size [64, 128, 256], BiLSTM hidden layer size [64, 128, 256], number of BiLSTM hidden layers [1, 2, 3], BiLSTM dropout on input and output layers [0.0, 0.1, 0.2, 0.5], word-by-word-attention for BiLSTM with window size 10 (Bahdanau et al., 2014) [True, False], skip-connections for the BiLSTM [True, False], batch size [32, 64, 128], label embedding size [16, 32, 64]. We use ReLU as an activation function for both the BiLSTM and the CNN. For the CNN, the following hyperparameters are used: number filters [32], kernel size [32]. We train using cross-entropy loss and the RMSProp optimiser with initial learning rate of 0.001 and perform early stopping on the dev set with a patience of 3.

5.2 Results

For each domain, we compute the Micro as well as Macro F1, then mean average results over all domains. Core results with all vs. no metadata are shown in Table 5. We first experiment with different base model variants and find that label embeddings improve results, and that the best proposed models utilising multiple domains outperform single-task models (see Table 8). This corroborates the findings of Augenstein et al. (2018). Per-domain results with the best model are shown in Table 6. Domain names are from hereon after abbreviated for brevity, see Table 11 in the appendix for correspondences to full website names. Unsurprisingly, it is hard to achieve a high Macro F1 for domains with many labels, e.g. tron and snes. Further, some domains, surprisingly mostly with small numbers of instances, seem to be very easy – a perfect Micro and Macro F1 score of 1.0 is achieved on ranz, bove, buca, fani and thal. We find that for those domains, the verdict is often already revealed as part of the claim using explicit wording.

Claim-Only vs. Evidence-Based Veracity Prediction. Our evidence-based claim veracity prediction models outperform claim-only veracity prediction models by a large margin. Unsurprisingly, *claim-only_embavg* is outperformed by *claim-only*. Further, *crawled_ranked* is our best-performing model in terms of Micro F1 and Macro F1, meaning that our model captures that not every piece of evidence is equally important, and can

Domain	# Insts	# Labs	Micro F1	Macro F1

utilise this for veracity prediction.

Metadata. We perform an ablation analysis of how metadata impacts results, shown in Table 7. Out of the different types of metadata, topic tags on their own contribute the most. This is likely because they offer highly complementary information to the claim text of evidence pages. Only using all metadata together achieves a higher Macro F1 at similar Micro F1 than using no metadata at all. To further investigate this, we split the test set into those instances for which no metadata is available vs. those for which metadata is available. We find that encoding metadata within the model hurts performance for domains where no metadata is available, but improves performance where it is. In practice, an ensemble of both types of models would be sensible, as well as exploring more involved methods of encoding metadata.

6 Analysis and Discussion

An analysis of labels frequently confused with one another, for the largest domain 'pomt' and best-performing model *crawled_ranked + meta* is shown in Figure 3. The diagonal represents when gold and predicted labels match, and the numbers signify the number of test instances. One can observe that the model struggles more to detect claims with labels 'true' than those with label 'false'. Generally, many confusions occur over close labels, e.g. 'half-true' vs. 'mostly true'.

We further analyse what properties instances that are predicted correctly vs. incorrectly have, using the model *crawled_ranked meta*. We find that, unsurprisingly, longer claims are harder to classify correctly, and that claims with a high direct token overlap with evidence pages lead to a high evidence ranking. When it comes to frequently occurring tags and entities, very general tags such as 'government-and-politics' or 'tax' that do not give away much, frequently co-occur with incorrect predictions, whereas more specific tags such as 'brisbane-4000' or 'hong-kong' tend to co-occur with correct predictions. Similar trends are observed for bigrams. This means that the model has an easy time succeeding for instances where the claims are short, where specific topics tend to co-occur with certain veracities, and where evidence documents are highly informative. Instances with longer, more complex claims where evidence is ambiguous remain challenging.

7 Conclusions

We present a new, real-world fact checking dataset, currently the largest of its kind. It consists of 34,918 claims collected from 26 fact checking websites, rich metadata and 10 retrieved evidence pages per claim. We find that encoding the metadata as well evidence pages helps, and introduce a new joint model for ranking evidence pages and predicting veracity.

Abstract

Textual network embeddings aim to learn a low-dimensional representation for every node in the network so that both the structural and textual information from the networks can be well preserved in the representations. Traditionally, the structural and textual embeddings were learned by models that rarely take the mutual influences between them into account. In this paper, a deep neural architecture is proposed to effectively fuse the two kinds of informations into one representation. The novelties of the proposed architecture are manifested in the aspects of a newly defined objective function, the complementary information fusion method for structural and textual features, and the mutual gate mechanism for textual feature extraction. Experimental results show that the proposed model outperforms the comparing methods on all three datasets.

1 Introduction

Networks provide an effective way to organize heterogeneous relevant data, which can often be leveraged to facilitate downstream applications. For example, the huge amount of textual and relationship data in social networks contains abundant information on people's preferences, and thus can be used for personalized advertising and recommendation. To this end, traditionally a matrix representing the network structure is often built first, then subsequent tasks proceed. However, matrix methods are computationally expensive and cannot be applied to large-scale networks.

Network embedding (NE) maps every node of a network into a low-dimensional vector, while seeking to retain the original network information. Subsequent tasks (*e.g.* similar vertices search, linkage prediction) can proceed by leveraging these low-dimensional features. To obtain network embeddings, (Perozzi et al., 2014) proposed to first generate sequences of nodes by randomly walking along connected nodes. Word embedding methods are then employed to produce the embeddings for nodes by noting the analogies between node sequences and sentences in natural languages. Second-order proximity information is further taken into account in (Tang et al., 2015). To gather the network connection information more efficiently, the random walking strategy in (Perozzi et al., 2014) is modified to favor the important nodes in (Grover and Leskovec, 2016). However, all these methods only took the network structure into account, ignoring the huge amount of textual data. In Twitter social network, for example, tweets posted by a user contain valuable information on the user's preferences, political standpoints, and so on (Bandyopadhyay et al., 2018).

To include textual information into the embeddings, (Tu et al., 2017) proposed to first learn embeddings for the textual data and network structure respectively, and then concatenate them to obtain the embeddings of nodes. The textual and structural embeddings are learned with an objective that encourages embeddings of neighboring nodes to be as similar as possible. Attention mechanism is further employed to highlight the important textual information by taking the impacts of texts from neighboring nodes into account. Later, (Shen et al., 2018b) proposed to use the fine-grained word alignment mechanism to replace the attention mechanism in (Tu et al., 2017) in order to absorb the impacts from neighboring texts more effectively. However, both methods require the textual and structural embeddings from neighboring nodes to be as close as possible even if the nodes share little common contents. This could be problematic since a social network user may be connected to users who post totally different viewpoints because of different political standpoints. If

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4698–4706, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

two nodes are similar, it is the node embeddings, rather than the individual textual or structural embeddings, that should be close. Forcing representations of dissimilar data to be close is prone to yield bad representations. Moreover, since the structural and textual embeddings contain some common information, if they are concatenated directly, as done in (Tu et al., 2017; Shen et al., 2018b), the information contained in the two parts is entangled in some very complicated way, increasing the difficulties of learning representative network embeddings.

In this paper, we propose a novel deep neural **I**nformation **F**usion **A**rchitecture for textual **N**etwork **E**mbedding (NEIFA) to tackle the issues mentioned above. Instead of forcing the separate embeddings of structures and texts from neighboring nodes to be close, we define the learning objective based on the node embeddings directly. For the problem of information entanglement, inspired by the gating mechanism of long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997), we extract the complementary informations from texts and structures and then use them to constitute the node embeddings. A mutual gate is further designed to highlight the node's textual information that is consistent with neighbors' textual contents, while diminishing those that contracdict to each other. In this way, the model provides a mechanism to only allow the information that is consistent among neighboring nodes to flow into the node embeddings. The proposed network embedding method is evaluated on the tasks of link prediction and vertex classification, using three real-world datasets from different domains. It is shown that the proposed method outperforms state-of-the-art network embedding methods on the task of link prediction by a substantial margin, demonstrating that the obtained embeddings well retain the information in original networks. Similar phenomenons can also be observed in the vertex classification task. These results suggest the effectiveness of the proposed neural information fusion architecture for textual network embeddings.

2 Related Work

Text Embedding There has been various methods to embed textual information into vector representations for NLP tasks. The classical method for embedding textual information could be one-hot vector, term frequency inverse document frequency (TF-IDF), etc. Due to the high-dimension and sparsity problems in here, (Mikolov et al., 2013a) proposed a novel neural network based skip-gram model to learn distributed word embeddings via word co-occurrences in a local window of textual content. To exploit the internal structure of text, convolutional neural networks (CNNs) (Blunsom et al., 2014; Kim, 2014) is applied to obtain latent features of local textual content. Then, by following a pooling layer, fixed-length representations are generated. To have the embeddings better reflect the correlations among texts, soft attention mechanisms (Bahdanau et al., 2014; Vaswani et al., 2017) is proposed to calculate the relative importances of words in a sentence by evaluating their relevances to the content of comparing sentences. Alternatively, gating mechanism is applied to strengthen the relevant textual information, while weakening the irrelevant one by controlling the information-flow path of a network in (Dauphin et al., 2017; Zhou et al., 2017).

Network Embedding Network embedding methods can be categorized into two classes: (1) methods that solely utilize structure information; and (2) methods that consider both structure and textual content associated with vertices. For the first type of methods, DeepWalk (Perozzi et al., 2014) was the first to introduce neural network technique into the network embedding field. In DeepWalk, node sequences are generated via randomly walking on the network, dense latent representations are by feeding those node sequences into the skip-gram model. LINE (Tang et al., 2015) exploited the first-order and second-order proximity information of vertices in network by optimizing the joint and condition probability of edges. Further, Node2Vec (Grover and Leskovec, 2016) proposed a biased random walk to search a network and generate node sequences based on the depth-first search and width-first search. However, those methods only embed the structure information into vector representations, while ignoring the informative textual contents associated with vertices. To address this issue, some recent work seeks to the joint impact of structure and textual contents to obtain better representations. TADW (Yang et al., 2015) proved that DeepWalk is equivalent to the matrix factorization and the textual information can be incorporated by simply adding the textual feature into the matrix factorization. CENE (Sun et al., 2016) extends the original net-

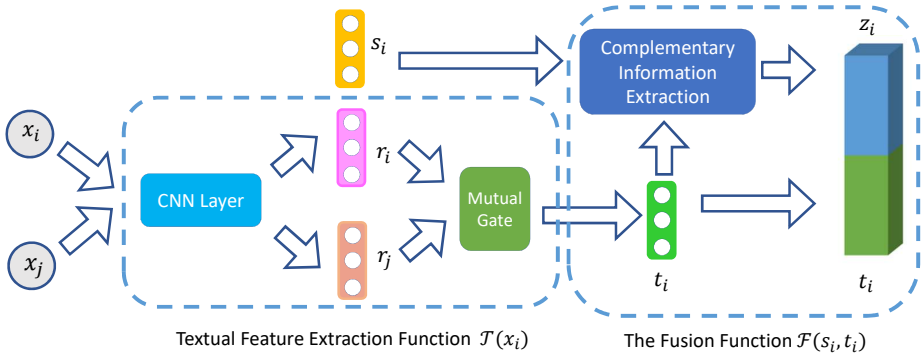

Figure 1: The overall framework of NEIFA.

works by transforming the textual content into another kinds of vertices, and the vertices are embedded into low-dimensional representations on the extended network. CANE (Tu et al., 2017) proposed to learn separate embeddings for the textual and structural information, and obtain the network embeddings by simply concatenating them, in which a mutual attention mechanism is used to model the semantic relationship between textual contents. WANE (Shen et al., 2018b) modified the semantic extraction strategy in CANE by introducing a fine-grained word alignment technique to learn word-level semantic information more effectively. However, most of recent methods force the textual and structural embeddings of two neighboring nodes close to each other irrespective of their underlying contents.

3 The Proposed Method

A textual network is defined as $G = \{V, E, T\}$, where V, E and T denote the vertices in the graph, edges between vertices and textual content associated with vertices, respectively. Each edge $e_{i,j} \in E$ suggests there is a relationship between vertex v_i and v_j.

3.1 Training Objective

Suppose the structural and textual features of node i are given and are denoted as s_i and t_i, respectively. Existing methods are built on the objectives that encourage the structural and textual features of neighboring nodes to be as similar as possible. As discussed in the previous sections, this may make the node embeddings deviate from the true information in the nodes. In this paper, we define the objective based on the node embeddings directly, that is,

$$\mathcal{L} = \sum_{\{i,j\} \in E} \log p(h_i|h_j), \tag{1}$$

where h_i is the network embedding of node i, and is constructed from s_i and t_i by

$$h_i = \mathcal{F}(s_i, t_i); \tag{2}$$

$\mathcal{F}(\cdot, \cdot)$ is the fusion function that maps the structural and textual features into the network embeddings; and $p(h_i|h_j)$ denotes the conditional probability of network embedding h_i given the network embedding h_j. Following LINE (Tang et al., 2015), the conditional probability in (1) is defined as:

$$p(h_i|h_j) = \frac{\exp(h_i \cdot h_j)}{\sum_{z \in V} \exp(h_i \cdot h_z)}. \tag{3}$$

Note that the structural feature s_i is randomly initialized and will be learned along with the other model parameters. For the textual feature t_i, it is obtained via a trainable feature extraction function from the given texts, i.e.,

$$t_i = \mathcal{T}(x_i), \tag{4}$$

where x_i represents the texts associated with node i. From the definition of objective function (1), it can be seen that it is the network embeddings of nodes, rather than the individual structural or textual embeddings, that are encouraged to be close for neighboring nodes.

Details on how to realize the fusion function $\mathcal{F}(\cdot, \cdot)$ and feature extraction function $\mathcal{T}(\cdot)$ are deferred to Section 3.2 and Section 3.3, respectively. The overall framework of our proposed NEIFA is shown in Fig.1.

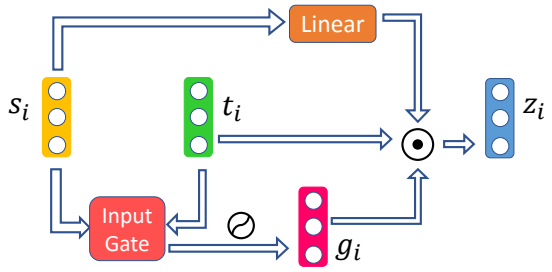

Figure 2: The Fusion Module.

3.2 Fusion of Structural and Textual Features $\mathcal{F}(s_i, t_i)$

In this section, we will present how to fuse the structural and textual features to yield the embeddings for nodes. The fusion module $\mathcal{F}(s_i, t_i)$ is illustrated in Fig.2. The simplest way to obtain network embeddings is to concatenate them directly, *i.e.* $h_i = [s_i; t_i]$. However, it is known that the structural and textual features are not fully exclusive, and often contain some common information. Thus, if the network embeddings are generated by simply concatenating the two features, different parts of the embeddings become entangled to each other in some unknown but complex way. This may make the process of optimizing the objective function more difficult and hinder the model to learn representative embeddings for the nodes. In this paper, we instead distill the information that is complementary to the textual feature t_i from s_i first, and then concatenate the two complementary information to constitute the embeddings of nodes.

To distill the complementary information from the structural feature s_i, inspired by LSTM, an input gate is designed to eliminate the information in s_i that has already appeared in t_i. Specifically, the gate is designed as

$$g_i = 1 - \sigma((\mathbf{P}s_i + b_g) \odot t_i), \tag{5}$$

where $\sigma(\cdot)$ is the sigmoid function; $\odot$ denotes the element-wise multiplication; $\mathbf{P}$ and b_g are used to align the structural feature s_i to the space of textual features t_i. From the definition of g_i, it can be seen that if the values on some specific dimension of $\mathbf{P}s_i + b_g$ and t_i are both large, which indicates the same information appears in both s_i and t_i, the gate g_i will be closed. So, if $(\mathbf{P}s_i + b_g) \odot t_i$ is multiplied to the gate g_i, only the information that is not contained in both s_i and t_i is allowed to pass through. Thus, $((\mathbf{P}s_i + b_g) \odot t_i) \odot g_i$ can be understood as the information in s_i that is complementary to t_i. In practice, we untie the values of $\mathbf{P}$ and b_g, and use a new trainable matrix $\mathbf{Q}$ and bias b_c instead. The complementary information is eventually computed as

$$z_i = ((\mathbf{Q}s_i + b_c) \odot t_i) \odot g_i. \tag{6}$$

Then, we concatenate complementary information z_i to the textual features t_i to produce the final network embedding

$$h_i = [z_i; t_i]. \tag{7}$$

In this way, given the structural and textual features s_i and t_i, we successfully extract the complementary information from s_i and generate the final network embedding h_i.

3.3 Textual Feature Extraction $\mathcal{T}(x_i)$

When extracting textual features for the embeddings of nodes, the impacts from neighboring nodes should also be taken into account, *i.e.* highlighting the consistent information, while dampening the inconsistent ones. To this end, we first repersent words with their corresponding embeddings, and then apply a one-layer CNN followed by an average pooling operator to extract the raw features for texts (Tu et al., 2017; Shen et al., 2018a). Given the raw textual features r_i and r_j of two neighboring nodes i and j, we diminish the information that are not consistent in the two raw features. Specifically, the final textual features are computed for nodes i and j as

$$t_i = r_i \odot \sigma(r_j), \tag{8}$$

$$t_j = r_j \odot \sigma(r_i), \tag{9}$$

where $\sigma(\cdot)$ serves as the role of gating. Since the raw textual feature r_i often exhibits specific meanings on different dimensions, the expressions (8) and (9) can be understood as a way to control which information is allowed to flow into the embeddings. Only the information that is consitent among neighboring nodes can appear in the textual feature t_i, which is then fused into the network embeddings. There are a variety of other nonlinear functions that can serve as the role of gating, but in this work, the simplest but effective sigmoid function is employed.

3.4 Training Details

Maximizing the objective function in (1) requires to compute the expensive softmax function repeatedly, in which the summation over all nodes of the networks is needed for iteration. To address this issue, for each edge $e_{i,j} \in E$, we introduce negative sampling (Mikolov et al., 2013b) to simplify the optimization process. Therefore, the conditional distribution $p(h_i|h_j)$ into the following form:

$$\log \sigma(h_i \cdot h_j) + \sum_{k=1}^{K} E_{h_k \sim P(h)}[\log \sigma(-h_k \cdot h_i)] \tag{10}$$

where K is the number of negative samples, and $P(v) \propto d_v^{3/4}$ is the distribution of vertices with d_v representing the out-degree of vertex v. Adam (Kingma and Ba, 2014) is employed to optimize the entire model based on randomly mini-batch of edges in each step.

4 Experiments

To evaluate the quality of the network embeddings generated by the proposed method, we apply them in two tasks: link prediction and vertex classification. Link prediction aims to predict whether there exists a link between two randomly chosen nodes based on the similarities of embeddings of the two nodes. Vertex classification, on the other hand, tries to classify the nodes into different categories based on the embeddings, provided that there exists some supervised information. Both tasks can achieve good performances only when the embeddings retain important information of the nodes, including both the structural and textual information. In the following, we will first introduce the datasets and baselines used in this paper, then describe the evaluation metric and experimental setups, and lastly report the performance of the proposed model on the tasks of link prediction and vertex classification, respectively.

4.1 Datasets and Baselines

Experiments are conducted on three real-world datasets: Zhihu (Sun et al., 2016), Cora (McCallum et al., 2000) and HepTh (Leskovec et al., 2005). Below shows the detailed descriptions of the three datasets, with their statistics summaries given in Table 1. The preprocessing procedure of the above datasets is the same as that in (Tu et al., 2017) [1].

Datasets	Zhihu	Cora	HepTh
Vertices	10000	2277	1038
Edges	43894	5214	1990
#(Edges)	2191	93	24
*(Text)	190	90	54
Labels	-	7	-

Table 1: Statistics of datasets, where #(Edges) denotes the max number of the connective relationship of a node, and *(Text) denotes the average lengths of the text.

- *Zhihu* (Sun et al., 2016) is a Q&A based community social network. In our experiment, 10000 active users and the descriptions of their interested topics are collected as the vertices and texts of the social network to be studied. There are total 43894 edges which indicate the relationship between active users.
- *Cora* (McCallum et al., 2000) is a citation network that consists of 2277 machine learning papers with text contents divided into 7 categories. The citation relations among the papers are reflected in the 5214 edges.
- *HepTh* (Leskovec et al., 2005) (High Energy Physics Theory) is a citation network from the e-print arXiv. In our experiment, 1038 papers with abstract information are collected, among which 1990 edges are observed.

To evaluate the effectiveness of our proposed model, several strong baseline methods are compared with, which are divided into two categories as follows:

- *Structure-only:* DeepWalk (Perozzi et al., 2014), LINE (Tang et al., 2015), Node2vec (Grover and Leskovec, 2016).
- *Structure and Text:* TADW (Yang et al., 2015), CENE (Sun et al., 2016), CANE (Tu et al., 2017), WANE (Shen et al., 2018b).

4.2 Evaluation Metrics and Experimental Setups

In link prediction, the performance criteria of area under the curve (AUC) (Hanley and McNeil,

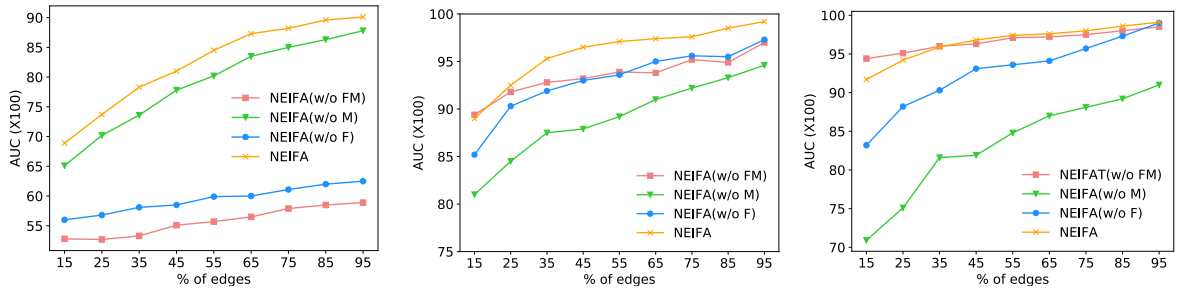
1982) is used, which represents the probability that vertices in a random unobserved link are more similar than those in a random non-existent link.

For the vertex classification task, a logistic regression model is first trained to classify the embeddings into different categories based on the provided labels of nodes. Then, the trained model is used to classify the network embeddings in test set, and the classification accuracy is used as the performance criteria of this task.

To have a fair comparison with competitive methods, the dimension of network embeddings is set to 200 for all considered methods. The number of negative samples is set to 1 and the mini-batch size is set to 64 to speed up the training processes. Adam (Kingma and Ba, 2014) is employed to train our model with a learning rate of 1×10^{-3}.



4.3 Link Prediction

We randomly extract a portion of edges from the whole edges to constitute the training datasets, and use the rest as the test datasets. The AUC scores of different models under proportions ranging from 15% to 95% on Zhihu, Cora and HepTh datasets are shown in Table 2, Table 3 and Table 4, respectively, with the best performance highlighted in bold.

