This paper introduces 2-hop distant supervision for relation extraction, based on the intuition that entity pairs in relational Web tables often share common relations. Given a target entity pair, we define and find its anchor entity pairs via Web tables and collect all sentences that mention the anchor entity pairs to help relation prediction. We develop a new neural RE method `REDS2` in the multi-instance learning paradigm which fuses information from 1-hop DS and 2-hop DS using a hierarchical model structure, and substantially outperforms existing RE methods on a benchmark dataset. Interesting future work includes: (1) Given that information from 2-hop DS is redundant and noisy, we can explore smarter sampling and/or better bag-level aggregation methods to capture the most representative information. (2) Metadata in Web tables like headers and column names also contain rich information, which can be incorporated to further improve RE performance.

Abstract

Rich entity representations are useful for a wide class of problems involving entities. Despite their importance, there is no standardized benchmark that evaluates the overall quality of entity representations. In this work, we propose EntEval: a test suite of diverse tasks that require nontrivial understanding of entities including entity typing, entity similarity, entity relation prediction, and entity disambiguation. In addition, we develop training techniques for learning better entity representations by using natural hyperlink annotations in Wikipedia. We identify effective objectives for incorporating the contextual information in hyperlinks into state-of-the-art pretrained language models (Peters et al., 2018a) and show that they improve strong baselines on multiple EntEval tasks.[1]

1 Introduction

Entity representations play a key role in numerous important problems including language modeling (Ji et al., 2017), dialogue generation (He et al., 2017), entity linking (Gupta et al., 2017), and story generation (Clark et al., 2018). One successful line of work on learning entity representations has been learning *static* embeddings: that is, assign a unique vector to each entity in the training data (Gupta et al., 2017; Yamada et al., 2016, 2017). While these embeddings are useful in many applications, they have the obvious drawback of not accommodating unknown entities. Another limiting factor is the lack of an evaluation benchmark: it is often difficult to know which entity representations are better for which tasks.

We introduce EntEval: a carefully designed benchmark for holistically evaluating entity representations. It is a test suite of diverse tasks that require nontrivial understanding of entities, including entity typing, entity similarity, entity relation prediction, and entity disambiguation. Motivated by the recent success of contextualized word representations (henceforth: CWRs) from pretrained models (McCann et al., 2017; Peters et al., 2018a; Devlin et al., 2018; Yang et al., 2019; Liu et al., 2019b), we propose to encode the mention context or the description to dynamically represent an entity. In addition, we perform an in-depth comparison of ELMo and BERT-based embeddings and find that they show different characteristics on different tasks. We analyze each layer of the CWRs and make the following observations:

- The dynamically encoded entity representations show a strong improvement on the entity disambiguation task compared to prior work using static entity embeddings.
- BERT-based entity representations require further supervised training to perform well on downstream tasks, while ELMo-based representations are more capable of performing zero-shot tasks.
- In general, higher layers of ELMo and BERT-based CWRs are more transferable to EntEval tasks.

To further improve contextualized and descriptive entity representations (CER/DER), we leverage natural hyperlink annotations in Wikipedia. We identify effective objectives for incorporating the contextual information in hyperlinks and improve ELMo-based CWRs on a variety of entity related tasks.

2 Related Work

EntEval and the training objectives considered in this work are built on previous works that involve reasoning over entities. We give a brief overview of relevant works.

Entity linking/disambiguation. Entity linking is a fundamental task in information extraction with a wealth of literature (He et al., 2013; Guo and Barbosa, 2014; Ling et al., 2015; Huang et al., 2015; Francis-Landau et al., 2016; Le and Titov, 2018; Martins et al., 2019). The goal of this task is to map a mention in context to the corresponding entity in a database. A natural approach is to learn entity representations that enable this mapping. Recent works focused on learning a fixed embedding for each entity using Wikipedia hyperlinks (Yamada et al., 2016; Ganea and Hofmann, 2017; Le and Titov, 2019). Gupta et al. (2017) additionally train context and description embeddings jointly, but this mainly aims to improve the quality of the fixed entity embeddings rather than using the context and description embeddings directly; we find that their context and description encoders perform poorly on EntEval tasks.

A closely related concurrent work by (Logeswaran et al., 2019) jointly encodes a mention in context and an entity description from Wikia to perform zero-shot entity linking. In contrast, here we seek to pretrain a general purpose entity representations that can function well either given or not given entity descriptions or mention contexts.

Other entity-related tasks involve entity typing (Yaghoobzadeh and Schütze, 2015; Murty et al., 2017; Del Corro et al., 2015; Rabinovich and Klein, 2017; Choi et al., 2018; Onoe and Durrett, 2019; Obeidat et al., 2019) and coreference resolution (Durrett and Klein, 2013; Wiseman et al., 2016; Lee et al., 2017; Webster et al., 2018; Kantor and Globerson, 2019).

Evaluating pretrained representations. Recent work has sought to evaluate the knowledge acquired by pretrained language models (Shi et al., 2016; Adi et al., 2017; Belinkov et al., 2017; Peters et al., 2018b; Conneau et al., 2018; Conneau and Kiela, 2018; Wang et al., 2018; Liu et al., 2019a; Chen et al., 2019a, *inter alia*). In this work, we focus on evaluating their capabilities in modeling entities.

Part of EntEval involves evaluating world knowledge about entities, relating them to fact checking (Vlachos and Riedel, 2014; Wang, 2017; Thorne et al., 2018; Yin and Roth, 2018; Chen et al., 2019b), and commonsense learning (Angeli and Manning, 2014; Bowman et al., 2015; Li et al., 2016; Mihaylov et al., 2018; Zellers et al., 2018; Trinh and Le, 2018; Talmor et al., 2019; Zellers et al., 2019; Sap et al., 2019; Rajani et al., 2019). Another related line of work is to integrate entity-related knowledge into the training of language models (Logan et al., 2019; Zhang et al., 2019; Sun et al., 2019).

Contextualized word representations. Contextualized word representations and pretrained language representation models, such as ELMo (Peters et al., 2018a) and BERT (Devlin et al., 2018), are powerful pretrained models that have been shown to be effective for a variety of downstream tasks such as text classification, sentence relation prediction, named entity recognition, and question answering. Recent work has sought to evaluate the knowledge acquired by such models (Shi et al., 2016; Adi et al., 2017; Belinkov et al., 2017; Conneau et al., 2018; Conneau and Kiela, 2018; Liu et al., 2019a). In this work, we focus on evaluating their capabilities in modeling entities.

3 EntEval

We are interested in two approaches: contextualized entity representations (henceforth: CER) and descriptive entity representations (henceforth: DER), both encoding fixed-length vector representations for entities.

The contextualized entity representations encodes an entity based on the context it appears regardless of whether the entity is seen before. The motivation behind contextualized entity representations is that we want an entity encoder that does not depend on entries in a knowledge base, but is capable of inferring knowledge about an entity from the context it appears.

As opposed to contextualized entity representations, descriptive entity representations do rely on entries in Wikipedia. We use a model-specific function f to obtain a fixed-length vector representation from the entity's textual description.

To evaluate CERs and DERs, we propose a wide range of entity related tasks. Since our purpose is for examining the learned entity representations, we only use a linear classifier and freeze the entity representations when performing the follow-

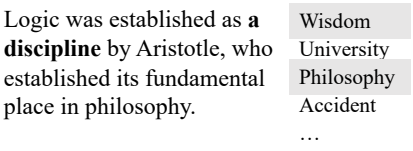

Figure 1: An example taken from ET. Targeted entity mention is bold. Candidate categories are on the right. Gold standard categories are in gray.

ing tasks. Unless otherwise noted, when the task involves a pair of entities, the input to the classifier are the entity representations x_1 and x_2, concatenated with their element-wise product and absolute difference: $[x_1, x_2, x_1 \odot x_2, |x_1 - x_2|]$. This input format has been used in SentEval (Conneau and Kiela, 2018).

The datasets used in EntEval tasks are summarized in table 1. It shows the number of instances in train/valid/test split for each dataset, and the number of target classes if this is a classification task. We describe the proposed tasks in the following subsections.

3.1 Entity Typing (ET)

The task of entity typing (ET) is to assign types to an entity given only the context of the entity mention. ET is context-sensitive, making it an effective approach to probe the knowledge of context encoded in pretrained representations. For example, in the sentence "Bill Gates has donated billions to eradicate malaria", "Bill Gates" has the type of "philanthropist" instead of "inventor" (Choi et al., 2018). In this task, we will contextualized entity representations, followed by a linear layer to make predictions. We use the annotated ultra-fine entity typing dataset of Choi et al. (2018) with standard data splits. As shown in Figure 1, there can be multiple labels for an instance. We use binary log loss for training using all positive and negative entity types, and report F_1 score. Thresholds are tuned based on validation set accuracy.

3.2 Coreference Arc Prediction (CAP)

Given two entities and the associated context, the task is to determine whether they refer to the same entity. Solving this task may require the knowledge of entities. For example, in the sentence "Revenues of \$14.5 billion were posted by Dell_1. The company_1 ...", there is no prior context of "Dell", so having known "Dell" is a company instead of the people "Michael Dell" will surely benefit the model (Durrett and Klein, 2014). Unlike other tasks, coreference typically involves longer context. To restrict the effect of broad context, we only keep two groups of coreference arcs from smaller context. One includes mentions that are in the same sentence ("same") for examining the model capability of encoding local context. The other includes mentions that are in consecutive sentences ("next") for the broader context. We create this task from the PreCo dataset (Chen et al., 2018), which has mentions annotated even when they are not part of coreference chains. We filter out instances in which both mentions are pronouns. All non-coreferent mention pairs are considered to be negative samples.

To make this task more challenging, for each instance we compute cosine similarity of mentions by averaging GloVe word vectors. We group the instances into bins by cosine similarity, and randomly select the same number of positive and negative instances from each bin to ensure that models do not solve this task by simply comparing similarity of mention names.

We use the contextualized entity representations of the two mentions to infer coreference arcs with supervised training and report the averaged accuracy of "same" and "next".

3.3 Entity Factuality Prediction (EFP)

The entity factuality prediction (EFP) task involves determining the correctness of statements regarding entities. We use the manually-annotated FEVER dataset (Thorne et al., 2018) for this task. FEVER is a task to verify whether a statement is supported by evidences. The original FEVER dataset includes three classes, namely "Supports", "Refutes", and "NotEnoughInfo" and evidences are additionally available for each instance. As our purpose is to examine the knowledge encoded in entity representations, we discard the last category ("NotEnoughInfo") and the evidence. In rare cases, instances in FEVER may include multiple entity mentions, so we randomly pick one. We randomly sample 10000, 2000, and 2000 instances for our training, validation, and test sets, respectively.

In this task, entity representations can be obtained either by contextualized entity representations or descriptive entity representations. In practice, we observe descriptive entity representations give better performance, which presumably is be-

	CAP		CERP	EFP	ET	KORE	WikiSRS		ERT	Rare	CoNLL

Score	Entity Name
-	Apple Inc.
20	Steve Jobs
...	...
11	Microsoft
...	...
1	Ford Motor Company

Table 2: An example from KORE. The task is to rank the candidate entities by similarity.

cause these statements are more similar to descriptions than entity mentions. As shown in Figure 2, without providing additional evidences, solving this task requires knowledge of entities encoded in representations. We directly use entity representations as input to the classifier.

3.4 Contexualized Entity Relationship Prediction (CERP)

The task of contexualized entity relationship prediction (CERP) modeling determines the connection between two entities appeared in the same context. We use sentences from ConceptNet (Speer et al., 2017) with automatically parsed mentions and templates used to construct the dataset. We filter out non-English concepts and relations such as 'related', 'translation', 'synonym', and 'likely to find' since we seek to evaluate more complicated knowledge of entities encoded in representations. We further filter out non-entity mentions and entities with type 'DATE', 'TIME', 'PERCENT', 'MONEY', 'QUANTITY', 'ORDINAL', and 'CARDINAL' according to SpaCy (Honnibal and Montani, 2017). After filtering, we have 13374 assertions.

Negative samples are generated based on the following rules:

1. For each relationship, we replace an entity with similar negative entities based on cosine similarity of averaged GloVe embeddings (Pennington et al., 2014).
2. We change the relationship in positive samples from affirmation to negation (e.g., 'is' to 'is not'). These serve as negative samples.
3. We further sample positive samples from (1) in an attempt to prevent the 'not' token from being biased towards negative samples. Therefore, for negative samples we get from (1), we change the relationship from affirmation to negation as in (2) to get positive samples.

For example, let 'A is B' be the positive sample. (1) changes it to 'C is B' which serves as a negative sample and (2) changes it to 'A is not B' as another negative sample. (3) changes it to 'C is not B' as a positive example. In the end, we randomly sample 7000 instances from each class. This ends up yielding a 10000/2000/2000 train/dev/test dataset. As shown in Figure 3, this task cannot be solved by relying on surface form of sentences, instead it requires the input representations to encode knowledge of entities based on the context.

We use contextualized entity representations in this task.

3.5 Entity Similarity and Relatedness (ESR)

Given two entities with their descriptions from Wikipedia, the task is to determine their similarity or relatedness. After the entity descriptions are encoded into vector representations, we compute their cosine similarity as predictions. We use the KORE (Hoffart et al., 2012) and Wik-

iSRS (Newman-Griffis et al., 2018) datasets in this task. Since the original datasets only provide entity names, we automatically add Wikipedia descriptions to each entity and manually ensure that every entity is matched to a Wikipedia description. We use Spearman's rank correlation coefficient between our computed cosine similarity and the gold standard similarity/relatedness scores to measure the performance of entity representations.

As KORE does not provide similarity scores of entity pairs, but simply ranks the candidate entities by their similarities to a target entity, we assign scores from 20 to 1 accordingly to each entity in the order of similarity. Table 2 shows an example from KORE. The fact that "Apple Inc." is more related to "Steve Jobs" than "Microsoft" requires multiple steps of inference, which motivates this task. Since the predictor we use is cosine similarity, which does not introduce additional parameters, we directly use encoded representations on the test set without any supervised training.

3.6 Entity Relationship Typing (ERT)

As another popular resource for common knowledge, we consider using Freebase (Bollacker et al., 2008) for probing the encoded knowledge by classifying the types of relations between pair of entities. First, we extract entity relation tuples (entity1, relation, entity2) from Freebase and then filter out easy tuples based on training a classifier using averaged GloVe vectors of entity names as input, which leaves us 626 types of relations, including "internet.website.owner", "film.film_art_director.films_art_directed", and "comic_books.comic_book_series.genre". We randomly sample 5 instances for each relation type to form our training set and 10 instances per type the for validation and test sets. We use Wikipedia descriptions for each entity in the pair whose relation we are predicting and we use descriptive entity representations for each entity with supervised training.

3.7 Named Entity Disambiguation (NED)

Named entity disambiguation is the task of linking a named-entity mention to its corresponding instance in a knowledge base such as Wikipedia. In this task, we consider CoNLL-YAGO (CoNLL; Hoffart et al., 2011) and Rare Entity Prediction (Rare; Long et al., 2017).

For CoNLL-YAGO, following Hoffart et al. (2011) and Yamada et al. (2016), we used the 27,816 mentions with valid entries in the knowledge base. For each entity mention m in its context, we generate a set of (at most) its top 30 candidate entities $C_m = \{c_j\}$ using CrossWikis (Spitkovsky and Chang, 2012). Some gold standard candidates c are not present in CrossWikis, so we set the prior probability $p_{\text{prior}}(y)$ for those to 1e-6 and normalize the resulting priors for the candidate entities. When adding Wikipedia descriptions, we manually ensure gold standard mentions are attached to a description, however, we discard candidate mentions that cannot be aligned to a Wikipedia page. We use contextualized entity representations for entity mentions and use descriptive entity representations for candidate entities. Training minimizes binary log loss using all negative examples. At test time, we use $\arg\max_{c \in C_m} [p_{\text{prior}}(c) + p_{\text{classifier}}(c)]$ as the prediction. We note that directly using prior as predictions yields an accuracy of 58.2%.

Figure 4: An example from CoNLL-YAGO. Only four candidates are shown due to space constraints. The target mention is underlined. Sentences in gray are Wikipedia descriptions. The gold standard is boldfaced.

Long et al. (2017) introduce the task of *rare entity prediction*. The task has a similar format to CoNLL-YAGO entity linking. Given a document with a blank in it, the task is to select an entity from a provided list of entities with descriptions. Only rare entities are used in this dataset so that performing well on the task requires the ability to effectively represent entity descriptions. We randomly select 10k/4k/4k examples to construct train/valid/test sets. For simplicity, we only keep instances with four candidate entities.

Figure 4 shows an example from CoNLL-YAGO, where the "China" in context has many deceptive meanings. Here the candidate "China" has exact string match of the entity name but it should not be selected as it is an after-game report on soccer. To match the entities, this task requires both effective contextualize entity representations and descriptive entity representation.

Practically, we encode the context using CER to be x_1, and encode each entity description using DER to be x_2, and pass $[x_1, x_2, x_1 \odot x_2, |x_1 - x_2|]$ to a linear model to predict whether it is the correct entity to fill in. The model is trained with cross entropy loss.

4 Methods

We first describe how we define encoders for contextualized entity representations (Section 4.1) and descriptive entity representations (Section 4.2), then we discuss how we train new encoders tailored to capture information from the hyperlink structure of Wikipedia (Section 4.3).

4.1 Encoders for Contextualized Entity Representations

For defining these encoders, we assume we have a sentence $s = (w_1, \ldots, w_T)$ where span $(w_i, \ldots, w_j)$ refers to an entity mention. When using ELMo, we first encode the sentence: $(c_1, \ldots, c_T) = \text{ELMo}(w_1, \cdots, w_T)$, and we use the average of contextualized hidden states corresponding to the entity span as the contextualized entity representation. That is, $f_{\text{ELMo}}(w_{1:T}, i, j) = \frac{\sum_{k=i}^{j} c_k}{j-i+1}$.

With BERT, following Onoe and Durrett (2019), we concatenate the full sentence with the entity mention, starting with [CLS] and separating the two by [SEP], i.e., $[\text{CLS}], w_1, \ldots, w_T, [\text{SEP}], w_i, \ldots, w_j, [\text{SEP}]$. We encode the full sequence using BERT and use the output from the [CLS] token as the entity mention representation.

4.2 Encoders for Descriptive Entity Representations

We encode an entity description by treating the entity description as a sentence, and use the average of the hidden states from ELMo as the entity description representation. With BERT, we use the output from the [CLS] token as the description representation.

4.3 Hyperlink-Based Training

An entity mentioned in a Wikipedia article is often linked to its Wikipedia page, which provides a useful description of the mentioned entity. The same Wikipedia page may correspond to many different entity mentions. Likewise, the same entity mention may refer to different Wikipedia pages depending on its context. For instance, as shown in Figure 5, based on the context, "France" is linked to the Wikipedia page of "France national football team" instead of the country. The specific entity in the knowledge base can be inferred from the context information. In such cases, we believe Wikipedia provides valuable complementary information to the current pretrained CWRs such as BERT and ELMo.

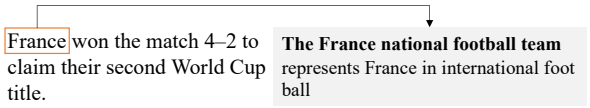

Figure 5: An example of hyperlinks in Wikipedia. "France" is linked to the Wikipedia page of "France national football team" instead of the country France.

To incorporate such information during training, we automatically construct a hyperlink-enriched dataset from Wikipedia that we will refer to as WIKIENT. Prior work has used similar resources (Singh et al., 2012; Gupta et al., 2017), but we aim to standardize the process and will release the dataset.

The WIKIENT dataset consists of sentences with contextualized entity mentions and their corresponding descriptions obtained via hyperlinked Wikipedia pages. When processing descriptions, we only keep the first 100 word tokens at most as the description of a Wikipedia page; similar truncation has been done in prior work (Gupta et al., 2017). For context sentences, we remove those without hyperlinks from the training data and duplicate those with multiple hyperlinks. We also remove context sentences for which we cannot find matched Wikipedia descriptions. These processing steps result in a training set of approximately 92 million instances and over 3 million unique entities.

We define a hyperlink-based training objective and add it to ELMo. In particular, we use contextualized entity representations to decode the hyperlinked Wikipedia description, and also use the descriptive entity representations to decode the linked context. We use bag-of-words decoders in both decoding processes. More specifically, given a context sentence $x_{1:T_x}$ with mention span (i, j) and a description sentence $y_{1:T_y}$, we use the same bidirectional language modeling

loss $l_{\text{lang}}(x_{1:T_x}) + l_{\text{lang}}(y_{1:T_y})$ in ELMo where

$$l_{\text{lang}}(u_{1:T}) = -\sum_{t=1}^{T} \log p(u_{t+1}|u_1, \ldots, u_t) + \log p(u_{t-1}|u_t, \ldots, u_T)$$

and p is defined by the ELMo parameters. In addition, we define the two bag-of-words reconstruction losses:

$$l_{\text{ctx}} = -\sum_t \log q(x_t | f_{\text{ELMo}}([\text{BOD}]y_{1:T_y}, 1, T_y))$$

$$l_{\text{desc}} = -\sum_t \log q(y_t | f_{\text{ELMo}}([\text{BOC}]x_{1:T_x}, i, j))$$

where [BOD] and [BOC] are special symbols prepended to sentences to distinguish descriptions from contexts. The distribution q is parameterized by a linear layer that transforms the conditioning embedding into weights over the vocabulary. The final training loss is

$$l_{\text{lang}}(x_{1:T_x}) + l_{\text{lang}}(y_{1:T_y}) + l_{\text{ctx}} + l_{\text{desc}} \quad (1)$$

Same as the original ELMo, each log loss is approximated with negative sampling (Jean et al., 2015). We write EntELMo to denote the model trained by Eq. (1). When using EntELMo for contextualized entity representations and descriptive entity representations, we use it analogously to ELMo.