As can be seen from Table 2, our proposed method outperforms all other baselines in Zhihu dataset substantially, with approximately a 10 percent improvement over the current state-of-the-art WANE model. This may be partially attributed to the complicated Zhihu dataset, in which both the structures and texts contain important informations. If the two individual features are concatenated directly, there may be sever information overlapping problem, limiting the models to learning good embeddings. The proposed complementary information fusion method alleviate the issue by disentangling the structural and textual features. In adition, the proposed mutual gate mechanism that removes inconsistent textual information from a node's textual feature also contribute to the performance gains. On the other hand, the substantial gain may also be partially attributed to the objective function that is directly defined on the

network embeddings. That is because the inconsistencies of the structural or textual information among neighboring nodes are more likely to happen in complex networks.

For the other two datasets, as shown in Table 3 and Table 4, our proposed method outperforms baseline methods overall. The results strongly demonstrate that the network embeddings generated by the proposed model are easier to preserve the original information in the nodes. It can be also seen that the performance gains observed in the Cora and HepTh datasets are not as substantial as that in Zhihu dataset. The relatively small improvement may be attributed to the fact that the number of edges and neighbors in Cora and HepTh datasets are much smaller that Zhihu datasets. We speculate that the information in structures of the two datasets is far less than that in texts, implying that the overlapping issue is not as sever as that in Zhihu. Hence, direct concatenation will not induce significant performance loss.

Ablation Study To demonstrate the effectiveness of proposed fusion method and mutual gate mechanism, three variants of the proposed model are evaluated: (1)NEIFA(w/o FM): NEIFA without both fusion process and mutual gated mechanism where the raw textual features r are directly regarded as network embeddings. (2) NEIFA(w/o F): NEIFA without fusion process where the textual features t are directly regarded as network embeddings. (3) NEIFA(w/o M): NEIFA without mutual gated mechanism where the network embeddings are obtained by fusing the structural features and raw textual features. The three variants are compared with original NEIFA model on the three datasets above. The results are showed in Fig.3. It can be seen that for networks with very sparse structure, such as Hepth, the method that simply uses the raw textual features as their network embeddings can achieve pretty good performance. In the simple datasets, the proposed model even exhibits worse performance in the case of small proportion of training edges. As the datasets become larger and more complex network structure is included, the performance of only using the textual embeddings decreases rapidly. The reason may be that as the networks grow, the differences of structural or textual data among neighboring nodes become more apparent, and the advantages of the mutual gate mechanism and information fu-

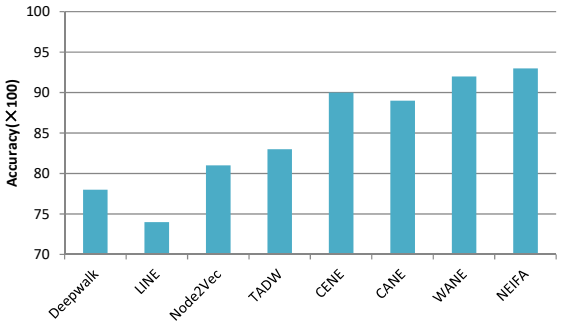

Figure 4: Vertex classification result on Cora dataset

sion method will show up.

4.4 Vertex Classification

To demonstrate the superiority of proposed method, the vertex classification experiment is also considered on the Cora dataset. This experiment is established on the basis that if the original network contains different types of nodes, good embeddings mean that they can be classified into specific classes by a simple classifier easily. For the proposed method, the embedding of a node varies as it interacts with different nodes. To have the embedding fixed, we follow procedures in (Tu et al., 2017) to yield a node's embedding by averaing the embeddings that are obtained when the node interacts with different neighbors.

To this end, we randomly split the node embeddings of all nodes with a proportion of 50%-50% into a training and testing set, respectively. A logistic regression classifier regularized by L_2 distance (Fan et al., 2008) is then trained on the node embeddings from training set. The classification performance is tested on the hold-out testing set. The above procedures are repeated 10 times and their average value is reported as the final performance. It can be seen from Fig.4 that methods considering both structural and textual information show better classification accuracies than methods leveraging only structural information, demonstrating the importance of incorporating textual information into the embeddings. Moreover, NEIFA outperforms all methods considered, which further proves the superiority of our proposed model.

To intuitively understand the embeddings produced by the proposed model, we employ t-SNE to map our learned embeddings to a 2-D space. The result is shown in Fig.5, where different colors indicate that the nodes belong to different categories. Note that, although the mapping in t-SNE is trained without using any category labels, the latent label information is still partially extracted out. As shown in Fig.5, the points with the same color are closer to each other, while the ones with different colors are far apart.

5 Conclusions

In this paper, a novel deep neural architecture is proposed to effectively fuse the structural and textual informations in networks. Unlike existing embeddings methods which encourage both textual and structural embeddings of two neighboring nodes close to each other, we define the training objective based on the node embeddings directly. To address the information duplication problem in the structural and textual features, a complementary information fusing method is further developed to fuse the two features. Besides, a mutual gate is designed to highlight the textual information in a node that is consistent with the textual contents of neighboring nodes, while diminishing those that are conflicting to each other. Exhaustive experimental results on several tasks manifest the advantages of our proposed model.

Abstract

Information about individuals can help to better understand what they say, particularly in social media where texts are short. Current approaches to modelling social media users pay attention to their social connections, but exploit this information in a static way, treating all connections uniformly. This ignores the fact, well known in sociolinguistics, that an individual may be part of several communities which are not equally relevant in all communicative situations. We present a model based on Graph Attention Networks that captures this observation. It dynamically explores the social graph of a user, computes a user representation given the most relevant connections for a target task, and combines it with linguistic information to make a prediction. We apply our model to three different tasks, evaluate it against alternative models, and analyse the results extensively, showing that it significantly outperforms other current methods.

1 Introduction

The idea that extra-linguistic information about speakers can help language understanding has recently gained traction in NLP. Several studies have successfully exploited social information to classify user-generated language in downstream tasks such as sentiment analysis (Yang and Eisenstein, 2017), abusive speech identification (Mishra et al., 2018) and sarcasm detection (Hazarika et al., 2018; Wallace et al., 2016). The underlying goal is to capture the sociological phenomenon of *homophily* (McPherson et al., 2001) – i.e., people's tendency to group together with others they share ideas, beliefs, and practices with – and to exploit it jointly with linguistic information to obtain richer text representations. In this paper, we advance this line of research. In particular, we address a common shortcoming in current models by using state-of-the-art graph neural networks to encode and leverage homophily relations.

Most current models represent speakers as multidimensional vectors derived by aggregating information about all known social relations of a given individual in a uniform way. A major limit of this approach is that it does not take into account the well known sociolinguistic observation that speakers typically belong to several communities at once, in the sense of 'communities of practice' (Eckert and McConnell-Ginet, 1992) denoting an aggregate of people defined by a common engagement, such as supporters of a political party or fans of a TV show. Membership to these communities has different relevance in different situations. For example, consider an individual who is both part of a supporters group of the USA Democratic Party and of a given sports team. While membership to these two communities can be equally important to characterise the person in general terms, the former is much more relevant when it comes to predicting whether linguistic content generated by this person expresses a certain stance towards president Trump. Current models fail to capture this context-dependent relevance.

In this work, we address this shortcoming, making the following contributions:

- We use Graph Attention Networks (Velickovic et al., 2018) to design a model that dynamically explores the social relations of an individual, learns which of these relations are more relevant for the task at hand, and computes the vector representation of the target individual accordingly. This is then combined with linguistic information to perform text classification tasks.
- To assess the generality and applicability of

*Research conducted when the author was at the University of Amsterdam.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4707–4717,

the model, we test it on three different tasks (sentiment analysis, stance detection, and hate speech detection) using three annotated Twitter datasets and evaluate its performance against commonly used models for user representation.

- We show that exploiting social information leads to improvements in two tasks (stance and hate speech detection) and that our model significantly outperforms competing alternatives.
- We perform an extended error analysis, in which we show the robustness across tasks of user representations based on social graphs, and the superiority of dynamic representations over static ones.

2 Related Work

Several strands of research have explored different social features to create user representations for NLP in social media. Hovy (2015) and Hovy and Fornaciari (2018) focus on demographic information (age and gender), while Bamman et al. (2014) and Hovy and Purschke (2018) exploit geographic location to account for regional variation. Demographic and geographic information, however, need to be made explicit by users and thus are often not available or not reliable. To address this drawback, other studies have aimed at extracting user information by just observing users' behaviour on social platforms.

To tackle sarcasm detection on Reddit, Kolchinski and Potts (2018) assign to each user a random embedding that is updated during the training phase, with the goal of learning individualised patterns of sarcasm usage. Wallace et al. (2016) and Hazarika et al. (2018) address the same task, using ParagraphVector (Le and Mikolov, 2014) to condense all the past comments/posts of a user into a low dimensional vector, which is taken to capture their interests and opinions. All these studies use the concatenation of author and post embeddings for the final prediction, showing that adding author information leads to significant improvements.

While the approaches discussed above consider users individually, a parallel line of work has focused on leveraging the social connections of users in Twitter data. This methodology relies on creating a social graph where users are nodes connected to each other by their retweeting, mentioning, or following behaviour. Techniques such as Line (Tang et al., 2015), Node2Vec (Grover and Leskovec, 2016) or Graph Convolutional Networks (GCNs, Kipf and Welling, 2017) are then used to learn low-dimensional embeddings for each user, which have been shown to be beneficial in different downstream tasks when combined with textual information. For example, Mishra et al. (2018) and Mishra et al. (2019) use the concatenation strategy mentioned above for abusive language detection; Yang et al. (2016) optimise social and linguistic representations with two distinct scoring functions to perform entity linking; while Yang and Eisenstein (2017) use an ensemble learning setup for sentiment analysis, where the final prediction is given by the weighted combination of several classifiers, each exploring the social graph independently.

Methods like Line, Node2Vec and GCNs create user representations by aggregating the information coming from their connections in the social graph, without making any distinction among them. In contrast, we use Graph Attention Networks (GATs, Velickovic et al., 2018), a recent neural architecture that applies self attention to assign different relevance to different connections, and computes node representations accordingly. These representations have been used in several domains to obtain state of the art results in classification tasks where nodes were, for example, texts in a citation network or proteins in human tissues (Velickovic et al., 2018). To our knowledge, we are the first to use Graph Attention Networks to model relations among social media users.

3 Model

The model we present operates on annotated corpora made up of triples (t, a, y), where t is some user-generated text, a is its author, and y is a label classifying t. We address the task of predicting y given (t, a). Our focus is on user representations: We investigate how model predictions vary depending on how authors are represented.

3.1 General Model Architecture

Our model consists of two modules, one encoding the linguistic information in t and the other one modelling social information related to a. The general architecture is shown in Figure 1. The output of the linguistic and social modules are vectors $l \in \mathbb{R}^d$ and $s \in \mathbb{R}^{d'}$, respectively. We adopt a standard *late fusion* approach in which these two vectors are concatenated and passed through a two-layer classifier, consisting of a layer W_1

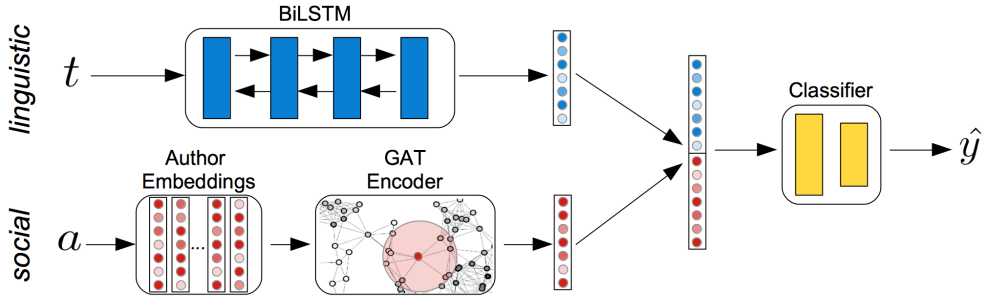

Figure 1: General model: The linguistic module returns a compact representation of the input tweet t. The social module takes as input the precomputed representation of the author a and updates it using the GAT encoder. The output embeddings of the two modules are concatenated and fed into a classifier.

$\in \mathbb{R}^{d+d' \times c}$, where c is a model parameter, and a layer $W_2 \in \mathbb{R}^{c \times o}$, where o is the number of output classes. The final prediction is computed as follows, where σ is a ReLU function (Nair and Hinton, 2010):

$$\hat{y} = softmax(W_2\,(\sigma\,(W_1\,(l \| s)))) \quad (1)$$

3.2 Linguistic Module

The linguistic module is implemented using a recurrent neural network, concretely an LSTM (Hochreiter and Schmidhuber, 1997). Since LSTMs have become ubiquitous in NLP, we omit a detailed description of the inner workings of the model here and refer readers to Tai et al. (2015); Tang et al. (2016); Barnes et al. (2017) for overviews. We use a bidirectional LSTM (BiLSTM) (Graves, 2012), whose final states are concatenated in order to obtain the representation of the input text.

3.3 Social Module

The goal of the social module is to return author representations which encode homophily relations among users, i.e., which assign similar vectors to users who are socially related.

We model social relations using graphs $G = (V, E)$, where V is the set of nodes representing individuals and E the set of edges representing relations among them. We use $v_i \in V$ to refer to a node in the social graph, and $e_{ij} \in E$ to denote the edge connecting nodes v_i and v_j. Finally, we use $N(v_i)$ to refer to v_i's neighbours, i.e., all nodes which are directly connected to v_i.[1]

In contrast to most existing models, where user representations are static, our model uses an encoder which takes as input a pre-computed user vector, performs a dynamic exploration of its neighbours in the social graph, and updates the user representation given the relevance of its connections for a target task. To pre-compute initial user representations we use Node2Vec (N2V, Grover and Leskovec, 2016). Similarly to word2vec's SkipGram model (Mikolov et al., 2013), for every node v, N2V implements a function $f : v \rightarrow \mathbb{R}^d$ which maps v to a low-dimensional embedding of size d that maximizes the probability of observing nodes belonging to $S(v)$, i.e., the set of n nodes encountered in the graph by taking k random walks starting from v (where n and k are parameters of the model). No distinction is made among neighbours, thus ignoring the fact that different neighbours may have different importance depending on the task at hand. Our model addresses this fundamental problem by leveraging Graph Attention Networks (GATs, Velickovic et al., 2018).

GATs extend the Graph Convolutional Networks proposed by Kipf and Welling (2017)[2] by introducing a self-attention mechanism (Bahdanau et al., 2015; Parikh et al., 2016; Vaswani et al., 2017) which is able to assign different relevance to different neighbouring nodes. For a target node $v \in V$, an attention coefficient e_{vu} is computed for every neighbouring node $u \in N(v)$ as:

$$e_{vu} = att\,(h_v \| h_u) \quad (2)$$

where h_v and $h_u \in \mathbb{R}^d$ are the vectors representing v and u, $\|$ is concatenation, and att is a single-layer feed-forward neural network, parametrized by a weight matrix $W^a \in \mathbb{R}^{2d}$ with Leaky ReLU non-linearity (Maas et al., 2013). The attention co-

[1] Throughout the paper, we use the terms 'individual', 'author', 'user' and 'node' interchangeably.

[2] For a detailed description of Graph Convolutional Networks see https://tkipf.github.io/graph-convolutional-networks/.

efficients for all the neighbours are then normalized using a softmax function. Finally, the update of a node is computed as:

$$h_v^{k+1} = \sigma\left(\sum_{u \in N(v)} \alpha_{vu}^k \left(W^k h_u^k + b^k\right)\right) \quad (3)$$

where W^k and b^k are the layer-specific parameters of the model, $N(v)$ is the set of neighbours of the target node v, h_v^{k+1} the updated node representation, σ a ReLU function, k the convolutional layer,[3] and α_{vu} the normalised attention coefficient, which defines how much neighbour u should contribute to the update of v.

To stabilize the learning process, multiple attention mechanisms, or *heads*, can be used. The number of heads is a hyperparameter of the model. Given n heads, n real-valued vectors $h_v^{k+1} \in \mathbb{R}^{d'}$ are computed and, subsequently, concatenated, thus obtaining a single embedding $h_v^{k+1} \in \mathbb{R}^{n*d'}$. The resulting vector is then concatenated with the output of the linguistic module and fed into the classifier.

4 Experimental Setup

4.1 Alternative Models

We compare the performance of our model against several competing models. All the models except Frequency baseline and LING compute a user representation which is concatenated with the linguistic information present in a tweet and fed into the classifier.

Frequency Baseline Labels are sampled according to their frequency in the whole dataset.

LING We use the linguistic module (LING) alone to assess the performance of the model when no social information is provided.

LING+random We implement a setting similar to Kolchinski and Potts (2018). Each individual is assigned a random embedding, which is updated during training. Our implementation differs from the Kolchinski and Potts's model in two aspects: They use GRUs (Cho et al., 2014) rather than LSTMs for the linguistic module, and their author vectors have size 15, while ours 200 for a fair comparison with the other models (see below).

[3]The number of layers defines the depth of the neighbourhood, hence k layers encode neighbours lying k hops away in the graph. Also, $v \in N(v)$, i.e., there exists a *self-loop* $(v, v) \in E$ for each node v which ensures that the initial representation of the node is considered during its update.

LING+PV In line with Wallace et al. (2016) and Hazarika et al. (2018), we compute a representation for each author by running Paragraph Vector (PV, Le and Mikolov, 2014) on the concatenation of all her previous tweets. Author representations are thus based on past linguistic usage.

LING+N2V While none of the previous models make use of the social graph, here we represent authors by means of the embeddings created with N2V (as e.g., Mishra et al., 2018). In contrast to our GAT-based model, the embeddings are computed without making any distinction among neighbours, and are not updated with respect to the task at hand.[4]

4.2 Hyperparameter Search

For all the models and for each dataset, we perform grid hyperparameter search on the validation set using early stopping. For batch size, we explore values 4, 8, 16, 32, 64; for dropout, values 0.0, ..., 0.9; and for L2 regularisation, values 0, 1^{e-05}, 1^{e-04}. For all the settings, we use Adam optimizer (Kingma and Ba, 2015) with learning rate of 0.001, β_1 = 0.9 and β_2 = 0.999. We run PV with the following hyperparameters: 30 epochs, minimum count of 5, vector size of 200. For N2V we use the default hyperparameters, except for vector size (200) and epochs (20). For the GAT encoder, we experiment with values 10, 15, 20, 25, 30, 50 for the size of the hidden layer; for the number of heads, we explore values 1, 2, 3, 4. We keep the number of hops equal to 1 and the alpha value for the Leaky ReLU of the attention heads equal to 0.2 across all the settings.[5]

Since our focus is on social information, we keep the hyperparameters of the linguistic module and the classifier fixed across all the settings. Namely, the BiLSTM has depth of 1, the hidden layer has 50 units, and uses 200-d GloVe embeddings pretrained on Twitter (Pennington et al., 2014). For the classifier, we set the dimensionality of the non-linear layer to 50.

[4]We also experimented with updating author embeddings during training, but did not observe any difference in the results.

[5]We implement PV using the Gensim library: https://radimrehurek.com/gensim/models/doc2vec.html. For N2V, we use the implementation at: https://github.com/aditya-grover/node2vec. For GAT, the implementation at: https://github.com/Diego999/pyGAT.

4.3 Tasks and Datasets

We test all the models on three Twitter datasets annotated for different tasks. For all datasets we tokenise and lowercase the text, and replace any URL, hashtag, and mention with placeholders.

Sentiment Analysis We use the dataset in Task-4 of SemEval-2017 (Rosenthal et al., 2017), which includes 62k tweets labelled as `POSITIVE` (35.6% of labels), `NEGATIVE` (18.8%) and `NEUTRAL` (45.6%). Tweets in the train set were collected between 2013 and 2015, while those in the test set in 2017. Information for old tweets is difficult to recover:[6] To have a more balanced distribution, we shuffle the dataset and then split it into train (80%), validation (10%) and test (10%).

Stance Detection We use the dataset released for Task-6 (Subtask A) of SemEval-2016 (Mohammad et al., 2016), which includes 4k tweets labelled as `FAVOR` (25.5% of labels), `AGAINST` (50.6%) and `NEUTRAL` (23.9%), with respect to five topics: 'Atheism', 'Climate change is a real concern', 'Feminist movement', 'Hillary Clinton', 'Legalization of abortion'. The dataset is split into train and test. We randomly extract 10% of tweets in the train split and use them for validation.

Hate Speech Detection We employ the dataset introduced by Founta et al. (2018), from which we keep only tweets labelled as `NORMAL` (93.4% of labels) and `HATEFUL` (6.6%) for a total of 44k tweets.[7] The latter are tweets which denigrate a person or group based on social features (e.g., ethnicity). We split into train (80%), validation (10%) and test (10%).

4.4 Optimization Metrics

We tune the models using different evaluation measures, according to the task at hand. The rationale behind this choice is to use, whenever possible, established metrics per task.

For Sentiment Analysis we use average recall, the same measure used for Task 4 of SemEval-2017 (Rosenthal et al., 2017), computed as:

$$AvgRec = \frac{1}{3}(R^P + R^N + R^U) \quad (4)$$

Where R^P, R^N and R^U refer to recall of the `POSITIVE`, the `NEGATIVE`, and the `NEUTRAL` class, respectively. The measure has been shown to have several desirable properties, among which robustness to class imbalance (Sebastiani, 2015).

For Stance Detection, we use the average of the F-score of `FAVOR` and `AGAINST` classes:

$$F_{avg} = \frac{F_{favor} + F_{against}}{2} \quad (5)$$

The measure, used for Task-6 (Subtask A) of SemEval-2016, is designed in such a way to optimize the performance of the model in the cases when an opinion toward the target entity is expressed, while it ignores the neutral class (Mohammad et al., 2016).

Finally, for Hate Speech Detection, a more recent task, we could not identify an established metric. We thus use F-score for the target class `HATEFUL`, the minority class accounting for 6.6% of the datapoints (see Section 4.3).

4.5 Social Graph Construction

In order to create the social graph, we initially retrieve, for each tweet, the `id` of its author using the Twitter API and scrape her timeline, i.e. her past tweets.[8] We then create an independent social graph $G = (V, E)$ for each dataset. We define V as the set of users authoring the tweets in the dataset, while for E we follow Yang and Eisenstein (2017) and instantiate an unweighted and undirected edge between two users if one retweets the other. Information about retweets is available in users' timeline. In order to make the graph more densely connected, we include external users not present in the dataset who have been retweeted by authors in the dataset at least 100 times. Information about the author of a tweet is not always available: In this case, we assign her an embedding computed as the centroid of the existing pre-computed author representations. We note that in our datasets, authors with more than one tweet are very rare (6.6% on average).

Table 1 summarises the main statistics of the datasets and their respective graphs. The three social graphs have different number of nodes: the network of the Sentiment dataset is the largest (∼62k nodes) while the Stance network is the smallest (∼4k nodes). The number of edges and the density of the network (i.e., the ratio of existing connections over the number of potential

[6] Tweets can be deleted by users or administrators. This happens more often for old tweets.

[7] The other labels in the dataset are `SPAM` and `ABUSIVE`.

[8] We access the API using the Python package Tweepy: `http://docs.tweepy.org/en/v3.5.0/`. The API returns a maximum of 3.2k tweets per user.

connections) vary according to graph size, while the number of connected components is 1 for all the graphs: this means that there are no disconnected sub-graphs in the social networks. The most relevant aspect for which we find differences across the three graphs is the amount of homophily observed, which we define as the percentage of edges which connect users whose tweets have the same label. This value is higher for the Stance and Hate Speech social graphs than for the Sentiment one. These figures indicate that, in our datasets, users expressing similar opinions about a topic (Stance) or using offensive language (Hate Speech) are more connected than those expressing the same sentiment in their tweets (Sentiment).

	Sentiment	**Stance**	**Hate**
# tweets	62,530	4,063	44,141
% with author	71.4%	71.7%	77.1%
# nodes	50k	6.9k	25k
# edges	4.1m	258k	1.3m
density	0.003	0.010	0.004
# components	1	1	1
homophily	38%	60%	68%

Table 1: Statistics for each dataset: Number of tweets; percentage of tweets for which we are able to retrieve information about the author; number of nodes; number of edges; density; number of connected components; and amount of homophily as percentage of connected authors whose tweets share the same label.

5 Results

We evaluate the performance of the models using the same metrics used for the optimization process (see Section 4.4). In Table 2 we report the results, that we compute as the average of ten runs with random parameter initialization.[9] We use the unpaired Welch's t test to check for statistically significant difference between models.

Tasks The results show that social information helps improve the performance on Stance and Hate Speech detection, while it has no effect for Sentiment Analysis. While this result contrasts with the one reported by Yang and Eisenstein (2017), who use a previous version of the Sentiment dataset (Rosenthal et al., 2015), it is not surprising given the analysis made in the previous section regarding the amount of homophily in the three social graphs: In our version of the data, sentiment is not as related to the social standing of individuals as stance and hatefulness are. We reserve a deeper investigation of the impact of social information on the sentiment task to future work.

Model	**Sentiment**	**Stance**	**Hate**
Frequency	0.332	0.397	0.057
LING	0.676	0.569	0.624
LING+random	0.657	0.571	0.600
LING+PV	0.671	0.601*	0.667*
LING+N2V	0.672	0.629$^{*\diamond}$	0.656*
LING+GAT	0.666	0.640$^{*\diamond\dagger}$	0.674$^{*\diamond\dagger}$

Table 2: Results for all the models on the three datasets in our experiment. Marked with * are the results which significantly improve over LING and LING+random ($p < 0.05$, also for the following results); $\diamond$ indicates a significant improvement over LING+PV; $\dagger$ a significant improvement over LING+N2V.

Models LING+random never improves over LING: We believe this is due to the fact that most of the authors have just one tweet, which hinders the possibility to learn at training time the representations of the users used at test time.

We find that both PV and N2V user representations lead to an improvement over LING. N2V vectors are especially effective for the Stance detection task, where LING+N2V outperforms LING+PV, while for Hate Speech the performance of the two models is comparable (the difference between LING+PV and LING+N2V is not statistically significative due to the high variance of the LING+PV results - see extended results table in the supplementary material).

Finally, our model outperforms any other model on both Stance and Hate Speech detection. This result confirms our initial hypothesis that a social attention mechanism which is able to assign different relevance to different neighbours allows for a more dynamic encoding of homophily relations in author embeddings and, in turn, leads to better results on the prediction tasks.[10]

[9] The standard deviation for all models is small, in the range [0.003-0.02]. The full table, including the results for each class, is in the supplementary material.

[10] In preliminary experiments, Graph Convolutional Networks with no attention showed no improvements over the N2V baseline. The result is to be expected since, similarly to N2V, the model computes the representation of the target node without making any distinction among its neighbours.

(1) *@user: Yurtle the Turtle needs to be slapped with a f***ing chair..many times!*	HATEFUL
(2) *You stay the same through the ages... Your love never changes... Your love never fails*	AGAINST atheism
(3) *Why are Tumblr feminists so territorial? Pro-lifers can't voice their opinions without being attacked*	AGAINST abortion
(4) *@user No, just pointed out how idiotic your statement was*	HATEFUL

Table 3: Examples from Stance (2, 3) and Hate Speech (1, 4) datasets, and their gold label.

6 Analysis

We analyse in more detail the strengths and weaknesses of the best models for the tasks where social information proved useful.

6.1 Paragraph Vector

Figure 2 (left) shows the user representations created with PV for the Hate Speech dataset.[11] The plot shows that users form sub-communities, with authors of hateful tweets (orange dots) mainly clustering at the top of the plot. The similarity between these individuals derives from their consistent use of strongly offensive words towards others over their posting history. This suggests that representing speakers in terms of their past linguistic usage can, to some extent, capture certain homophily relations. For example, tweet (1) in Table 3 is incorrectly labelled as NORMAL by the LING model.[12] By leveraging the PV author representation (which, given previous posting behaviour, is highly similar to authors of hateful tweets) the LING+PV model yields the right prediction in this case.

For Stance detection, which arguably is a less lexically determined task (Mohammad et al., 2016), PV user representations are less effective. This is illustrated in Figure 2 (center), where no clear clusters are visible. Still, PV vectors capture some meaningful relations, such as a small, close-knit cluster of users against atheism (see zoom in the figure), who tweet mostly about Islam.

6.2 Node2Vec

User representations created by exploiting the social network of individuals are more robust across datasets. For Hate Speech, the user representations computed with PV and N2V are very similar.[13] However, for the Stance dataset, N2V user representations are more informative. This is readily apparent when comparing the plots in the center and right of Figure 2: Users who were scattered when represented with PV now form community-related clusters, which leads to better predictions. For example, tweet (2) in Table 3 is authored by a user who is socially connected to other users who tweet against atheism (the orange cluster in the right-hand side plot of Figure 2). The LING+N2V model is able to exploit this information and make the right prediction, while the tweet is incorrectly classified by LING and LING+PV, which do not take into account the author's social standing.

N2V, however, is not effective for users connected to multiple sub-communities, because by definition the model will conflate this information into a fixed vector located between clusters in the social space.[14] For instance, the author of tweet (1) is connected to both users who post hateful tweets and users whose posts are not hateful. In the N2V user space, the ten closest neighbours of this author are equally divided between these two groups. In this case, the social network information captured by N2V is not informative enough and, as a result, the tweet ends up being wrongly labeled as NORMAL by the LING+N2V model, i.e., there is no improvement over LING.

6.3 Graph Attention Network

As hypothesised, the GAT model allows us to address the shortcoming of N2V we have described above. When creating a representation for the author of tweet (1), the GAT encoder identifies the connection to one of the authors of a hateful tweet as the most relevant for the task at hand, and assigns it the highest value. The user vector is updated accordingly, which results in the LING+GAT model correctly predicting the HATEFUL label.

This dynamic exploration of the social connections has the capacity to highlight homophily relations that are less prominent in the social network of a user, but more relevant in a given context. This is illustrated by how the models deal with tweet (3) in Table 3, which expresses a nega-

[11] Plots are created using the Tensorflow Projector available at: https://projector.tensorflow.org.

[12] Note that *'f***ing'* is often used with positive emphasis and is thus not a reliable clue for hate speech.

[13] The plot showing N2V user representations for the Hate Speech dataset is in the supplementary material.

[14] This effect has some parallels with how word2vec derives representations for polysemous words.

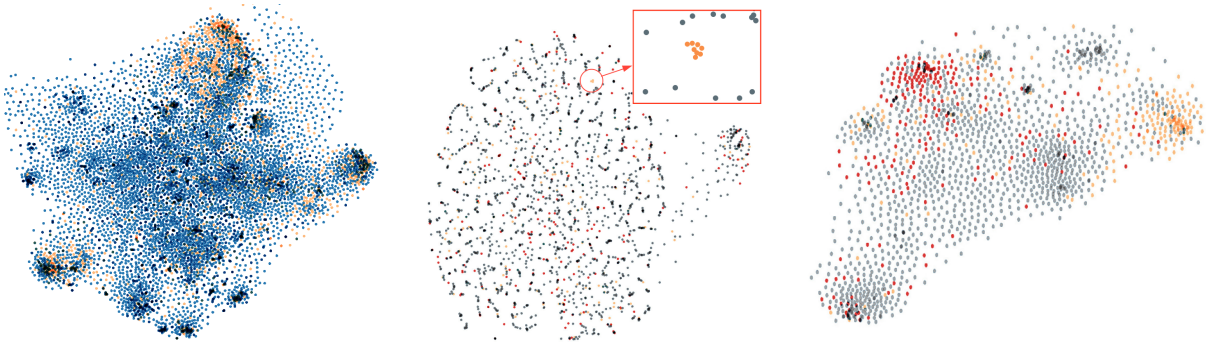

Figure 2: **Left**: PV user representations for the Hate Speech dataset. Orange dots are authors of HATEFUL tweets, blue dots of NORMAL tweets. **Center** and **Right**: PV and N2V user representations, respectively, for the Stance dataset. In both plots, orange dots are authors of tweets AGAINST atheism, red dots authors in FAVOR of 'climate change is a real concern'. All other users are represented as grey dots.

tive stance towards legalisation of abortion, and is incorrectly classified by LING and LING+PV. The social graph contributes rich information about its author, who is connected to many users (46 overall). Most of them are authors who tweet in favour of feminism: The N2V model effectively captures this information, as the representation of the target user is close to these authors in the vector space. Consequently, by simply focusing on the majority of the neighbourhood, the LING+N2V model misclassifies the tweet (i.e., it infers FAVOR for tweet (3) on the legalisation of abortion from a social environment that mostly expresses stances in favour of feminism). However, the information contributed by the majority of neighbours is not the most relevant in this case. In contrast, the GAT encoder identifies the connections with two users who tweet against legalisation of abortion as the most relevant ones, and updates the author representation in such a way to increase the similarity with them – see Figure 3 for an illustration of this dynamic process – which leads the LING+GAT model to make the right prediction.

Interestingly, GAT is able to recognise when the initial N2V representation already encodes the necessary information. For example, the LING+N2V model correctly classifies tweet (4) in Table 3, as the N2V vector of its author is close in social space to that of other users who post hateful tweets (7 out of 10 closest neighbours). In this case, the LING+GAT model assigns the highest value to the self-loop connection, thus avoiding to modify a representation which is already well tuned for the task.

Our error analysis reveals that there are two main factors which affect the performance of the GAT model. One is the size of the neighbourhood: As the size increases, the normalised attention values tend to be very small and equally distributed, which makes the model incapable of identifying relevant connections. The second is related to the fact that a substantial number of users ($\sim$800 for Stance and $\sim$2.4k for Hate Speech) are not connected to the relevant sub-community. This means that in the case of Stance, for example, a user is not connected to any other individual expressing the same stance towards a certain topic. While external nodes in the graph (see Section 4.5) help to alleviate the problem by allowing the information to propagate through the graph, this lack of connections is detrimental to GAT.

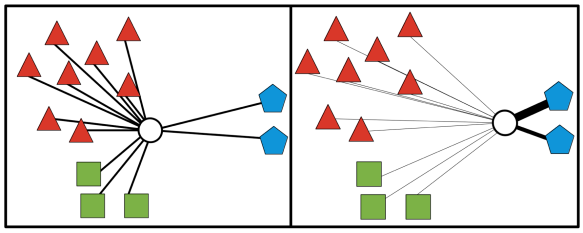

Figure 3: **Left:** Author of tweet (3) (white node) has many connections with users tweeting in favour of feminism (red triangles), fewer with authors tweeting in favour of Clinton (green squares) and against legalization of abortion (blue pentagons) (for simplicity, only some connections are shown). Recall that no label is available for nodes (users), and that their color is based on the label of the tweet they posted. Proximity in the space reflects vector similarity. **Right:** the GAT encoder assigns higher values to connections with the relevant neighbours (0.54 and 0.14; all other connections have values $\leq$ 0.02; thickness of the edges is proportional to their values) and updates the target author vector to make it proximal to them in social space.

7 Conclusion

In this work, we investigated representations for users in social media and their usefulness in downstream NLP tasks. We introduced a model that captures the fact that not all the social connections of an individual are equally relevant in different communicative situations. The model dynamically explores the connections of a user, identifies the ones that are more relevant for a specific task, and computes her representation accordingly. We showed that, when social information is proved useful, the dynamic representations computed by our model better encode homophily relations compared to the static representations obtained with other models. In contrast to most models proposed in the literature so far, which are tested on one single task, we applied our model to three tasks, comparing its performance against several competing models. Finally, we performed an extended analysis of the performance of all the models that effectively encode author information, highlighting strengths and weaknesses of each model.

In future work, we plan to perform a deeper investigation of cases in which social information does not prove beneficial, and to assess the ability of our model to dynamically update the representation of the *same* author in different contexts, a task that, due to the nature of the data, was not possible in present work.

8 Acknowledgements

This research was partially funded by the Netherlands Organisation for Scientific Research (NWO) under VIDI grants *Asymmetry in Conversation* (276-89-008) and *Semantic Parsing in the Wild* (639-022-518). We are grateful to the Integrated Research Training Group of the Collaborative Research Center SFB 732 for generously funding a research visit by Marco Del Tredici to the University of Stuttgart that fostered some of the ideas in this work. Finally, we kindly thank Mario Giulianelli and Jeremy Barnes for their valuable contribution to earlier versions of the models.

Abstract

Insightful findings in political science often require researchers to analyze documents of a certain subject or type, yet these documents are usually contained in large corpora that do not distinguish between pertinent and non-pertinent documents. In contrast, we can find corpora that label relevant documents but have limitations (e.g., from a single source or era), preventing their use for political science research. To bridge this gap, we present *adaptive ensembling*, an unsupervised domain adaptation framework, equipped with a novel text classification model and time-aware training to ensure our methods work well with diachronic corpora. Experiments on an expert-annotated dataset show that our framework outperforms strong benchmarks. Further analysis indicates that our methods are more stable, learn better representations, and extract cleaner corpora for fine-grained analysis.

1 Introduction

Recent progress in natural language processing and computational social science have pushed political science research into new frontiers. For example, scholars have studied language use in presidential elections (Acree et al., 2018), legislative text in Congress (de Marchi et al., 2018), and similarities in national constitutions (Elkins and Shaffer, 2019). However, datasets used by political scientists are mostly homogeneous in terms of subject (e.g., immigration) or document type (e.g., constitutions). Labeled corpora with pertinent documents usually only stem from a single source; this makes it difficult to generalize conclusions derived from them to other sources. On the other hand, corpora spanning multiple decades and sources tend to be unlabeled. These corpora are largely untouched by political scientists; to illustrate some problems that arise with studying such data, Table 1 shows a sample of topics generated by Latent Dirichlet Allocation (LDA) (Blei et al., 2003), a popular topic model in social science, trained on 60,000 documents sampled from the Corpus of Historical American English (COHA) (Davies, 2008). The generated topics are extremely vague and not specific to politics.

Topic 1	like, day, would, a.m., center
Topic 2	two, samour, family, veronica, son
Topic 3	would, hospital, also, car, hyundai
Topic 4	said, people, one, years, think
Topic 5	city, 6-4, last, wine, york

Table 1: Randomly sampled topics and top keywords derived from a 50-topic LDA model trained on a sample of COHA documents. Topic modeling results on a political subset of COHA are presented in Table 5. Additionally, topic model hyperparameters are detailed in Appendix A.

This paper bridges the gap between labeled and unlabeled corpora by framing the problem as one of domain adaptation. We develop *adaptive ensembling*, an unsupervised domain adaptation framework that learns from a single-source, labeled corpus (the source domain) and utilizes these representations effectively to obtain labels for a multi-source, unlabeled corpus (the target domain). Our method draws upon *consistency regularization*, a popular technique that stabilizes model predictions under input or weight perturbations (Athiwaratkun et al., 2019). At the framework-level, we introduce an adaptive, feature-specific approach to optimization; at the model-level, we develop a novel text classification model that works well with our framework. To better handle the diachronic nature of our corpora, we also incorporate time-aware training and representations.

Our experiments use the New York Times Annotated Corpus (NYT) (Sandhaus, 2008) as our source domain corpus and COHA as our target do-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4718–4730, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

main corpus. Concretely, we construct two classification tasks: a *binary task* to determine whether a document is political or non-political; and a *multi-label task* to categorize a document under three major areas of political science in the US: *American Government*, *Political Economy*, and *International Relations* (Goodin, 2009). We subsequently introduce an expert-labeled test set from COHA to evaluate our methods.

Our framework, equipped with our best model, significantly outperforms existing domain adaptation algorithms on our tasks. In particular, adaptive ensembling achieves gains of 11.4 and 10.1 macro-averaged F1 on the binary and multi-label tasks, respectively. Qualitatively, adaptive ensembling conditions the optimization process, learns smoother latent representations, and yields precise but diverse topics as demonstrated by LDA on an extracted political subcorpus of COHA. We release our code and datasets at `http://github.com/shreydesai/adaptive-ensembling`.

2 Motivation from Political Science

Quantitative studies of American public opinion over time have mostly been restricted to surveys such as the American National Election Survey (Baldassarri and Gelman, 2008; Campbell et al., 1980). However, surveys often do not pose well-formed questions, reflect true voter opinion, or capture mass public opinion (Zaller et al., 1992; Bishop, 2004). Therefore, researchers often seek to compare survey findings with those of mass media as the relationship between public opinion and the media has been widely established (Baum and Potter, 2008; McCombs, 2018). Press media, one form of mass media, manifests itself in large, diachronic collections of newspaper articles; such corpora provide a promising avenue for studying public opinion and testing theories, provided scholars can be confident that the measures they obtain over time are substantively invariant (Davidov et al., 2014). However, as alluded to earlier, such diachronic corpora are often unlabeled; political scientists cannot draw conclusions from these corpora in their raw form as they are unable to distinguish between political and non-political articles. We frame this problem as an exchange between two domains: a source, labeled corpus with modern articles (NYT) and a target, unlabeled corpus with decades of articles originating from a multitude of news sources (COHA). Using domain adaptation methods, we can extract a political subcorpus from COHA that would be amenable for the study of public opinion research over time.

3 Unsupervised Domain Adaptation

In this section, we detail the core concepts behind our unsupervised domain adaptation framework. We describe the problem setup (§3.1), an overview of self-ensembling and consistency regularization (§3.2-§3.4), and our novel contributions to this framework (§3.5-§3.6).

3.1 Problem Setup

Let $\mathcal{X}$ and $\mathcal{Y}$ denote the input and output spaces, respectively. We have access to labeled samples $\{x_L^{(i)}, y_L^{(i)}\}_{i=1}^N$ from a source domain $\mathcal{D}_S$ and unlabeled samples $\{x_U^{(i)}\}_{i=1}^M$ from a target domain $\mathcal{D}_T$. The goal of unsupervised domain adaptation is to learn a function $f : \mathcal{X} \rightarrow \mathcal{Y}$ that maximizes the likelihood of the target domain samples by only leveraging supervision from the source domain samples. We also assume the existence of a small amount of labeled target domain samples in order to create a development set, following existing work in unsupervised domain adaptation (Glorot et al., 2011; Chen et al., 2012; French et al., 2018; Zhang et al., 2017).

3.2 Self-Ensembling

Our unsupervised domain adaptation framework builds on top of *self-ensembling* (Laine and Aila, 2017), a semi-supervised learning algorithm based on *consistency regularization*, whereby models are trained to be robust against injected noise (Athiwaratkun et al., 2019).

Self-ensembling is an interplay between two neural networks: a student network $f(x; \theta)$ and a teacher network $f(x; \phi)$. The inputs to both networks are perturbed separately, and the objective is to measure the consistency of the student network's predictions against the teacher's. Both networks share the same base model architecture and initial parameter values, but follow different training paradigms (Laine and Aila, 2017). In particular, the student network is updated via backpropagation, then the teacher network is updated with an exponential average of the student network's parameters (Tarvainen and Valpola, 2017). The networks are trained in an alternating fashion until they converge. During test time, the teacher

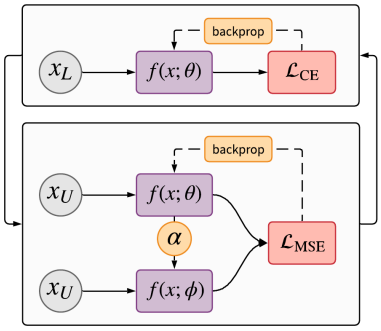

Figure 1: Visualization of the self-ensembling training procedure. Descriptions of individual components are detailed in §3.2-§3.4.

network is used to infer the labels for target domain samples. Figure 1 visualizes the overall training procedure. Further intuition behind self-ensembling is available in Appendix B.

Next, we discuss the training process for the student network (§3.3), the original fixed ensembling method in Tarvainen and Valpola (2017) (§3.4), and our proposed adaptive ensembling method (§3.5).

3.3 Student Training

The student network uses labeled samples from the source domain and unlabeled samples from the target domain to learn domain-invariant features. This is realized by using multiple loss functions, each with its own objective. The **supervised loss** is simply the cross-entropy loss of the student network outputs given source domain samples:

$$\mathcal{L}_{\text{CE}}(\theta) = \sum_{(x,y)\in\mathcal{D}_S} \log p(y|x')$$

However, the supervised loss alone prevents the student network from learning anything useful about the target domain. To address this, Laine and Aila (2017) introduce an **unsupervised loss** to ensure that the student and teacher networks have similar predictions for target domain samples. French et al. (2018) only enforce the consistency constraint for target domain samples, but we propose using both source *and* target domain samples with separately perturbed inputs x' and x''; this provides a balanced source of supervision to train our adaptive constants, discussed in §3.5:

$$\mathcal{L}_{\text{MSE}}(\theta,\phi) = \sum_{x\in\mathcal{D}_S\cup\mathcal{D}_T} ||f(x';\theta) - f(x'';\phi)||^2$$

The overall objective is a combination of the two loss functions:

$$\mathcal{L}(\theta,\phi) = \mathcal{L}_{\text{CE}} + \mathcal{L}_{\text{MSE}}$$

3.4 Fixed Ensembling

The teacher network's parameters form an ensemble of the student network's parameters over the course of training:

$$\phi^{(t+1)} \leftarrow \alpha\phi^{(t)} + (1-\alpha)\theta^{(t)}$$

where α is a smoothing factor that controls the magnitude of the parameter updates. Since the labels for the target domain samples are inherently unknown, ensembling parameters in the presence of noise helps the teacher network's predictions converge to the *true* label (Tarvainen and Valpola, 2017).

Limitations Empirically, we find that the highly unstable loss surface presented by textual datasets causes large instabilities in the optimization process. One of the key insights of this paper is that these instabilities are due to the dynamics of the unsupervised loss. Because the unsupervised loss effectively regularizes the source domain representations to work well in the target domain (Laine and Aila, 2017), performance degrades rapidly if this loss fails to converge. This is a strong indicator that self-ensembling fails to learn useful, shared representations for knowledge transfer between textual domains. Qualitative evidence of the unsupervised loss' instability is shown in Figure 6a and further discussed in §7.

3.5 Adaptive Ensembling

We hypothesize that smoothing with a fixed hyperparameter α is responsible for said instabilities. For any given weight matrix (or bias vector), each hidden unit can be conceptualized as controlling one highly specific feature or attribute (Bau et al., 2019). These units may need to be updated with varying degrees throughout the course of training; therefore, smoothing each unit with a fixed constant severely overlooks dynamics at the parameter-level. We propose modifying fixed ensembling by introducing trainable smoothing constants for each unit—hereafter termed *adaptive constants*—as opposed to using a fixed smoothing constant:

$$\phi^{(t+1)} \leftarrow \mathbf{C}^{(t)} \odot \phi^{(t)} + (\mathbf{1} - \mathbf{C}^{(t)}) \odot \theta^{(t)}$$

where a matrix of adaptive constants $\mathbf{C}$ is applied element-wise to ϕ and θ at each step.