5 Experiments

5.1 Setup

As a baseline for hyperlink-based training, we train EntELMo on the WIKIENT dataset with only a bidirectional language model loss. Due to the limitation of computational resources, both variants of EntELMo are trained for one epoch (3 weeks time) with smaller dimensions than ELMo. We set the hidden dimension of each directional long short-term memory network (LSTM; Hochreiter and Schmidhuber, 1997) layer to be 600, and project it to 300 dimensions. The resulting vectors from each layer are thus 600 dimensional. We use 1024 as the negative sampling size for each positive word token. For bag-of-words reconstruction, we randomly sample at most 50 word tokens as positive samples from the the target word tokens. Other hyperparameters are the same as ELMo. EntELMo is implemented based on the official ELMo implementation.[2]

[2]Our implementation is available at https://github.com/mingdachen/bilm-tf

As a baseline for contextualized and descriptive entity representations, we use GloVe word averaging of the entity mention as the "contextualized" entity representation, and use word averaging of the truncated entity description text as its description representation. We also experiment two variants of EntELMo, namely EntELMo w/o l_{ctx} and EntELMo with l_{etn}. For second variant, we replace l_{ctx} with l_{etn}, where we only decode entity mentions instead of the whole context from descriptions. We lowercased all training data as well as the evaluation benchmarks.

We evaluate the transferrability of ELMo, EntELMo, and BERT by using trainable mixing weights for each layer. For ELMo and EntELMo, we follow the recommendation from Peters et al. (2018a) to first pass mixing weights through a softmax layer and then multiply the weighted-summed representations by a scalar. For BERT, we find it better to just use unnormalized mixing weights. In addition, we investigate per-layer performance for both models in Section 6.

5.2 Results

Table 3 shows the performance of our models on the EntEval tasks. Our findings are detailed below:

- Pretrained CWRs (ELMo, BERT) perform the best on EntEval overall, indicating that they capture knowledge about entities in contextual mentions or as entity descriptions.
- BERT performs poorly on entity similarity and relatedness tasks. Since this task is zero-shot, it validates the recommended setting of finetuning BERT (Devlin et al., 2018) on downstream tasks, while the embedding of the [CLS] token does not necessarily capture the semantics of the entity.
- BERT Large is better than BERT Base on average, showing large improvements in ERT and NED. To perform well at ERT, a model must either glean particular relationships from pairs of lengthy entity descriptions or else leverage knowledge from pretraining about the entities considered. Relatedly, performance on NED is expected to increase with both the ability to extract knowledge from descriptions and by starting with increased knowledge from pretraining. The Large model appears to be handling these capabilities better than the Base model.
- EntELMo improves over the EntELMo baseline (trained without the hyperlinking loss) on some

	CAP	CERP	EFP	ET	ESR	ERT	NED	Average
GloVe	71.9	52.6	67.0	10.3	50.9	40.8	41.2	47.8
BERT Base	**80.6**	65.6	74.8	32.0	28.8	42.2	50.6	53.5
BERT Large	79.1	**66.9**	**76.7**	32.3	32.6	**48.8**	**54.3**	55.8
ELMo	80.2	61.2	75.8	**35.6**	60.3	46.8	51.6	**58.8**
EntELMo baseline	78.0	59.6	71.5	31.3	**61.6**	46.5	48.5	56.7
EntELMo	76.9	59.9	72.4	32.2	59.7	45.7	49.0	56.5
EntELMo w/o l_{ctx}	73.5	59.4	71.1	33.2	53.3	44.6	48.9	54.9
EntELMo w/ l_{etn}	76.2	60.4	70.9	33.6	49.0	42.9	49.3	54.6

Table 3: Performances of entity representations on EntEval tasks. Best performing model in each task is boldfaced. CAP: coreference arc prediction, CERP: contexualized entity relationship prediction, EFP: entity factuality prediction, ET: entity typing, ESR: entity similarity and relatedness, ERT: entity relationship typing, NED: named entity disambiguation. EntELMo baseline is trained on the same dataset as EntELMo but not using the hyperlink-based training. EntELMo w/ l_{etn} is trained with a modified version of l_{ctx}, where we only decode entity mentions instead of the whole context.

	Rare		CoNLL		ERT	
	Des.	Name	Des.	Name	Des.	Name
ELMo	38.1	36.7	63.4	71.2	46.8	31.5
BERT Base	42.2	36.6	64.7	74.3	42.2	34.3
BERT Large	48.8	44.0	64.6	74.8	48.8	32.6

Table 4: Accuracies (%) in comparing the use of description encoder (Des.) to entity name (Name).

	CoNLL
ELMo	71.2
Gupta et al. (2017)	65.1
Deep ED	66.7

Table 5: Accuracies (%) on CoNLL-YAGO with static or non-static entity representations.

tasks but suffers on others. The hyperlink-based training helps on CERP, EFP, ET, and NED. Since the hyperlink loss is closely-associated to the NED problem, it is unsurprising that NED performance is improved. Overall, we believe that hyperlink-based training benefits contextualized entity representations but does not benefit descriptive entity representations (see, for example, the drop of nearly 2 points on ESR, which is based solely on descriptive representations). This pattern may be due to the difficulty of using descriptive entity representations to reconstruct their appearing context.

6 Analysis

Is descriptive entity representation necessary? A natural question to ask is whether the entity description is needed, as for humans, the entity names carry sufficient amount of information for a lot of tasks. To answer this question, we experiment with encoding entity names by the descriptive entity encoder for ERT (entity relationship typing) and NED (named entity disambiguation) tasks. The results in Table 4 show that encoding the entity names by themselves already captures a great deal of knowledge regarding entities, especially for CoNLL-YAGO. However, in tasks like ERT, the entity descriptions are crucial as the names do not reveal enough information to categorize their relationships.

Table 5 reports the performance of different descriptive entity representations on the CoNLL-YAGO task. The three models all use ELMo as the context encoder. "ELMo" encodes the entity name with ELMo as descriptive encoder, while both Gupta et al. (2017) and Deep ED (Ganea and Hofmann, 2017) use their trained static entity embeddings. [3] As Gupta et al. (2017) and Deep ED have different embedding sizes from ELMo, we add an extra linear layer after them to map to the same dimension. These two models are designed for entity linking, which gives them potential advantages. Even so, ELMo outperforms them both by a wide margin.

Per-Layer Analysis. We evaluate each ELMo and EntELMo layer, i.e., the character CNN layer and two bidirectional LSTM layers, as well as each BERT layer on the EntEval tasks. Figure 6 reveals that for ELMo models, the first and second LSTM layers capture most of the entity knowledge from context and descriptions. The BERT layers show more diversity. Lower layers perform better on ESR (entity similarity and relatedness), while

[3] We note that the numbers reported here are not strictly comparable to the ones in their original paper since we keep all the top 30 candidates from Crosswiki while prior work employs different pruning heuristics.

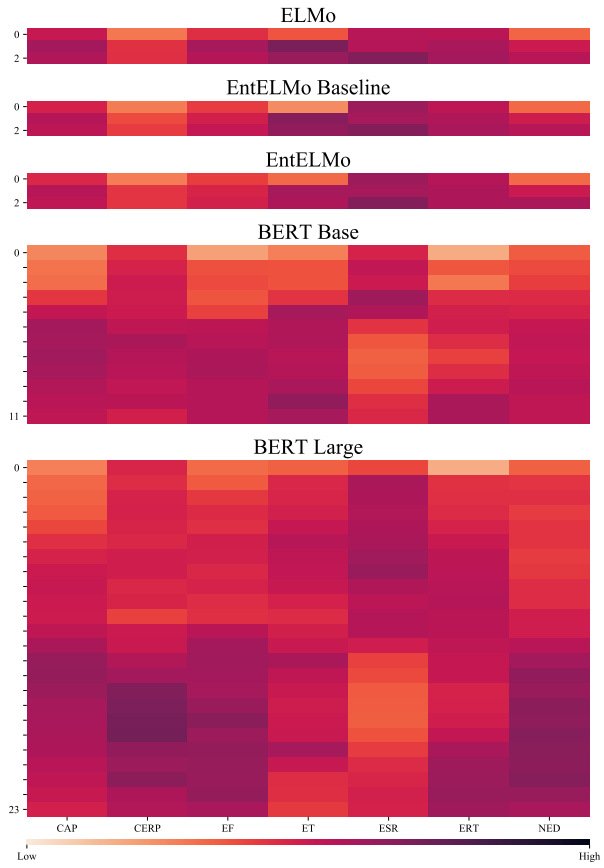

Figure 6: Heatmap showing per-layer performances for ELMo, EntELMo baseline, EntELMo, BERT Base, and BERT Large.

for other tasks higher layers are more effective.

7 Conclusion

Our proposed EntEval test suite provides a standardized evaluation method for entity representations. We demonstrate that EntEval tasks can benefit from the success of contextualized word representations such as ELMo and BERT. Augmenting encoding-decoding loss leveraging natural hyperlinks from Wikipedia further improves ELMo on some EntEval tasks. As shown by our experimental results, the contextualized entity encoder benefits more from this hyperlink-based training objective, suggesting future works to prioritize encoding entity description from its mention context.

Abstract

We propose a joint event and temporal relation extraction model with shared representation learning and structured prediction. The proposed method has two advantages over existing work. First, it improves event representation by allowing the event and relation modules to share the same contextualized embeddings and neural representation learner. Second, it avoids error propagation in the conventional pipeline systems by leveraging structured inference and learning methods to assign both the event labels and the temporal relation labels jointly. Experiments show that the proposed method can improve both event extraction and temporal relation extraction over state-of-the-art systems, with the end-to-end F_1 improved by 10% and 6.8% on two benchmark datasets respectively.

1 Introduction

The extraction of temporal relations among events is an important natural language understanding (NLU) task that can benefit many downstream tasks such as question answering, information retrieval, and narrative generation. The task can be modeled as building a graph for a given text, whose nodes represent events and edges are labeled with temporal relations correspondingly. Figure 1a illustrates such a graph for the text shown therein. The nodes **assassination**, **slaughtered**, **rampage**, **war**, and **Hutu** are the candidate events, and different types of edges specify different temporal relations between them: **assassination** is *BEFORE* **rampage**, **rampage** *INCLUDES* **slaughtered**, and the relation between **slaughtered** and **war** is *VAGUE*. Since "Hutu" is actually not an event, a system is expected to annotate the relations between "Hutu" and all other nodes in the graph as *NONE* (i.e., no relation).

As far as we know, all existing systems treat this task as a pipeline of two separate subtasks,

(a) Temporal Relation Graph

(b) Pipeline Model

(c) Structured Joint Model

Figure 1: An illustration of event and relation models in our proposed joint framework. (a) is a (partial) graph of the output of the relation extraction model. "Hutu" is not an event and hence all relations including it should be annotated as *NONE*. (b) and (c) are comparisons between a pipeline model and our joint model.

i.e., event extraction and temporal relation classification, and they also assume that gold events are given when training the relation classifier (Verhagen et al., 2007, 2010; UzZaman et al., 2013; Chambers et al., 2014; Ning et al., 2017; Meng and Rumshisky, 2018). Specifically, they built end-to-end systems that extract events first and then predict temporal relations between them (Fig. 1b). In these pipeline models, event extraction errors will propagate to the relation classification step and cannot be corrected afterwards. **Our first contribution** is the proposal of a joint model that ex-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 434–444, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

tracts both events and temporal relations simultaneously (see Fig. 1c). The motivation is that if we train the relation classifier with *NONE* relations between non-events, then it will potentially have the capability of correcting event extraction mistakes. For instance in Fig. 1a, if the relation classifier predicts *NONE* for (**Hutu**, **war**) with a high confidence, then this is a strong signal that can be used by the event classifier to infer that at least one of them is not an event.

Our second contribution is that we improve event representations by sharing the same contextualized embeddings and neural representation learner between the event extraction and temporal relation extraction modules for the first time. On top of the shared embeddings and neural representation learner, the proposed model produces a graph-structured output representing all the events and relations in the given sentences.

A valid graph prediction in this context should satisfy two structural constraints. First, the temporal relation should always be *NONE* between two non-events or between one event and one non-event. Second, for those temporal relations among events, no loops should exist due to the transitive property of time (e.g., if **A** is before **B** and **B** is before **C**, then **A** must be before **C**). The validity of a graph is guaranteed by solving an integer linear programming (ILP) optimization problem with those structural constraints, and our joint model is trained by structural support vector machines (SSVM) in an end-to-end fashion.

Results show that, according to the end-to-end F_1 score for temporal relation extraction, the proposed method improves CAEVO (Chambers et al., 2014) by 10% on TB-Dense, and improves CogCompTime (Ning et al., 2018c) by 6.8% on MATRES. We further show ablation studies to confirm that the proposed joint model with shared representations and structured learning is very effective for this task.

2 Related Work

In this section we briefly summarize the existing work on event extraction and temporal relation extraction. To the best of our knowledge, there is no prior work on joint *event* and relation extraction, so we will review joint *entity* and relation extraction works instead.

Existing **event extraction** methods in the temporal relation domain, as in the TempEval3 workshop (UzZaman et al., 2013), all use conventional machine learning models (logistic regression, SVM, or Max-entropy) with hand-engineered features (e.g., ClearTK (Bethard, 2013) and NavyTime (Chambers, 2013)). While other domains have shown progress on event extraction using neural methods (Nguyen and Grishman, 2015; Nguyen et al., 2016; Feng et al., 2016), recent progress in the temporal relation domain is focused more on the setting where gold events are provided. Therefore, we first show the performance of a neural event extractor on this task, although it is not our main contribution.

Early attempts on **temporal relation extraction** use local pair-wise classification with hand-engineered features (Mani et al., 2006; Verhagen et al., 2007; Chambers et al., 2007; Verhagen and Pustejovsky, 2008). Later efforts, such as ClearTK (Bethard, 2013), UTTime (Laokulrat et al., 2013), NavyTime (Chambers, 2013), and CAEVO (Chambers et al., 2014) improve earlier work with better linguistic and syntactic rules. Yoshikawa et al. (2009); Ning et al. (2017); Leeuwenberg and Moens (2017) explore structured learning for this task, and more recently, neural methods have also been shown effective (Tourille et al., 2017; Cheng and Miyao, 2017; Meng et al., 2017; Meng and Rumshisky, 2018).

In practice, we need to extract both events and those temporal relations among them from raw text. All the works above treat this as two subtasks that are solved in a pipeline. To the best of our knowledge, there has been no existing work on **joint event-temporal relation extraction**. However, the idea of "joint" has been studied for *entity*-relation extraction in many works. Miwa and Sasaki (2014) frame their joint model as table filling tasks, map tabular representation into sequential predictions with heuristic rules, and construct global loss to compute the best joint predictions. Li and Ji (2014) define a global structure for joint entity and relation extraction, encode local and global features based on domain and linguistic knowledge. and leverage beam-search to find global optimal assignments for entities and relations. Miwa and Bansal (2016) leverage LSTM architectures to jointly predict both entity and relations, but fall short on ensuring prediction consistency. Zhang et al. (2017) combine the benefits of both neural net and global optimization with beam

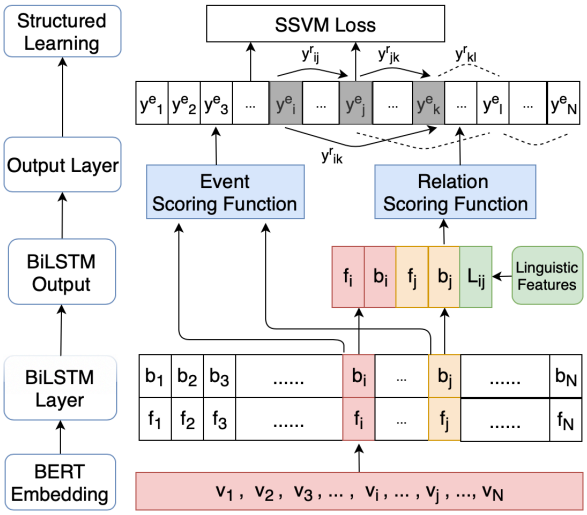

Figure 2: Deep neural network architecture for joint structured learning. Note that on the structured learning layer, grey bars denote tokens being predicted as events. Edge types between events follow the same notations as in 1a. $y_l^e = 0$ (non-event), so all edges connecting to y_l^e are *NONE*. $y_i^e = 1, y_j^e = 1, y_k^e = 1$ (events) and hence edges between them are forced to be the same ($y_{ij}^r = y_{jk}^r = y_{ik}^r =$ *BEFORE* in this example) by transitivity. These global assignments are input to compute the SSVM loss.

search. Motivated by these works, we propose an end-to-end trainable neural structured support vector machine (neural SSVM) model to *simultaneously* extract events and their relations from text and ensure the global structure via ILP constraints. Next, we will describe in detail our proposed method.

3 Joint Event-Relation Extraction Model

In this section we first provide an overview of our neural SSVM model, and then describe each component in our framework in detail (i.e., the multi-tasking neural scoring module, and how inference and learning are performed). We denote the set of all possible relation labels (including *NONE*) as $\mathcal{R}$, all event candidates (both events and non-events) as $\mathcal{E}$, and all relation candidates as $\mathcal{EE}$.

3.1 Neural SSVM

Our neural SSVM adapts the SSVM loss as:

$$\mathcal{L} = \sum_{n=1}^{l} \frac{C}{M^n} \big[\max_{\hat{\boldsymbol{y}}^n \in \mathcal{Y}} \big(0, \Delta(\boldsymbol{y}^n, \hat{\boldsymbol{y}}^n) + \bar{S}_{\mathcal{R}}^n + C_{\mathcal{E}} \bar{S}_{\mathcal{E}}^n\big)\big] + ||\Phi||^2, \quad (1)$$

where $\bar{S}_{\mathcal{E}}^n = S(\hat{\boldsymbol{y}}_{\mathcal{E}}^n; \boldsymbol{x}^n) - S(\boldsymbol{y}_{\mathcal{E}}^n; \boldsymbol{x}^n)$ and $\bar{S}_{\mathcal{R}}^n = S(\hat{\boldsymbol{y}}_{\mathcal{R}}^n; \boldsymbol{x}^n) - S(\boldsymbol{y}_{\mathcal{R}}^n; \boldsymbol{x}^n)$; Φ denotes model parameters, n indexes instances, $M^n = |\mathcal{E}|^n + |\mathcal{EE}|^n$ denotes the total number of relations $|\mathcal{E}|^n$ and events $|\mathcal{EE}|^n$ in instance n. $\boldsymbol{y}^n, \hat{\boldsymbol{y}}^n$ denote the gold and predicted global assignments of events and relations for instance n—each of which consists of either one hot vector representing true and predicted relation labels $\boldsymbol{y}_{\mathcal{R}}^n, \hat{\boldsymbol{y}}_{\mathcal{R}}^n \in \{0,1\}^{|\mathcal{EE}|}$, or entity labels $\boldsymbol{y}_{\mathcal{E}}^n, \hat{\boldsymbol{y}}_{\mathcal{E}}^n \in \{0,1\}^{|\mathcal{E}|}$. A maximum a posteriori probability (MAP) inference is needed to find $\hat{\boldsymbol{y}}^n$, which we formulate as an interger linear programming (ILP) problem and describe more details in Section 3.3. $\Delta(\boldsymbol{y^n}, \hat{\boldsymbol{y}}^n)$ is a distance measurement between the gold and the predicted assignments; we simply use the Hamming distance. C and $C_{\mathcal{E}}$ are the hyper-parameters to balance the losses between event, relation and the regularizer, and $S(\boldsymbol{y}_{\mathcal{E}}^n; \boldsymbol{x}^n), S(\boldsymbol{y}_{\mathcal{R}}^n; \boldsymbol{x}^n)$ are scoring functions, which we design a multi-tasking neural architecture to learn.

The intuition behind the SSVM loss is that it requires the score of gold output structure $\boldsymbol{y}^n$ to be greater than the score of the best output structure under the current model $\hat{\boldsymbol{y}}^n$ with a margin $\Delta(\boldsymbol{y}^n, \hat{\boldsymbol{y}}^n)$[1] or else there will be some loss. The training objective is to minimize the loss.

The major difference between our neural-SSVM and the traditional SSVM model is the scoring function. Traditional SSVM uses a linear function over hand-crafted features to compute the scores, whereas we propose to use a recurrent neural network to estimate the scoring function and train the entire architecture end-to-end.

3.2 Multi-Tasking Neural Scoring Function

The recurrent neural network (RNN) architecture has been widely adopted by prior temporal extraction work to encode context information (Tourille et al., 2017; Cheng and Miyao, 2017; Meng et al., 2017). Motivated by these works, we adopt a RNN-based scoring function for both event and relation prediction in order to learn features in a data driven way and capture long-term contexts in the input. In Fig. 2, we skip the input layer for simplicity.[2]

The bottom layer corresponds to contextualized word representations denoted as v_k. We use $(i, j) \in \mathcal{EE}$ to denote a candidate relation and $i \in \mathcal{E}$ to

[1] Note that if the best prediction is the same as the gold structure, the margin is zero; there will be no loss.

[2] Following the convention of event relation prediction literature (Chambers et al., 2014; Ning et al., 2018a,b), we only consider event pairs that occur in the same or neighboring sentences, but the architecture can be easily adapted to the case where inputs are longer than two sentences.

indicate a candidate event in the input sentences of length N. We fix word embeddings computed by a pre-trained BERT-base model (Devlin et al., 2018). They are then fed into a BiLSTM layer to further encode task-specific contextual information. Both event and relation tasks share this layer.

The event scorer is illustrated by the left two branches following the BiLSTM layer. We simply concatenate both forward and backward hidden vectors to encode the context of each token. As for the relation scorer shown in the right branches, for each pair (i, j) we take the forward and backward hidden vectors corresponding to them, f_i, b_i, f_j, b_j, and concatenate them with linguistic features as in previous event relation prediction research. We denote linguistic features as $L_{i,j}$ and only use simple features provided in the original datasets: token distance, tense, and polarity of events.

Finally, all hidden vectors and linguistic features are concatenated to form the input to compute the probability of being an event or a softmax distribution over all possible relation labels—which we refer to as the RNN-based **scoring function** in the following sections.

3.3 MAP Inference

A MAP inference is needed both during training to obtain $\hat{\boldsymbol{y}}^n$ in the loss function (Equation 1), as well as during the test time to get globally coherent assignments. We formulate the inference problem as an ILP problem. The inference framework is established by constructing a global objective function using scores from local scorers and imposing several global constraints: 1) one-label assignment, 2) event-relation consistency, and 3) symmetry and transitivity as in Bramsen et al. (2006); Chambers and Jurafsky (2008); Denis and Muller (2011); Do et al. (2012); Ning et al. (2017).