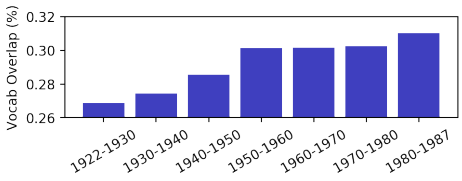

Figure 2: Vocabulary overlap between COHA and NYT, by decade. We collect COHA documents in each decade, create a decade vocabulary, and calculate the percentage overlap between each decade's vocabulary and the overall NYT vocabulary.

Example Assume we are training an arbitrary weight matrix $\mathbf{W} \in \mathbb{R}^{m \times n}$ in the kth layer of a fixed network architecture. Both the student and teacher network have their own copy of $\mathbf{W}$, denoted as $\mathbf{W}_{\text{STU}}$ and $\mathbf{W}_{\text{TEA}}$, respectively. To ensure each parameter $\mathbf{W}_{ij}$ has a corresponding adaptive constant α_{ij}, $\mathbf{C}$ shares the same dimensionality as $\mathbf{W}_{\text{STU}}$ and $\mathbf{W}_{\text{TEA}}$. The previous equation can then be written as:

$$\mathbf{W}_{\text{TEA}}^{(t+1)} \leftarrow \mathbf{C}^{(t)} \odot \mathbf{W}_{\text{TEA}}^{(t)} + (\mathbf{1} - \mathbf{C}^{(t)}) \odot \mathbf{W}_{\text{STU}}^{(t)}$$

Supervision Because the adaptive constants are designed to stabilize training, it is a natural fit to train them using the unsupervised loss:

$$\mathbf{C}^{(t+1)} \leftarrow \mathbf{C}^{(t)} - \epsilon \nabla_{\mathbf{C}} \mathcal{L}_{\text{MSE}}$$

This forms a crucial difference between self-ensembling and adaptive ensembling: in the former method, the teacher network has no say in how its parameters are modified. Adaptive ensembling equips the teacher network with fine-grained control over gradient updates, making it far easier to align activations under a noisy setting.

3.6 Temporal Curriculum

Diachronic datasets important in political science can be difficult to adapt to given the minimal vocabulary overlap between the source and target domain documents. Source and target articles mention named entities and events that, for the most part, do not appear across both datasets. To ease the difficulty of domain adaptation, we exploit the temporal information in our datasets to introduce a curriculum (Bengio et al., 2009).

In particular, each article comes with metadata that includes the year in which the article was published. Figure 2 shows that COHA articles written closer to the time of NYT articles have a larger vocabulary overlap than those written in the distant past. Intuitively, it is easier to learn features from target domain samples that are more like the source domain samples. Hence, we sort the target domain mini-batches by year; the learning task becomes progressively harder as opposed to confusing the models during the early stages of training.

4 Model

In this section, we introduce a new convolutional neural network (CNN) as the plug-in model for our unsupervised domain adaptation framework. We motivate the use of CNNs (§4.1), formalize the model input (§4.2), and introduce several novel components for our task (§4.3).

4.1 Motivation

CNNs have emerged as strong baselines for text classification in NLP (Kim, 2014). CNNs are desirable candidates for our framework as they exhibit a high degree of parameter sharing, significantly reducing the number of parameters to train. In addition, they can be designed to solely optimize the log-likelihood of the training data. Experimentally, we find that models that optimize other distributions (e.g., attention distributions in Transformers (Vaswani et al., 2017) or Hierarchical Attention Networks (Yang et al., 2016)) do not work well with this framework.

4.2 Model Input

Given a discrete input $x = [w_1, \cdots, w_n]$ and vocabulary V, an embedding matrix $\mathbf{E} \in \mathbb{R}^{|V| \times d}$ replaces each word w_i with its respective d-dimensional embedding. The resulting embeddings are stacked row-wise to obtain an input matrix $\mathbf{X} \in \mathbb{R}^{n \times d}$. Following the notion of input perturbation used in consistency regularization algorithms (Athiwaratkun et al., 2019), we design several methods to inject noise into the input layer. Each input is perturbed with additive, isotropic Gaussian noise: $\tilde{\mathbf{X}} = \mathbf{X} + \mathcal{N}(0, \mathbf{I})$. Then, we apply dropout on the perturbed inputs to eliminate dependencies on any one word: $\mathbf{X}' = \tilde{\mathbf{X}} \odot \mathbf{M}$ where $\mathbf{M} \in \mathbb{R}^{n \times d}$ is a Bernoulli mask applied element-wise to the input matrix.

4.3 Model Architecture

Background: 1D Convolutions CNNs for text classification generally use 2D convolutions over the input matrix (Kim, 2014), but architectures using 1D convolutions have also been explored in

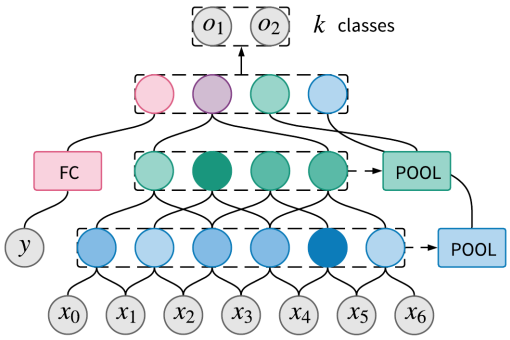

Figure 3: Example three-layer CNN architecture with sequence squeezing, state connections, and time embeddings. Detailed information about individual components is available in §4.3. FC represents a fully-connected layer; POOL represents a pooling layer. Best viewed in color.

other contexts, e.g., sequence modeling (Bai et al., 2018), machine translation (Kalchbrenner et al., 2016), and text generation (Yang et al., 2017). Our model draws upon the latter approach for political document classification. CNNs utilizing 1D convolutions are typically autoregressive in nature; that is, each output y_t only depends on the inputs $x_{<t}$ to avoid information leakage into the future. Two approaches have been proposed to achieve this: history-padding (Bai et al., 2018, 2019) and masked convolutions (Kalchbrenner et al., 2016). Further, each successive convolution uses an exponentially increasing dilation factor, reducing the depth of the network significantly. Below, we elaborate on the components of our model:

Sequence Squeezing Given a model with ℓ layers, previous approaches (Bai et al., 2018, 2019) history-pad the input with $\sum_{i=1}^{\ell} d^{(i-1)}(f-1)$ zeros to obtain an output of length n, where d is the dilation factor and f is the filter size. However, we propose history-padding the input with $(\sum_{i=1}^{\ell} d^{(i-1)}(f-1)) - n + 1$ zeros to ensure the convolutions compress the sequence down to *one* output unit. Formally, this produces an output feature map of dimension $B \times C \times 1$ where B is the batch size and C is the number of channels; one can use a simple `squeeze()` operation to obtain the compact feature matrix $B \times C$. Though this is a subtle difference, our approach yields much richer representations for classification.

State Connections In each layer ℓ_i, a kernel $\mathbf{W}_i$ convolves across an intermediate sequence, inducing a feature map $\mathbf{A}_i$. Because the input is presented as a sequence, the application of $\mathbf{W}_i$ along a one-dimensional axis encourages $\mathbf{A}_i$ to encode temporal features, similar to how the hidden state is formed by applying shared weights across a sequence in recurrent architectures. Further, because the receptive field grows exponentially, the convolutions build hierarchical representations of the input, implying $\mathbf{A}_{i+1}$ builds a more abstract representation of the input than $\mathbf{A}_i$. We exploit this stateful information by pooling each activation map $\mathbf{A}_i$ into a vector and concatenating them row-wise to create a *state matrix*:

$$\mathbf{S} = \text{Concat}(\text{Pool}(\mathbf{A}_1), \cdots, \text{Pool}(\mathbf{A}_{\ell-1}))$$

To the best of our knowledge, our paper is the first to explicitly use the temporal state embedded in causal 1D convolution activations as representations for an end task.

Time Embedding To make our model time aware, we learn representations for the years of the documents (available as metadata in COHA). Such time representations allow the model to reason about content as it appears in different decades. Given a year y (e.g. 1954), we normalize it to the closed unit interval $[0, 1]$ and linearly transform it into a low-dimensional embedding $\mathbf{e}$:

$$\mathbf{e} = \mathbf{W}_e \left[\frac{y - \max_y}{\max_y - \min_y} \right] + b_e$$

where $\max_y$ and $\min_y$ represent the maximum and minimum observed years in the training dataset, respectively.

Overall Architecture We concatenate the various components of our model $[\mathbf{X}'; \mathbf{S}; \mathbf{e}]$ to create a collective representation for classification. We use a 1D convolution ($f = 1$ and $d = 1$) to project this representation to k classes:

$$\mathbf{y} = \text{Conv1D}([\mathbf{X}'; \mathbf{S}; \mathbf{e}]; \mathbf{W}_k)$$

We did not observe any performance advantages from using a fully-connected layer to perform the projection, so we opt to use a fully-convolutional architecture to minimize the number of parameters (Long et al., 2015). Finally, we apply softmax to the output vector $\mathbf{y} \in \mathbb{R}^k$ to obtain a valid probability distribution over the classes. An example of our model architecture is depicted in Figure 3.

5 Datasets

We present a dataset for identifying political documents with manual annotation from political science graduate students. The dataset is constructed for *binary* and *multi-label* tasks: (1) identifying whether a document is political (i.e. containing notable political content) and (2) if so, the area(s) among three major political science subfields in the US: *American Government*, *Political Economy*, and *International Relations* (Goodin, 2009).

Source We use NYT as the source dataset as it contains fine-grained descriptors of article content. We sample 4,800 articles with the descriptor US POLITICS & GOVERNMENT. To obtain non-political articles, we sample 4,800 documents whose descriptors do not overlap with an exhaustive list of political descriptors identified by a political science graduate student. For our multi-label task, the annotator grouped descriptors in NYT that belong to each area label we consider[1].

Target Our target data are historical documents from COHA, which contains a large collection of news articles since the 1800s. To ensure our dataset is useful for diachronic analysis (e.g., public opinion over time), we sample only from news sources that consistently appear across the decades. Further, we ensure there are at least 8,000 total documents in each decade group; this narrows down our time span to 1922–1986. From this subset, we sample ∼250 documents from each decade for annotation. Two political science graduate students each annotated a subset of the data.

To train our unsupervised domain adaptation framework, we use 9,600 unlabeled target examples (same number as NYT). The expert-annotated dataset is divided into three subsets: a training set of 984 documents (*only* for training the In-Domain classifier discussed in §6.2), development set of 246 documents, and test set of 350 documents (50 per decade)[2].

6 Experiments

6.1 Settings

Our CNN has 8 layers, each with 256 channels, $f = 3$, $d = 2^i$ (for the ith layer), and ReLU activation. We enforce a maximum sequence length of 200 and minimum word count from $[1, 2, 3]$ to build the vocabulary. The embedding matrix uses 300-D GloVe embeddings (Pennington et al., 2014) with a dropout rate of 0.5 (Srivastava et al., 2014). We history-pad our input with a zero vector, the state connections are obtained using average pooling, and the time embedding has a dimensionality of 10. The model is optimized with Adam (Kingma and Ba, 2015), learning rate from $[10^{-4}, 5 \cdot 10^{-5}, 10^{-5}]$, and mini-batch size from $[16, 32]$. Hyperparameters were discovered using a grid search on the held-out development set.

[1]These descriptors are available in Appendix C.

[2]The news sources used and label distributions for the expert-annotated dataset are available in Appendix D.

6.2 Framework Results

Using our best model, we benchmark our unsupervised domain adaptation framework against established methods: (1) **Marginalized Stacked Denoising Autoencoders (mSDA):** Denoising autoencoders that marginalize out noise, enabling learning on *infinitely many* corrupted training samples (Chen et al., 2012). (2) **Self-Ensembling (SE):** A consistency regularization framework that stabilizes student and teacher network predictions under injected noise (discussed in detail in §3.2-§3.4) (Laine and Aila, 2017; Tarvainen and Valpola, 2017; French et al., 2018). (3) **Domain-Adversarial Neural Network (DANN):** Multi-component framework that learns domain-invariant representations through adversarial training (Ganin et al., 2016). We also benchmark against **Source Only** (classifier trained on the source domain only) and **In-Domain** (classifier trained on the target domain only) to establish lower and upper performance bounds, respectively (Zhang et al., 2017).

Framework results are presented in Table 2. Our

	Binary Task		Multi-Label Task		
Model	Mi-F	Ma-F	Ma-P	Ma-R	Ma-F
LR	63.7	60.9	53.3	67.3	31.9

+ time emb	77.4	**77.1**	48.2	83.5	**61.1**

Table 3: Model results with adaptive ensembling for the binary label task (left) and multi-label task (right). For the binary task, we show micro- and macro-averaged F1 scores. For the multi-label task, we show macro-averaged precision, recall, and F1 scores.

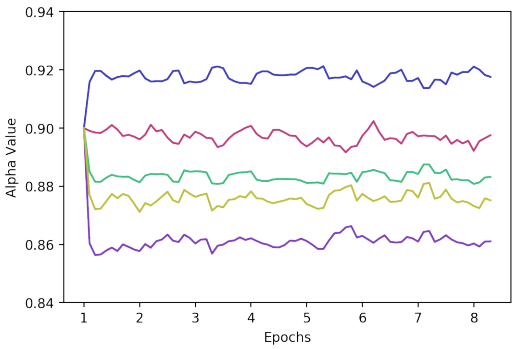

Figure 4: Trajectories of five randomly sampled adaptive constants from our CNN over the course of training. Best viewed in color.

method achieves the highest F1 scores for both tasks. The temporal curriculum further improves our results by a large margin, validating its effectiveness for domain adaptation on diachronic corpora. Although DANN achieves higher precision on the multi-label task, its recall largely suffers.

6.3 Model Results

Next, we ablate the various components of our model and evaluate several other strong text classification baselines under our framework: (1) **Logistic Regression (LR):** We average the word embeddings of each token in the sequence, then use these to train a logistic regression classifier. (2) **Bidirectional LSTM (BiLSTM):** A bidirectional LSTM obtains forwards and backwards input representations $[\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}]$ (Hochreiter and Schmidhuber, 1997); they are concatenated and passed through a fully-connected layer. (3) **CNN (2D):** A CNN using 2D kernels 3×300, 4×300, and 5×300 obtains representations (Kim, 2014). They are max-pooled, concatenated row-wise, and passed through a fully-connected layer.

Model ablations and results are presented in Table 3. Our full model achieves the highest F1 scores on both the binary and multi-label tasks, and each component consistently contributes to the overall F1 score. The 2D CNN also has decent F1 scores, showing that our framework works with standard CNN models. Further, the time embedding significantly improves both F1 scores, indicating the model effectively utilizes the unique temporal information present in our corpora.

7 Analysis

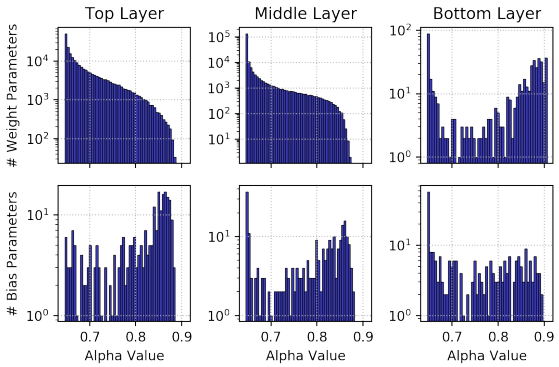
In this section, we pose and qualitatively answer numerous probing questions to further understand the strong performance of adaptive ensembling. We analyze several characteristics of the overall framework (§7.1), then qualitatively inspect its performance on our datasets (§7.2).

7.1 Framework

Are the adaptive constants different across hidden units? We randomly sample five adaptive constants and track their value trajectories over the course of training. Figure 4 shows all of them sharply converge to and bounce around the same general neighboorhood. This is strong evidence that we cannot use a fixed hyperparameter α to smooth each parameter, rather we need per-parameter smoothing constants to account for the functionality and behavior of each unit.

How do the adaptive constants change by layer? Figure 5 shows the distribution of weight and bias parameters of adaptive constants for a top, middle, and bottom layer of our CNN. For the weight parameters, the teacher relies heavily on the student (α is skewed towards smaller smoothing rates) in the top layer, but gradually reduces its dependence by learning target domain features in the lower layers (α is skewed towards larger smoothing rates). For the bias parameters, the teacher prominently shifts the student features to work for the target domain in the top layer, but reduces its dependence on the student in the lower layers. This shows why using a fixed hyperparameter α does not account for layer-wise dynamics, i.e. each layer requires a specific distribution of α values to achieve strong performance.

Do adaptive constants benefit training and latent representations? Figure 6a depicts the unsupervised loss trajectories for self-ensembling



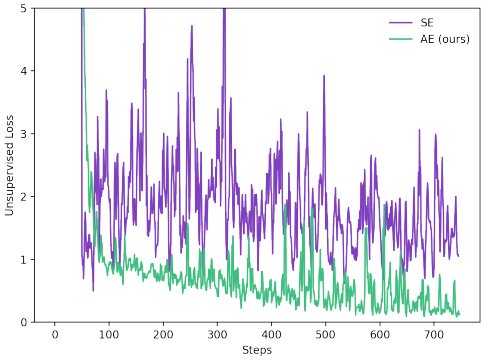


Figure 5: Distribution of teacher network adaptive constants for a top, middle, and bottom layer. We display adaptive constants for both weight (top) and bias (bottom) parameters. The x-axis is shared for both the weight and bias distributions.

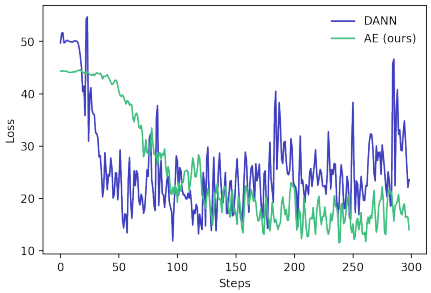

(SE) and adaptive ensembling (AE). Compared to SE, the adaptive constants significantly stabilize the unsupervised loss. Next, Figure 6b shows the general training curves for AE and domain-adversarial neural networks (DANN). The DANN loss oscillates uncontrollably as the adversarial weight increases, but increasing the unsupervised loss weight for AE does not result in as much instability. We also compare the latent representations learned by SE and AE in Figure 7. While SE shows evidence of feature alignment, AE learns a much smoother manifold where source and target domain representations are intertwined.

7.2 Datasets

Does adaptive ensembling yield better topics? In Table 1, we showed that applying LDA directly on COHA yields noisy, unrecognizable topics. Here, we use the SOURCE ONLY model and the adaptive ensembling framework to obtain labels for the unlabeled pool of COHA documents. We extract the political documents, run a topic model on the political subcorpus, and randomly sample topics. The SOURCE ONLY results are shown in Table 4 and the adaptive ensembling results are shown in Table 5. The SOURCE ONLY model has poor recall, as most of the topics are extracted are vague and not inherently political in nature. In contrast, our framework is able to extract a wide range of clean, identifiable political topics. For example, the first topic reflects documents related to the Vietnam conflict while the third topic reflects documents related to important court proceedings.

(a) Loss curves for self-ensembling (SE) and adaptive ensembling (AE) over the course of training.

(b) Loss curves for domain-adversarial neural networks (DANN) and adaptive ensembling (AE). The adversarial loss weight and unsupervised loss weight are annealed for both methods. For fair comparison, we employ the adversarial weight annealing schedule outlined in Ganin et al. (2016).

Topic 1	dr, women, week, medical, doctors
Topic 2	city, police, street, car, avenue
Topic 3	trial, years, police, prison, court
Topic 4	union, strike, workers, lewis, service
Topic 5	like, man, years, little, week

Table 4: Randomly sampled topics and top keywords derived from a 50-topic LDA model trained on 28K COHA articles identified as political using the SOURCE ONLY model.

Does adaptive ensembling preserve the integrity of the original corpus? In order for political scientists to effectively study latent variables—such as political polarization—over time, the extracted political subcorpus must contain a similar integrity as the original corpus. That is, the subcorpus' distribution of documents across years and sources must relatively match that of the original corpus. First, we analyze the document counts for each decade bin, shown in Figure 8. The political subcorpus shows a relatively consistent count across the deacdes, notably also capturing salient peaks from the 1920-1930s. Next, we analyze the document counts for each news source. Once again, the political subcorpus features documents from *all* sources that appear in

Topic 2	germany, britain, france, europe, soviet
Topic 3	court, justice, commission, law, attorney
Topic 4	tax, oil, prices, petroleum, industry
Topic 5	coal, union, strike, workers, miners

Table 5: Randomly sampled topics and top keywords derived from a 50-topic LDA model trained on 28K COHA articles identified as political using ADAPTIVE ENSEMBLING.

the original corpus. In addition, the varied distribution across sources is also captured; Time Magazine (TM) has the most documents whereas Wall Street Journal (WSJ) has the least documents. Together, these results show that the resulting subcorpus is amenable for political science research as it exhibits important characteristics derived from the original COHA corpus.

8 Related Work

Early approaches for unsupervised domain adaptation use shared autoencoders to create cross-domain representations (Glorot et al., 2011; Chen et al., 2012). More recently, Ganin et al. (2016) introduce a new paradigm that create domain-invariant representations through adversarial training. This has gained popularity in NLP (Zhang et al., 2017; Fu et al., 2017; Chen et al., 2018), however the difficulties of adversarial training are well-established (Salimans et al., 2016; Arjovsky and Bottou, 2017). Consistency regularization methods (e.g., self-ensembling) outperform adversarial methods on visual semi-supervised and domain adaptation tasks (Athiwaratkun et al., 2019), but have rarely been applied to textual data (Ko et al., 2019). Finally, Huang and Paul (2018) establish the feasibility of using domain adaptation to label documents from discrete time periods.

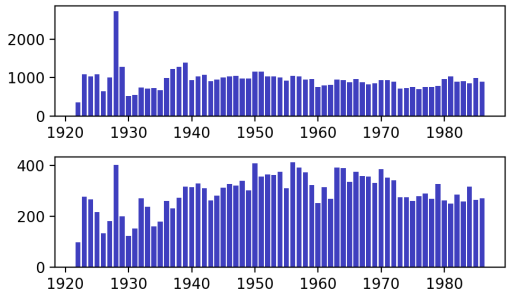

Figure 8: Document counts per decade for the original COHA corpus (top) and the extracted political subcorpus (bottom).

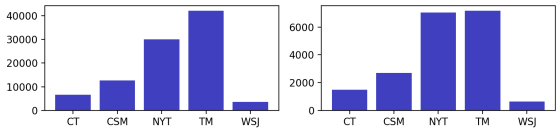

Figure 9: Document counts per news source for the original COHA corpus (left) and the extracted political subcorpus (right). The sources displayed include Chicago Tribute (CT), Christian Science Monitor (CSM), New York Times (NYT), Time Magazine (TM), and Wall Street Journal (WSJ).

Our work departs from previous work by proposing an adaptive, time-aware approach to consistency regularization provisioned with causal convolutional networks.

9 Conclusion

We present *adaptive ensembling*, an unsupervised domain adaptation framework capable of identifying political texts for a multi-source, diachronic corpus by only leveraging supervision from a single-source, modern corpus. Our methods outperform strong benchmarks on both binary and multi-label classification tasks. We release our system, as well as an expert-annotated set of political articles from COHA, to facilitate domain adaptation research in NLP and political science research on public opinion over time.

A LDA Topic Model

We experimented with a range of hyperparameters to ensure the Latent Dirichlet Allocation (LDA) model was best optimized for our datasets, leveraging the Gensim[3] library. In particular, we removed all stopwords, extremely rare words (tail 10-20% from a unigram distribution), and set the number of topics to 50.

B Self-Ensembling

The core intuition behind consistency regularization is that ensembled predictions are more likely to be correct than single predictions (Laine and Aila, 2017; Tarvainen and Valpola, 2017). To this end, Laine and Aila (2017) introduce a **student** and **teacher** network that yield single predictions and ensembled predictions, respectively.

After learning from labeled samples, the student may produce varying, dissimilar predictions for unlabeled samples due to the stochastic nature of optimization. One potential solution is to ensemble predictions across time to converge at the *most likely* prediction (Laine and Aila, 2017). Tarvainen and Valpola (2017) improve upon this method by showing that ensembling parameters (as opposed to predictions) results in better predictions. Because the teacher's parameters are smoothed with the student's learned parameters at each iteration, the teacher effectively becomes an ensemble of the student across time.

Further, to ensure that the features learned from the labeled samples are compatible with the unlabeled samples, Laine and Aila (2017); Tarvainen and Valpola (2017); French et al. (2018) motivate a consistency-enforcing approach to bring the student and teacher's predictions closer together. In essence, if a feature learned from samples in the labeled domain is incompatible with samples in the unlabeled domain, the consistency (unsupervised) loss penalizes its incompatibility. Therefore, the interplay between these two networks creates a robust, domain-invariant feature space that characterizes both labeled and unlabeled samples (French et al., 2018). A detailed visualization of the training procedure is presented in Figure 1 in the main body of this paper.

Dev	82	1	33	116
Test	125	8	47	208

Table 6: Distribution of train (In-Domain benchmark *only*), dev, test documents in our expert-annotated COHA subcorpus. For political documents, we break down the distribution into American Government (AG), Political Economy (PE), and International Relations (IR).

C NYT Descriptors

We build a list of "political" descriptors in NYT to determine (a) which labels we can or cannot sample non-political documents from; and (b) which descriptors fall under the three areas of political science we consider for our multi-label task (American Government, Political Economy, and International Relations).

Because documents can be tagged with multiple descriptors, we build a list of descriptors whose documents have significant overlap with US POLITICS & GOVERNMENT. The second author, a political science graduate student, filtered this list to 57 descriptors that are political in nature.

For (a), we sample 4,600 non-political documents whose descriptors do not overlap with the 57 political descriptors described above. For (b), the same political science graduate student assigns each descriptor with one or more area labels. We use this label information to build an NYT dataset for our tasks. The 57 political descriptors and their corresponding area labels are tabulated in Table 7.

D Expert-Annotated Dataset

To create an initial COHA subcorpus of 56,000 documents (8,000 per decade), we sample from the following news sources that consistently appear in across decades: Chicago Tribune, Christian Science Monitor, New York Times, Time Magazine, and Wall Street Journal. Note that these NYT articles (up to year 1986) do not appear in the NYT annotated corpus (Sandhaus, 2008) (starting from year 1987), which we used as our source, training dataset.

From this subcorpus, we perform additional steps to create an expert-annotated dataset (§5). Label distributions for our dataset are presented in Table 6. Although political economy (PE) is

severely underrepresented, we experimentally find that these documents have salient features and are not as difficult to classify. In addition, we employ class imbalance penalties to prevent our model from ignoring these documents.

The source dataset (NYT) was already annotated; to ensure label agreement with our target dataset (COHA), we sampled documents from the source dataset and had our political science graduate students label them to compare against the original label. There were minimal problems here—because NYT has fine-grained labels for their documents, the politically-labeled articles were clearly political and vice-versa.

The target datatset (COHA) was divided into halves and each political science graduate student annotated a half. Prior to annotation, they agreed upon a set of rules to minimize bias in the annotation process. In addition, both of them worked side-by-side during all annotation periods, so they were able to ask each other's opinion in case there was confusion. We also took measures to ensure label correctness after annotation was completed. Each political science graduate student sampled a batch of their political and non-political annotations and sent it to the other to evaluate. Again, there was not much disagreement here as the rules decided upon in the beginning were sufficient to cover most edge cases. Quantitatively, Cohen's $\kappa = 0.95$ as calculated on a mutually annotated subset (Cohen, 1960).

Abstract

Accurate estimation of user location is important for many online services. Previous neural network based methods largely ignore the hierarchical structure among locations. In this paper, we propose a hierarchical location prediction neural network for Twitter user geolocation. Our model first predicts the home country for a user, then uses the country result to guide the city-level prediction. In addition, we employ a character-aware word embedding layer to overcome the noisy information in tweets. With the feature fusion layer, our model can accommodate various feature combinations and achieves state-of-the-art results over three commonly used benchmarks under different feature settings. It not only improves the prediction accuracy but also greatly reduces the mean error distance.

1 Introduction

Accurate estimation of user location is an important factor for many online services, such as recommendation systems (Quercia et al., 2010), event detection (Sakaki et al., 2010), and disaster management (Carley et al., 2016). Though internet service providers can directly obtain users' location information from some explicit metadata like IP address and GPS signal, such private information is not available for third-party contributors. With this motivation, researchers have developed location prediction systems for various platforms, such as Wikipedia (Overell, 2009), Facebook (Backstrom et al., 2010), and Twitter (Han et al., 2012).

In the case of Twitter, due to the sparsity of geotagged tweets (Graham et al., 2014) and the unreliability of user self-declared home location in profile (Hecht et al., 2011), there is a growing body of research trying to determine users' locations automatically. Various methods have been proposed for this purpose. They can be roughly divided into three categories. The first type consists of tweet text-based methods, where the word distribution is used to estimate geolocations of users (Roller et al., 2012; Wing and Baldridge, 2011). In the second type, methods combining metadata features such as time zone and profile description are developed to improve performance (Han et al., 2013). Network-based methods form the last type. Several studies have shown that incorporating friends' information is very useful for this task (Miura et al., 2017; Ebrahimi et al., 2018). Empirically, models enhanced with network information work better than the other two types, but they do not scale well to larger datasets (Rahimi et al., 2015a).

In recent years, neural network based prediction methods have shown great success on this Twitter user geolocation prediction task (Rahimi et al., 2017; Miura et al., 2017). However, these neural network based methods largely ignore the hierarchical structure among locations (eg. country versus city), which have been shown to be very useful in previous study (Mahmud et al., 2012; Wing and Baldridge, 2014). In recent work, Huang and Carley (2017) also demonstrate that country-level location prediction is much easier than city-level location prediction. It is natural to ask whether we can incorporate the hierarchical structure among locations into a neural network and use the coarse-grained location prediction to guide the fine-grained prediction. Besides, most of these previous work uses word-level embeddings to represent text, which may not be sufficient for noisy text from social media.

In this paper, we present a hierarchical location prediction neural network (HLPNN) for user geolocation on Twitter. Our model combines text features, metadata features (personal description, profile location, name, user language, time zone), and network features together. It uses a character-aware word embedding layer to deal with the noisy

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4732–4742,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

text and capture out-of-vocabulary words. With transformer encoders, our model learns the correlation between different feature fields and outputs two classification representations for country-level and city-level predictions respectively. It first computes the country-level prediction, which is further used to guide the city-level prediction. Our model is flexible in accommodating different feature combinations, and it achieves state-of-the-art results under various feature settings.

2 Related Work

Because of insufficient geotagged data (Graham et al., 2014; Huang and Carley, 2019), there is a growing interest in predicting Twitter users' locations. Though there are some potential privacy concerns, user geolocation is a key factor for many important applications such as earthquake detection (Earle et al., 2012), and disaster management (Carley et al., 2016), health management (Huang and Carley, 2018).

Early work tried to identify users' locations by mapping their IP addresses to physical locations (Buyukokkten et al., 1999). However, such private information is only accessible to internet service providers. There is no easy way for a third-party to find Twitter users' IP addresses. Later, various text-based location prediction systems were proposed. Bilhaut et al. (2003) utilize a geographical gazetteer as an external lexicon and present a rule-based geographical references recognizer. Amitay et al. (2004) extracted location-related information listed in a gazetteer from web content to identify geographical regions of webpages. However, as shown in (Berggren et al., 2016), performances of gazetteer-based methods are hindered by the noisy and informal nature of tweets.

Moving beyond methods replying on external knowledge sources (e.g. IP and gazetteers), many machine learning based methods have recently been applied to location prediction. Typically, researchers first represent locations as earth grids (Wing and Baldridge, 2011; Roller et al., 2012), regions (Miyazaki et al., 2018; Qian et al., 2017), or cities (Han et al., 2013). Then location classifiers are built to categorize users into different locations. Han et al. (2012) first utilized feature selection methods to find location indicative words, then they used multinomial naive Bayes and logistic regression classifiers to find correct locations. Han et al. (2013) further present a stacking based method that combines tweet text and metadata together. Along with these classification methods, some approaches also try to learn topic regions automatically by topic modeling, but these do not scale well to the magnitude of social media (Hong et al., 2012; Zhang et al., 2017).

Recently, deep neural network based methods are becoming popular for location prediction (Miura et al., 2016). Huang and Carley (2017) integrate text and user profile metadata into a single model using convolutional neural networks, and their experiments show superior performance over stacked naive Bayes classifiers. Miura et al. (2017); Ebrahimi et al. (2018) incorporate user network connection information into their neural models, where they use network embeddings to represent users in a social network. Rahimi et al. (2018) also uses text and network feature together, but their approach is based on graph convolutional neural networks.

Similar to our method, some research has tried to predict user location hierarchically (Mahmud et al., 2012; Wing and Baldridge, 2014). Mahmud et al. (2012) develop a two-level hierarchical location classifier which first predicts a coarse-grained location (country, time zone), and then predicts the city label within the corresponding coarse region. Wing and Baldridge (2014) build a hierarchical tree of earth grids. The probability of a final fine-grained location can be computed recursively from the root node to the leaf node. Both methods have to train one classifier separately for each parent node, which is quite time-consuming for training deep neural network based methods. Additionally, certain coarse-grained locations may not have enough data samples to train a local neural classifier alone. Our hierarchical location prediction neural network overcomes these issues and only needs to be trained once.

3 Method

There are seven features we want to utilize in our model — tweet text, personal description, profile location, name, user language, time zone, and mention network. The first four features are text fields where users can write anything they want. User language and time zone are two categorical features that are selected by users in their profiles. Following previous work (Rahimi et al., 2018), we construct mention network directly from mentions in tweets, which is also less expensive to collect

than following network[1].

The overall architecture of our hierarchical location prediction model is shown in Figure 1. It first maps four text features into a word embedding space. A bidirectional LSTM (Bi-LSTM) neural network (Hochreiter and Schmidhuber, 1997) is used to extract location-specific features from these text embedding vectors. Following Bi-LSTM, we use a word-level attention layer to generate representation vectors for these text fields. Combining all the text representations, a user language embedding, a timezone embedding, and a network embedding, we apply several layers of transformer encoders (Vaswani et al., 2017) to learn the correlation among all the feature fields. The probability for each country is computed after a field-level attention layer. Finally, we use the country probability as a constraint for the city-level location prediction. We elaborate details of our model in the following sections.

3.1 Word Embedding

Assume one user has T tweets, there are $T+3$ text fields for this user including personal description, profile location, and name. We first map each word in these $T+3$ text fields into a low dimensional embedding space. The embedding vector for word w is computed as $x_w = [E(w), CNN_c(w)]$, where $[,]$ denotes vector concatenation. $E(w)$ is the word-level embedding retrieved directly from an Embedding matrix $E \in R^{V \times D}$ by a lookup operation, where V is the vocabulary size, and D is the word-level embedding dimension. $CNN_c(w)$ is a character-level word embedding that is generated from a character-level convolutional layer. Using character-level word embeddings is helpful for dealing with out-of-vocabulary tokens and overcoming the noisy nature of tweet text.

The character-level word embedding generation process is as follows. For a character c_i in the word $w = (c_1, ..., c_k)$, we map it into a character embedding space and get a vector $v_{c_i} \in R^d$. In the convolutional layer, each filter $u \in R^{l_c \times d}$ generates a feature vector $\boldsymbol{\theta} = [\theta_1, \theta_2, ..., \theta_{k-l_c+1}] \in R^{k-l_c+1}$, where $\theta_i = \textit{relu}(u \circ v_{c_i:c_{i+l_c-1}} + b)$. b is a bias term, and "$\circ$" denotes element-wise inner product between u and character window $v_{c_i:c_{i+l_c-1}} \in R^{l_c \times d}$. After this convolutional operation, we use a max-pooling operation to select the most representative feature $\hat{\theta} = max(\boldsymbol{\theta})$. With D such filters, we get the character-level word embedding $CNN_c(w) \in R^D$.

3.2 Text Representation

After the word embedding layer, every word in these $T+3$ texts are transformed into a $2D$ dimension vector. Given a text with word sequence $(w_1, ..., w_N)$, we get a word embedding matrix $X \in R^{N \times 2D}$ from the embedding layer. We then apply a Bi-LSTM neural network to extract high-level semantic representations from text embedding matrices.

At every time step i, a forward LSTM takes the word embedding x_i of word w_i and previous state $\overrightarrow{h_{i-1}}$ as inputs, and generates the current hidden state $\overrightarrow{h}_i$. A backward LSTM reads the text from w_N to w_1 and generates another state sequence. The hidden state $h_i \in R^{2D}$ for word w_i is the concatenation of $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$. Concatenating all the hidden states, we get a semantic matrix $H \in R^{N \times 2D}$

$$\overrightarrow{h_i} = \overrightarrow{LSTM}(x_i, \overrightarrow{h_{i-1}})$$
$$\overleftarrow{h_i} = \overleftarrow{LSTM}(x_i, \overleftarrow{h_{i+1}})$$

Because not all words in a text contribute equally towards location prediction, we further use a multi-head attention layer (Vaswani et al., 2017) to generate a representation vector $f \in R^{2D}$ for each text. There are h attention heads that allow the model to attend to important information from different representation subspaces. Each head computes a text representation as a weighted average of these word hidden states. The computation steps in a multi-head attention layer are as follows.

$$f = \text{MultiHead}(q, H) = [\text{head}_1, ..., \text{head}_\text{h}]W^O$$
$$\text{head}_\text{i}(q, H) = \text{softmax}(\frac{qW_i^Q \cdot (HW_i^K)^T}{\sqrt{d_k}})HW_i^V$$

where $q \in R^{2d}$ is an attention context vector learned during training, $W_i^Q, W_i^K, W_i^V \in R^{2D \times d_k}$, and $W^O \in R^{2D \times 2D}$ are projection parameters, $d_k = 2D/h$. An attention head $head_i$ first projects the attention context q and the semantic matrix H into query and key subspaces by W_i^Q, W_i^K respectively. The matrix product between query qW_i^Q and key HW_i^K after softmax normalization is an attention weight that indicates important words among the projected value vectors HW_i^V. Concatenating h heads together, we

[1] https://developer.twitter.com

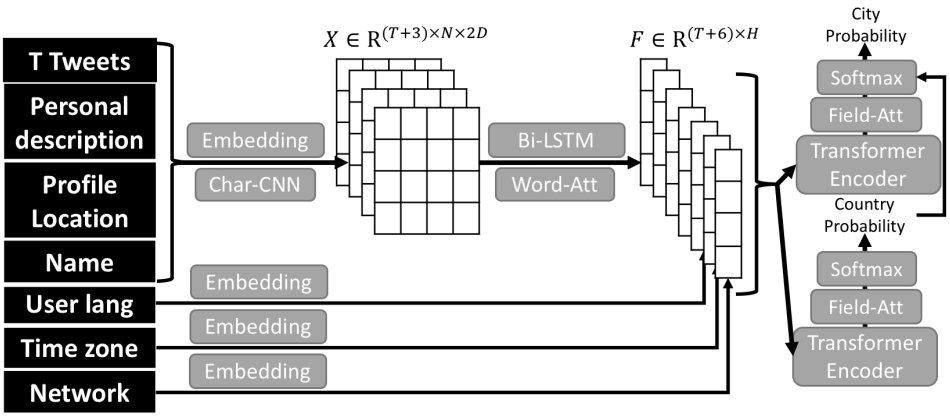

Figure 1: The architecture of our hierarchical location prediction neural network.

get one representation vector $f \in R^{2D}$ after projection by W^O for each text field.

3.3 Feature Fusion

For two categorical features, we assign an embedding vector with dimension $2D$ for each time zone and language. These embedding vectors are learned during training. We pretrain network embeddings for users involved in the mention network using LINE (Tang et al., 2015). Network embeddings are fixed during training. We get a feature matrix $F \in R^{(T+6)\times 2D}$ by concatenating text representations of $T+3$ text fields, two embedding vectors of categorical features, and one network embedding vector.

We further use several layers of transformer encoders (Vaswani et al., 2017) to learn the correlation between different feature fields. Each layer consists of a multi-head self-attention network and a feed-forward network (FFN). One transformer encoder layer first uses input feature to attend important information in the feature itself by a multi-head attention sub-layer. Then a linear transformation sub-layer FFN is applied to each position identically. Similar to Vaswani et al. (2017), we employ residual connection (He et al., 2016) and layer normalization (Ba et al., 2016) around each of the two sub-layers. The output F_1 of the first transformer encoder layer is generated as follows.

$$F' = \mathrm{LayerNorm}(\mathrm{MultiHead}(F, F) + F)$$
$$F_1 = \mathrm{LayerNorm}(\mathrm{FFN}(F') + F')$$

where $\mathrm{FFN}(F') = \max(0, F'W_1 + b_1)W_2 + b2$, $W_1 \in R^{2D\times D_{ff}}$, and $W_2 \in R^{D_{ff}\times 2D}$.

Since there is no position information in the transformer encoder layer, our model cannot distinguish between different types of features, eg. tweet text and personal description. To overcome this issue, we add feature type embeddings to the input representations F. There are seven features in total. Each of them has a learned feature type embedding with dimension $2D$ so that one feature type embedding and the representation of the corresponding feature can be summed.

Because the input and the output of transformer encoder have the same dimension, we stack L layers of transformer encoders to learn representations for country-level prediction and city-level prediction respectively. These two sets of encoders share the same input F, but generate different representations F_{co}^L and F_{ci}^L for country and city predictions.

The final classification features for country-level and city-level location predictions are the row-wise weighted average of F_{co} and F_{ci}. Similar to the word-level attention, we use a field-level multi-head attention layer to select important features from $T+6$ vectors and fuse them into a single vector.

$$F_{co} = \mathrm{MultiHead}(q_{co}, F_{co}^L)$$
$$F_{ci} = \mathrm{MultiHead}(q_{ci}, F_{ci}^L)$$

where $q_{co}, q_{ci} \in R^{2D}$ are two attention context vectors.

3.4 Hierarchical Location Prediction

The final probability for each country is computed by a softmax function

$$P_{co} = \mathrm{softmax}(W_{co}F_{co} + b_{co})$$

where $W_{co} \in R^{M_{co}\times 2D}$ is a linear projection parameter, $b_{co} \in R^{M_{co}}$ is a bias term, and M_{co} is the number of countries.

	Twitter-US			Twitter-World			WNUT		
	Train	Dev.	Test	Train	Dev.	Test	Train	Dev.	Test
# users	429K	10K	10K	1.37M	10K	10K	742K	7.46K	10K
# users with meta	228K	5.32K	5.34K	917K	6.50K	6.48K	742K	7.46K	10K
# tweets	36.4M	861K	831K	11.2M	488K	315K	8.97M	90.3K	99.7K
# tweets per user	84.60	86.14	83.12	8.16	48.83	31.59	12.09	12.10	9.97

Table 1: A brief summary of our datasets. For each dataset, we report the number of users, number of users with metadata, number of tweets, and average number of tweets per user. We collected metadata for 53% and 67% of users in Twitter-US and Twitter-World. Time zone information was not available when we collected metadata for these two datasets. About 25% of training and development users' data was inaccessible when we collected WNUT in 2017.

After we get the probability for each country, we further use it to constrain the city-level prediction

$$P_{ci} = \text{softmax}(W_{ci}F_{ci} + b_{ci} + \lambda P_{co}Bias)$$

where $W_{ci} \in R^{M_{ci} \times 2D}$ is a linear projection parameter, $b_{ci} \in R^{M_{ci}}$ is a bias term, and M_{ci} is the number of cities. $Bias \in R^{M_{co} \times M_{ci}}$ is the country-city correlation matrix. If city j belongs to country i, then $Bias_{ij}$ is 0, otherwise -1. λ is a penalty term learned during training. The larger of λ, the stronger of the country constraint. In practise, we also experimented with letting the model learn the country-city correlation matrix during training, which yields similar performance.

We minimize the sum of two cross-entropy losses for country-level prediction and city-level prediction.

$$loss = -(Y_{ci} \cdot logP_{ci} + \alpha Y_{co} \cdot logP_{co})$$

where Y_{ci} and Y_{co} are one-hot encodings of city and country labels. α is the weight to control the importance of country-level supervision signal. Since a large α would potentially interfere with the training process of city-level prediction, we just set it as 1 in our experiments. Tuning this parameter on each dataset may further improve the performance.

4 Experiment Settings

4.1 Datasets

To validate our method, we use three widely adopted Twitter location prediction datasets. Table 1 shows a brief summary of these three datasets. They are listed as follows.

Twitter-US is a dataset compiled by Roller et al. (2012). It contains 429K training users, 10K development users, and 10K test users in North America. The ground truth location of each user is set to the first geotag of this user in the dataset. We assign the closest city to each user's ground truth location using the city category built by Han et al. (2012). Since this dataset only covers North America, we change the first level location prediction from countries to administrative regions (eg. state or province). The administrative region for each city is obtained from the original city category.

Twitter-World is a Twitter dataset covering the whole world, with 1,367K training users, 10K development users, and 10K test users (Han et al., 2012). The ground truth location for each user is the center of the closest city to the first geotag of this user. Only English tweets are included in this dataset, which makes it more challenging for a global-level location prediction task.

We downloaded these two datasets from Github [2]. Each user in these two datasets is represented by the concatenation of their tweets, followed by the geo-coordinates. We queried Twitter's API to add user metadata information to these two datasets in February 2019. We only get metadata for about 53% and 67% users in Twitter-US and Twitter-World respectively. Because of Twitter's privacy policy change, we could not get the time zone information anymore at the time of collection.

WNUT was released in the 2nd Workshop on Noisy User-generated Text (Han et al., 2016). The original user-level dataset consists of 1 million training users, 10K users in development set and test set each. Each user is assigned with the closest city center as the ground truth label. Because of Twitter's data sharing policy, only tweet IDs

[2]https://github.com/afshinrahimi/geomdn

of training and development data are provided. We have to query Twitter's API to reconstruct the training and development dataset. We finished our data collection around August 2017. About 25% training and development users' data cannot be accessed at that time. The full anonymized test data is downloaded from the workshop website [3].