3.3.1 Objective Function

The objective function of the global inference is to find the global assignment that has the highest probability under the current model, as specified in Equation 2:

$$\hat{y} = \arg\max \sum_{(i,j)\in\mathcal{EE}} \sum_{r\in\mathcal{R}} y^r_{i,j} S(y^r_{i,j}, \boldsymbol{x}) + C_{\mathcal{E}} \sum_{k\in\mathcal{E}} \sum_{e\in\{0,1\}} y^e_k S(y^e_k, \boldsymbol{x}) \quad (2)$$

$$\textbf{s.t.}\ y^r_{i,j}, y^e_k \in \{0,1\}\,,\ \sum_{r\in\mathcal{R}} y^r_{i,j} = 1,\ \sum_{e\in\{0,1\}} y^e_k = 1,$$

where y^e_k is a binary indicator of whether the k-th candidate is an event or not, and $y^r_{i,j}$ is a binary indicator specifying whether the global prediction of the relation between (i, j) is $r \in \mathcal{R}$. $S(y^e_k, \boldsymbol{x}), \forall e \in \{0, 1\}$ and $S(y^r_{i,j}, \boldsymbol{x}), \forall r \in \mathcal{R}$ are the scoring functions obtained from the event and relation scoring functions, respectively. The output of the global inference $\hat{\mathbf{y}}$ is a collection of optimal label assignments for all events and relation candidates in a fixed context. $C_{\mathcal{E}}$ is a hyper-parameter controlling weights between relation and event. The constraint that follows immediately from the objective function is that the global inference should only assign one label for all entities and relations.

3.3.2 Constraints

We introduce several additional constraints to ensure the resulting optimal output graph forms a valid and plausible event graph.

Event-Relation Consistency. Event and relation prediction consistency is defined with the following property: **a pair of input tokens have a positive temporal relation if and only if both tokens are events**. The following global constraints will satisfy this property,

$$\forall(i,j) \in \mathcal{EE}, e^P_i \geq r^P_{i,j}\,,\ e^P_j \geq r^P_{i,j}$$

$$\text{and } e^N_i + e^N_j \geq r^N_{i,j}$$

where e^P_i denotes an event and e^N_i denotes a non-event token. $r^P_{i,j}$ indicates positive relations: *BEFORE*, *AFTER*, *SIMULTANEOUS*, *INCLUDES*, *IS_INCLUDED*, *VAGUE* and $r^N_{i,j}$ indicate a negative relation, i.e., *NONE*. A formal proof of this property can be found in Appendix A.

Symmetry and Transitivity Constraint. We also explore the symmetry and transitivity constraints of relations. They are specified as follows:

$$\forall(i,j),(j,k) \in \mathcal{EE}, y^r_{i,j} = y^{\bar{r}}_{j,i},\ \text{(symmetry)}$$

$$y^{r_1}_{i,j} + y^{r_2}_{j,k} - \sum_{r_3\in Trans(r_1,r_2)} y^{r_3}_{i,k} \leq 1,\ \text{(transitivity)}$$

Intuitively, the symmetry constraint forces two pairs of events with flipping orders to have reversed relations. For example, if $r_{i,j}$ = *BEFORE*, then $r_{j,i}$ = *AFTER*. The transitivity constraint rules that if (i, j), (j, k) and (i, k) pairs exist in the graph, the label (relation) prediction of (i, k) pair

has to fall into the transitivity set specifyed by (i, j) and (j, k) pairs. The full transitivity table can be found in Ning et al. (2018a).

3.4 Learning

We begin by experimenting with optimizing SSVM loss directly, but model performance degrades.[3] Therefore, we develop a two-state learning approach which first trains a pipeline version of the joint model without feedback from global constraints. In other words, the local neural scoring functions are optimized with cross-entropy loss using gold events and relation candidates that are constructed directly from the outputs of the event model. During the second stage, we switch to the global SSVM loss function in Equation 1 and re-optimize the network to adjust for global properties. We will provide more details in Section 4.

4 Implementation Details

In this section we describe implementation details of the baselines and our four models to build an end-to-end event temporal relation extraction system with an emphasis on the structured joint model. In Section 6 we will compare and contrast them and show why our proposed structured joint model works the best.

4.1 Baselines

We run two event and relation extraction systems, CAEVO[4] (Chambers et al., 2014) and CogCompTime[5] (Ning et al., 2018c), on TB-Dense and MATRES, respectively. These two methods both leverage conventional learning algorithms (i.e., MaxEnt and averaged perceptron, respectively) based on manually designed features to obtain separate models for events and temporal relations, and conduct end-to-end relation extraction as a pipeline. Note Chambers et al. (2014) does not report event and end-to-end temporal relation extraction performances, so we calculate the scores per our implementation.

[3] We leave further investigation for future work.

[4] https://www.usna.edu/Users/cs/nchamber/caevo/

[5] http://cogcomp.org/page/publication_view/844

4.2 End-to-End Event Temporal Relation Extraction

Single-Task Model. The most basic way to build an end-to-end system is to train separate event detection and relation prediction models with gold labels, as we mentioned in our introduction. In other words, the BiLSTM layer is not shared as in Fig. 2. During evaluation and test time, we use the outputs from the event detection model to construct relation candidates and apply the relation prediction model to make the final prediction.

Multi-Task Model. This is the same as the single-task model except that the BiLSTM layer is now shared for both event and relation tasks. Note that both single-task and multi-task models are not trained to tackle the *NONE* relation directly. They both rely on the predictions of the event model to annotate relations as either positive pairs or *NONE*.

Pipeline Joint Model. This shares the same architecture as the multi-task model, except that during training, we use the predictions of the event model to construct relation candidates to train the relation model. This strategy will generate *NONE* pairs during training if one argument of the relation candidate is not an event. These *NONE* pairs will help the relation model to distinguish negative relations from positive ones, and thus become more robust to event prediction errors. We train this model with gold events and relation candidates during the first several epochs in order to obtain a relatively accurate event model and switch to a pipeline version afterwards inspired by Miwa and Bansal (2016).

Structured Joint Model. This is described in detail in Section 3. However, we experience difficulties in training the model with SSVM loss from scratch. This is due to large amounts of non-event tokens, and the model is not capable of distinguishing them in the beginning. We thus adopt a two-stage learning procedure where we take the best pipeline joint model and re-optimize it with the SSVM loss.

To restrict the search space for events in the ILP inference of the SSVM loss, we use the predicted probabilities from the event detection model to filter out non-events since the event model has a strong performance, as shown in Section 6. Note that this is very different from the pipeline

model where events are first predicted and relations are constructed with *predicted* events. Here, we only leverage an additional hyper-parameter T_{evt} to filter out highly unlikely event candidates. Both event and relation labels are assigned *simultaneously* during the global inference with ILP, as specified in Section 3.3. We also filter out tokens with POS tags that do not appear in the training set as most of the events are either nouns or verbs in TB-Dense, and all events are verbs in MATRES.

Hyper-Parameters. All single-task, multi-task and pipeline joint models are trained by minimizing cross-entropy loss. We observe that model performances vary significantly with dropout ratio, hidden layer dimensions of the BiLSTM model and entity weight in the loss function (with relation weight fixed at 1.0). We leverage a pre-trained BERT model to compute word embedding[6] and all MLP scoring functions have one hidden layer.[7] In the SSVM loss function, we fix the value of $C = 1$, but fine-tune $C_{\mathcal{E}}$ in the objective function in Equation 2. Hyper-parameters are chosen using a standard development set for TB-Dense and a random holdout-set based on an 80/20 split of training data for MATRES. To solve ILP in the inference process, we leverage an off-the-shelf solver provided by Gurobi optimizer; i.e. the best solutions from the Gurobi optimizer are inputs to the global training. The best combination of hyper-parameters can be found in Table 9 in our appendix.[8]

5 Experimental Setup

In this section we first provide a brief overview of temporal relation data and describe the specific datasets used in this paper. We also explain the evaluation metrics at the end.

5.1 Temporal Relation Data

Temporal relation corpora such as TimeBank (Pustejovsky et al., 2003) and RED (O'Gorman et al., 2016) facilitate the research in temporal relation extraction. The common issue in these corpora is missing annotations. Collecting densely annotated temporal relation corpora with all events and relations fully annotated is reported to be a challenging task as annotators could easily overlook some facts (Bethard et al., 2007; Cassidy et al., 2014; Chambers et al., 2014; Ning et al., 2017), which made both modeling and evaluation extremely difficult in previous event temporal relation research.

	TB-Dense	MATRES
# of Documents		
Train	22	183
Dev	5	-
Test	9	20
# of Pairs		
Train	4032	6332
Dev	629	-
Test	1427	827

Table 1: Data overview. Note that the numbers reported for MATRES do not include the AQUAINT section.

The TB-Dense dataset mitigates this issue by forcing annotators to examine all pairs of events within the same or neighboring sentences, and it has been widely evaluated on this task (Chambers et al., 2014; Ning et al., 2017; Cheng and Miyao, 2017; Meng and Rumshisky, 2018). Recent data construction efforts such as MATRES (Ning et al., 2018a) further enhance the data quality by using a multi-axis annotation scheme and adopting a start-point of events to improve inter-annotator agreements. We use TB-Dense and MATRES in our experiments and briefly summarize the data statistics in Table 1.

5.2 Evaluation Metrics

To be consistent with previous research, we adopt two different evaluation metrics. The first one is the standard **micro-average scores**. For densely annotated data, the micro-average metric should share the same precision, recall and F1 scores. However, since our joint model includes *NONE* pairs, we follow the convention of IE tasks and exclude them from evaluation. The second one is similar except that we exclude both *NONE* and *VAGUE* pairs following (Ning et al., 2018c). Please refer to Figure 4 in the appendix for a visualizations of the two metrics.

6 Results and Analysis

The main results of this paper can be found in Table 2. All best-recall and F1 scores are achieved by our structured joint model, and the results outperform the baseline systems by 10.0% and 6.8% on end-to-end relation extraction per F1 scores and

[6] We use a pre-trained BERT-Base model with 768 hidden size, 12 layers, 12 heads implemented by https://github.com/huggingface/pytorch-pretrained-BERT

[7] Let H, K denotes the dimension of (concatenated) vector from BiLSTM and number of output classes. MLP layer consists of $|H| * |K| + |K| * |K|$ parameters

Table 3: Further ablation studies on event and relation extractions. Relation (G) denotes train and evaluate using gold events to compose relation candidates, whereas Relation (E) means end-to-end relation extraction. † is the event extraction and pipeline relation extraction F1 scores for CAEVO (Chambers et al., 2014). 57.0‡ is the best previously reported micro-average score for temporal relation extraction based on gold events by Meng and Rumshisky (2018). All MATRES baseline results are provided by Ning et al. (2018c).

3.5% and 2.6% on event extraction per F1 scores. The best precision score for the TB-Dense dataset is achieved by CAEVO, which indicates that the linguistic rule-based system can make highly precise predictions by being conservative.

Table 3 shows a more detailed analysis, in which we can see that our single-task models with BERT embeddings and a BiLSTM encoder already outperform the baseline systems on end-to-end relation extraction tasks by 4.9% and 4.4% respectively. In the following sections we discuss step-by-step improvement by adopting multi-task, pipeline joint, and structured joint models on end-to-end relation extraction, event extraction, and relation extraction on gold event pairs.

6.1 End-to-End Relation Extraction

TB-Dense. The improvements over the single-task model per F1 score are 4.1% and 4.2% for the multi-task and pipeline joint model respectively. This indicates that the pipeline joint model is helpful only marginally. Table 4 shows that the structured joint model improves both precision and recall scores for *BEFORE* and *AFTER* and achieves the best end-to-end relation extraction performance at 49.4%—which outperforms the baseline system by 10.0% and the single-task model by 5.1%.

MATRES. Compared to the single-task model, the multi-task model improves F1 scores by 1.5%, while the pipeline joint model improves F1 scores by 1.3%—which means that pipeline joint training does not bring any gains for MATRES. The structured joint model reaches the best end-to-end F1 score at 59.6%, which outperforms the baseline system by 6.8% and the single-task model by 2.4%. We speculate that the gains come from the joint model's ability to help deal with *NONE* pairs, since recall scores for *BEFORE* and *AFTER* increase by 1.5% and 1.1% respectively (Table 10 in our appendix).

6.2 Event Extraction

TB-Dense. Our structured joint model outperforms the CAEVO baseline by 3.5% and the single-task model by 1.3%. Improvements on event extraction can be difficult because our single-task model already works quite well with a close-to 89% F1 score, while the inter-annotator agreement for events in TimeBank documents is merely 87% (UzZaman et al., 2013).

MATRES. The structured model outperforms the the baseline model and the single-task model by 2.6% and 0.9% respectively. However, we observe that the multi-task model has a slight drop in event extraction performance over the single-task model (86.4% vs. 86.9%). This indicates

	CAEVO			Pipeline Joint			Structure Joint		
	P	R	F1	P	R	F1	P	R	F1
B	41.4	19.5	26.5	59.0	46.9	52.3	59.8	46.9	52.6
A	42.1	17.5	24.7	69.3	45.3	54.8	71.9	46.7	56.6
I	50.0	3.6	6.7	-	-	-	-	-	-
II	38.5	9.4	15.2	-	-	-	-	-	-
S	14.3	4.5	6.9	-	-	-	-	-	-
V	44.9	59.4	51.1	45.1	55.0	49.5	45.9	55.8	50.4
Avg	43.8	35.7	39.4	51.5	45.9	48.5	52.6	46.5	**49.4**

Table 4: Model performance breakdown for TB-Dense. "-" indicates no predictions were made for that particular label, probably due to the small size of the training sample. *BEFORE* (**B**), *AFTER* (**A**), *INCLUDES* (**I**), *IS_INCLUDED* (**II**), *SIMULTANEOUS* (**S**), *VAGUE* (**V**)

that incorporating relation signals are not particularly helpful for event extraction on MATRES. We speculate that one of the reasons could be the unique event characteristics in MATERS. As we described in Section 5.1, all events in MATRES are verbs. It is possible that a more concentrated single-task model works better when events are homogeneous, whereas a multi-task model is more powerful when we have a mixture of event types, e.g., both verbs and nouns as in TB-Dense.

6.3 Relation Extraction with Gold Events

TB-Dense. There is much prior work on relation extraction based on gold events in TB-Dense. Meng and Rumshisky (2018) proposed a neural model with global information that achieved the best results as far as we know. The improvement of our single-task model over that baseline is mostly attributable to the adoption of BERT embedding. We show that sharing the LSTM layer for both events and relations can help further improve performance of the relation classification task by 2.6%. For the joint models, since we do not train them on gold events, the evaluation would be meaningless. We simply skip this evaluation.

MATRES. Both single-task and multi-task models outperform the baseline by nearly 10%, while the improvement of multi-task over single task is marginal. In MATRES, a relation pair is equivalent to a verb pair, and thus the event prediction task probably does not provide much more information for relation extraction.

In Table 4 we further show the breakdown performances for each positive relation on TB-Dense. The breakdown on MATRES is shown in Table 10 in the appendix. *BEFORE*, *AFTER* and *VAGUE* are the three dominant label classes in TB-Dense. We observe that the linguistic rule-based model, CAEVO, tends to have a more evenly spread-out

Labels	TB-Dense	MATRES
BEFORE	384	417
AFTER	274	266
INCLUDES	56	–
IS_INCLUDED	53	–
SIMULTANEOUS	22	31
VAGUE	638	113

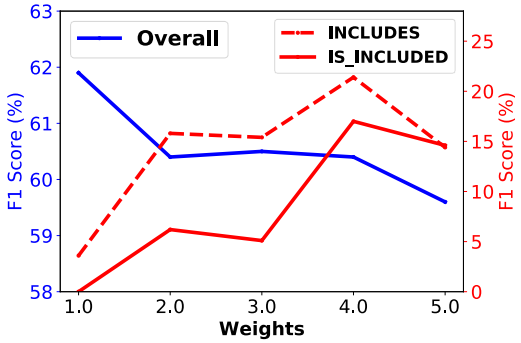

Figure 3: Performances from a single-task relation model under different class weights. Left-axis: overall model; right-axis: two minority relations.

performance, whereas our neural network-based models are more likely to have concentrated predictions due to the imbalance of the training sample across different label classes.

6.4 Discussion

Label Imbalance. One way to mitigate the label imbalance issue is to increase the sample weights for small classes during model training. We investigate the impact of class weights by refitting our single-task model with larger weights on *INCLUDES*, *IS_INCLUDED* and *VAGUE* in the cross-entropy loss.

Figure 3 shows that increasing class weights up to 4 times can significantly improve the F1 scores of *INCLUDES* and *IS_INCLUDED* classes with a decrease less than 2% for the overall F1 score. Performance of *INCLUDES* and *IS_INCLUDED* eventually degrades when class weights are too large. These results seem to suggest that more labels are needed in order to improve the performance on both of these two classes and the overall model. For *SIMULTANEOUS*, our model does not make any correct predictions for both TB-DENSE and MATRES by increasing class weight up to 10 times, which implies that *SIMULTANEOUS* could be a hard temporal relation to predict in general.

Global Constraints. In Table 6 we conduct an ablation study to understand the contributions from the event-relation prediction consis-

Micro-average	TB-Dense	MATRES
No Structure	48.5	58.5
+ $\mathcal{ER}$ Consistency	49.4	59.5
+ Transitivity	49.4	59.6

Table 6: Ablation Study on Global Constraints

tency constraint and the temporal relation transitivity constraint for the structured joint model. As we can see, the event-relation consistency helps improve the F1 scores by 0.9% and 1% for TB-Dense and MATRES, respectively, but the gain by using transitivity is either non-existing or marginal. We hypothesize two potential reasons: 1) We leveraged BERT contextualized embedding as word representation, which could tackle transitivity in the input context; 2) *NONE* pairs could make transitivity rule less useful, as positive pairs can be predicted as *NONE* and transitivity rule does not apply to *NONE* pairs.

Error Analysis. By comparing gold and predicted labels for events and temporal relations and examining predicted probabilities for events, we identified three major sources of mistakes made by our structured model, as illustrated in Table 7 with examples.

Type 1. Both events in Ex 1 are assigned low scores by the event module ($<< 0.01$). Although the structured joint model is designed to predict events and relations jointly, we leverage the event module to filter out tokens with scores lower than a threshold. Consequently, some true events can be mistakenly predicted as non-events, and the relation pairs including them are automatically assigned *NONE*.

Type 2. In Ex 2 the event module assigns high scores to tokens **happened** (0.97) and **according** (0.89), but **according** is not an event. When the structured model makes inference jointly, the decision will weigh heavily towards assigning **1** (event) to both tokens. With the event-relation consistency constraint, this pair is highly likely to be predicted as having a positive temporal relation. Nearly all mistakes made in this category follow the same pattern illustrated by this example.

Type 3. The existence of *VAGUE* makes temporal relation prediction challenging as it can be easily confused with other temporal relations, as shown in Ex 3. This challenge is compounded with *NONE* in our end-to-end extraction task.

Type 1 and Type 2 errors suggest that building a stronger event detection module will be helpful for both event and temporal relation extraction tasks. To improve the performance on *VAGUE* pairs, we could either build a stronger model that incorporates both contextual information and commonsense knowledge or create datasets with annotations that better separate *VAGUE* from other positive temporal relations.

Type 1: Event predicted as non-event	189 pairs
Ex 1. What Microsoft gets are developers around the world **working** on ideas that could potentially **open** up Kinect for Windows ...	
Type 2: *NONE* predicted as true relation	135 pairs
Ex 2. Mr. Netanyahu told Mr. Erdogan that what **happened** on board the Mavi Marmara was "unintentional" ... , **according** to the statement.

Ex 3. Microsoft **said** it has identified 3 companies for the China program to run through June. The company **gives** each participating startup $ 20,000 to create ...	

Table 7: Error Types Based on MATRES Test Data

7 Conclusion

In this paper we investigate building an end-to-end event temporal relation extraction system. We propose a novel neural structured prediction model with joint representation learning to make predictions on events and relations simultaneously; this can avoid error propagation in previous pipeline systems. Experiments and comparative studies on two benchmark datasets show that the proposed model is effective for end-to-end event temporal relation extraction. Specifically, we improve the performances of previously published systems by 10% and 6.8% on the TB-Dense and MATRES datasets, respectively.

Future research can focus on creating more robust structured constraints between events and relations, especially considering event types, to improve the quality of global assignments using ILP. Since a better event model is generally helpful for relation extraction, another promising direction would be to incorporate multiple datasets to enhance the performance of our event extraction systems.

Abstract

While existing hierarchical text classification (HTC) methods attempt to capture label hierarchies for model training, they either make local decisions regarding each label or completely ignore the hierarchy information during inference. To solve the mismatch between training and inference as well as modeling label dependencies in a more principled way, we formulate HTC as a Markov decision process and propose to learn a **L**abel **A**ssignment **P**olicy via deep reinforcement learning to determine *where to place* an object and *when to stop* the assignment process. The proposed method, **HiLAP**, explores the hierarchy during both training and inference time in a *consistent* manner and makes *inter-dependent* decisions. As a general framework, HiLAP can incorporate different neural encoders as *base models* for end-to-end training. Experiments on five public datasets and four base models show that HiLAP yields an average improvement of 33.4% in Macro-F1 over flat classifiers and outperforms state-of-the-art HTC methods by a large margin.[1]

1 Introduction

In recent years there has been a surge of interest in leveraging hierarchies (taxonomies) to organize objects (*e.g.*, documents), leading to the development of hierarchical text classification (HTC)—a task that aims to predict for an object multiple appropriate labels in a given label hierarchy, which together constitute a sub-tree. HTC methods have found a wide range of applications such as question answering (Qu et al., 2012), online advertising (Agrawal et al., 2013), and scientific literature organization (Peng et al., 2016). In contrast to "flat" classification, the key challenges of HTC lie in modeling the large-scale, imbalanced, and in particular, structured label space.