4.2 Text Preprocessing & Network Construction

For all the text fields, we first convert them into lower case, then use a tweet-specific tokenizer from NLTK[4] to tokenize them. To keep a reasonable vocabulary size, we only keep tokens with frequencies greater than 10 times in our word vocabulary. Our character vocabulary includes characters that appear more than 5 times in the training corpus.

We construct user networks from mentions in tweets. For WNUT, we keep users satisfying one of the following conditions in the mention network: (1) users in the original dataset (2) users who are mentioned by two different users in the dataset. For Twitter-US and Twitter-World, following previous work (Rahimi et al., 2018), a unidirectional edge is set if two users in our dataset directly mentioned each other, or they co-mentioned another user. We remove celebrities who are mentioned by more than 10 different users from the mentioning network. These celebrities are still kept in the dataset and their network embeddings are set as 0.

4.3 Evaluation Metrics

We evaluate our method using four commonly used metrics listed below.

Accuracy: The percentage of correctly predicted home cities.

Acc@161: The percentage of predicted cities which are within a 161 km (100 miles) radius of true locations to capture near-misses.

Median: The median distance measured in kilometer from the predicted city to the true location coordinates.

Mean: The mean value of error distances in predictions.

4.4 Hyperparameter Settings

In our experiments, we initialize word embeddings with released 300-dimensional Glove vectors (Pennington et al., 2014). For words not appearing in Glove vocabulary, we randomly initialize them from a uniform distribution U(-0.25, 0.25). We choose the character embedding dimension as 50. The character embeddings are randomly initialized from a uniform distribution U(-1.0,1.0), as well as the timezone embeddings and language embeddings. These embeddings are all learned during training. Because our three datasets are sufficiently large to train our model, the learning is quite stable and performance does not fluctuate a lot.

Network embeddings are trained using LINE (Tang et al., 2015) with parameters of dimension 600, initial learning rate 0.025, order 2, negative sample size 5, and training sample size 10000M. Network embeddings are fixed during training. For users not appearing in the mention network, we set their network embedding vectors as 0.

	Twitter-US	Twitter-World	WNUT
Batch size	32	64	64
Initial learning rate	10^{-4}	10^{-4}	10^{-4}
D: Word embedding dimension	300	300	300
d: Char. embedding dimension	50	50	50
l_c: filter sizes in Char. CNN	3,4,5	3,4,5	3,4,5
Filter number for each size	100	100	100
h: number of heads	10	10	10
L: layers of transformer encoder	3	3	3
λ: initial penalty term	1	1	1
α: weight for country supervision	1	1	1
D_{ff}: inner dimension of FFN	2400	2400	2400
Max number of tweets per user	100	50	20

Table 2: A summary of hyperparameter settings of our model.

A brief summary of hyperparameter settings of our model is shown in Table 2. The initial learning rate is 10^{-4}. If the validation accuracy on the development set does not increase, we decrease the learning rate to 10^{-5} and train the model for additional 3 epochs. Empirically, training terminates within 10 epochs. Penalty λ is initialized as 1.0 and is adapted during training. We apply dropout on the input of Bi-LSTM layer and the output of two sub-layers in transformer encoders with dropout rate 0.3 and 0.1 respectively. We use the Adam update rule (Kingma and Ba, 2014)

Table 3: Comparisons between our method and baselines. We report results under four different feature settings: Text, Text+Metadata, Text+Network, Text+Metadata+Network. "-" signifies that no results were published for the given dataset, "*" denotes that results are cited from Rahimi et al. (2017). Note that Miura et al. (2017) only used 279K users added with metadata in their experiments of Twitter-US.

to optimize our model. Gradients are clipped between -1 and 1. The maximum numbers of tweets per user for training and evaluating on Twitter-US are 100 and 200 respectively. We only tuned our model, learning rate, and dropout rate on the development set of WNUT.

5 Results

5.1 Baseline Comparisons

In our experiments, we evaluate our model under four different feature settings: Text, Text+Meta, Text+Network, Text+Meta+Network. HLPNN-Text is our model only using tweet text as input. HLPNN-Meta is the model that combines text and metadata (description, location, name, user language, time zone). HLPNN-Net is the model that combines text and mention network. HLPNN is our full model that uses text, metadata, and mention network for Twitter user geolocation.

We present comparisons between our model and previous work in Table 3. As shown in the table, our model outperforms these baselines across three datasets under various feature settings.

Only using text feature from tweets, our model HLPNN-Text works the best among all these text-based location prediction systems and wins by a large margin. It not only improves prediction accuracy but also greatly reduces mean error distance. Compared with a strong neural model equipped with local dialects (Rahimi et al., 2017), it increases Acc@161 by an absolute value 4% and reduces mean error distance by about 400 kilometers on the challenging Twitter-World dataset, without using any external knowledge. Its mean error distance on Twitter-World is even comparable to some methods using network feature (Do et al., 2017).

With text and metadata, HLPNN-Meta correctly predicts locations of 57.2% users in WNUT dataset, which is even better than these location prediction systems that use text, metadata, and network. Because in the WNUT dataset the ground truth location is the closest city's center, Our model achieves 0 median error when its accuracy is greater than 50%. Note that Miura et al. (2017) used 279K users added with metadata in their experiments on Twitter-US, while we use all 449K users for training and evaluation, and only 53% of them have metadata, which makes it difficult to make a fair comparison.

Adding network feature further improves our model's performances. It achieves state-of-the-art results combining all features on these three datasets. Even though unifying network information is not the focus of this paper, our model still outperforms or has comparable results to some well-designed network-based location prediction systems like (Rahimi et al., 2018). On Twitter-US dataset, our model variant HLPNN-Net achieves a

4.6% increase in Acc@161 against previous state-of-the-art methods (Do et al., 2017) and (Rahimi et al., 2018). The prediction accuracy of HLPNN-Net on WNUT dataset is similar to (Miura et al., 2017), but with a noticeable lower mean error distance.

5.2 Ablation Study

In this section, we provide an ablation study to examine the contribution of each model component. Specifically, we remove the character-level word embedding, the word-level attention, the field-level attention, the transformer encoders, and the country supervision signal one by one at a time. We run experiments on the WNUT dataset with text features.

	Accuracy	Acc@161	Median	Mean
HLPNN	37.3	52.9	109.3	1289.4
w/o Char-CNN	36.3	51.0	130.8	1429.9
w/o Word-Att	36.4	51.5	130.2	1377.5
w/o Field-Att	37.0	52.0	121.8	1337.5
w/o encoders	36.8	52.5	117.4	1402.9
w/o country	36.7	52.6	124.8	1399.2

Table 4: An ablation study on WNUT dataset.

The performance breakdown for each model component is shown in Table 4. Compared to the full model, we can find that the character-level word embedding layer is especially helpful for dealing with noisy social media text. The word-level attention also provides performance gain, while the field-level attention only provides a marginal improvement. The reason could be the multi-head attention layers in the transformer encoders already captures important information among different feature fields. These two transformer encoders learn the correlation between features and decouple these two level predictions. Finally, using the country supervision can help model to achieve a better performance with a lower mean error distance.

5.3 Country Effect

To directly measure the effect of adding country-level supervision, we define a relative country error which is the percentage of city-level predictions located in incorrect countries among all misclassified city-level predictions.

$$\text{relative country error} = \frac{\#\text{ of incorrect country}}{\#\text{ of incorrect city}}$$

The lower this metric means the better one model can predict the city-level location, at least in the correct country.

We vary the weight α of country-level supervision signal in our loss function from 0 to 20. The larger α means the more important the country-level supervision during the optimization. When α equals 0, there is no country-level supervision in our model. As shown in Figure 2, increasing α would improve the relative country error from 26.2% to 23.1%, which shows the country-level supervision signal indeed can help our model predict the city-level location towards the correct country. This possibly explains why our model has a lower mean error distance when compared to other methods.

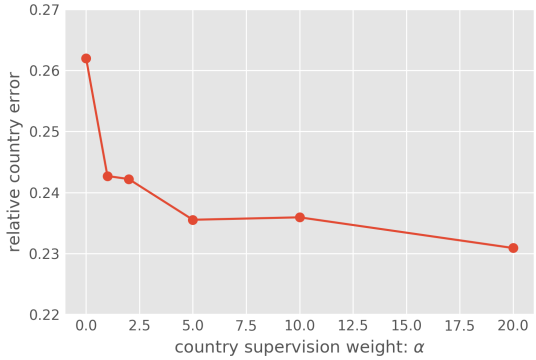

Figure 2: Relative country error with varying α on test dataset. Experiments were conducted on WNUT dataset with text feature.

6 Conclusion

In this paper, we propose a hierarchical location prediction neural network, which combines text, metadata, network information for user location prediction. Our model can accommodate various feature combinations. Extensive experiments have been conducted to validate the effectiveness of our model under four different feature settings across three commonly used benchmarks. Our experiments show our HLPNN model achieves state-of-the-art results on these three datasets. It not only improves the prediction accuracy but also significantly reduces the mean error distance. In our ablation analysis, we show that using character-aware word embeddings is helpful for overcoming noise in social media text. The transformer encoders effectively learn the correlation between different features and decouple the two different

level predictions. In our experiments, we also analyzed the effect of adding country-level regularization. The country-level supervision could effectively guide the city-level prediction towards the correct country, and reduce the errors where users are misplaced in the wrong countries.

Though our HLPNN model achieves great performances under Text+Net and Text+Meta+Net settings, potential improvements could be made using better graph-level classification frameworks. We currently only use network information to train network embeddings as user-level features. For future work, we would like to explore ways to combine graph-level classification methods and our user-level learning model. Propagating features from connected friends would provide much more information than just using network embedding vectors. Besides, our model assumes each post of one user all comes from one single home location but ignores the dynamic user movement pattern like traveling. We plan to incorporate temporal states to capture location changes in future work.

Trouble on the Horizon: Forecasting the Derailment of Online Conversations as they Develop

Abstract

Online discussions often derail into toxic exchanges between participants. Recent efforts mostly focused on detecting antisocial behavior after the fact, by analyzing single comments in isolation. To provide more timely notice to human moderators, a system needs to preemptively detect that a conversation is heading towards derailment before it actually turns toxic. This means modeling derailment as an emerging property of a conversation rather than as an isolated utterance-level event.

Forecasting emerging conversational properties, however, poses several inherent modeling challenges. First, since conversations are dynamic, a forecasting model needs to capture the flow of the discussion, rather than properties of individual comments. Second, real conversations have an unknown horizon: they can end or derail at any time; thus a practical forecasting model needs to assess the risk in an online fashion, as the conversation develops. In this work we introduce a conversational forecasting model that learns an unsupervised representation of conversational dynamics and exploits it to predict future derailment as the conversation develops. By applying this model to two new diverse datasets of online conversations with labels for antisocial events, we show that it outperforms state-of-the-art systems at forecasting derailment.

1 Introduction

>
> – Dante Alighieri, Divina Commedia, Paradiso

Antisocial behavior is a persistent problem plaguing online conversation platforms; it is both widespread (Duggan, 2014) and potentially damaging to mental and emotional health (Raskauskas and Stoltz, 2007; Akbulut et al., 2010). The strain this phenomenon puts on community maintainers has sparked recent interest in computational approaches for assisting human moderators.

(1) **[User A]** What does [quote omitted] refer to? I assume it should be written from June 2010 to December 2011 and we should precise [sic] the months.
(2) **[User B]** No. It refers to 2007-2011 Belgian political crisis
(3) **[User A]** 2007-2011 Belgian political crisis is a little bit [of original research]. It merges 2 crisis in 1. Sources 2 and 4 in the article talk about a 18 months crisis in 2010-2011, ie what I refer to. What are the reliable sources that make this crisis go back to 2007?
(4) **[User B]** Yes it's not ridiculous at all to claim [it's original research] because it doesn't fit your argument. A crisis can be composed out of several smaller crisis. It's not original research if some of your sources only talk about parts [...]
(5) **[User A]** Where is the source that claim the crisis is 4 year long? Sources state claim it is 18 month long and refer to the period from June 2010 to December 2011.
(6) **[User B]** There were 4 governments and 2 years of no government in 4 years time. You can not sanely claim that this Must be viewed as two seperate crisis. What exactly splits them up? [...]

Figure 1: Example start of a conversation that will eventually derail into a personal attack.

Prior work in this direction has largely focused on *post-hoc* identification of various kinds of antisocial behavior, including hate speech (Warner and Hirschberg, 2012; Davidson et al., 2017), harassment (Yin et al., 2009), personal attacks (Wulczyn et al., 2017), and general toxicity (Pavlopoulos et al., 2017). The fact that these approaches only identify antisocial content *after the fact* limits their practicality as tools for assisting *pre-emptive* moderation in conversational domains.

Addressing this limitation requires *forecasting* the future derailment of a conversation based on early warning signs, giving the moderators time to potentially intervene before any harm is done (Liu et al. 2018, Zhang et al. 2018a, see Jurgens et al. 2019 for a discussion). Such a goal recognizes derailment as emerging from the devel-

[1] "The arrow one foresees arrives more gently."

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 4743–4754, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

opment of the conversation, and belongs to the broader area of *conversational forecasting*, which includes future-prediction tasks such as predicting the eventual length of a conversation (Backstrom et al., 2013), whether a persuasion attempt will eventually succeed (Tan et al., 2016; Wachsmuth et al., 2018; Yang et al., 2019), whether team discussions will eventually lead to an increase in performance (Niculae and Danescu-Niculescu-Mizil, 2016), or whether ongoing counseling conversations will eventually be perceived as helpful (Althoff et al., 2016).[2]

Approaching such *conversational forecasting* problems, however, requires overcoming several inherent modeling challenges. First, conversations are *dynamic* and their outcome might depend on how subsequent comments interact with each other. Consider the example in Figure 1: while no individual comment is outright offensive, a human reader can sense a tension emerging from their succession (e.g., dismissive answers to repeated questioning). Thus a forecasting model needs to capture not only the content of each individual comment, but also the *relations* between comments. Previous work has largely relied on hand-crafted features to capture such relations—e.g., similarity between comments (Althoff et al., 2016; Tan et al., 2016) or conversation structure (Zhang et al., 2018b; Hessel and Lee, 2019)—, though neural attention architectures have also recently shown promise (Jo et al., 2018).

The second modeling challenge stems from the fact that conversations have an *unknown horizon*: they can be of varying lengths, and the to-be-forecasted event can occur at any time. So when is it a good time to make a forecast? Prior work has largely proposed two solutions, both resulting in important practical limitations. One solution is to assume (unrealistic) prior knowledge of when the to-be-forecasted event takes place and extract features up to that point (Niculae et al., 2015; Liu et al., 2018). Another compromising solution is to extract features from a fixed-length window, often at the start of the conversation (Curhan and Pentland, 2007; Niculae and Danescu-Niculescu-Mizil, 2016; Althoff et al., 2016; Zhang et al., 2018a, inter alia). Choosing a catch-all window-size is however impractical: short windows will miss information in comments they do not encompass (e.g., a window of only two comments would miss the chain of repeated questioning in comments 3 through 6 of Figure 1), while longer windows risk missing the to-be-forecasted event altogether if it occurs before the end of the window, which would prevent *early* detection.

In this work we introduce a model for forecasting conversational events that overcomes both these inherent challenges by processing comments, and their relations, as they happen (i.e., in an online fashion). Our main insight is that models with these properties already exist, albeit geared toward generation rather than prediction: recent work in context-aware dialog generation (or "chatbots") has proposed sequential neural models that make effective use of the intra-conversational dynamics (Sordoni et al., 2015b; Serban et al., 2016, 2017), while concomitantly being able to process the conversation as it develops (see Gao et al. (2018) for a survey).

In order for these systems to perform well in the generative domain they need to be trained on massive amounts of (unlabeled) conversational data. The main difficulty in directly adapting these models to the supervised domain of conversational forecasting is the relative scarcity of labeled data: for most forecasting tasks, at most a few thousands labeled examples are available, insufficient for the notoriously data-hungry sequential neural models.

To overcome this difficulty, we propose to decouple the objective of learning a neural representation of conversational dynamics from the objective of predicting future events. The former can be *pre-trained* on large amounts of unsupervised data, similarly to how chatbots are trained. The latter can piggy-back on the resulting representation after *fine-tuning* it for classification using relatively small labeled data. While similar pre-train-then-fine-tune approaches have recently achieved state-of-the-art performance in a number of NLP tasks—including natural language inference, question answering, and commonsense reasoning (discussed in Section 2)—to the best of our knowledge this is the first attempt at applying this paradigm to conversational forecasting.

To test the effectiveness of this new architecture in forecasting derailment of online conversations, we develop and distribute two new datasets. The

[2]We can distinguish two types of forecasting tasks, depending on whether the to-be-forecasted target is an event that might take place within the conversation (e.g., derailment) or an outcome measured after the conversation will eventually conclude (e.g., helpfulness). The following discussion of modeling challenges holds for both.

first triples in size the highly curated 'Conversations Gone Awry' dataset (Zhang et al., 2018a), where civil-starting Wikipedia Talk Page conversations are crowd-labeled according to whether they eventually lead to personal attacks; the second relies on in-the-wild moderation of the popular subreddit ChangeMyView, where the aim is to forecast whether a discussion will later be subject to moderator action due to "rude or hostile" behavior. In both datasets, our model outperforms existing fixed-window approaches, as well as simpler sequential baselines that cannot account for inter-comment relations. Furthermore, by virtue of its online processing of the conversation, our system can provide substantial prior notice of upcoming derailment, triggering on average 3 comments (or 3 hours) before an overtly toxic comment is posted.

To summarize, in this work we:

- introduce the first model for forecasting conversational events that can capture the dynamics of a conversation *as it develops*;
- build two diverse datasets (one entirely new, one extending prior work) for the task of forecasting derailment of online conversations;
- compare the performance of our model against the current state-of-the-art, and evaluate its ability to provide *early* warning signs.

Our work is motivated by the goal of assisting human moderators of online communities by preemptively signaling at-risk conversations that might deserve their attention. However, we caution that any automated systems might encode or even amplify the biases existing in the training data (Park et al., 2018; Sap et al., 2019; Wiegand et al., 2019), so a public-facing implementation would need to be exhaustively scrutinized for such biases (Feldman et al., 2015).

2 Further Related Work

Antisocial behavior. Antisocial behavior online comes in many forms, including harassment (Vitak et al., 2017), cyberbullying (Singh et al., 2017), and general aggression (Kayany, 1998). Prior work has sought to understand different aspects of such behavior, including its effect on the communities where it happens (Collier and Bear, 2012; Arazy et al., 2013), the actors involved (Cheng et al., 2017; Volkova and Bell, 2017; Kumar et al., 2018; Ribeiro et al., 2018) and connections to the outside world (Olteanu et al., 2018).

Post-hoc classification of conversations. There is a rich body of prior work on classifying the outcome of a conversation after it has concluded, or classifying conversational events after they happened. Many examples exist, but some more closely related to our present work include identifying the winner of a debate (Zhang et al., 2016; Potash and Rumshisky, 2017; Wang et al., 2017), identifying successful negotiations (Curhan and Pentland, 2007; Cadilhac et al., 2013), as well as detecting whether deception (Girlea et al., 2016; Pérez-Rosas et al., 2016; Levitan et al., 2018) or disagreement (Galley et al., 2004; Abbott et al., 2011; Allen et al., 2014; Wang and Cardie, 2014; Rosenthal and McKeown, 2015) has occurred.

Our goal is different because we wish to *forecast* conversational events before they happen and while the conversation is still ongoing (potentially allowing for interventions). Note that some post-hoc tasks can also be re-framed as forecasting tasks (assuming the existence of necessary labels); for instance, predicting whether an ongoing conversation *will* eventually spark disagreement (Hessel and Lee, 2019), rather than detecting already-existing disagreement.

Conversational forecasting. As described in Section 1, prior work on forecasting conversational outcomes and events has largely relied on hand-crafted features to capture aspects of conversational dynamics. Example feature sets include statistical measures based on similarity between utterances (Althoff et al., 2016), sentiment imbalance (Niculae et al., 2015), flow of ideas (Niculae et al., 2015), increase in hostility (Liu et al., 2018), reply rate (Backstrom et al., 2013) and graph representations of conversations (Garimella et al., 2017; Zhang et al., 2018b). By contrast, we aim to automatically learn neural representations of conversational dynamics through pre-training.

Such hand-crafted features are typically extracted from fixed-length windows of the conversation, leaving unaddressed the problem of unknown horizon. While some work has trained *multiple* models for different window-lengths (Liu et al., 2018; Hessel and Lee, 2019), they consider these models to be independent and, as such, do not address the issue of aggregating them into a single forecast (i.e., deciding at what point to make

a prediction). We implement a simple sliding windows solution as a baseline (Section 5).

Pre-training for NLP. The use of pre-training for natural language tasks has been growing in popularity after recent breakthroughs demonstrating improved performance on a wide array of benchmark tasks (Peters et al., 2018; Radford et al., 2018). Existing work has generally used a language modeling objective as the pre-training objective; examples include next-word prediction (Howard and Ruder, 2018), sentence autoencoding, (Dai and Le, 2015), and machine translation (McCann et al., 2017). BERT (Devlin et al., 2019) introduces a variation on this in which the goal is to predict the next sentence in a document given the current sentence. Our pre-training objective is similar in spirit, but operates at a *conversation* level, rather than a document level. We hence view our objective as *conversational modeling* rather than (only) language modeling. Furthermore, while BERT's sentence prediction objective is framed as a multiple-choice task, our objective is framed as a generative task.

3 Derailment Datasets

We consider two datasets, representing related but slightly different forecasting tasks. The first dataset is an expanded version of the annotated Wikipedia conversations dataset from Zhang et al. (2018a). This dataset uses carefully-controlled crowdsourced labels, strictly filtered to ensure the conversations are civil up to the moment of a personal attack. This is a useful property for the purposes of model analysis, and hence we focus on this as our primary dataset. However, we are conscious of the possibility that these strict labels may not fully capture the kind of behavior that moderators care about in practice. We therefore introduce a secondary dataset, constructed from the subreddit ChangeMyView (CMV) that does not use post-hoc annotations. Instead, the prediction task is to forecast whether the conversation will be subject to moderator action in the future.

Wikipedia data. Zhang et al.'s 'Conversations Gone Awry' dataset consists of 1,270 conversations that took place between Wikipedia editors on publicly accessible talk pages. The conversations are sourced from the WikiConv dataset (Hua et al., 2018) and labeled by crowdworkers as either containing a *personal attack* from within (i.e., hostile behavior by one user in the conversation directed towards another) or remaining civil throughout.

A series of controls are implemented to prevent models from picking up on trivial correlations. To prevent models from capturing topic-specific information (e.g., political conversations are more likely to derail), each attack-containing conversation is paired with a clean conversation from the same talk page, where the talk page serves as a proxy for topic.[3] To force models to actually capture conversational dynamics rather than detecting already-existing toxicity, human annotations are used to ensure that all comments preceding a personal attack are civil.

To the ends of more effective model training, we elected to expand the 'Conversations Gone Awry' dataset, using the original annotation procedure. Since we found that the original data skewed towards shorter conversations, we focused this crowdsourcing run on longer conversations: ones with 4 or more comments preceding the attack.[4] Through this additional crowdsourcing, we expand the dataset to 4,188 conversations, which we are publicly releasing as part of the Cornell Conversational Analysis Toolkit (ConvoKit).[5]

We perform an 80-20-20 train/dev/test split, ensuring that paired conversations end up in the same split in order to preserve the topic control. Finally, we randomly sample another 1 million conversations from WikiConv to use for the unsupervised pre-training of the generative component.

Reddit CMV data. The CMV dataset is constructed from conversations collected via the Reddit API. In contrast to the Wikipedia-based dataset, we explicitly avoid the use of post-hoc annotation. Instead, we use as our label whether a conversation eventually had a comment removed by a moderator for violation of Rule 2: "Don't be rude or hostile to other users".[6]

Though the lack of post-hoc annotation limits the degree to which we can impose controls on the data (e.g., some conversations may contain toxic comments not flagged by the moderators) we do reproduce as many of the Wikipedia data's controls as we can. Namely, we replicate the topic

[3] Paired conversations were also enforced to be similar in length, so that length distribution is the same between classes.

[4] We cap the length at 10 to avoid overwhelming the crowdworkers.

[5] convokit.cornell.edu

[6] The existence of this specific rule, the standardized moderation messages and the civil character of the ChangeMyView subreddit was our initial motivation for choosing it.

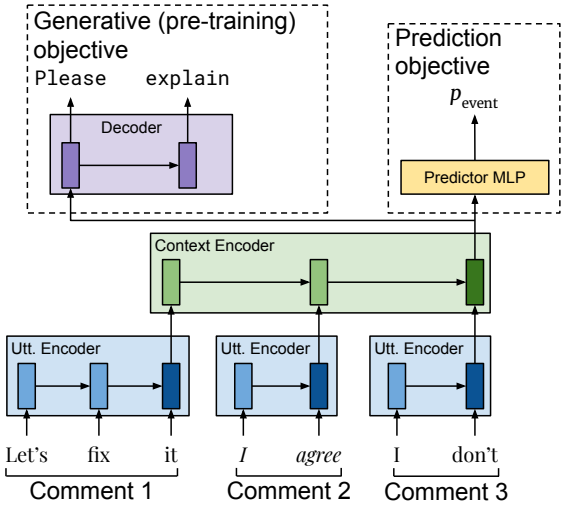

Figure 2: Sketch of the CRAFT architecture.

control pairing by choosing pairs of positive and negative examples that belong to the same top-level post, following Tan et al. (2016);[7] and enforce that the removed comment was made by a user who was previously involved in the conversation.[8] This process results in 6,842 conversations, to which we again apply a pair-preserving 80-20-20 split. Finally, we gather over 600,000 conversations that do not include any removed comment, for unsupervised pre-training.

4 Conversational Forecasting Model

We now describe our general model for forecasting future conversational events. Our model integrates two components: (a) a generative dialog model that learns to represent conversational dynamics in an unsupervised fashion; and (b) a supervised component that fine-tunes this representation to forecast future events. Figure 2 provides an overview of the proposed architecture, henceforth CRAFT (Conversational Recurrent Architecture for ForecasTing).

Terminology. For modeling purposes, we treat a conversation as a sequence of N comments $C = \{c_1, \ldots, c_N\}$. Each comment, in turn, is a sequence of tokens, where the number of tokens may vary from comment to comment. For the n-th comment ($1 \leq n \leq N$), we let M_n denote the number of tokens. Then, a comment c_n can be represented as a sequence of M_n tokens: $c_n = \{w_1, \ldots, w_{M_n}\}$.

[7] The top-level post is not part of the conversations.

[8] We also impose the same length restriction on the number of comments preceding the removed comment, for comparability and for computational considerations.

Generative component. For the generative component of our model, we use a hierarchical recurrent encoder-decoder (HRED) architecture (Sordoni et al., 2015a), a modified version of the popular sequence-to-sequence (seq2seq) architecture (Sutskever et al., 2014) designed to account for dependencies between consecutive inputs. Serban et al. (2016) showed that HRED can successfully model conversational context by encoding the temporal structure of previously seen comments, making it an ideal fit for our use case. Here, we provide a high-level summary of the HRED architecture, deferring deeper technical discussion to Sordoni et al. (2015a) and Serban et al. (2016).

An HRED dialog model consists of three components: an utterance encoder, a context encoder, and a decoder. The utterance encoder is responsible for generating semantic vector representations of comments. It consists of a recurrent neural network (RNN) that reads a comment token-by-token, and on each token w_m updates a hidden state h^{enc} based on the current token and the previous hidden state:

$$h_m^{\text{enc}} = f^{\text{RNN}}(h_{m-1}^{\text{enc}}, w_m) \tag{1}$$

where f^{RNN} is a nonlinear gating function (our implementation uses GRU (Cho et al., 2014)). The final hidden state h_M^{enc} can be viewed as a vector encoding of the entire comment.

Running the encoder on each comment c_n results in a sequence of N vector encodings. A second encoder, the context encoder, is then run over this sequence:

$$h_n^{\text{con}} = f^{\text{RNN}}(h_{n-1}^{\text{con}}, h_{M_n}^{\text{enc}}) \tag{2}$$

Each hidden state h_n^{con} can then be viewed as an encoding of the full conversational context up to and including the n-th comment. To generate a response to comment n, the context encoding h_n^{con} is used to initialize the hidden state h_0^{dec} of a decoder RNN. The decoder produces a response token by token using the following recurrence:

$$\begin{aligned} h_t^{\text{dec}} &= f^{\text{RNN}}(h_{t-1}^{\text{dec}}, w_{t-1}) \\ w_t &= f^{\text{out}}(h_t^{\text{dec}}) \end{aligned} \tag{3}$$

where f^{out} is some function that outputs a probability distribution over words; we implement this using a simple feedforward layer. In our implementation, we further augment the decoder with attention (Bahdanau et al., 2014; Luong et al.,

2015) over context encoder states to help capture long-term inter-comment dependencies. This generative component can be pre-trained using unlabeled conversational data.

Prediction component. Given a pre-trained HRED dialog model, we aim to extend the model to predict from the conversational context whether the to-be-forecasted event will occur. Our predictor consists of a multilayer perceptron (MLP) with 3 fully-connected layers, leaky ReLU activations between layers, and sigmoid activation for output. For each comment c_n, the predictor takes as input the context encoding h_n^{con} and forwards it through the MLP layers, resulting in an output score that is interpreted as a probability $p_{\text{event}}(c_{n+1})$ that the to-be-forecasted event will happen (e.g., that the conversation will derail).

Training the predictive component starts by initializing the weights of the encoders to the values learned in pre-training. The main training loop then works as follows: for each positive sample—i.e., a conversation containing an instance of the to-be-forecasted event (e.g., derailment) at comment c_e—we feed the context $c_1, \ldots, c_{e-1}$ through the encoder and classifier, and compute cross-entropy loss between the classifier output and expected output of 1. Similarly, for each negative sample—i.e., a conversation where none of the comments exhibit the to-be-forecasted event and that ends with c_N—we feed the context $c_1, \ldots, c_{N-1}$ through the model and compute loss against an expected output of 0.

Note that the parameters of the generative component are not held fixed during this process; instead, backpropagation is allowed to go all the way through the encoder layers. This process, known as *fine-tuning*, reshapes the representation learned during pre-training to be more directly useful to prediction (Howard and Ruder, 2018).

We implement the model and training code using PyTorch, and we are publicly releasing our implementation and the trained models together with the data as part of ConvoKit.

5 Forecasting Derailment

We evaluate the performance of CRAFT in the task of forecasting conversational derailment in both the Wikipedia and CMV scenarios. To this end, for each of these datasets we pre-train the generative component on the unlabeled portion of the data and fine-tune it on the labeled training split (data size detailed in Section 3).

In order to evaluate our sequential system against conversational-level ground truth, we need to aggregate comment level predictions. If *any* comment in the conversation *triggers* a positive prediction—i.e., $p_{\text{event}}(c_{n+1})$ is greater than a threshold learned on the development split—then the respective conversation is predicted to derail. If this forecast is triggered in a conversation that actually derails, but *before* the derailment actually happens, then the conversation is counted as a true positive; otherwise it is a false positive. If no positive predictions are triggered for a conversation, but it actually derails then it counts as a false negative; if it does not derail then it is a true negative.

Fixed-length window baselines. We first seek to compare CRAFT to existing, fixed-length window approaches to forecasting. To this end, we implement two such baselines: *Awry*, which is the state-of-the-art method proposed in Zhang et al. (2018a) based on pragmatic features in the first comment-reply pair,[9] and *BoW*, a simple bag-of-words baseline that makes a prediction using TF-IDF weighted bag-of-words features extracted from the first comment-reply pair.

Online forecasting baselines. Next, we consider simpler approaches for making forecasts as the conversations happen (i.e., in an online fashion). First, we propose *Cumulative BoW*, a model that recomputes bag-of-words features on all comments seen thus far every time a new comment arrives. While this approach does exhibit the desired behavior of producing updated predictions for each new comment, it fails to account for relationships between comments.

This simple cumulative approach cannot be directly extended to models whose features are strictly based on a fixed number of comments, like Awry. An alternative is to use a *sliding window*: for a feature set based on a window of W comments, upon each new comment we can extract features from a window containing that comment and the $W-1$ comments preceding it. We apply this to the Awry method and call this model *Sliding Awry*. For both these baselines, we aggregate comment-level predictions in the same way as in our main model.

CRAFT ablations. Finally, we consider two modified versions of the CRAFT model in order

[9] We use the ConvoKit implementation.

Table 1: Comparison of the capabilities of each baseline and our CRAFT models (full and without the Context Encoder) with regards to capturing inter-comment (D)ynamics, processing conversations in an (O)nline fashion, and automatically (L)earning feature representations, as well as their performance in terms of (A)ccuracy, (P)recision, (R)ecall, False Positive Rate (FPR), and F1 score. Awry is the model previously proposed by Zhang et al. (2018a) for this task.

to evaluate the impact of two of its key components: (1) the pre-training step, and (2) its ability to capture inter-comment dependencies through its hierarchical memory.

To evaluate the impact of pre-training, we train the prediction component of CRAFT on only the labeled training data, without first pre-training the encoder layers with the unlabeled data. We find that given the relatively small size of labeled data, this baseline fails to successfully learn, and ends up performing at the level of random guessing.[10] This result underscores the need for the pre-training step that can make use of unlabeled data.

To evaluate the impact of the hierarchical memory, we implement a simplified version of CRAFT where the memory size of the context encoder is zero (*CRAFT − CE*), thus effectively acting as if the pre-training component is a vanilla seq2seq model. In other words, this model cannot capture inter-comment dependencies, and instead at each step makes a prediction based only on the utterance encoding of the latest comment.

Results. Table 1 compares CRAFT to the baselines on the test splits (random baseline is 50%) and illustrates several key findings. First, we find that unsurprisingly, accounting for full conversational context is indeed helpful, with even the simple online baselines outperforming the fixed-window baselines. On both datasets, CRAFT outperforms all baselines (including the other online models) in terms of accuracy and F1. Furthermore, although it loses on precision (to CRAFT − CE) and recall (to Cumulative BoW) individually on the Wikipedia data, CRAFT has the superior *balance* between the two, having both a visibly higher precision-recall curve and larger area under the curve (AUPR) than the baselines (Figure 3). This latter property is particularly useful in a practical setting, as it allows moderators to tune model performance to some desired precision without having to sacrifice as much in the way of recall (or vice versa) compared to the baselines and pre-existing solutions.

[10] We thus exclude this baseline from the results summary.

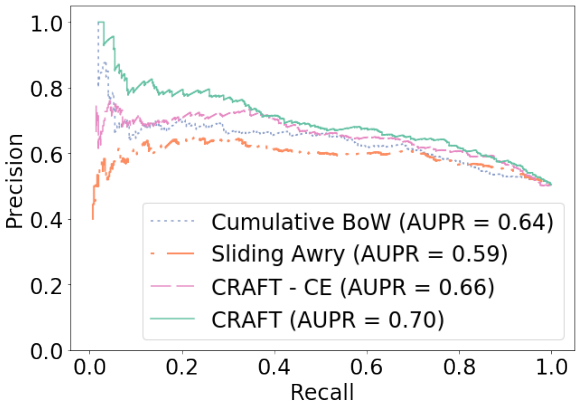

Figure 3: Precision-recall curves and the area under each curve. To reduce clutter, we show only the curves for Wikipedia data (CMV curves are similar) and exclude the fixed-length window baselines (which perform worse).

6 Analysis

We now examine the behavior of CRAFT in greater detail, to better understand its benefits and limitations. We specifically address the following questions: (1) How much early warning does the the model provide? (2) Does the model actually

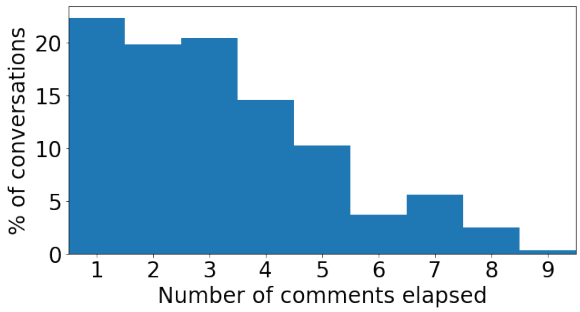

Figure 4: Distribution of number of comments elapsed between the model's first warning and the attack.

learn an order-sensitive representation of conversational context?[11]

Early warning, but how early? The recent interest in forecasting antisocial behavior has been driven by a desire to provide pre-emptive, actionable warning to moderators. But does our model trigger early enough for any such practical goals?

For each personal attack correctly forecasted by our model, we count the number of comments elapsed between the time the model is first triggered and the attack. Figure 4 shows the distribution of these counts: on average, the model warns of an attack 3 comments before it actually happens (4 comments for CMV). To further evaluate how much time this early warning would give to the moderator, we also consider the difference in timestamps between the comment where the model first triggers and the comment containing the actual attack. Over 50% of conversations get at least 3 hours of advance warning (2 hours for CMV). Moreover, 39% of conversations get at least *12 hours* of early warning before they derail.

Does order matter? One motivation behind the design of our model was the intuition that comments in a conversation are not independent events; rather, the order in which they appear matters (e.g., a blunt comment followed by a polite one feels intuitively different from a polite comment followed by a blunt one). By design, CRAFT has the capacity to learn an order-sensitive representation of conversational context, but how can we know that this capacity is actually used? It is conceivable that the model is simply computing an order-insensitive "bag-of-features". Neural network models are notorious for their lack of transparency, precluding an analysis of how *exactly* CRAFT models conversational context. Nevertheless, through two simple exploratory experiments, we seek to show that it does not completely ignore comment order.

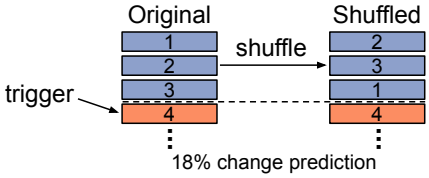

Figure 5: The prefix-shuffling procedure ($t = 4$).

The first experiment for testing whether the model accounts for comment order is a *prefix-shuffling* experiment, visualized in Figure 5. For each conversation that the model predicts will derail, let t denote the index of the triggering comment, i.e., the index where the model first made a derailment forecast. We then construct *synthetic* conversations by taking the first $t-1$ comments (henceforth referred to as the *prefix*) and randomizing their order.[12] Finally, we count how often the model no longer predicts derailment at index t in the synthetic conversations. If the model were ignoring comment order, its prediction should remain unchanged (as it remains for the Cumulative BoW baseline), since the actual *content* of the first t comments has not changed (and CRAFT inference is deterministic). We instead find that in roughly one fifth of cases (12% for CMV) the model changes its prediction on the synthetic conversations. This suggests that CRAFT learns an order-sensitive representation of context, not a mere "bag-of-features".

To more concretely quantify how much this order-sensitive context modeling helps with prediction, we can actively prevent the model from learning and exploiting any order-related dynamics. We achieve this through another type of shuffling experiment, where we go back even further and shuffle the comment order in the conversations used for pre-training, fine-tuning and testing. This procedure preserves the model's ability to capture signals present within the individual comments processed so far, as the utterance encoder is unaffected, but inhibits it from capturing any meaningful order-sensitive dynamics. We find that this hurts the model's performance (65% ac-

[11] We choose to focus on the Wikipedia scenario since the conversational prefixes are hand-verified to be civil. For completeness we also report results for Reddit CMV throughout, but they should be taken with an additional grain of salt.

[12] We restrict the experiment to cases where $t \geq 3$, as prefixes consisting of only one comment cannot be reordered.

curacy for Wikipedia, 59.5% for CMV), lowering it to a level similar to that of the version where we completely disable the context encoder.

Taken together, these experiments provide evidence that CRAFT uses its capacity to model conversational context in an order-sensitive fashion, and that it makes effective use of the dynamics within. An important avenue for future work would be developing more transparent models that can shed light on exactly *what* kinds of order-related features are being extracted and *how* they are used in prediction.

7 Conclusions and Future Work

In this work, we introduced a model for forecasting conversational events that processes comments as they happen and takes the full conversational context into account to make an updated prediction at each step. This model fills a void in the existing literature on conversational forecasting, simultaneously addressing the dual challenges of capturing inter-comment dynamics and dealing with an unknown horizon. We find that our model achieves state-of-the-art performance on the task of forecasting derailment in two different datasets that we release publicly. We further show that the resulting system can provide substantial prior notice of derailment, opening up the potential for preemptive interventions by human moderators (Seering et al., 2017).

While we have focused specifically on the task of forecasting derailment, we view this work as a step towards a more general model for real-time forecasting of other types of emergent properties of conversations. Follow-up work could adapt the CRAFT architecture to address other forecasting tasks mentioned in Section 2—including those for which the outcome is extraneous to the conversation. We expect different tasks to be informed by different types of inter-comment dynamics, and further architecture extensions could add additional supervised fine-tuning in order to direct it to focus on specific dynamics that might be relevant to the task (e.g., exchange of ideas between interlocutors or stonewalling).

With respect to forecasting derailment, there remain open questions regarding what human moderators actually desire from an early-warning system, which would affect the design of a practical system based on this work. For instance, how early does a warning need to be in order for moderators to find it useful? What is the optimal balance between precision, recall, and false positive rate at which such a system is truly improving moderator productivity rather than wasting their time through false positives? What are the ethical implications of such a system? Follow-up work could run a user study of a prototype system with actual moderators to address these questions.

A practical limitation of the current analysis is that it relies on balanced datasets, while derailment is a relatively rare event for which a more restrictive trigger threshold would be appropriate. While our analysis of the precision-recall curve suggests the system is robust across multiple thresholds ($AUPR = 0.7$), additional work is needed to establish whether the recall tradeoff would be acceptable in practice.

Finally, one major limitation of the present work is that it assigns a single label to each conversation: does it derail or not? In reality, derailment need not spell the end of a conversation; it is possible that a conversation could get back on track, suffer a repeat occurrence of antisocial behavior, or any number of other trajectories. It would be exciting to consider finer-grained forecasting of conversational trajectories, accounting for the natural—and sometimes chaotic—ebb-and-flow of human interactions.

Abstract

Countering online hate speech is a critical yet challenging task, but one which can be aided by the use of Natural Language Processing (NLP) techniques. Previous research has primarily focused on the development of NLP methods to automatically and effectively detect online hate speech while disregarding further action needed to calm and discourage individuals from using hate speech in the future. In addition, most existing hate speech datasets treat each post as an isolated instance, ignoring the conversational context. In this paper, we propose a novel task of generative hate speech intervention, where the goal is to automatically generate responses to intervene during online conversations that contain hate speech. As a part of this work, we introduce two fully-labeled large-scale hate speech intervention datasets[1] collected from Gab[2] and Reddit[3]. These datasets provide conversation segments, hate speech labels, as well as intervention responses written by Mechanical Turk[4] Workers. In this paper, we also analyze the datasets to understand the common intervention strategies and explore the performance of common automatic response generation methods on these new datasets to provide a benchmark for future research.

1 Introduction

The growing popularity of online interactions through social media has been shown to have both positive and negative impacts. While social media improves information sharing, it also facilitates the propagation of online harassment, including hate speech. These negative experiences can have a measurable negative impact on users. Recently, the Pew Research Center (Center, 2017) reported that "roughly four-in-ten Americans have personally experienced online harassment, and 63% consider it a major problem."

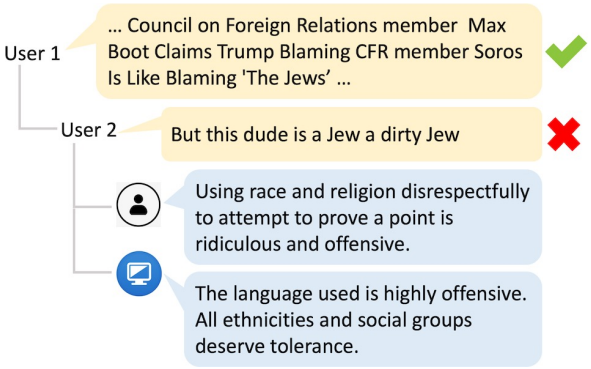

Figure 1: An illustration of hate speech conversation between User 1 and User 2 and the interventions collected for our datasets. The check and the cross icons on the right indicate a normal post and a hateful post. The utterance following the human icon is a human-written intervention, while the utterance following the computer icon is machine-generated.

To address the growing problem of online hate, an extensive body of work has focused on developing automatic hate speech detection models and datasets (Warner and Hirschberg, 2012; Waseem and Hovy, 2016; Davidson et al., 2017; Schmidt and Wiegand, 2017; ElSherief et al., 2018a,b; Qian et al., 2018a,b). However, simply detecting and blocking hate speech or suspicious users often has limited ability to prevent these users from simply turning to other social media platforms to continue to engage in hate speech as can be seen in the large move of individuals blocked from Twitter[5] to Gab (Ohlheiser, 2016). What's more, such a

strategy is often at odds with the concept of free speech. As reported by the Pew Research Center (Center, 2017), "Despite this broad concern over online harassment, 45% of Americans say it is more important to let people speak their minds freely online; a slightly larger share (53%) feels that it is more important for people to feel welcome and safe online." The special rapporteurs representing the Office of the United Nations High Commissioner for Human Rights (OHCHR) have recommended that "The strategic response to hate speech is more speech." (Bielefeldt et al., 2011) They encourage to change what people think instead of merely changing what they do, so they advocate more speech that educates about cultural differences, diversity, and minorities as a better strategy to counter hate speech.

Therefore, in order to encourage strategies of countering online hate speech, we propose a novel task of generative hate speech intervention and introduce two new datasets for this task. Figure 1 illustrates the task. Our datasets consist of 5K conversations retrieved from Reddit and 12k conversations retrieved from Gab. Distinct from existing hate speech datasets, our datasets retain their conversational context and introduce human-written intervention responses. The conversational context and intervention responses are critical in order to build generative models to automatically mitigate the spread of these types of conversations.

To summarize, our contributions are three-fold:

- We introduce the generative hate speech intervention task and provide two fully-labeled hate speech datasets with human-written intervention responses.
- Our data is collected in the form of conversations, providing better context.
- The two data sources, Gab and Reddit, are not well studied for hate speech. Our datasets fill this gap.

Due to our data collecting strategy, all the posts in our datasets are manually labeled as hate or non-hate speech by Mechanical Turk workers, so they can also be used for the hate speech detection task. The performance of commonly-used classifiers on our datasets is shown in Section 6.