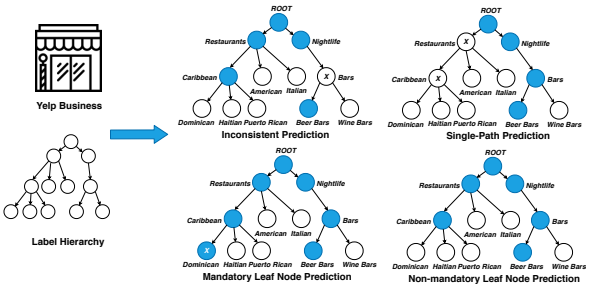

Figure 1: We aim at **consistent, multi-path, and non-mandatory leaf node prediction**. For a Caribbean restaurant with a beer bar, inconsistent prediction may place it to node "Beer Bars" but not "Bars", which contradicts with each other; Single-path prediction may only recognize that it is a beer bar; Mandatory leaf node prediction would have to assign a leaf node "Dominican" even if the nation of the cuisine is uncertain.

Based on how the hierarchy is explored, HTC methods can be summarized into *flat*, *local*, and *global* approaches (Silla and Freitas, 2011). Flat approaches (Hayete and Bienkowska, 2005; Johnson and Zhang, 2014) assume all the labels in the given hierarchy are independent. Some predict labels at the leaf nodes and heuristically add their ancestor labels, which is problematic as the labels of some objects may not be at the leaf nodes (*non-mandatory leaf node prediction*, see Fig. 1) and all the non-leaf nodes are completely neglected. Some simply ignore the hierarchy and perform standard multi-label classification, in which *label inconsistencies* (one label is predicted positive but its ancestors are not) may occur and post-processing is needed to correct such contradictions. Local approaches (Koller and Sahami, 1997; Cesa-Bianchi et al., 2006) train a set of local classifiers that function *independently* and predictions are usually made in a top-down order: one node is visited if and only if its ancestors have

[1]Data and code can be found at https://github.com/morningmoni/HiLAP.

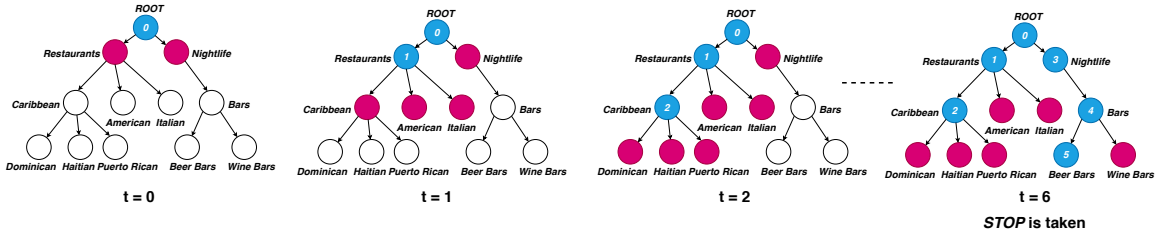

Figure 2: **An illustrative example of the label assignment policy.** At $t = 0$, x_i is placed at the root label and the policy would decide if x_i should be placed to its two children (*red*). At $t = 1$, x_i is placed at label "Restaurants", which adds its three children as the candidates. At $t = 6$, the *stop* action is taken and the label assignment is thus terminated. We then take all the labels where x_i has been placed (*blue*) as x_i's labels.

been predicted positive. One critical issue is that the number of local classifiers depends on the size of the label hierarchy, making local approaches infeasible to scale.

Global approaches use one single classifier and model the label hierarchy more explicitly. Traditional global approaches (Wang et al., 2001; Silla Jr and Freitas, 2009) are largely based on specific flat models and often make unrealistic assumptions (Cai and Hofmann, 2004) as in flat approaches. Recent neural approaches (Kim, 2014; Yang et al., 2016) mainly focus on flat classification while their performance in HTC is relatively less studied. Even if the classification is supposed to be hierarchical, prior work (Gopal and Yang, 2013; Johnson and Zhang, 2014; Peng et al., 2018) still make *flat* and *independent* predictions or utilize simple constraints without considering the holistic quality of label assignment. One recent framework (Wehrmann et al., 2018) attempts to leverage both local and global information but it uses static features as input and its inference process is still flat.

In this paper, we formulate HTC as a Markov decision process to better capture *label dependencies* and measure the *holistic quality* of label assignment. We present HiLAP, a global framework that learns a label assignment policy to determine *where to place* the objects and *when to stop* the assignment process. HiLAP explores the label hierarchy during both training and inference in a consistent manner, which alleviates the exposure bias often found in prior local and global approaches. By learning when to stop, HiLAP is more flexible than approaches that only support mandatory leaf node prediction or require thresholding. In addition, HiLAP supports multi-path prediction and its predictions of one object on different paths are *inter-dependent*, which not only guarantees *label consistency* but matches the nature of HTC. Furthermore, HiLAP estimates the holistic quality of all the labels assigned to one object via reinforcement learning instead of evaluating each label independently via maximum likelihood as in prior studies. To summarize, HiLAP achieves better effectiveness compared to flat and local approaches as it examines the label hierarchy during both training and inference. HiLAP has more flexibility and generalization capacity than previous global approaches in that it has no constraints on the structure of the hierarchy or the labels of the objects (Cai and Hofmann, 2004), generalizes to neural representation learning models (Gopal and Yang, 2013), and makes inter-dependent predictions while ensuring label consistency (Wehrmann et al., 2018; Peng et al., 2018).

HiLAP can be combined with various neural encoding models and trained in an end-to-end fashion. In our experiments, we select four representative encoding models as the *base models* to evaluate the effectiveness of HiLAP. Experimental results on five public datasets from different domains show that combining the base models with HiLAP yields an average performance improvement of 33.4% in Macro-F1 over corresponding flat classifiers and outperforms state-of-the-art HTC methods by a large margin. In particular, ablation study shows that HiLAP is especially beneficial to those unpopular labels at the bottom levels.

2 Hierarchical Label Assignment

2.1 Overview

Problem Formulation. We define a label hierarchy $H = (L, E)$ as a tree or DAG (directed acyclic graph)-structured hierarchy with a set of nodes (labels) L and a set of edges E indicating the parent-child relation between the labels. Taking a set of objects $\mathcal{X} = \{x_1, x_2, ..., x_N\}$ and their labels $\mathcal{L} = \{L_1, L_2, ..., L_N\}$ as input, we aim to

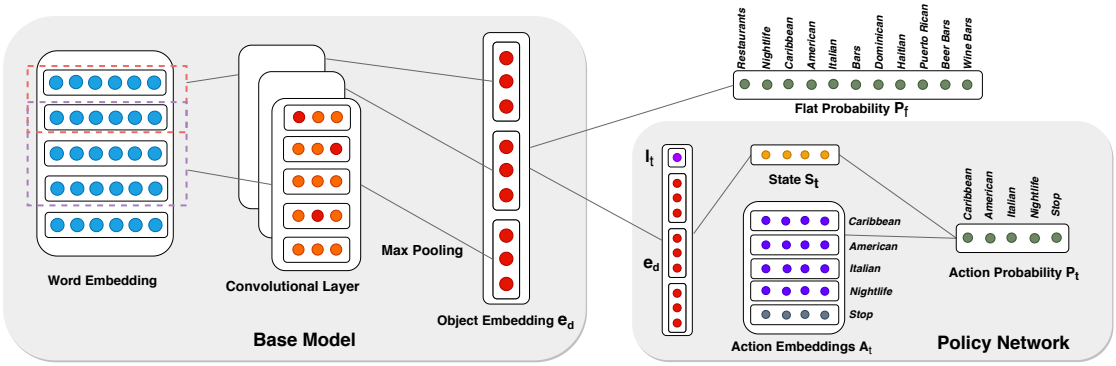

Figure 3: **The architecture of the proposed framework HiLAP**. One CNN model (Kim, 2014) is used as the base model for illustration. The object embedding $\mathbf{e}_d$ generated by the base model is combined with the embedding of currently assigned label $\mathbf{l}_t$ and used as the state representation $\mathbf{s}_t$, based on which actions are taken by the policy network. The time corresponds to $t = 1$ in Fig. 2.

learn a label assignment policy $\mathcal{P}$ to place each object x_i to its labels L_i on the label hierarchy H. The label assignment is supposed to be *consistent, multi-path, and non-mandatory leaf node prediction* (refer to Figs. 1 and 2). We define one *base model* $\mathcal{B}$ as a mapping f that converts raw object x_i to a finite dimensional vector, *i.e.*, the object embedding $\mathbf{e}_d \in \mathbb{R}^D$. $\mathcal{B}$ can be any neural representation learning model and its output $\mathbf{e}_d$ is used as the input of $\mathcal{P}$ for policy learning. The major challenge, compared to standard classification setup, is that we need to model E, *i.e.*, the relation between labels.

Our Framework. Prior studies either have a mismatch between training and inference as different routines are followed in the two phases, or compute losses with respect to each individual label and make flat predictions during inference time. In contrast, we learn a policy that (1) makes consistent, inter-dependent predictions by traversing the label hierarchy and maintaining state representation; (2) measures the holistic quality of label assignment via reinforcement learning. Specifically, the policy $\mathcal{P}$ puts x_i at the root label in the beginning. At each time step, $\mathcal{P}$ decides which label x_i should be further placed to, among all the *children* labels of where x_i has been placed, until a special *stop* action is taken. An illustration of how HiLAP labels one object is shown in Fig. 2 and the overall architecture of HiLAP is shown in Fig. 3.

2.2 Reinforcement Learning for Hierarchical Label Assignment

We describe the details of policy learning including its actions, rewards, states, and the policy network in this section. We formulate HTC as a Markov decision process (MDP): at each time step, the agent observes current state, takes an action, and receives a reward. The end goal is to train a policy network to determine where to place the objects and when to stop.

Actions. Specifically, we regard the process of placing an object x_i to the right positions on the label hierarchy as making a sequence of actions, where an action a_t at time step t is to select one label l_{t+1} from the action space $\mathcal{A}_t$ and place x_i to that label l_{t+1}. We denote the children of label l_t as $\mathcal{C}(l_t)$. At the beginning of each episode, x_i is placed at the root label l_0 and the action space $\mathcal{A}_0 = \mathcal{C}(l_0)$, *i.e.*, all the labels at level 1. When x_i is placed at another label l_1, its children $\mathcal{C}(l_1)$ are then added to the action space $\mathcal{A}_1$ while l_1 itself is removed. In addition, one *stop* action with embedding $\mathbf{e}_{\text{stop}} \in \mathbb{R}^C$ is included in the action space so that the model can automatically learn when to stop placing object x_i to new labels. Intuitively, when the confidence of placing x_i to another label is lower than the *stop* action, the label assignment process would be terminated.

In short, the action space $\mathcal{A}_t$ consists of all the *unvisited* children labels of where the object x_i *has been placed* and the *stop* action. One distinction of HiLAP is that it takes the inter-dependencies of labels across different paths and levels into consideration while previous approaches make independent predictions on different paths. For example, HiLAP can first place x_i to a label at level 3 if the probability of that label is high and then place it to another label at level 1 on another path.

Rewards. The agent receives scalar rewards as feedback for its actions. Different from exist-

ing work where each label of one example[2] is treated independently, HiLAP measures the quality of all the labels assigned to each example x_i by rewarding the agent with the *Example-based F1* (see Sec. 4.1 for details of this metric). Intuitively, the agent would realize how similar the assigned and the ground-truth labels of *one example* are. Instead of waiting until the end of the label assignment process and comparing the predicted labels with the gold labels, we use reward shaping (Mao et al., 2018), *i.e.*, giving intermediate rewards at each time step, to accelerate the learning process. Specifically, we set the reward r of x_i at time step t to be the difference of Example-based F1 scores between current and the last time step: $r_t^{x_i} = \text{F1}_t^{x_i} - \text{F1}_{t-1}^{x_i}$.

If current F1 is better than that at the last time step, the reward would be positive, and vice versa. The cumulative reward from current time step to the end of an episode would cancel the intermediate rewards and thus reflect whether the current action improves the holistic label assignment or not. As a result, the learned policy would not focus on the current placement but have a long-term view that takes following actions into account.

States and Policy Network. We parameterize action a_t by a policy network $\pi(\mathbf{a} \mid \mathbf{s}; \mathbf{W})$. For each object, its representation $\mathbf{e}_d$ is generated by the base model $\mathcal{B}$. For each label, a label embedding $\mathbf{l} \in \mathbb{R}^C$ is randomly initialized and updated during training. The embeddings of the object $\mathbf{e}_d$ and currently assigned label $\mathbf{l}_t$ are concatenated and projected to a vector $\mathbf{s}_t \in \mathbb{R}^C$ via a two-layer feed-forward network. $\mathbf{s}_t$ has the same size as the label embedding $\mathbf{l}$ and is used as the state representation at time step t. By stacking the action embeddings (*i.e.*, the embeddings of candidate labels and *stop* action), we obtain an action matrix $\mathbf{A}_t$ with size $|\mathcal{A}| \times C$. $\mathbf{A}_t$ is multiplied with the state embedding $\mathbf{s}_t$, which outputs the probability distribution of actions. Finally, an action a_t is sampled based on the probability distribution of the action space.

$$\begin{aligned} \mathbf{s}_t &= \text{ReLU}(\mathbf{W}_l^1 \text{ReLU}(\mathbf{W}_l^2[\mathbf{e}_d; \mathbf{l}_t])), \\ \pi(\mathbf{a}_t \mid \mathbf{s}; \mathbf{W}) &= \text{softmax}(\mathbf{A}_t \mathbf{s}_t), \\ a_t &\sim \pi(\mathbf{a}_t \mid \mathbf{s}; \mathbf{W}). \end{aligned}$$

We use policy gradient (Williams, 1992) as the optimization algorithm. In addition, we adopt a *self-critical* training approach (Rennie et al., 2017). For each object x_i, two label assignments are generated: $\tilde{L}_{x_i}$ is sampled from the probability distribution, and $\hat{L}_{x_i}$, the baseline label assignment, is greedily obtained by choosing the action with the highest probability at each time step. We use $\tilde{r}_t^{x_i} = r_t^{\tilde{L}_{x_i}} - r_t^{\hat{L}_{x_i}}$ as the actual reward, which ensures that the policy network learns to place the object to positions with higher F1 score than the greedy baseline. Formally, we measure the global loss $\mathcal{O}_g$ as follows.

$$\mathcal{O}_g = -\sum_{i=1}^{N}\sum_{t=1}^{T} log\pi^{x_i}(a_t \mid \mathbf{s}; \mathbf{W}) \times v_t^{x_i},$$

where $v_j^{x_i} = \sum_{t=j}^{T} \gamma^{t-j} \tilde{r}_t^{x_i}$ is the cumulative future reward at time j and $\gamma \in [0, 1]$ is the discount factor. At the time of inference, we greedily select labels with the highest probability as $\hat{L}_{x_i}$.

3 End-to-End Model Learning

3.1 Top-Down Supervised Pre-Training

Instead of learning from scratch, we use supervised learning to pre-train HiLAP. We denote the supervised variant as HiLAP-SL. While most parameters of HiLAP-SL are shared and used to initialize HiLAP (except that $\mathbf{e}_{\text{stop}}$ is randomly initialized), its way of exploring the label hierarchy H is dissimilar.

The major difference is that HiLAP-SL explores the label hierarchy H in a top-down manner independently. At each time step t, the object goes down one level on the hierarchy and the labels under the same parent are discriminated locally. Specifically, the local per-parent label probability distribution $\mathbf{p}_t^{\text{Local}}$ is estimated as $\mathbf{p}_t^{\text{Local}} = \sigma(\mathbf{C}_t \mathbf{s}_t)$, where σ denotes the sigmoid function, and $\mathbf{C}_t \in \mathbb{R}^{|\mathcal{C}(l_t)| \times C}$ denotes the candidate embeddings of HiLAP-SL, *i.e.*, an embedding matrix consisting of the children of *current* label l_t, rather than *all* the labels where x_i has been placed.

Another difference is that in HiLAP the actions are sampled and thus might place the objects to incorrect labels, while in HiLAP-SL only the ground-truth positions are traversed during training. Specifically, if there are $K(\geq 1)$ *ground-truth* labels at the same level, the object embedding $\mathbf{e}_d$ would be copied K times and losses on the K different paths would be measured independently (see Fig. 6 in Appendix for illustration). The local loss of HiLAP-SL is defined as $\mathcal{O}_l = \sum_{t=0}^{T} \mathcal{O}_t$, where T is the lowest label's

[2] We use "example" and "object" interchangeably.

level of one example and $\mathcal{O}_t$ estimates the binary cross entropy over the candidate labels $\mathcal{C}(l_t)$: $\mathcal{O}_t = -\sum_{i=1}^{N}\sum_{l\in\mathcal{C}(l_{t,i})} L_i(l) \times log\mathbf{p}_{t,i}^{\text{Local}}(l) + (1 - L_i(l)) \times log(1 - \mathbf{p}_{t,i}^{\text{Local}}(l))$, where $L_i(l)$ and $\mathbf{p}_{t,i}^{\text{Local}}(l)$ evaluate label l of x_i. Intuitively, HiLAP-SL works as if there were a set of local classifiers, although most of its parameters (except for the label embedding $\mathbf{l}$) are shared by all the labels so that there is no need to train multiple classifiers.

3.2 Combining Flat, Local, and Global Information for Policy Learning

We further add a *flat component* to HiLAP as a regularization of the base model. Specifically, the flat component is a feed-forward network that projects the object embedding $\mathbf{e}_d$ to a label probability distribution $\mathbf{p}^{\text{Flat}}$ of all the labels on the hierarchy: $\mathbf{p}^{\text{Flat}} = \sigma(\mathbf{W}^{\text{Flat}}\mathbf{e}_d)$. The combination of the base model and the flat component functions the same as a flat model and ensures that the object representation $\mathbf{e}_d$ has the capability of flat classification. We denote the flat loss that measures the binary cross entropy over all the labels by $\mathcal{O}_f = -\sum_{i=1}^{N}\sum_{l\in L} L_i(l) \times log\mathbf{p}_i^{\text{Flat}}(l) + (1 - L_i(l)) \times log(1 - \mathbf{p}_i^{\text{Flat}}(l))$. Combining the flat and local losses, the supervised loss in HiLAP-SL is defined as $\mathcal{O}_{\text{SL}} = \lambda\mathcal{O}_f + (1 - \lambda)\mathcal{O}_l$, where $\lambda \in [0, 1]$ is the mixing ratio. Similar to Celikyilmaz et al. (2018), we also found that mixing a proportion of the supervised loss is beneficial to the learning process of HiLAP. Further combining the global information $\mathcal{O}_g$ (*i.e.*, $\mathcal{O}_{\text{RL}}$), the total loss of HiLAP is defined as $\mathcal{O} = \mathcal{O}_{\text{RL}} + \alpha\mathcal{O}_{\text{SL}}$, where α is a scaling factor accounting for the difference in magnitude between $\mathcal{O}_{\text{RL}}$ and $\mathcal{O}_{\text{SL}}$. While we do not use the flat component during inference, it helps the representation learning of the base model and improves the performance of both HiLAP-SL and HiLAP (see Sec. 4.5).

4 Experiments

4.1 Experiment Setup

Datasets. We conduct extensive experiments on five public datasets from various domains (summarized in Table 1 and detailed in Appendix A). The first two datasets are related to news categorization, including RCV1 (Lewis et al., 2004) and the NYT annotated corpus (Sandhaus, 2008). The third dataset is the Yelp Dataset Challenge 2018[3]. We hypothesize that one business can be represented by its reviews and use the reviews to predict business categories. The last two datasets are related to protein functional catalogue (FunCat) and gene ontology (GO) prediction (Vens et al., 2008), which are used to test the generalization ability of HiLAP to non-textual data. For all the datasets, the lowest labels of one example may not be at the leaf nodes and there could be multiple labels at each level, making them harder and more realistic than *mandatory-leaf* or *single-path* datasets such as IPC (WIPO, 2014) and LSHTC (Partalas et al., 2015).

Table 1: **Statistics of the datasets.** $|L|$ denotes the number of labels in the label hierarchy. Avg($|L_i|$) and Max($|L_i|$) denote the average and maximum number of labels of one object, respectively.

Dataset	Hierarchy	$\|L\|$	Avg($\|L_i\|$)	Max($\|L_i\|$)	Training	Validation	Test
RCV1	Tree	103	3.24	17	23,149	2,315	781,265
NYT	Tree	115	2.52	14	25,279	2,528	10,828
Yelp	DAG	539	3.77	32	87,375	8,737	37,265
FunCat	Tree	499	8.76	45	1,628	848	1,281
GO	DAG	4,125	34.9	141	1,625	848	1,278

Evaluation Metrics. We use standard metrics (Johnson and Zhang, 2014; Meng et al., 2018; Peng et al., 2018) for HTC, including **Micro-F1**, **Macro-F1**, and **Example-based F1 (EBF)** (Partalas et al., 2015; Peng et al., 2016). Let TP_i, FP_i, FN_i denote the true positive, false positive, and false negative for the i-th *example* x_i in object set X, respectively. EBF calculates the F1 scores of all the *examples* independently and averages them. $P^{x_i} = \frac{TP_i}{TP_i+FP_i}$, $R^{x_i} = \frac{TP_i}{TP_i+FN_i}$, $\text{F1}^{x_i} = \frac{2P^{x_i}\times R^{x_i}}{P^{x_i}+R^{x_i}}$, and $\text{EBF} = \frac{1}{N}\sum_{i=1}^{N}\text{F1}^{x_i}$. Recall that F1^{x_i} is used as the reward in HiLAP.

Base Models for Feature Encoding. Different from most of existing *global* HTC methods that rely on pre-specified features (Gopal and Yang, 2013) as input or build on specific models (Cai and Hofmann, 2004; Vens et al., 2008; Silla Jr and Freitas, 2009), our framework is trained in an end-to-end manner by leveraging a differentiable feature representation learning model as the *base model*. Specifically, we use **TextCNN** (Kim, 2014), **HAN** (Yang et al., 2016), **bow-CNN** (Johnson and Zhang, 2014) on the three textual datasets, and a **feed-forward network** on the two non-textual datasets. The details of the base models

[3] https://www.yelp.com/dataset/challenge

Table 2: **Performance comparison on RCV1.** * denotes the results reported in Peng et al. (2018) on the same dataset split. Note that the results of HR-SVM reported in Gopal and Yang (2013) are not comparable as they use a different hierarchy with 137 labels.

	Method	Micro-F1	Macro-F1	EBF

HMCN	72.2	47.4	74.2	66.4	42.7	67.6
HiLAP (TextCNN)	69.9	43.2	72.8	65.5	37.3	68.4
HiLAP (HAN)	65.2	28.7	68.0	**69.7**	38.1	**72.4**
HiLAP (bow-CNN)	**74.6**	**51.6**	**76.6**	68.9	**42.8**	71.5

are provided in Appendix C due to limited space.

To incorporate one base model into our framework, we remove its final feed-forward layer that projects the object representation $\mathbf{e}_d$ to a flat probability distribution of all labels ($\mathbf{p}^{\text{Flat}}$), and use $\mathbf{e}_d$ directly as the input of HiLAP. As one will see in the later experiments, HiLAP consistently improves the base model by modeling the label hierarchy in an effective manner.

4.2 Compared Methods

1. Traditional HTC Methods. A major line of work for HTC is Support Vector Machines (SVM) and its hierarchical variants. Specifically, **SVM** performs standard multi-label classification using one-vs-the-rest (OvR) strategy. **Leaf-SVM** treats each leaf node as a label and adds the ancestors of predicted leaf nodes. Variants such as **HSVM** (Tsochantaridis et al., 2005), Top-Down SVM (**TD-SVM**) (Liu et al., 2005), and Hierarchically Regularized SVM (**HR-SVM**) (Gopal and Yang, 2013) are also tested. Other state-of-the-art HTC methods that we compare with include **Clus-HMC** (Vens et al., 2008) and **CSSA** (Bi and Kwok, 2011).

2. Neural HTC Methods. There are not many neural methods that specifically target HTC. We mainly compare with two *latest* neural models: **HR-DGCNN** (Peng et al., 2018), which extends hierarchical regularization (Gopal and Yang, 2013) to Graph-CNN and compares favorably to flat models like RCNN (Lai et al., 2015) and XML-CNN (Liu et al., 2017), and **HMCN** (Wehrmann et al., 2018), which outperforms state-of-the-art HTC methods such as HMC-LMLP (Cerri et al., 2016). We also compare with the base models that we use for feature encoding. The main aim is to see how much gain they could obtain by combining each one of them with HiLAP.

4.3 Implementation Details

For datasets without held-out set, we randomly sample 10% from the training set as the validation set following Johnson and Zhang (2014); Peng et al. (2018). We only use the first 256 tokens of each document for representation learning. All the models are trained using an Adam optimizer with initial learning rate 1e-3 and weight decay 1e-6. We use GloVe (Pennington et al., 2014) with size 50 as word embeddings for TextCNN (Kim, 2014) and HAN (Yang et al., 2016). We create a vocabulary of the most frequent 30,000 words in the training data and generate multi-hot vectors as the input of bow-CNN (Johnson and Zhang, 2014). For our framework, since the parameter updates are performed after T steps, we cache the object representation $\mathbf{e}_d$ and reuse it at each step for better efficiency. More details are provided in Appendix D for reproducibility.

4.4 Performance Comparison

1. Comparison with State-of-the-art Methods. We compare the performance of HiLAP to state-of-the-art HTC methods and show the results in Tables 2 and 3. On RCV1, HiLAP (HAN) achieves similar performance to HR-DGCNN even though the corresponding base model HAN is originally worse than HR-DGCNN. HiLAP (TextCNN) outperforms most baselines in Macro-F1 and perform similarly to TD-SVM despite that it uses one global classifier while TD-

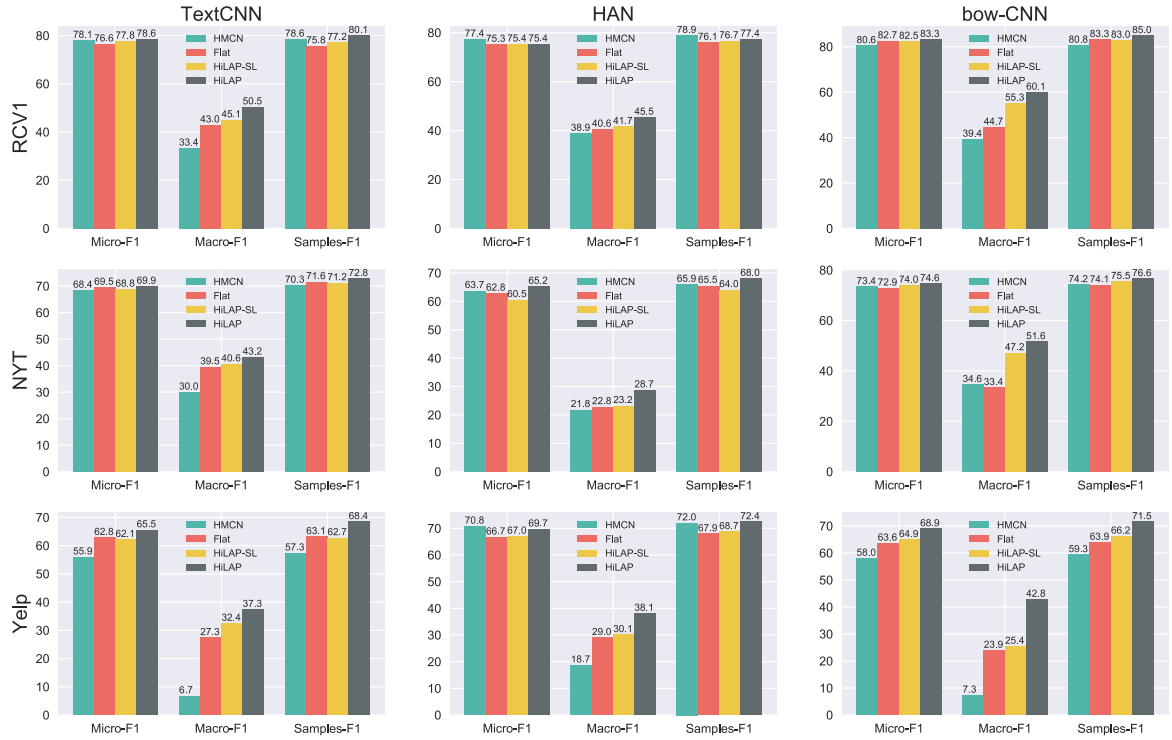

Figure 4: **Performance comparison of different classification frameworks using the same base models.** We compare HiLAP with its flat, supervised variants, and HMCN. Results show that HiLAP exhibits consistent improvement over flat classifiers and larger gains than HMCN.

SVM uses a set of classifiers. Among all compared methods, HiLAP (bow-CNN) achieves the best performance on all the three metrics.[4] On NYT, similar results are observed: TextCNN and HAN are both improved when combining with HiLAP and HiLAP (bow-CNN) again achieves the best performance. On Yelp, HiLAP (HAN) achieves the best Micro-F1 and EBF, while HiLAP (bow-CNN) obtains the highest Macro-F1.

2. Comparison using Same Base Models. We compare the performance of different frameworks that support the use of *exactly the same* base models and summarize the results in Fig. 4.[5] Due to the extreme imbalance of the data, directly applying a flat model may suffer from low Macro-F1, *i.e.*, the predictions of flat models are inevitably biased to the most popular labels. HMCN also has the same issue, resulting in Macro-F1 lower than 10 when combining with some base models. In contrast, HiLAP outperforms the baselines significantly in Macro-F1, which implies that our method is better at tackling labels with relatively few examples. It is also observed that HiLAP-SL sometimes may have a negative effect in terms of Micro-F1, although it is usually marginal compared with the gains in Macro-F1. However, such negative effects are eliminated by HiLAP through better exploration of the label hierarchy. Overall, HiLAP achieves the highest performance on 24 of 27 results among the combinations of three datasets, three base models, and three evaluation metrics. In particular, HiLAP yields an average improvement of 33.4% in Macro-F1 compared to corresponding base models.

Table 4: **Performance comparison on Functional Catalogue and Gene Ontology.** We compare with state-of-the-art hierarchical classification methods that take exactly the same raw features as input (*i.e.*, we exclude models designed specifically for text objects).

Method	FunCat			GO		
	Micro-F1	Macro-F1	EBF	Micro-F1	Macro-F1	EBF
SVM	2.72	1.21	3.42	34.1	1.46	36.8
CSSA	16.0	4.60	14.8	11.6	0.76	11.5
CLUS-HMC	25.2	4.14	24.1	41.4	3.01	40.3
HMCN	21.3	5.07	21.5	43.2	3.81	43.3
HiLAP	**26.5**	**7.50**	**27.4**	**45.4**	**5.87**	**45.2**

3. Results on Functional Genomics Prediction. We compare HiLAP with CSSA (Bi and

[4]The results are not comparable with Johnson and Zhang (2014) due to implementation details and the fact that they tune the threshold for each label using k-fold cross-validation. See Appendix B for more discussions.

[5]For HMCN, we replace its static features with the same base model for fair comparison.

Table 5: **Ablation study of HiLAP.** We evaluate variants of HiLAP using bow-CNN (Johnson and Zhang, 2014) on RCV1 (Lewis et al., 2004).

Method	Micro-F1	Macro-F1	EBF
Flat-Only	82.7	44.7	83.3
HiLAP-SL-NoFlat	81.0	52.1	81.7
HiLAP-SL	82.5	55.3	83.0
HiLAP-NoSL	83.2	59.3	85.0
HiLAP-NoFlat	83.0	59.8	84.7
HiLAP	**83.3**	**60.1**	**85.0**

Kwok, 2011), CLUS-HMC (Vens et al., 2008), and HMCN (Wehrmann et al., 2018) on the FunCat and GO datasets, as they represent the state-of-the-art on these datasets. An SVM classifier is also evaluated to better understand the difficulties of the task. We use the same raw features as the input of all the methods for apples-to-apples comparison and list the results in Table 4. Note that the metric *area under the average precision-recall curve (AUPRC)* (Wehrmann et al., 2018) is not applicable because HiLAP does not use a flat probability distribution of all the labels. As one can see, HiLAP outperforms all the baselines on both datasets by a large margin. In particular, we observe significant improvement on Macro-F1 over the best baseline (47.9% and 53.9%, respectively), which shows that our method is especially better at classifying sparse labels than previous approaches.

4.5 Performance Analysis

1. Ablation Study on Different Framework Components. We show the ablation analysis of HiLAP in Table 5. Using *Flat-Only* degenerates HiLAP to the flat baseline. By comparing the results of *Flat-Only* and HiLAP-SL-NoFlat (a variant of HiLAP-SL without flat loss), we further confirm that flat approaches are likely to neglect sparse labels, which results in low Macro-F1. Local approaches (HiLAP-SL-NoFlat), on the other hand, are slightly worse in terms of Micro-F1 and EBF but significantly better on Macro-F1. By combining flat and local information, HiLAP-SL achieves performance close to *Flat-Only* on Micro-F1 and EBF, and even higher Macro-F1 than HiLAP-SL-NoFlat. HiLAP-NoSL is initialized by the pre-trained HiLAP-SL model without mixing the supervised loss during its training. We can see that using the reinforced loss alone still improves the performance on all the three metrics. After removing the flat loss during the training of HiLAP, HiLAP-NoFlat shows slightly lower performance than the full HiLAP model, indicating that the flat component serves as a regularization of the base model and is beneficial to the overall performance.

2. Performance Study on Label Granularity and Popularity. We analyze the sources of performance gains by dividing the labels based on their levels and number of supporting examples. Fig. 5 shows the absolute Macro-F1 differences between several methods and the base model. We observe similar results for other setups and omit them for a clearer view. As depicted in Fig. 5, HiLAP and HiLAP-SL are especially beneficial to unpopular labels (P3) at the bottom levels (L3).

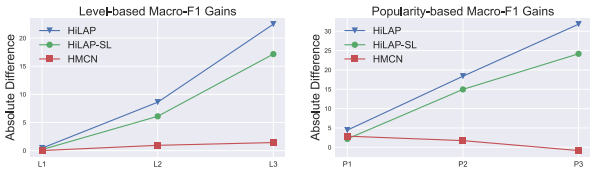

Figure 5: **Performance Study on Label Granularity and Popularity.** We compute level-based and popularity-based Macro-F1 gains on NYT with bow-CNN as base model. We denote the levels of the hierarchy with L1, L2, and L3 (*left*) and divide the labels into three equal sized categories (P1, P2, and P3) in a descending order by their number of examples (*right*).

3. Analysis of Label Inconsistency. Label inconsistencies often happen in approaches that perform flat inference, but they are not measured by standard evaluation metrics like F1 scores. To provide a picture of how severe the issue is, we further conduct experiments to check the percentage of objects that are predicted with inconsistent labels (Table 6). We found, for example, 29,186/781,265 (3.74%) predictions of TextCNN have inconsistent on RCV1. In contrast, HiLAP ensures **0%** label inconsistency without the need of post-processing, because its predictions are always valid sub-trees of the label hierarchy (refer to Fig. 2).

Table 6: **Analysis of Label Inconsistency.** We compare various methods by the percentage of predictions with inconsistent labels on RCV1 (Lewis et al., 2004).

SVM	TextCNN	HMCN	HiLAP
4.83%	3.74%	3.84%	**0%**

5 Related Work

Hierarchical classification approaches have been developed for many applications. For text classification, both traditional methods (Lewis et al., 2004; Gopal and Yang, 2013) and neural methods (Johnson and Zhang, 2014; Peng et al., 2018) have been proposed to classify, *e.g.*, the topics of newswire and web content (Sun and Lim, 2001) or categories of laws and patents (Bi and Kwok, 2015; Cai and Hofmann, 2004; Rousu et al., 2005). Many previous studies (Liu et al., 2005; Sun and Lim, 2001) train a set of local classifiers and make predictions in a top-down manner. In particular, Bi and Kwok (2015) develop Bayes-optimal predictions that minimize the global risks but their model is still locally trained. Such local approaches are not popularly used among recent neural-based HTC models (Johnson and Zhang, 2014; Peng et al., 2018) since it is usually infeasible to train many neural classifiers locally.

Global methods, on the other hand, train only one classifier. Although global methods are desirable, they are relatively less studied due to the complexity of the problem. Existing global models are generally modified based on specific flat models. Hierarchical-SVM (Cai and Hofmann, 2004; Qiu et al., 2009) generalizes Support Vector Machine (SVM) learning based on discriminant functions that are structured in a way that mirrors the label hierarchy. One limitation is that Hierarchical-SVM only supports balanced tree (all possible labels are presumed to be at the same level in their experiments). Hierarchical naive Bayes (Silla Jr and Freitas, 2009) modifies naive Bayes by updating weights of one's ancestors as well whenever one label's weights are updated. There are other global methods that are based on association rules (Wang et al., 2001), C4.5 (Clare and King, 2003), kernel machines (Rousu et al., 2005), and decision tree (Vens et al., 2008). Constraints such as the regularization that enforces the parameters of one node and its parent to be similar (Gopal and Yang, 2013) are also proposed to leverage the label hierarchy while maintaining scalability. However, their use of the label hierarchies is somewhat limited compared with HiLAP.

6 Conclusions

We proposed an end-to-end reinforcement learning approach to hierarchical text classification (HTC) where objects are labeled by placing them at the proper positions in the label hierarchy. The proposed framework makes *consistent* and *inter-dependent* predictions, in which any neural-based representation learning model can be used as a base model and a label assignment policy is learned to determine where to place the objects and when to stop the assignment process. Experiments on five public datasets and four base models showed that our approach outperforms state-of-the-art HTC methods significantly. For future work, we will explore the effectiveness of the proposed framework on other base models and forms of data (*e.g.*, images). We will introduce more losses covering other aspects in the objective function to further improve the performance of our framework.

Abstract

As an essential component of natural language processing, text classification relies on deep learning in recent years. Various neural networks are designed for text classification on the basis of word embedding. However, polysemy is a fundamental feature of the natural language, which brings challenges to text classification. One polysemic word contains more than one sense, while the word embedding procedure conflates different senses of a polysemic word into a single vector. Extracting the distinct representation for the specific sense could thus lead to fine-grained models with strong generalization ability. It has been demonstrated that multiple senses of a word actually reside in linear superposition within the word embedding so that specific senses can be extracted from the original word embedding. Therefore, we propose to use capsule networks to construct the vectorized representation of semantics and utilize hyperplanes to decompose each capsule to acquire the specific senses. A novel dynamic routing mechanism named 'routing-on-hyperplane' will select the proper sense for the downstream classification task. Our model is evaluated on 6 different datasets, and the experimental results show that our model is capable of extracting more discriminative semantic features and yields a significant performance gain compared to other baseline methods.

1 Introduction

Text classification is a crucial task in natural language processing, which has many applications, such as sentiment analysis, intent identification and topic labeling[Aggarwal and Zhai, 2012; Wang and Manning, 2012a]. Recent years, many studies rely on neural networks and have shown promising performance.

The success of deep learning model for NLP is based on the progress in learning distributed word representations in semantic vector space, where each word is mapped to a vector called a word embedding. The word's representation is calculated relying on the *distributional hypothesis* - the assumption that semantically similar or related words appear in similar contexts [Mikolov *et al.*, 2013; Langendoen, 1959]. Normally, each word's representation is constructed by counting all its context features. However, for the polysemic word which contains multiple senses, the context features of different senses are mixed together, leading to inaccurate word representation. As demonstrated in [Arora *et al.*, 2018], multiple senses of a word actually reside in linear superposition within the word embedding:

$$v \approx \alpha_1 v_{sense1} + \alpha_2 v_{sense2} + \alpha_3 v_{sense3} + \cdots , \quad (1)$$

where coefficients α_i are nonnegative and $v_{sense1}, v_{sense2}...$ are the hypothetical embeddings of different senses. As a result, the word embedding v deviates from any sense, which brings ambiguity for the subsequent task. It demands us to extract the separate senses from the overall word representation to avoid the ambiguity.

Similar to the word embedding, the recently proposed capsule network constructs vectorized representations for different entities[Hinton *et al.*, 2018; Sabour *et al.*, 2017; Hinton *et al.*, 2011]. A dynamic routing mechanism, 'routing-by-agreement', is implemented to ensure that the output of the capsule gets sent to an appropriate parent in the layer above. Very recently, capsule network is applied in the field of NLP where each capsule is obtained from the word embedding. Compared with the standard neural nets using a single scalar (the output of a neural unit) to represent the detected semantics, the vectorized rep-

resentation in capsule network enables us to utilize hyperplanes to extract the component from the overall representation and get the specific sense.

Therefore, we propose to attach different hyperplanes to capsules to tackle the ambiguity caused by polysemy. Each capsule is decomposed by projecting the output vector on the hyperplanes, which can extract the specific semantic feature. The projected capsule denotes a specific sense of the target words, and a novel dynamic routing mechanism named 'routing-on-hyperplane' will decide which specific senses are selected for the downstream classification and which senses are ignored. Similar to routing-by-agreement [Sabour *et al.*, 2017], we aim to activate a higher-level capsule whose output vector is agreed with the predictions from the lower-level capsules. Differently, before the active capsule at a level makes predictions for the next-level capsules, the capsule's output vector will be projected on the trainable hyperplane. The hyperplanes will be trained discriminatively to extract specific senses. Moreover, in order to encourage the diversity of the hyperplanes, a well-designed penalization term is implemented in our model. We define the cosine similarity between the normal vectors of the hyperplanes as a measure of redundancy, and minimize it together with the original loss.

We test our model (HCapsNet) on the text classification task and conduct extensive experiments on 6 datasets. Experimental results show that the proposed model could learn more discriminative features and outperform other baselines. Our main contributions are summarized as follows:

- We explore the capsule network for text classification and propose to decompose capsules by means of projecting on hyperplanes to tackle the polysemy problem in natural language.
- Propose routing-on-hyperplane to dynamically select specific senses for the subsequent classification. A penalization term is designed to obtain diversified hyperplanes and offer multiple senses representations of words.
- Our work is among the few studies which prove that the idea of capsule networks have promising applications on natural language processing tasks.

2 Related Work

2.1 Neural Networks for Text Classification

Various neural networks for text classification have been proposed based on the word embedding. Commonly used models include convolutional neural networks [Kim, 2014], recursive neural network [Socher *et al.*, 2013] and recurrent neural networks. There have been several recent studies of CNN for text classification in the large training dataset and deep complex model structures [Schwenk *et al.*, 2017; Johnson and Zhang, 2017]. Some models were proposed to combine the strength of CNN and RNN [Lai *et al.*, 2015; Zhang *et al.*, 2016]. Moreover, the accuracy was further improved by attention-based neural networks[Lin *et al.*, 2017; Vaswani *et al.*, 2017; Yang *et al.*, 2016]. However, these models are less efficient than capsule networks.

As a universal phenomenon of language, polysemy calls much attention of linguists. It has been demonstrated that learning a distinct representation for each sense of an ambiguous word could lead to more powerful and fine-grained models based on vector-space representations [Li and Jurafsky, 2015].

2.2 Capsule Network

Capsule network was proposed to improve the representational limitations of CNN and RNN by extracting features in the form of vectors. The technique was firstly proposed in [Hinton *et al.*, 2011] and improved in [Sabour *et al.*, 2017] and [Hinton *et al.*, 2018]. Vector-based representation is able to encode latent inter-dependencies between groups of input features during the learning process. Introducing capsules also allows us to use routing mechanism to generate high-level features which is a more efficient way for feature encoding.

Several types of capsule networks have been proposed for natural language processing. Yang *et al.* [2018] investigated capsule networks with routing-by-agreement for text classification. They also found that capsule networks exhibit significant improvement when transfer single-label to multi-label text classification. Capsule networks also show a good performance in multi-task learning [Xiao *et al.*, 2018]. Xia *et al.* [2018] discovered the capsule-based model's potential on zero-shot learning. However, existing capsule networks for natural language processing cannot model the

polysemic words or phrases which contain multiple senses.

3 Model

In this section, we begin by introducing the idea of routing-on-hyperplane and formulate it in details. Then the architecture of the HCapsNet is formally presented in the second subsection. Finally, the penalization term and loss function implemented in this paper are explained.

3.1 Routing-on-hyperplane

Suppose that we have already decided on the output vectors of all the capsules in the layer L and we now want to decide which capsules to activate in the layer $L+1$. We should also consider how to assign each active capsule in the layer L to one active capsule in the layer $L+1$. The output vector of capsule i in the layer L is denoted by $\boldsymbol{u}_i$, and the output vector of capsule j in the layer $L+1$ is denoted by $\boldsymbol{v}_j$.