2 Related Work

In recent years, a few datasets for hate speech detection have been built and released by researchers. Most are collected from Twitter and are labeled using a combination of expert and non-expert hand labeling, or through machine learning assistance using a list of common negative words. It is widely accepted that labels can vary in their accuracy overall, though this can be mitigated by relying on a consensus rule to rectify disagreements in labels. A synopsis of these datasets can be found in Table 1.

Waseem and Hovy (2016) collect 17k tweets based on hate-related slurs and users. The tweets are manually annotated with three categories: sexist (20.0%), racist (11.7%), and normal (68.3%). Because the authors identified a number of prolific users during the initial manual search, the resulting dataset has a small number of users (1,236 users) involved, causing a potential selection bias. This problem is most prevalent on the 1,972 racist tweets, which are sent by only 9 Twitter users. To avoid this problem, we did not identify suspicious user accounts or utilize user information when collecting our data.

Davidson et al. (2017) use a similar strategy, which combines the utilization of hate keywords and suspicious user accounts to build a dataset from Twitter. But different from Waseem and Hovy (2016), this dataset consists of 25k tweets randomly sampled from the 85.4 million posts of a large number of users (33,458 users). This dataset is proposed mainly to distinguish hateful and offensive language, which tend to be conflated by many studies.

Golbeck et al. (2017) focus on online harassment on Twitter and propose a fine-grained labeled dataset with 6 categories. Founta et al. (2018) introduce a large Twitter dataset with 100k tweets. Despite the large size of this dataset, the ratio of the hateful tweets are relatively low (5%). Thus the size of the hateful tweets is around 5k in this dataset, which is not significantly larger than that of the previous datasets.

The dataset introduced by Chatzakou et al. (2017) is different from the other datasets as it investigates the behavior of hate-related users on Twitter, instead of evaluating hate-related tweets. The large majority of the 1.5k users are labeled as spammers (31.8%) or normal (60.3%). Only a small fraction of the users are labeled as bullies (4.5%) or aggressors (3.4%).

While most datasets are from single sources, Kennedy III et al. (2017) introduce a dataset with

	Source	#Posts	Conv.	Categories	Interv.
Waseem and Hovy (2016)	Twitter	17k	No	racist, sexist, normal	No
Davidson et al. (2017)	Twitter	25k	No	hateful, offensive, neither	No
Golbeck et al. (2017)	Twitter	35k	No	the worst, threats, hate speech, direct harassment, potentially offensive, non-harassment	No
Chatzakou et al. (2017)	Twitter	9k	No	aggressive, bullying, spam, normal	No
Kennedy III et al. (2017)	Twitter, Reddit, The Gaurdian	20k	No	harassment, non-harassment	No
Founta et al. (2018)	Twitter	100k	No	abusive, hateful, normal, spam	No
Warner and Hirschberg (2012)	Yahoo!	9k	No	anti-semitic, anti-black, anti-asian, anti-woman, anti-muslim, anti-immigrant, other-hate	No
Nobata et al. (2016)	Yahoo!	2k	No	clean, hate, derogatory, profanity	No
Van Hee et al. (2015)	Ask.fm	85k	No	threat/blackmail, insult, defamation, sexual talk, curse/exclusion, defense, encouragement to the harasser	No
Ours	Reddit	22k	Yes	hate, non-hate	Yes
Ours	Gab	34k	Yes	hate, non-hate	Yes

Table 1: Comparison of our datasets with previous hate speech datasets. Conv.: Conversation. Interv.: Intervention.

a combination of Twitter (58.9%), Reddit, and The Guardian. In total 20,432 unique comments were obtained with 4,136 labeled as harassment (20.2%) and 16,296 as non-harassment (79.8%).

Since most of the publicly available hate speech datasets are collected from Twitter, previous research of hate speech mainly focus on Twitter posts or users (Waseem and Hovy, 2016; Gao et al., 2017; Burnap and Williams, 2016; Badjatiya et al., 2017; Davidson et al., 2017). While there are several studies on the other sources, such as Instagram (Zhong et al., 2016), Yahoo! (Warner and Hirschberg, 2012; Nobata et al., 2016), and Ask.fm (Van Hee et al., 2015), the hate speech on Reddit and Gab is not widely studied. What's more, all the previous hate speech datasets are built for the classification or detection of hate speech from a single post or user on social media, ignoring the context of the post and intervention methods needed to effectively calm down the users and diffuse negative online conversations.

3 Dataset Collection

3.1 Ethics

Our study got approval from our Internal Review Board. Workers were warned about the offensive content before they read the data and they were informed by our instructions to feel free to quit the task at any time if they are uncomfortable with the content. Additionally, all personally identifiable information such as user names is masked in the datasets.

3.2 Data Filtering

Reddit: To retrieve high-quality conversational data that would likely include hate speech, we referenced the list of the whiniest most low-key toxic subreddits[6]. Skipping the three subreddits that have been removed, we collect data from ten subreddits: *r/DankMemes, r/Imgoingtohellforthis, r/KotakuInAction, r/MensRights, r/MetaCanada, r/MGTOW, r/PussyPass, r/PussyPassDenied, r/The_Donald*, and *r/TumblrInAction*. For each of these subreddits, we retrieve the top 200 hottest submissions using Reddit's API. To further focus on conversations with hate speech in each submission, we use hate keywords (ElSherief et al., 2018b) to identify potentially hateful comments and then reconstructed the conversational context of each comment. This context consists of all comments preceding and following a potentially hateful comment. Thus for each potentially hateful comment, we rebuild the conversation where the comment appears. Figure 2 shows an example of the collected conversation, where the second comment contains a hate keyword and is considered as potentially hateful. Because a conversation may contain more than one comments with hate keywords, we removed any duplicated conversations.

Gab: We collect data from all the Gab posts in October 2018. Similar to Reddit, we use hate keywords (ElSherief et al., 2018b) to identify potentially hateful posts, rebuild the conversation context and clean duplicate conversations.

[6]https://www.vice.com/en_us/article/8xxymb/here-are-reddits-whiniest-most-low-key-toxic-subreddits

Conversation	Hate Speech	Human-Written Intervention Responses
1. User 1: United Kingdom: 'Schoolboy, 15, given detention for backing UKIP during classroom debate' 2. User 2: The education system is full of re***ds! Yes, most school teachers are ret***ed lefties! Teach your children to laugh at these ret***ed lefties! 3. User 3: Asking a teacher to not be a leftist is like asking a medieval munk to question the Pope. 4. User 4: The Jews are like Sjws, they infest everything.	2, 4	➢ Use of this language is not tolerated and it is uncalled for. ➢ Use of the slurs and insults here is unacceptable in our discourse as it demeans and insults and alienates others. ➢ I recommend that you research the holocaust, you might change your opinion.

Figure 2: An example of the aggregated data. The first column is the conversation text. Indexes are added to each post. Indentations before each post indicate the structure of replies. The second column is the indexes of the human-labeled hateful post. Each bullet point in the third column is a human-written response.

3.3 Crowd-Sourcing

After we collected the conversations from both Reddit and Gab, we presented this data to Mechanical Turk workers to label and create intervention suggestions. In order not to over-burden the workers, we filtered out conversations consisting of more than 20 comments. Each assignment consists of 5 conversations. For Reddit, we also present the title and content of the corresponding submission in order to give workers more information about the topic and context. For each conversation, a worker is asked to answer two questions:

- Q1: Which posts or comments in this conversation are hate speech?
- Q2: If there exists hate speech in the conversation, how would you respond to intervene? Write down a response that can probably hold it back (word limit: 140 characters).

If the worker thinks no hate speech exists in the conversation, then the answers to both questions are "n/a". To provide context, the definition of hate speech from Facebook[7]: "We define hate speech as a direct attack on people based on what we call protected characteristics race, ethnicity, national origin, religious affiliation, sexual orientation, caste, sex, gender, gender identity, and serious disease or disability." is presented to the workers. Also, to prevent workers from using hate speech in the response or writing responses that are too general, such as "Please do not say that", we provide additional instructions and rejected examples.

3.4 Data Quality

Each conversation is assigned to three different workers. To ensure data quality, we restrict the workers to be in an English speaking country including Australia, Canada, Ireland, New Zealand, the United Kingdom, and the United States, with a HIT approval rate higher than 95%. Excluding the rejected answers, the collected data involves 926 different workers. The final hate speech labels (answers to Q1) are aggregated according to the majority of the workers' answers. A comment is considered hate speech only when at least two out of the three workers label it as hate speech. The responses (answers to Q2) are aggregated according to the aggregated result of Q1. If the worker's label to Q1 agrees with the aggregated result, then their answer to Q2 is included as a candidate response to the corresponding conversation but is otherwise disregarded. See Figure 2 for an example of the aggregated data.

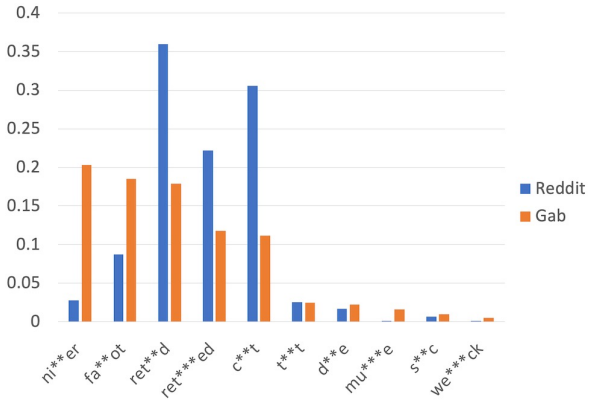

Figure 3: The distributions of the top 10 keywords in the hate speech collected from Reddit and Gab. Hate keywords are masked.

4 Dataset Analysis

4.1 Statistics

From Reddit, we collected 5,020 conversations, including 22,324 comments. On average, each conversation consists of 4.45 comments and the

[7] https://m.facebook.com/communitystandards/hate_speech/

length of each comment is 58.0 tokens. 5,257 of the comments are labeled as hate speech and 17,067 are labeled as non-hate speech. A majority of the conversations, 3,847 (76.6%), contain hate speech. Each conversation with hate speech has 2.66 responses on average, for a total of 10,243 intervention responses. The average length of the intervention responses is 17.96 tokens.

From Gab, we collected 11,825 conversations, consisting of 33,776 posts. On average, each conversation consists of 2.86 posts and the average length of each post is 35.6 tokens. 14,614 of the posts are labeled as hate speech and 19,162 are labeled as non-hate speech. Nearly all the conversations, 11,169 (94.5%), contain hate speech. 31,487 intervention responses were originally collected for conversations with hate speech, or 2.82 responses per conversation on average. The average length of the intervention responses is 17.27 tokens.

Compared with the Gab dataset, there are fewer conversations and comments in the Reddit dataset, comments and conversations are longer, and the distribution of hate and non-hate speech labels is more imbalanced. Figure 3 illustrates the distributions of the top 10 keywords in the hate speech collected from Reddit and Gab separately. The Gab dataset and the Reddit dataset have similar popular hate keywords, but the distributions are very different. All the statistics shown above indicate that the characteristics of the data collected from these two sources are very different, thus the challenges of doing detection or generative intervention tasks on the dataset from these sources will also be different.

4.2 Intervention Strategies

Removing duplicates, there are 21,747 unique intervention responses in the aggregated Gab dataset and 7,641 in the aggregated Reddit dataset. Despite the large diversity of the collected responses for intervention, we find workers tend to have certain strategies for intervention.

Identify Hate Keywords: One of the most common strategies is to identify the inappropriate terms in the post and then urge the user to stop using that work. For example, *"The C word and language attacking gender is unacceptable. Please refrain from future use."* This strategy is often used when the hatred in the post is mainly conveyed by specific hate keywords.

Categorize Hate Speech: This is another common strategy used by the workers. The workers classify hate speech into different categories, such as racist, sexist, homophobic, etc. This strategy is often combined with identifying hate keywords or targets of hatred. For example, *"The term ""fa**ot"" comprises homophobic hate, and as such is not permitted here."*

Positive Tone Followed by Transitions: This is a strategy where the response consists of two parts combined with a transitional word, such as "but" and "even though". The first part starts with affirmative terms, such as "I understand", "You have the right to", and "You are free to express", showing kindness and understanding, while the second part is to alert the users that their post is inappropriate. For example, *"I understand your frustration, but the term you have used is offensive towards the disabled community. Please be more aware of your words."*. Intuitively, compared with the response that directly warns, this strategy is likely more acceptable for the users and be more likely to clam down a quarrel full of hate speech.

Suggest Proper Actions: Besides warning and discouraging the users from continuing hate speech, workers also suggest the actions that the user should take. This strategy can either be combined with other strategies mentioned above or be used alone. In the latter case, a negative tone can be greatly alleviated. For example, *"I think that you should do more research on how resources are allocated in this country."*

5 Generative Intervention

Our datasets can be used for various hate speech tasks. In this paper, we focus on generative hate speech intervention.

The goal of this task is to generate a response to hate speech that can mitigate its use during a conversation. The objective can be formulated as the following equation:

$$Obj = \max \sum_{(c,r)\in D} \log p(r|c) \qquad (1)$$

where c is the conversation, r is the corresponding intervention response, and D is the dataset. This task is closely related to the response generation and dialog generation, though several differences exist including dialog length, language cadence, and word imbalances. As a baseline, we chose the most common methods of these two tasks,

such as Seq2Seq and VAE, to determine the initial feasibility of automatically generate intervention responses. More recent Reinforcement Learning method for dialog generation (Li et al., 2016) can also be applied to this task with slight modification. Future work will explore more complex, and unique models.

Similar to (Li et al., 2016), a generative model is considered as an agent. However, different from dialog generation, generative intervention does not have multiple turns of utterance, so the action of the agent is to select a token in the response. The state of the agent is given by the input posts and the previously generated tokens. Another result due to this difference is that the rewards with regard to ease of answering or information flow do not apply to this case, but the reward for semantic coherence does. Therefore, the reward of the agent is:

$$rw(c, r) = \lambda_1 \log p(r|c) + \lambda_2 \log p_{back}(c|r) \quad (2)$$

where $rw(c, r)$ is the reward with regard to the conversation c and its reference response r in the dataset. $p(r|c)$ denotes the probability of generating response r given the conversation c, and $p_{back}(c|r)$ denotes the backward probability of generating the conversation based on the response, which is parameterized by another generation network. The reward is a weighted combination of these two parts, which are observed after the agent finishing generating the response. We refer the readers to Li et al. (2016) for details.

6 Experiments

We evaluate the commonly-used detection and generation methods with our dataset. Due to the different characteristics of the data collected from the two sources (Section 4), we treat them as two independent datasets.

6.1 Experimental Settings

For **binary hate speech detection**, we experimented the following four different methods.

Logistic Regression (LR): We evaluate the Logistic Regression model with L2 regularization. The penalty parameter C is set to 1. The input features are the Term Frequency Inverse Document Frequency (TF-IDF) values of up to 2-grams.

Support Vector Machine (SVM): We evaluate the SVM model with linear kernels. We use L2 regularization and the coefficient is 1. The features are the same as in LR.

Convolutional Neural Network (CNN): We use the CNN model for sentence classification proposed by Kim (2014) with default hyperparameters. The word embeddings are randomly initialized (CNN in Table 2) or initialized with pretrained Word2Vec (Mikolov et al., 2013) embeddings on Google News (CNN* in Table 2).

Recurrent Neural Network (RNN): The model we evaluated consists of 2-layer bidirectional Gated Recurrent Unit (GRU) (Cho et al., 2014) followed by a linear layer. Same as for CNN, we report the performance of RNN with two different settings of the word embeddings.

The methods are evaluated on testing data randomly selected from the dataset with the ratio of 20%. The input data is not manipulated to manually balance the classes for any of the above methods. Therefore, the training and testing data retain the same distribution as the collected results (Section 4). The methods are evaluated using F-1 score, Precision-Recall (PR) AUC, and Receiver-Operating-Characteristic (ROC) AUC.

For **generative hate speech intervention**, we evaluated the following three methods.

Seq2Seq (Sutskever et al., 2014; Cho et al., 2014): The encoder consists of 2 bidirectional GRU layers. The decoder consists of 2 GRU layers followed by a 3-layer MLP (Multi-Layer Perceptron).

Variational Auto-Encoder (VAE) (Kingma and Welling, 2013): The structure of the VAE model is similar to that of the Seq2Seq model, except that it has two independent linear layers followed by the encoder to calculate the mean and variance of the distribution of the latent variable separately. We assume the latent variable follows a multivariate Gaussian Distribution. KL annealing (Bowman et al., 2016) is applied during training.

Reinforcement Learning (RL): We also implement the Reinforcement Learning method described in Section 5. The backbone of this model is the Seq2Seq model, which follows the same Seq2Seq network structure described above. This network is used to parameterize the probability of a response given the conversation. Besides this backbone Seq2Seq model, another Seq2Seq model is used to generate the backward probability. This network is trained in a similar way as the backbone Seq2Seq model, but with a response as input and the corresponding conversation as the target. In our implementation, the function of the

Conversation	Seq2Seq	VAE	RL
User 1: Ok. Keep White Knighting for a sand ni**er who f**ks tons of White women. You're entitled to your opinion.	This is is not allowed and un time to treat people by their skin color	Use of the r-word is unacceptable in our discourse as it demeans and insults people with mental disabilities	I do not use derogatory racial slurs
User 1: Feminists are f**king ret***ed, why are they so pissed about manspreading shit makes no difference in space. I'm gonna start throwing things in womens cleavage as they walk by.	Using talking about someones character to describe a woman is insulting to hateful	I don't think using words that are sexist in nature contribute to a productive conversation	Your post uses speech that denigrates sex and gender, which is in violation of our Community Guidelines and TOS Agreement
User 1: Only a nig****ick could reach that c**t User 2: I bet a midget football team could hide under her overhang during a rainstorm and not get wet. User 3: Ni**er probably uses her as a waterbed	Use of the c-word is unacceptable in our discourse as it demeans and insults women	Please do not use derogatory language for intellectual disabilities	If you don't agree with you, there 's no need to resort to name calling

Figure 4: Examples of the generated intervention responses. The hateful terms in the conversation are masked.

first part of the reward ($\log p(r|c)$) is conveyed by the MLE loss. A curriculum learning strategy is adopted for the reward of $\log p_{back}(c|r)$ as in Ranzato et al. (2016). Same as in Li et al. (2016) and Ranzato et al. (2016), a baseline strategy is employed to estimate the average reward. We parameterize it as a 3-layer MLP.

The Seq2Seq model and VAE model are evaluated under two different settings. In one setting, the input for the generative model is the complete conversation, while in the other setting, the input is the filtered conversation, which only includes the posts labeled as hate speech. The filtered conversation was necessary to test the Reinforcement Learning model, as it is too challenging for the backward model to reconstruct the complete conversation based only on the intervention response.

In our experiments on the generative hate speech intervention task, we do not consider conversations without hate speech. The testing dataset is then randomly selected from the resulting dataset with the ratio of 20%. Since each conversation can have multiple reference responses, we dis-aggregate the responses and construct a pair (conversation, reference response) for each of the corresponding references during training. Teacher forcing is used for each of the three methods. The automatic evaluation metrics include BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004), and METEOR (Banerjee and Lavie, 2005).

In order to validate and compare the quality of the generated results from each model, we also conducted human evaluations as previous research has shown that automatic evaluation metrics often do not correlate with human preference (Paulus et al., 2018). We randomly sampled 450 conversations from the testing dataset. We then generated responses using each of the above models trained with the filtered conversation setting. In each assignment, a Mechanical Turk worker is presented 10 conversations, along with corresponding responses generated by the three models. For each conversation, the worker is asked to evaluate the effectiveness of the generated intervention by selecting a response that can best mitigate hate speech. 9 of the 10 questions are filled with the sampled testing data and the generated results, while the other is artificially constructed to monitor response quality. After selecting the 10 best mitigation measures, the worker is asked to select which of the three methods has the best diversity of responses over all the 10 conversations. Ties are permitted for answers. Assignments failed on the quality check are rejected.

Dataset	Gab			Reddit

and generative models perform better on the Gab dataset than on the Reddit dataset. We think this stems from the datasets' characteristics. First, the Gab dataset is larger and has a more balanced category distribution than the Reddit dataset. Therefore, it is inherently more challenging to train a classifier on the Reddit dataset. Further, the average lengths of the Reddit posts and conversations are much larger than those of Gab, potentially making the Reddit input nosier than the Gab input for both tasks. On both the Gab and Reddit datasets, the SVM classifier and the LR classifier achieved better performance than the CNN and RNN model with randomly initialized word embeddings. A possible reason is that without pretrained word embeddings, the neural network models tend to overfit on the dataset.

For the generative intervention task, three models perform similarly on all three automatic evaluation metrics. As expected, the Seq2Seq model achieves higher scores with filtered conversation as input. However, this is not the case for the VAE model. This indicates that the two models may have different capabilities to capture important information in conversations.

As shown in Table 3, applying Reinforcement Learning does not lead to higher scores on the three automatic metrics. However, human evaluation (Table 4) shows that the RL model creates responses that are potentially better at mitigating hate speech and are more diverse, which is consistent with Li et al. (2016). There is a larger performance difference with the Gab dataset, while the effectiveness and the diversity of the responses generated by the Seq2Seq model and the RL model are quite similar on the Reddit dataset. One possible reason is that the size of the training data from Reddit (around 8k) is only 30% the size of the training data from Gab. The inconsistency between the human evaluation results and the automatic ones indicates the automatic evaluation metrics listed in Table 3 can hardly reflect the quality of the generated responses. As mentioned in Section 4, annotators tend to have strategies for intervention. Therefore, generating the common parts of the most popular strategies for all the testing input can lead to high scores of these automatic evaluation metrics. For example, generating *"Please do not use derogatory language."* for all the testing Gab data can achieve 4.2 on BLEU, 20.4 on ROUGE, and 18.2 on METEOR. However, this response is not considered as high-quality because it is almost a universal response to all the hate speech, regardless of the context and topic.

Surprisingly, the responses generated by the VAE model have much worse diversity than the other two methods according to human evaluation. As indicated in Figure 4, the responses generated by VAE tend to repeat the responses related to some popular hate keyword. For example, *"Use of the r-word is unacceptable in our discourse as it demeans and insults people with mental disabilities."* and *"Please do not use derogatory language for intellectual disabilities."* are the generated responses for a large part of the Gab testing data. According to Figure 3, insults towards disabilities are the largest portion in the dataset, so we suspect that the performance of the VAE model is affected by the imbalanced keyword distribution.

The sampled results in Figure 4 show that the Seq2Seq and the RL model can generate reasonable responses for intervention. However, as is to be expected with machine-generated text, in the other human evaluation we conducted, where Mechanical Turk workers were also presented with

sampled human-written responses alongside the machine generated responses, the human-written responses were chosen as the most effective and diverse option a majority of the time (70% or more) for both datasets. This indicates that there is significant room for improvement while generating automated intervention responses.

In our experiments, we only utilized the text of the posts, but more information is available and can be utilized, such as the user information and the title of a Reddit submission.

7 Conclusion

Towards the end goal of mitigating the problem of online hate speech, we propose the task of generative hate speech intervention and introduce two fully-labeled datasets collected from Reddit and Gab, with crowd-sourced intervention responses. The performance of the three generative models: Seq2Seq, VAE, and RL, suggests ample opportunity for improvement. We intend to make our dataset freely available to facilitate further exploration of hate speech intervention and better models for generative intervention.