Firstly, for all the capsules in the layer L, we attach the trainable hyperplane to each capsule. Capsule's output vectors will be projected on the hyperplanes before making predictions. More specifically, for capsule i, we define the trainable matrix $\boldsymbol{W}_i^h$, which is used to decide the normal vector $\boldsymbol{w}_i$ of the attached hyperplane. By restricting $\|\boldsymbol{w}_i\|_2 = 1$, we can get the projected capsule's output vector $\boldsymbol{u}_{\perp i}$:

$$\boldsymbol{w}_i = \boldsymbol{W}_i^h \boldsymbol{u}_i. \tag{2}$$

$$\boldsymbol{u}_{\perp i} = \boldsymbol{u}_i - \boldsymbol{w}_i^{\mathsf{T}} \boldsymbol{u}_i \boldsymbol{w}_i. \tag{3}$$

In this way, the output vectors of capsules will be projected on the specific hyperplanes to get different components which denote the specific senses in our task. To retain or ignore a specific sense (projected capsule) will be decided through an iterative procedure. The procedure contains making predictions and calculating the agreement. When one projected capsule's prediction is highly agreed with one target parent capsule, the probability of retaining the projected capsule gets gradually larger. In another word, when a specific sense is highly relevant with the subsequent classification, we choose to keep it and ignore others.

Therefore, the $\boldsymbol{u}_{\perp i}$ will then be used to make predictions for the $L+1$ layer's capsules and calculate coupling coefficients c_{ij}. When making predictions, the capsules in the layer L will multiply their projected output vector $\boldsymbol{u}_{\perp i}$ by a weight matrix $\boldsymbol{W}_{ij}$:

$$\hat{\boldsymbol{u}}_{\perp j|i} = \boldsymbol{W}_{ij} \boldsymbol{u}_{\perp i}, \tag{4}$$

where $\hat{\boldsymbol{u}}_{\perp j|i}$ denotes the 'vote' of the capsule i for the capsule j. The agreement between the prediction vector $\hat{\boldsymbol{u}}_{\perp j|i}$ with current output vector of parent capsule j will be fed back to the coupling coefficients c_{ij} between the two capsules: increase c_{ij} if highly agreed. Similar with [Sabour *et al.*, 2017] we define the agreement as scalar product between the two vectors. b_{ij} is the accumulation of the agreement after each iteration and the softmax function is implemented to ensure the coupling coefficients between the capsule i and all the capsules in the layer above sum to one:

$$b_{ij} \leftarrow b_{ij} + \hat{\boldsymbol{u}}_{\perp j|i} \cdot \boldsymbol{v}_j \tag{5}$$

$$c_{ij} = \frac{exp(b_{ij})}{\sum_k exp(b_{ik})} \tag{6}$$

Algorithm 1 Routing-on-hyperplane returns the output vector of capsule j in the layer $L+1$ given the output vector of capsule i in the layer L. $\boldsymbol{W}_{ij}$ are trainable parameters denoting the transformation matrix between the two adjacent layers. $\boldsymbol{W}_i^h$ are trainable parameters for each capsule i to calculate the proposed hyperplane's normal vectors $\boldsymbol{w}_i$, we restrict that $\|\boldsymbol{w}_i\|_2 = 1$.

initialize the routing logits:
for all capsule i in the layer L and capsule j in the layer $L+1$: $b_{ij} \leftarrow 0$;
for every capsule i in the layer L: $\boldsymbol{w}_i = \boldsymbol{W}_i^h \boldsymbol{u}_i$
for every capsule i in the layer L: $\boldsymbol{u}_{\perp i} \leftarrow \boldsymbol{u}_i - \boldsymbol{w}_i^{\mathsf{T}} \boldsymbol{u}_i \boldsymbol{w}_i$
for every capsule i in the layer L: $\hat{\boldsymbol{u}}_{\perp j|i} = \boldsymbol{W}_{ij} \boldsymbol{u}_{\perp i}$
for r iterations **do**
  for all capsule i and j: $c_{ij} \leftarrow \frac{exp(b_{ij})}{\sum_k exp(b_{ik})}$
  for all capsule j in the layer $L+1$: $\boldsymbol{s}_{\perp j} \leftarrow \sum_i c_{ij} \hat{\boldsymbol{u}}_{\perp j|i}$
  for all capsule j in the layer $L+1$: $\boldsymbol{v}_j \leftarrow \frac{\|\boldsymbol{s}_{\perp j}\|^2}{1+\|\boldsymbol{s}_{\perp j}\|^2} \frac{\boldsymbol{s}_{\perp j}}{\|\boldsymbol{s}_{\perp j}\|}$
  for all capsule i and capsule j: $b_{ij} \leftarrow b_{ij} + \hat{\boldsymbol{u}}_{\perp j|i} \cdot \boldsymbol{v}_j$
end for
return $\boldsymbol{v}_j$

Each iteration will result in a temporary output vector of the capsule j: the weighted sum over all prediction vectors $\hat{\boldsymbol{u}}_{\perp j|i}$ using coefficient c_{ij}. Moreover, to ensure the length of the output vector of capsule j is able to represent the probability and prevent it from being too big, we use a non-linear 'squashing' function to make the vector's length range from zero to one without changing the vector's direction:

$$\boldsymbol{s}_{\perp j} = \sum_i c_{ij} \hat{\mathbf{u}}_{\perp j|i}. \tag{7}$$

$$\boldsymbol{v}_j = \frac{\|\boldsymbol{s}_{\perp j}\|^2}{1 + \|\boldsymbol{s}_{\perp j}\|^2} \frac{\boldsymbol{s}_{\perp j}}{\|\boldsymbol{s}_{\perp j}\|}. \tag{8}$$

The $\boldsymbol{v}_j$ will then be returned as input to calculate the agreement for the next iteration. The coupling coefficients c_{ij} and the output vector of capsule j gradually converge after several iterations. After the last iteration of the routing process, the coupling coefficients c_{ij} is determined. Hyperplane plays the role to extract specific senses and assist to route the lower-level capsules to the right parent capsules. We detail the whole routing-on-hyperplane algorithm in Algorithm 1.

3.2 HCapsNet Model Architecture

We propose a model named HCapsNet for text classification based on the theory of capsule network and routing-on-hyperplane. The architecture is illustrated in Figure 1. The model consists of three layers: one bi-directional recurrent layer, one convolutional capsule layer, and one fully connected capsule layer. The input of the model is a sentence S consisting of a sequence of word tokens $t_1, t_2, ..., t_n$. The output of the model contains a series of capsules. Each top-level capsule corresponds to a sentence category. The length of the top-level capsule's output vector is the probability p that the input sentence S belongs to the corresponding category.

The recurrent neural network can capture long-distance dependencies within a sentence. For this strength, a bi-directional recurrent neural network is the first layer of HCapsNet. We concatenate the left context and the right context as the word's elementary representation x_i, which is the input to the second layer:

$$c_l(t_i) = \overrightarrow{RNN}(t_i), \tag{9}$$

$$c_r(t_i) = \overleftarrow{RNN}(t_i), \tag{10}$$

$$x_i = [c_l(t_i), c_r(t_i)]. \tag{11}$$

The second layer is a convolutional capsule layer. This is the first layer consisting of capsules, we call capsules in this layer as primary capsules. Primary capsules are groups of detected features which means piecing instantiated parts together to make familiar wholes. Since the output of the bi-directional recurrent neural network is not in the form of capsules, no routing method is used in this layer.

The final layer is fully connected capsule layer. Each capsule corresponds to a sentence class. All the capsules in this layer receive the output of the lower-level capsules by the routing-on-hyperplane method as we described in Section 3.1. The length of the top-level capsule's output vector represents the probability that the input sentence belongs to the corresponding category.

3.3 Penalization Term

The HCapsNet may suffer from redundancy problem if the output vectors of capsules are always getting projected on the similar hyperplanes at the routing-on-hyperplane procedure. Thus, we need a penalization term to encourage the diversity of the hyperplanes. We introduce an easy penalization term with low time complexity and space cost. Firstly, we construct a matrix X_i the columns of which is the normal vectors w of the hyperplanes for the ith word. The dot product of X_i and its transpose, subtracted by an identity matrix is defined as a measure of redundancy. The penalization term is the sum of all the words' redundancy:

$$P_i = ||(X_i X_i^{\mathsf{T}} - I)||_F^2. \tag{12}$$

$$P = \sum_i P_i, \tag{13}$$

where $||\bullet||_F$ stands for the Frobenius norm of a matrix. Similar to adding the L2 regularization term, this penalization term P will be multiplied by a coefficient, and we minimize it together with the original loss.

Let's consider the two columns w^a and w^b in X_i, which are two normal vectors of hyperplanes for the ith word. We have restricted that $||w|| = 1$ as described in Algorithm 1. For any non-diagonal elements x_{ab} $(a \neq b)$ in the $X_i X_i^{\mathsf{T}}$ matrix, it corresponds to the cosine similarity between the two

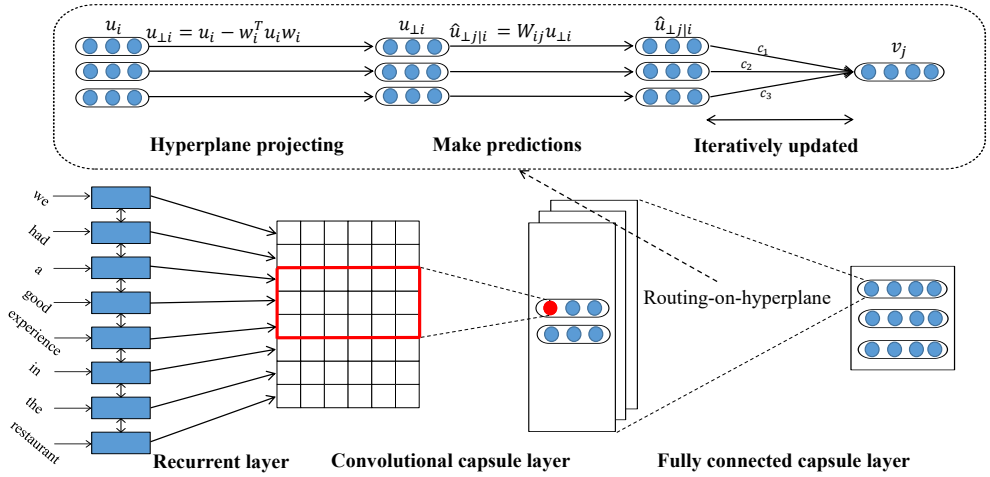

Figure 1: The architecture of HCapsNet

normal vectors:

$$-1 < x_{ab} = \sum_k w_k^a w_k^b < 1. \quad (14)$$

where w_k^a and w_k^b are k-th element in the w^a and w^b vectors, respectively. In the most extreme case, where the two normal vectors of hyperplanes are orthometric with each other, i.e. the word is projected to two extremely different meanings, the corresponding x_{ab} is 0. Otherwise, the absolute value will be positive. In the other most extreme case, where the two normal vectors of hyperplanes are identical, i.e. the word is projected to the same vector, the corresponding absolute value of x_{ab} is 1. The diagonal elements x_{ab} $(a = b)$ in the $X_i X_i^\mathsf{T}$ matrix is the normal vectors' cosine similarity with themselves, so they are all 1. The $X_i X_i^\mathsf{T}$ is subtracted by an identity matrix I so as to eliminate the meaningless elements. We minimize the Frobenius norm of P_i to encourage the non-diagonal elements in P_i to converge to 0, in another word, to encourage word vector to be projected on orthometric hyperplanes and get diversified explanation.

3.4 Loss Function

In HCapsNet, each top-level capsule corresponds to a sentence category. The length of the top-level capsule's output vector represents the probability that the input sentence belongs to the corresponding category. We would like the top-level capsule for the category k to have a long output vector if the input sentence belongs to the category k and have a short output vector if the input sentence does not belong to the category k. Similar with [Sabour *et al.*, 2017], We use a separate margin loss, L_k for each top-level capsule k. The total loss L is simply the sum of the losses of all top-level capsules:

$$L = \sum_k \{T_k \max(0, m^+ - ||\boldsymbol{v_k}||)^2 + \lambda_1 (1 - T_k) \max(0, ||\boldsymbol{v_k}|| - m^-)^2\} + \lambda_2 P, \quad (15)$$

where T_k will be 1 if the sentence belongs to the k class, or else T_k will be 0. $||\boldsymbol{v_k}||$ is the length of the output vector of capsule k. We introduce λ_1 to reduce the penalization to avoid shrinking the length of the capsules' output vectors in the initial learning stage. P is the penalization term introduced in Section 3.3. In our experiments, $m^+ = 0.9$, $m^- = 0.1$, $\lambda_1 = 0.5$.

4 Experiments

We compare our method with the widely used text classification methods and baseline models (listed in Table 1).

4.1 Datasets

HCapsNet is evaluated on six widely studied datasets including three common text classification tasks: sentiment analysis, question classification and topic classification. These datasets are Stanford Sentiment Treebank [Socher *et al.*, 2013], Movie Review Data [Pang and Lee, 2005], Subjectivity dataset [Pang and Lee, 2004], TREC [Li and Roth, 2002] and AG's corpus of news articles [Zhang *et al.*, 2015b]. Summary statistics of the datasets are listed in Table2.

4.2 Hyperparameters

In our experiments, we use 300-dimensional word2vec [Mikolov *et al.*, 2013] vectors to initialize word representations. In the first bi-directional RNN layer of HCapsNet, we use Long Short Term Memory network, the dimension of the hidden state is 256. The second layer contains 32 channels of primary capsules and the number of capsules in one channel depends on the sentence length. Each primary capsule contains 8 atoms which means that the dimension of the primary capsules is 8. The top-level capsules are obtained after 3 routing iterations. The dimension of the output vector of top-level capsules is 16. For all the datasets, we conduct mini-batch with size 25. We use Adam [Kingma and Ba, 2014] as our optimization method with $1e-3$ learning rate. λ_2 is 0.01.

4.3 Results and Discussions

Table 1 reports the results of our model on different datasets comparing with the widely used text classification methods and state-of-the-art approaches. We can have the following observations.

Our HCapsNet achieves the best results on 5 out of 6 datasets, which verifies the effectiveness of our model. In particular, HCapsNet outperforms vanilla capsule network Capsule-B[Yang *et al.*, 2018] by a remarkable margin, which only utilizes the dynamic routing mechanism without hyperplane projecting.

HCapNet does not perform best on the TREC dataset. One main reason maybe TREC dataset is used for question type classification, where samples are all question sentences. The task is mainly determined by interrogative words. For example, the sentence containing 'where' will probably be classified to 'location'. The ability to tackle polysemy doesn't play an important role. So, our model gets a similar result with Capsule-B.

4.4 Ablation Study

To analyze the effect of different components including hyperplane projection, penalization term, and routing iterations, we report the results of variants of HCapsNet in Table 4.

The results show that capsule network performs best when conducting 3 routing iterations, which stays in line with the conclusion in [Sabour *et*

the **[cold]** and dreary weather is a perfect metaphor for the movie itself , which contains few laughs and not much drama	[-0.3810, -0.3923, -0.3016, -0.3045, 0.2417, -0.3109, 0.5999, -0.0391]	N$^{\times}$	P$^{\checkmark}$

Table 3: Projected primary capsule's representations for polysemic words. P and N denote positive and negative classification results, respectively. ✓ denotes the right classification and × denotes the incorrect classification.

- Almost every scene in this film is a gem that could stand alone, a perfectly realized observation of mood, behavior and intent.
- A spunky, original take on a theme that will resonate with singles of many ages.
- The story drifts so inexorable into cliches about tortured lrb and torturing rrb artists and consuming but impossible love that you can't help but become more disappointed as each overwrought new sequence plods on.
- The premise is in extremely bad taste, and the film's supposed insights are so poorly thought out and substance free that even a high school senior taking his or her first psychology class could dismiss them.

Figure 2: Examples of routing results for SST-2.

al., 2017; Yang *et al.*, 2018]. Compared with the vanilla capsule network (row 3), applying routing-on-hyperplane brings a noticeable improvement (row 2). This demonstrates the necessity of integrating hyperplane projecting at the routing procedure to tackle the polysemy problems. Moreover, the penalization term described in Section 3.3 also marginally improves the accuracy, which proves that the orthogonal constraint on hyperplane is beneficial for text classification.

Hyperplane	Pena.	Iterations	Accuracy
✓	✓	3	**83.5**
✓	×	3	83.2
×	×	3	82.5
✓	✓	1	81.5
✓	✓	5	82.6

Table 4: Ablation study on MR dataset. "Pena." denotes Penalization Term in Section 3.3.

4.5 Case Study

Table 3 shows some sample cases from SST validation dataset, which are movie reviews for sentiment analysis. We analyze the attended primary capsule representation for the polysemic words in brackets. Specifically, we report the output vectors of the projected primary capsule, which is mostly attended by the routing mechanism.

The word 'wonder' in the first sample sentence means something that fills you with surprise and admiration, which shows a very positive sentiment. However, the polysemic word 'wonder' in the second and third sentences means to think about something and try to decide what is true, which is neutral in sentiment. We can observe that for the same word, the attended projected capsule representations are quite different according to different word senses. The projected representations for the same sense are similar, the Euclidean distance is 0.23 (row 2,3). On the contrary, for the different senses, the Euclidean distance is 1.12 (row 1,2). This property helps our model to make the predictions all correctly, while Capsule-B [Yang *et al.*, 2018] can not handle the latter two sentences. Similarly, the word 'cold' conveys two different senses in the last two samples (row 4-5), which means cruel and low temperature, respectively. The corresponding projected vectors are also quite different, which verifies the ability to tackle polysemy by routing-on-hyperplane.

4.6 Visualizing Routing Results

After several iterations of the routing algorithm, each primary capsule and the top-level capsule will be connected via a calculated coupling coefficient. The coupling coefficient corresponds to how much contribution of a low-level capsule to a specific high-level capsule. Routing-on-hyperplane can also be viewed as a parallel attention mech-

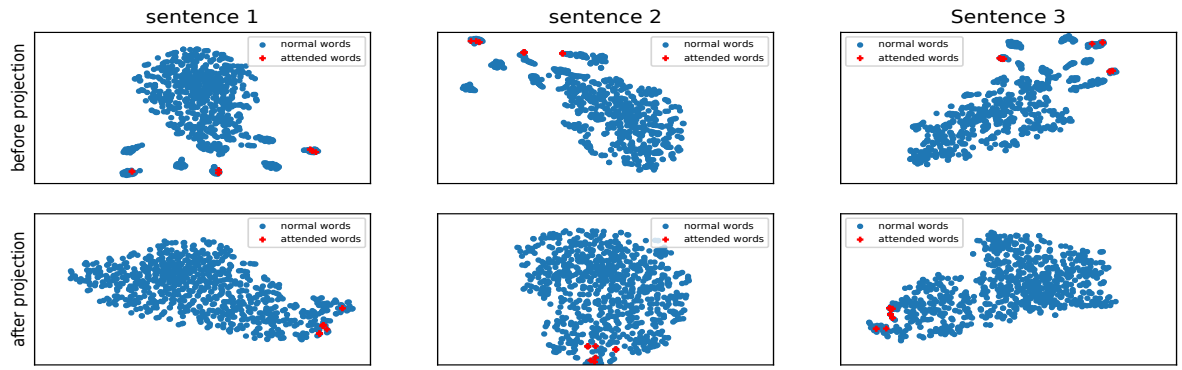

Figure 3: Illustrating the effect of the hyperplane.

anism that allows each capsule at one level to attend to some active capsules at the level below and to ignore others. We can thus draw a heat map to figure which phrases are taken into account a lot, and which ones are skipped by the routing-on-hyperplane in the task of text classification.

We randomly select 4 examples of reviews from the test set of SST, when the model has a high confidence (>0.8) in predicting the label. As shown in Figure 2, the words whose coupling coefficient greater than 0.7 are marked. It is easy to conclude that our routing method can effectively extract the sentimental words that indicate strongly on the sentiment behind the sentence and assign a greater coupling coefficient between the corresponding capsules. For example, '*gem*', '*spunky*', '*disappointed*', '*bad taste*' etc.

4.7 Visualizing Effects of The Hyperplane

In order to assess the effect of the hyperplane, we randomly select 3 examples in SST dataset and draw the distribution maps of primary capsules' output vectors before and after the projection operation respectively. As the dimension of the primary capsule's output vector is 8, T-Distributed Stochastic Neighbor Embedding (t-SNE) is performed on the vectors to reduce the dimension for visualization. As illustrated in Figure 3, the three pictures in the first line show the distribution before the projection operation for the three example sentences respectively. And the three pictures in the second line show the distribution after the projection. The blue points in the distribution maps denote the normal words and the red crosses denote the words attended by the routing algorithm which are defined in Section 4.6.

The relationship between the semantic capsules can be estimated by analyzing the distribution of the low-dimensional data in Figure 3. We find that originally scattered points which denote attended words converge after the projection. The attended words' projected vectors are close with each other, showing that they contain similar senses which are beneficial for the subsequent task. On the contrary, the capsules before projection contain multiple senses and show a scattered pattern. This demonstrates that the hyperplanes can effectively extract the guided senses and get attended by the routing-on-hyperplane mechanism.

5 Conclusion and Future Work

In this paper, we explore the capsule network for text classification and propose to decompose the capsule by means of projecting on hyperplanes to tackle the polysemy problem in natural language. Routing-on-hyperplane, a dynamic routing method, is implemented to select the sense-specific projected capsules for the subsequent classification task. We assess the effect of the hyperplane by case study and analyzing the distribution of the capsules' output vectors. The experiments demonstrate the superiority of HCapsNet and our proposed routing-on-hyperplane method outperforms the existing routing method in the text classification task.

In future, we would like to investigate the application of our theory in various tasks including reading comprehension and machine translating. We believe that capsule networks have broad applicability on the natural language processing tasks. Our core idea that decomposing the semantic capsules by projecting on hyperplanes is a necessary complement to capsule network to tackle the polysemy problem in various natural language processing tasks.

Abstract

Multi-label text classification (MLTC) aims to tag most relevant labels for the given document. In this paper, we propose a **L**abel-**S**pecific **A**ttention **N**etwork (**LSAN**) to learn the new document representation. LSAN takes advantage of label semantic information to determine the semantic connection between labels and document for constructing label-specific document representation. Meanwhile, the self-attention mechanism is adopted to identify the label-specific document representation from document content information. In order to seamlessly integrate the above two parts, an adaptive fusion strategy is designed, which can effectively output the comprehensive document representation to build multi-label text classifier. Extensive experimental results on four benchmark datasets demonstrate that LSAN consistently outperforms the state-of-the-art methods, especially on the prediction of low-frequency labels. The code and hyper-parameter settings are released to facilitate other researchers [1].

1 Introduction

Text classification is a fundamental text mining task including multi-class classification and multi-label classification. The former only assigns one label to the given document, while the latter classifies one document into different topics. In this paper, we focus on multi-label text classification (MLTC) because it has become one of the core tasks in natural language processing and has been widely applied in topic recognition (Yang et al., 2016), question answering (Kumar et al., 2016), sentimental analysis (Cambria et al., 2014) and so on. With the boom of big data, MLTC becomes significantly challenging because it has to handle the massive documents, words and labels simultaneously. Therefore, it is an emergency to develop effective multi-label text classifier for various practical applications.

Multi-label text classification allows for the coexistence of more than one label in a single document, thus, there are semantical correlations among labels because they may share the same subsets of document. Meanwhile, the document may be long and complicated semantic information may be hidden in the noisy or redundant content. Furthermore, most documents fall into few labels while a large number of "tail labels" only contain very few positive documents. To handle these issues, researchers pay much attention on three facets: 1) how to sufficiently capture the semantic patterns from the original documents, 2) how to extract the discriminative information related to the corresponding labels from each document, and 3) how to accurately mine the correlation among labels.

Till now, in the community of machine learning and natural language processing, researchers have paid tremendous efforts on developing MLTC methods in each facet. Among them, deep learning-based methods such as CNN (Liu et al., 2017; Kurata et al., 2016), RNN (Liu et al., 2016), combination of CNN and RNN (Lai et al., 2015; Chen et al., 2017), attention mechanism (Yang et al., 2016; You et al., 2018), (Adhikari et al., 2019) and etc., have achieved great success in document representation. However, most of them only focus on document representation but ignore the correlation among labels. Recently, some methods including DXML(Zhang et al., 2018), EXAM(Du et al., 2018), SGM(Yang et al., 2018), GILE(Pappas and Henderson, 2019) are proposed to capture the label correlations by exploiting label structure or label content. Although they obtained promising results in some cases, they still

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 466–475, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

cannot work well when there is no big difference between label texts (e.g., the categories *Management* vs *Management moves* in Reuters News), which makes them hard to distinguish.

In MLTC task, one document may contain multiple labels, and each label can be taken as one aspect or component of the document, thus, the overall semantics of the whole document can be formed by multiple components. Motivated by the above-mentioned observations, we propose a novel **L**abel-**S**pecific **A**ttention **N**etwork model (**LSAN**) to learn document representation by sufficiently exploiting the document content and label content. To capture the label-related component from each document, we adopt the self-attention mechanism to measure the contribution of each word to each label. Meanwhile, **LSAN** takes advantage of label texts to embed each label into a vector like word embedding, so that the semantic relations between document words and labels can be explicitly computed. Thereafter, an adaptive fusion strategy is designed to extract the proper amount of information from these two aspects and construct the label-specific representation for each document. We summarize the main contributions:

- A label-specific attention network model is proposed to handle multi-label text classification task by considering document content and label texts simultaneously.
- An adaptive fusion strategy is first designed to adaptively extract the proper semantical information to construct label-specific document representation.
- The performance of **LSAN** is thoroughly investigated on four widely-used benchmark datasets in terms of several evaluation metrics, indicating its advantage over the state-of-the-art baselines.

The rest of the paper is organized as follows. Section 2 describes the proposed **LSAN** model for multi-label text classification. The experiments on real-word datasets are conducted in Section 3 and their results are discussed in detail. Section 4 lists the related work. The brief conclusions and future work are given in Section 5.

2 Proposed Method

In this section, we introduce the proposed label-specific attention network, as shown in Figure 1. **LSAN** consists of two main parts. The first part is to capture the label-related components from each document by exploiting both document content and label texts. The second part aims to adaptively extract the proper information from two aspects. Finally, the classification model can be trained on the fused label-specific document representations.

2.1 Preliminaries

Problem Definition: Let $D = \{(x_i, y_i)\}_{i=1}^{N}$ denote the set of documents, which consists of N documents with corresponding labels $Y = \{y_i \in \{0,1\}^l\}$, here l is the total number of labels. Each document contains a sequence of words. Each word can be encoded to a low-dimensional space and represented as a d-dimension vector via word2vector technique (Pennington et al., 2014). Let $x_i = \{w_1, \cdots, w_p, \cdots, w_n\}$ denote the i-th document, $w_p \in \mathbb{R}^k$ is the p-th word vector in the document, n is the number of words in document.

For text classification, each label contains textual information. Thus, similar to the document word, one label can be represented as an embedding vector and the label set will be encoded by a trainable matrix $C \in \mathbb{R}^{l \times k}$. Given the input documents and their associated labels D, MLTC aims to train a classifier to assign the most relevant labels to the new coming documents.

Input Text Representation: To capture the forward and backward sides contextual information of each word, we adopt the bidirectional long short-term memory (Bi-LSTM) (Zhou et al., 2016) language model to learn the word embedding for each input document. At time-step p, the hidden state can be updated with the aid of input and $(p-1)$-th step output.

$$\begin{aligned} \overrightarrow{h_p} &= LSTM(\overrightarrow{h_{p-1}}, w_p) \\ \overleftarrow{h_p} &= LSTM(\overleftarrow{h_{p-1}}, w_p) \end{aligned} \tag{1}$$

where w_p is the embedding vector of the p-th word in the corresponding document, and $\overrightarrow{h_p}, \overleftarrow{h_p} \in \mathbb{R}^k$ indicate the forward and backward word context representations respectively. Then, the whole document can be represented by Bi-LSTM as follows.

$$\begin{aligned} H &= (\overrightarrow{H}, \overleftarrow{H}) \\ \overrightarrow{H} &= (\overrightarrow{h_1}, \overrightarrow{h_2}, \cdots, \overrightarrow{h_n}) \\ \overleftarrow{H} &= (\overleftarrow{h_1}, \overleftarrow{h_2}, \cdots, \overleftarrow{h_n}) \end{aligned} \tag{2}$$

In this case, the whole document set can be taken as a matrix $H \in \mathbb{R}^{2k \times n}$.

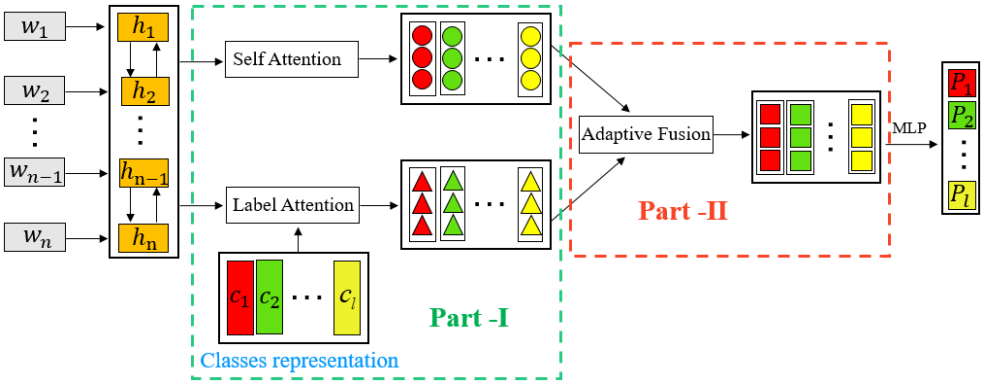

Figure 1: The architecture of the proposed label-specific attention network model (LSAN).

2.2 Label-Specific Attention Network

In this subsection, we will give the proposed attention network model for label-specific document representation learning. It aims to determin the label-related component from each document. Actually, this strategy is intuitive for text classification. For example, regarding the text *"June a friday, in the lawn, a war between the young boys of the football game starte"*, it is assigned into two categories *youth* and *sports*. Obviously, the content *"young boy"* is much more related to *youth* than to *sports*, while *"football game"* should be directly related to *sports*. Next, we will show how to capture this characteristic with our model.

2.2.1 Self-attention Mechanism

As mentioned above, the multi-label document may be tagged by more than one label, and each document should have the most relative contexts with its corresponding labels. In other words, each document may contain multiple components, and the words in one document make different contributions to each label. To capture different components for each label, we adopt the self-attention mechanism (Lin et al., 2017), which has been successful used in various text mining tasks (Tan et al., 2018; Al-Sabahi et al., 2018; You et al., 2018). The label-word attention score ($A^s \in \mathbb{R}^{l \times n}$) can be obtained by

$$A^{(s)} = softmax(W_2 tanh(W_1 H)) \tag{3}$$

where $W_1 \in \mathbb{R}^{d_a \times 2k}$ and $W_2 \in \mathbb{R}^{l \times d_a}$ are the so-called self-attention parameters to be trained. d_a is a hyper-parameter we can set arbitrarily. Each row $A^{(s)}_{j\cdot}$ (an n-dim row vector where n is the total number of words) indicates the contribution of all words to the j-th label. Then, we can obtain the the linear combination of the context words for each label with the aid of label-word attention score ($A^{(s)}$) as follows.

$$M^{(s)}_{j\cdot} = A^{(s)}_{j} H^T \tag{4}$$

which can be taken as a new representation of the input document along the j-th label. Then the whole matrix $M^{(s)} \in \mathbb{R}^{l \times 2k}$ is the label-specific document representation under the self-attention mechanism.

2.2.2 Label-Attention Mechanism

Self-attention mechanism can be taken as content-based attention because it only considers the document content. As we all know, labels have specific semantics in text classification, which is hidden in the label texts or descriptions. To make use of the semantic information of labels, they are preprocessed and represented as a trainable matrix $C \in \mathbb{R}^{l \times k}$ in the same latent k-dim space with the words.

Once having the word embedding from Bi-LSTM in (1) and the label embedding in C, we can explicitly determine the semantic relation between each pair of word and label. A simple way is calculating the dot product between $\overrightarrow{h}_p$ (or $\overleftarrow{h}_p$) and $C_{j\cdot}$ as follows.

$$\begin{aligned} \overrightarrow{A}^{(l)} &= C\overrightarrow{H} \\ \overleftarrow{A}^{(l)} &= C\overleftarrow{H} \end{aligned} \tag{5}$$

where $\overrightarrow{A}^{(l)} \in \mathbb{R}^{l \times n}$ and $\overleftarrow{A}^{(l)} \in \mathbb{R}^{l \times n}$ indicate the forward and backward sides semantic relation between words and labels. Similar to the previous self-attention mechanism, the label-specific document representation can be constructed by linear combining the label's context words as follows.

$$\begin{aligned} \overrightarrow{M}^{(l)} &= \overrightarrow{A}^{(l)} \overrightarrow{H}^T \\ \overleftarrow{M}^{(l)} &= \overleftarrow{A}^{(l)} \overleftarrow{H}^T \end{aligned} \tag{6}$$

Finally, the document can be re-represented along all labels via $M^{(l)} = (\overrightarrow{M}^{(l)}, \overleftarrow{M}^{(l)}) \in \mathbb{R}^{l \times 2k}$. This representation is based on the label texts, thus, we called it as label-attention mechanism.

2.3 Adaptive Attention Fusion Strategy

Both $M^{(s)}$ and $M^{(l)}$ are label-specific document representation, but they are different. The former focuses on the document content, while the later prefers to the semantic correlation between document content and label text. In order to take advantage these two parts, in this subsection, an attention fusion strategy is proposed to adaptively extract proper amount of information from them and build comprehensive label-specific document representation.

More specifically, two weight vectors ($\alpha, \beta \in \mathbb{R}^l$) are introduced to determine the importances of the above two mechanisms, which can obtained by a fully connected layer on the input $M^{(s)}$ and $M^{(l)}$.

$$\begin{aligned} \alpha &= sigmoid(M^{(s)} W_3) \\ \beta &= sigmoid(M^{(l)} W_4) \end{aligned} \tag{7}$$

$W_3, W_4 \in \mathbb{R}^{2k}$ are the parameters to be trained. α_j and β_j indicate the importances of self-attention and label-attention to construct the final document representation along the j-th label respectively. Therefore, we add the constraint on them:

$$\alpha_j + \beta_j = 1 \tag{8}$$

Then, we can obtain the final document representation along the j-th label based on fusion weights as follows.

$$M_{j\cdot} = \alpha_j M^{(s)}_{j\cdot} + \beta_j M^{(l)}_{j\cdot} \tag{9}$$

The label-specific document representation along all labels can be described as a matrix $M \in \mathbb{R}^{l \times 2k}$.

2.4 Label Prediction

Once having the comprehensive label-specific document representation, we can build the multi-label text classifier via a multilayer perceptron with two fully connected layers. Mathematically, the predicted probability of each label for the coming document can be estimated via

$$\hat{y} = sigmoid(W_6 f(W_5 M^T)) \tag{10}$$

Here $W_5 \in \mathbb{R}^{b \times 2k}, W_6 \in \mathbb{R}^b$ are the trainable parameters of the fully connected layer and output layer respectively. f is the ReLU nonlinear activation function. The sigmoid function is used to transfer the output value into a probability, in this case, the cross-entropy loss can be used as the loss function which has been proved suitable for multi-label text classification task (Nam et al., 2014).

$$\begin{aligned} \mathcal{L} = -\sum_{i=1}^{N}\sum_{j=1}^{l} &(y_{ij} \log(\hat{y}_{ij})) \\ &+ (1 - y_{ij}) \log(1 - \hat{y}_{ij}) \end{aligned} \tag{11}$$

where N is the number of training documents, l is the number of labels, $\hat{y}_{ij} \in [0, 1]$ is the predicted probability, and $y_{ij} \in \{0, 1\}$ indicates the ground truth of the i-th document along the j-th label.

3 Experiments

In this section, we evaluate the proposed model on four datasets (with various number of labels from 54 to 3956) by comparing with the state-of-the-art methods in terms of widely used metrics.

3.1 Experimental Setting

Datasets: There are several multi-label text datasets, however, only few of them have label text information. Thus, in this paper, four benchmark multi-label datasets including three small-scale datasets (RCV1, AAPD and EUR-Lex) and one medium-scale dataset (KanShan-Cup) are used to construct the experiments.

- **Reuters Corpus Volume I (RCV1)** (Lewis et al., 2004) contains more than 80K manually categorized news belonging to 103 classes.
- **AAPD**[2] (Yang et al., 2018) collects the abstract and the corresponding subjects of 55840 papers from arXiv in the filed of computer science.
- **EUR-Lex** (Mencia and Fürnkranz, 2008) is a collection of documents about European Union law belonging to 3956 subjects. The public version[3] contains 11585 training instances and 3865 testing instances.
- **KanShan-Cup**[4] is released by the largest Chinese community question answering platform, Zhihu. It contains near 3 million questions about 1999 topics.

For the first three data sets, only last 500 words were kept for each document, while the last 50

N is the number of training instances, M is the number of test instances, D is the total number of words, L is the total number of classes, $\bar{L}$ is the average number of labels per document, $\tilde{L}$ is the average number of documents per label, $\bar{W}$ is the average number of words per document in the training set, $\tilde{W}$ is the average number of words per document in the testing set.

words were used in KanShan-Cup dataset. Once the document has less than the predifined number of words, we extend it by padding zeros. All methods are trained and tested on the given training and testing datasets which are summarized in Table 1.

Evaluation Metrics: We use two kinds of metric, precision at top K ($P@k$) and the Normalized Discounted Cumulated Gains at top K ($nDCG@k$) to evaluate the prediction performance. $P@k$ and $nDCG@k$ are defined according to the predicted score vector $\hat{y} \in \mathbb{R}^l$ and the ground truth label vector $y \in \{0,1\}^l$ as follows.

$$P@k = \frac{1}{k} \sum_{l \in rank_k(\hat{y})} y_l$$

$$DCG@k = \sum_{l \in rank_k(\hat{y})} \frac{y_l}{\log(l+1)}$$

$$nDCG@k = \frac{DCG@k}{\sum_{l=1}^{\min(k, \|y\|_0)} \frac{1}{\log(l+1)}}$$

where $rank_k(y)$ is the label indexes of the top k highest scores of the current prediction result. $\|y\|_0$ counts the number of relevant labels in the ground truth label vector y.

Baseline Models: The proposed LSAN is a deep neural network model, thus the recent state-of-the-art deep learning-based MLTC methods are selected as baselines.

- **XML-CNN:** (Liu et al., 2017) adopts Convolutional Neural Network (CNN) and a dynamic pooling technique to extract high-level feature for multi-label text classification.
- **SGM:** (Yang et al., 2018) applies a sequence generation model from input document to output label to construct the multi-label text classifier.
- **DXML:** (Zhang et al., 2018) tries to explore the label correlation by considering the label structure from the label co-occurrence graph.
- **AttentionXML:** (You et al., 2018) builds the label-aware document representation only based on the document content, thus, it can be taken as one special case of our proposed **LSAN** with arbitrarily setting $\alpha = 0$.
- **EXAM:** (Du et al., 2018) is the most similar work to **LSAN** because both of them exploit the label text to learn the interaction between words and labels. However, EXAM suffers from the situation where different labels have similar text.

Parameter Setting: For the KanShan-Cup dataset, we use the pre-trained word embedding and label embedding public in the official website, where the embedding space size is 256, i.e., $k = 256$. The parameters corresponding to the weights between neurals are $d_a = 200$ for W_1 and W_2, $b = 256$ for W_5 and W_6. For other three datasets, $k = 300$, $d_a = 200$ and $b = 300$. The whole model is trained via Adam (Kingma and Ba, 2014) with the learning rate being 0.001. The parameters of all baselines are either adopted from their original papers or determined by experiments.

3.2 Comparison Results and Discussion

In this section, the proposed LSAN is evaluated on four benchmark datasets by comparing with five baselines in terms of $P@K$ and $nDCG@K(K = 1, 3, 5)$. Table 2 and Table 3 show the averaged performance of all test documents. According to the formula of $P@K$ and $nDCG@K$, we know $P@1 = nDCG@1$, thus only $nDCG@3$ and $nDCG@5$ are listed in Table 3. In each line, the best result is marked in bold.

From Table 2 and 3, we can make a number of observations about these results. Firstly, XML-CNN is worse than other four methods because it only considers the document content but ignores the label correlation which has been proven very important for multi-label learning. Secondly, AttentionXML is superior to EXAM on datasets RCV1 and Kanshan-Cup, because these two datases have hierarchical label structures. In this case, parent label and child label may contain similar text, which makes them hard to distinguish according to the text-based embedding and further reduce the performance of EXAM. By compar-

Table 3: Comparing LSAN with five baselines in terms of $nDCG@K$ (K=3,5) on four benchmark datasets.

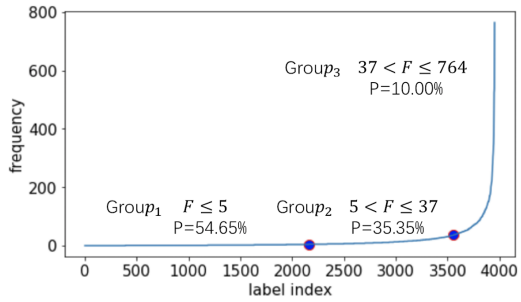

Figure 2: The label distribution of EUR-Lex

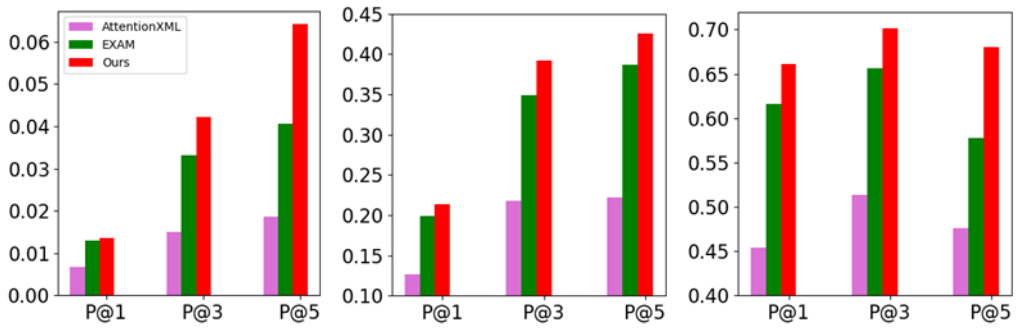
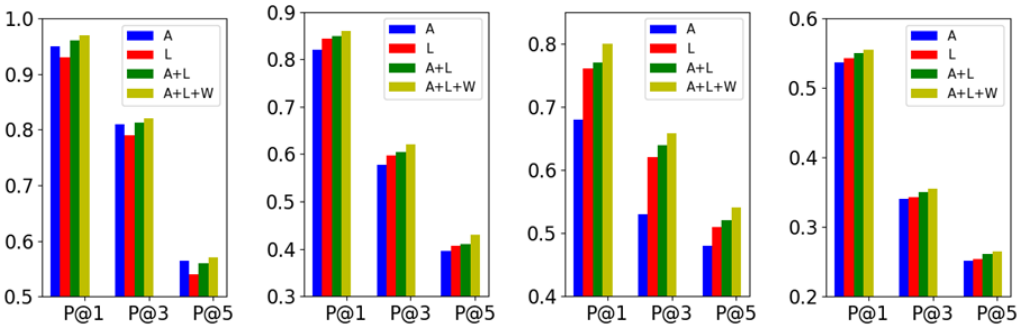
ing with EXAM and the proposed LSAN, however, AttentionXML performs worse on EUR-Lex dataset The main reason is that AttentionXML only focuses on the document content, which will make it not sufficiently trained once there are only few documents in some labels. Fortunately, EXAM and LSAN benefit from the label texts. Last one, as expected, is that LSAN consistently outperforms all baselines on all experimental datasets. This result further confirms that the proposed adaptive attention fusion strategy is much helpful to learn the label-specific document representation for multi-label text classification.



3.3 Comparison on Sparse Data

In order to verify the performance of LSAN on low-frequency labels, we divided labels in EUR-Lex into three groups according to their occurring frequency. Figure 2 shows the distribution of label frequency on EUR-Lex, F is the frequency of label. Among it, nearly 55% of labels occur between 1 and 5 times to form the first label group (Group1). The labels appearing 5-37 times are assigned into Group2, which is 35% of the whole label set. The remaining 10% frequent labels form the last group (Group3). Obviously, Group1 is much harder than other two groups due to the lack of training documents.

Figure 3 shows the prediction results in terms of $P@1$, $P@3$ and $P@5$ obtained by AttentionXML, EXAM and LSAN. Three methods become better and better from Group1 to Group3, which is reasonable because more and more documents are included in each label from Group1 to Group3. LSAN significantly improves the prediction performance on Group1. Especially, LSAN obtains an average of more than 83.82%, 182.55%, 244.62% gain on three metrices for group 1 to AttentionXML, and 3.85%, 27.19%, 58.27% gain to EXAM. This result demonstrates the superiority of the proposed model on multi-label text data with tail labels.



3.4 Ablation Test

The proposed LSAN can be taken as a joint attention strategy including three parts. One is self-attention based on document content (denoted as A). The second one is label-attention based on label text (denoted as L). Another one is fusion attention by adaptively integrating A and L with proper weights (denoted as W). In this section, we

(a) Gropu1 ($F \leq 5$) (b) Gropu2 ($5 < F \leq 37$) (c) Gropu3 ($F > 37$)

Figure 4: Result of the ablation test. 'A' denotes the Self-Attention, 'L' denotes the Label-Attention, 'W' denotes the Fusion Attention with Adaptive Weights.

try to demonstrate the effection of each component via an ablation test.

Figure 4 lists the prediction results on four datasets in terms of $P@1, P@3$ and $P@5$. (i.e., S+L gets better results than S and L). S prefers to finding the useful content when constructing the label-specific document representation, but it ignores the label information. L takes adantage of label text to explicitly determine the semantic relation between documents and labels, however, label text is not easy to distinguish the difference between labels (e.g., *Management* vs. *Management movies*). Therefore, coupling with both attentions is really reasonable. Furthermore, adaptively extracting proper amount of information from these two attentions benefits the final multi-label text classification.

To further verify the effectiveness of attention adaptive fusion, Figure 5 lists the distribution of weights on Self-attention and Label-attention on two representative datasets, one for sparse data (EUR-Lex) and the other for dense data (AAPD). As expected, the label-attention is much more useful than self-attention for sparse data, vice versa for dense data. In dense data, each label has sufficient documents, therefore, self-attention can sufficiently obtain label-specific document representation. On the other hand, label text is helpful to extract the semantic relations between labels and documents. Results on other two datasets have the similar trends which are omitted due to page limitation.

For investigating the effect of label-attention, we visualize the attention weights on the original document using heat map, as shown in Figure 6. Among it, the example AAPD document belongs to two categories *Computer Vision* and *Neural and Evolutionary Computing*. From the attention weights, we can see that each category has its own most related words, which confirms that the proposed label specific attention network is able to extract the label-aware content and further construct label-specific document representation.

4 Related work

In the line of MLTC, most works focus on two issues, one is document representation learning and

the other is label correlation detection.

For document representation, along with the recent success in CNN, many works are proposed based on CNN (Kim, 2014; Liu et al., 2017; Chen et al., 2017), which can capture the local correlations from the consecutive context windows. Although they obain promising results, these methods suffer from the limitation of window size so that they cannot determine the long-distance dependency of text. Meanwhile, they treat all words equally no matter how noisy the word is. Later, RNN and attention mechanism are introduced to get brilliant results (Yang et al., 2016). To implicitly learn the document representation for each label, the self-attention mechanism (Lin et al., 2017) is adopted for multi-label classification (You et al., 2018).

To determine the label correlation among multi-label data, in literatures, researchers proposed various methods. Kurata et al. (2016) adopt an initialization method to leverage label co-occurrence information. SLEEC (Bhatia et al., 2015) divides dataset into several clusters, and in each cluster it detects embedding vectors by capturing non-linear label correlation. DXML (Zhang et al., 2018) establishes an explicit label co-occurrence graph to explore label embedding in low-dimension latent space. Yang et al. (2018) use sequence-to-sequence(Seq2Seq) model to consider the correlations between labels. Recently, the textual information of labels are used to guide MLTC. EXAM (Du et al., 2018) introduces the interaction mechanism to incorporate word-level matching signals into the text classification task. GILE (Pappas and Henderson, 2019) proposes a joint input-label embedding model for neural text classification. Unfortunately, they cannot work well when there is no big difference between label texts.

5 Conclusions and Future Work

A new label-specific attention network, in this paper, is proposed for multi-label text classification. It makes use of document content and label text to learn the label-specific document representation with the aid of self-attention and label-attention mechanisms. An adaptive fusion is designed to effectively integrate these two attention mechanisms to improve the final prediction performance. Extensive experiments on four benchmark datasets prove the superiority of LSAN by comparing with the state-of-the-art methods, especially on the dataset with large subset of low-frequency labels.

In real applications, more precious information can be collected, such as label description, la-

bel topology (e.g., hierarchical structure) and etc. Therefore, it is interesting to extend the current model with such extra information.

Abstract

Most of the current effective methods for text classification task are based on large-scale labeled data and a great number of parameters, but when the supervised training data are few and difficult to be collected, these models are not available. In this paper, we propose a hierarchical attention prototypical networks (HAPN) for few-shot text classification. We design the feature level, word level, and instance level multi cross attention for our model to enhance the expressive ability of semantic space. We verify the effectiveness of our model on two standard benchmark few-shot text classification datasets – FewRel and CSID, and achieve the state-of-the-art performance. The visualization of hierarchical attention layers illustrates that our model can capture more important features, words, and instances separately. In addition, our attention mechanism increases support set augmentability and accelerates convergence speed in the training stage.

1 Introduction

The dominant text classification models in deep learning (Kim, 2014; Zhang et al., 2015a; Yang et al., 2016; Wang et al., 2018) require a considerable amount of labeled data to learn a large number of parameters. However, such methods may have difficulty in learning the semantic space in the case that only few data are available. Few-shot learning has became an effective approach to solve this challenge, it can train a neural network with a few parameters using few data but achieve good performance. A typical example of this approach is prototypical networks (Snell et al., 2017), which averages the vector of few support instances as the class prototype and computes distance between target query and each prototype, then classify the query to the nearest prototype's class. However, prototypical networks is rough and does not consider the adverse effects of various noises in the data, which weakens the discrimination and expressiveness of the prototype.

In this paper, we propose a hierarchical attention prototypical networks for few-shot text classification by using attention mechanism in three levels. For feature level attention, we use convolutional neural networks to get the feature scores which is different for various classes. For word level attention, we adopt an attention mechanism to learn the importance of each word hidden state in an instance. For instance level multi cross attention, with the help of multi cross attention between support set and target query, we can determine the importance of different instances in the same class and enable the model to get a more discriminative prototype of each class.

In the actual scenario, we apply HAPN on intention detection of our open domain chatbots with different character. If we create a chatbot for old people, the user intentions will focus on children, health or expectation, so we can define specific intentions and supply related responses. And because of only few data are needed, we can expand the number of classes quickly. The model helps chatbot to identify user intentions precisely, makes the dialogue process smoother, more knowledgeable and more controllable.

There are three main parts of our contribution: first of all, we propose a hierarchical attention prototypical networks for few-shot text classification, then we achieve state-of-the-art performance on FewRel and CSID datasets, and the experiments prove our model is faster and more extensible.

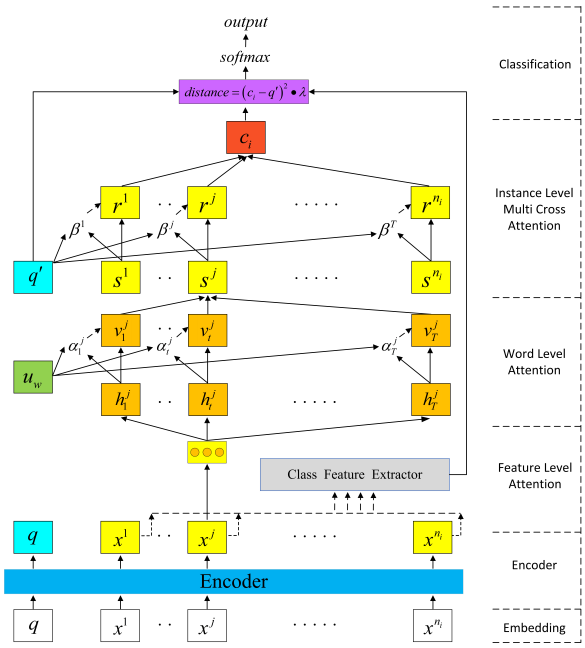

Figure 1: Hierarchical Attention Prototypical Networks architecture

proposed to solve it. The traditional methods mainly focus on feature engineerings such as bag-of-words or n-grams (Wang and Manning, 2012) or SVMs (Tang et al., 2015). The neural network based methods like Kim (2014) applies convolutional neural networks for sentence classification. Then, Johnson and Zhang (2015) use a one-hot word order CNN, and Zhang et al. (2015b) apply a character level CNN. C-LSTM (Zhou et al., 2015) combines CNN and RNN for sentence representation and text classification. Yang et al. (2016) explore the hierarchical structure of documents classification, they use a GRU-based attention to build representations of sentences and another GRU-based attention to aggregate them into a document representation. But above supervised learning methods require large-scale labeled data and can't classify unseen classes.

2.2 Few-Shot Learning

Few-Shot Learning (FSL) aims to solve classification problems by training a classifier with few instances in each class, and it can apply to unseen classes. The early works aim to use transfer learning approaches, Caruana (1994) and Bengio (2011) adopt the target task from the pre-trained models. Then Koch et al. (2015) explore a method for learning siamese neural networks which employs an unique structure to rank similarity between inputs. Vinyals et al. (2016) use matching networks to map a small labeled support set and an unlabelled example to its label, and obviate the need for fine-tuning to adapt to new class types. Prototypical networks (Snell et al., 2017) learns a metric space in which the model can perform well by computing distance between query and prototype representations of each class and classify the query to the nearest prototype's class. Sung et al. (2018) propose a two-branch relation networks, which learns to compare query against few-shot labeled sample support data. Dual TriNet structure (Chen et al., 2018) can efficiently and directly augment multi-layer visual features to boost the few-shot classification.But all of the above works mainly concentrate on computer vision field, the research and applications in NLP field are extremely limited. Recently, Yu et al. (2018) propose an adaptive metric learning approach that automatically determines the best weighted combination from a set of metrics obtained from meta-training tasks for a newly seen few-shot task such as intention classification, Han et al. (2018) present a relation classification dataset – FewRel, and adapt most recent state-of-the-art few-shot learning methods for it, Gao et al. (2019) propose a hybrid attention-based prototypical networks for noisy few-shot relation classification. However, these methods do not consider mining semantic information or reducing the impact of noise more precisely. And in most of the realistic settings, we may increase the number of instances gradually, so model capacity needs more attention.

3 Task Definition

In few-shot text classification task, our goal is to learn a function : $G(D, S, x) \rightarrow y$. D is the labeled data, we divide D into three parts: D_{train}, $D_{validation}$, and D_{test}, and each part has specific label space. We use D_{train} to optimize parameters, $D_{validation}$ to select best hyper parameters, and D_{test} to evaluate the model.

The "episode" training strategy that Vinyals et al. (2016) proposed has proved to be effective. For each training episode, we first sample a label set $\mathcal{L}$ from D_{train}, then use $\mathcal{L}$ to sample the support set S and the query set Q, finally, we feed S and Q to the model and minimize the loss. If $\mathcal{L}$ includes N different classes and each class of S contains K instances, we call the target problem N-way K-shot learning. For this paper, we consider N = 5 or 10, and K = 5 or 10.

For exactly, in an episode, we are given a support set S

$$\begin{aligned} S = &\{(x_1^1, l_1), (x_1^2, l_1), \ldots, (x_1^{n_1}, l_1), \\ &\cdots, \\ &(x_m^1, l_m), (x_m^2, l_m), \ldots, (x_m^{n_m}, l_m)\}, \\ &l_1, l_2, \cdots, l_m \in \mathcal{L} \end{aligned} \tag{1}$$

consists of n_i text instances for each class $l_i \in \mathcal{L}$, x_i^j means it is the j support instance belonging to calss l_i, and instance x_i^j includes $T_{i,j}$ words $\{w_1, w_2, \ldots, w_{T_{i,j}}\}$.

Then x is an unlabeled instance of query set Q to classify, and $y \in \mathcal{L}$ is the output label followed by the prediction of G.

4 Method

4.1 Model Overview

The overall architecture of the Hierarchical Attention Prototypical Networks is shown in Figure 1. We introduce different components in the following subsections:

Instance Encoder Each instance in support set or query set will be first represented to a input vector by transforming each word into embeddings. Considering the lightweight and speed of the model, we achieve this part with one layer convolutional neural networks (CNN). For ease of comparison, its details are the same as Han et al. (2018) proposed.

Hierarchical Attention In order to get more important information from rare data, we adopt a hierarchical attention mechanism. Feature level attention enhances or reduces the importance of different feature in each class, word level attention highlight the important words for meaning of the instance, and instance level multi cross attention can extract the important support instances for different query instances, these three attention mechanisms work together to improve the classification performance of our model.

Prototypical Networks Prototypical networks compute a prototype vector as the representation of each class, and this vector is the mean vector of the embedded support instances belonging to its class. We compare the distance between all prototype vectors and a target query vector, then classify this query to the nearest one.

4.2 Instance Encoder

The instance encoder part consists of two layers: embedding layer and instance encoding layer.

4.2.1 Embedding Layer

Given an instance $x = \{w_t, w_2, \ldots, w_T\}$ with T words. We use an embedding matrix W_E,$\boldsymbol{w}_t = W_E w_t$ to embed each word to a vector

$$\{\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_T\}, \boldsymbol{w}_t \in \mathbb{R}^d \tag{2}$$

where d is the word embedding dimension.

4.2.2 Encoding Layer

Following we apply a convolutional neural network Zeng et al. (2014) as encoding layer to get the hidden annotations of each word by a convolution kernel with the window size m

$$\boldsymbol{h}_t = \text{CNN}(\boldsymbol{w}_{t-\frac{m-1}{2}}, \ldots, \boldsymbol{w}_{t-\frac{m+1}{2}}) \tag{3}$$

Especially, if the word w_t has a position embedding $\boldsymbol{p}_t$, we should concat $\boldsymbol{w}_t$ and $\boldsymbol{p}_t$

$$\boldsymbol{wp}_t = [\boldsymbol{w}_t \oplus \boldsymbol{p}_t] \tag{4}$$

where $\oplus$ is a concatation, the $\boldsymbol{h}_t$ will be as follow

$$\boldsymbol{h}_t = \text{CNN}(\boldsymbol{wp}_{t-\frac{m-1}{2}}, \ldots, \boldsymbol{wp}_{t-\frac{m+1}{2}}) \tag{5}$$

Then, we aggregate all $\boldsymbol{h}_t$ to get the overall representation of instance x

$$\boldsymbol{x} = \{\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_t\} \tag{6}$$

Finally, we define those two layers as a comprehensive function

$$\boldsymbol{x} = g_\theta(x) \tag{7}$$

θ in this function are the networks parameters to be learned.

4.3 Prototypical Networks

The prototypical networks (Snell et al., 2017) has achieved excellent performance in few-shot image classification and few-shot text classification (Han et al., 2018; Gao et al., 2019) tasks respectively, so our model is based on prototypical networks and aims to get promotion.

The fundamental idea of prototypical networks is simple but efficient: we can use a prototype vector $\boldsymbol{c}_i$ as the representative feature of class l_i, each prototype vector can be calculated by averaging all the embedded instances in its support set

$$\boldsymbol{c}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} g_\theta(x_i^j) \tag{8}$$

Then the probability distribution over the classes in $\mathcal{L}$ can be produced by a softmax function over distances between all prototypes vector and the target query q

$$p_\theta(y = l_i|q) = \frac{\exp(-d(g_\theta(q), \boldsymbol{c}_i)}{\Sigma_{l=1}^{|\mathcal{L}|} \exp(-d(g_\theta(q), \boldsymbol{c}_l)} \tag{9}$$

As Snell et al. (2017) mentioned, squared Euclidean distance is a reasonable choice, however, we will introduce a more effective method in section 4.4.1, which combines squared Euclidean distance with class feature scores, and achieves definite improvement.

4.4 Hierarchical Attention

We focus on sentence-level text classification in this work. The proposed model gets a feature scores vector and transfers the support set of each class into a vector representation, on which we build a classifier to perform few-shot text classification.

4.4.1 Feature Level Attention

Obviously, the same dimension belonging to different classes has different importance when we calculate the euclidean distance. In other words, some feature dimensions are more discriminative for distinguishing specific class in the feature level space, and other features are confusing and useless at the same time.

So we apply a CNN-based feature attention mechanism similar to Gao et al. (2019) proposed as a class feature extractor. It depends on all the instances in the support set of each class and will dynamiclly change with different classes.

Given a support set $\boldsymbol{S}_i \in \mathbb{R}^{n_i \times T \times d}$ of class l_i as the output of above instance encoder part

$$\boldsymbol{S}_i = \{\boldsymbol{x}^1, \boldsymbol{x}^2, \ldots, \boldsymbol{x}^{n_i}\} \tag{10}$$

we apply a max pooling layer over each instance in $\boldsymbol{S}_i$ to get a new feature map $\boldsymbol{S}_{\boldsymbol{c}i} \in \mathbb{R}^{n_i \times d}$. Then we use three convolution layers to obtain $\boldsymbol{\lambda}_i \in \mathbb{R}^d$, which is the scores vector of class l_i. The specific structure of above class feature extractor is shown in Table 1.

layer name	kernel size	stride	output size
pool	$T \times 1$	1×1	$K \times d \times 1$
conv_1	$K \times 1$	1×1	$K \times d \times 32$
	ReLU		
conv_2	$K \times 1$	1×1	$K \times d \times 64$
	ReLU		
conv_3	$K \times 1$	$K \times 1$	$1 \times d \times 1$
	ReLU		

Table 1: Class feature extractor architecture

So we get a new distance calculation method as follow

$$d(\boldsymbol{c}_i, \boldsymbol{q}^{'}) = (\boldsymbol{c}_i - \boldsymbol{q}^{'})^2 \cdot \boldsymbol{\lambda}_i \tag{11}$$

where $\boldsymbol{q}^{'}$ is the query vector passed through the word level attention mechanism which will be introduced in the next subsection.

4.4.2 Word Level Attention

The importance of different words to the meanings of an instance is unequal, thus it is worth pointing out which words are useful and which words are useless. Therefore, we apply an attention mechanism (Yang et al., 2016) to get those important words and assemble them to compose a more informative instance vector $\boldsymbol{s}^j$, and the definitions are as follows

$$\boldsymbol{u}_t^j = \tanh(\boldsymbol{W}_w \boldsymbol{h}_t^j + \boldsymbol{b}_w) \tag{12}$$

$$v_t^j = \boldsymbol{u}_t^{j\top} \boldsymbol{u}_w \tag{13}$$

$$\alpha_t^j = \frac{\exp(v_t^j)}{\Sigma_t \exp(v_t^j)} \tag{14}$$

$$\boldsymbol{s}^j = \sum_t \alpha_t^j \boldsymbol{h}_t^j \tag{15}$$

where $\boldsymbol{h}_t^j$ is the t hidden word embedding of instance $\boldsymbol{x}^j$, it was encoded through the instance encoder, and has the same hidden size with $\boldsymbol{x}^j$.

Firstly, the $\boldsymbol{W}_w$ and $\boldsymbol{b}_w$ followed by activation function $\tanh$ make up a MLP layer to transform $\boldsymbol{h}_t^j$ to the new hidden representation $\boldsymbol{u}_t^j$. Immediately, we apply a dot product operation between $\boldsymbol{u}_t^j$ and a word level weight vector $\boldsymbol{u}_w$ to compute similarity v_t^j as the importance weight of $\boldsymbol{u}_t^j$. Then we use a softmax function to normalize v_t^j to α_t^j. Finally, we calculate the instance level vector $\boldsymbol{s}^j$ through the weighted sum of α_t^j and $\boldsymbol{h}_t^j$. As memory networks (Sukhbaatar et al., 2015) proposed, $\boldsymbol{u}_w$ can help us to select the important words in each instance, it will be randomly initialized at the beginning of the training stage, and be optimized together with the networks parameters θ.

4.4.3 Instance Level Multi Cross Attention

The previous prototypical networks use the mean vector of support instances as the class prototype. Because of the diversity and lack of the support instances, the gap between each support vector and prototype maybe wide, meanwhile, different query instances can be expressed in several ways, so not every instance in a support set contributes equally to the class prototype when they face a target query instance. To highlight the importance of support instances which are useful clues to classify a query instance correctly, we propose a multi cross attention mechanism.

Given a support set $\boldsymbol{S}_i^{'} \in \mathbb{R}^{n_i \times d}$ for class l_i and a query vector $\boldsymbol{q}^{'} \in \mathbb{R}^d$, they are all encoded through the instance encoder and word level attention. We consider each support vector $\boldsymbol{s}_i^j$ in $\boldsymbol{S}_i^{'}$ has its own weight β_i^j to query $\boldsymbol{q}^{'}$. So the formula (8) will be rewritten as follow

$$\boldsymbol{c}_i = \sum_{j=1}^{n_i} \beta_i^j \boldsymbol{s}_i^j \tag{16}$$

where we define $\boldsymbol{r}_i^j = \beta_i^j \boldsymbol{s}_i^j$ as the weighted prototype vector and the definitions of β_i^j are as follows

$$\beta_i^j = \frac{\exp(\gamma_i^j)}{\Sigma_{j=1}^{n_i} \exp(\gamma_i^j)} \tag{17}$$

$$\gamma_i^j = \text{sum}\{\sigma(f_\varphi(mca))\} \tag{18}$$

$$mca = [\boldsymbol{s}_{i\phi}^j \oplus \boldsymbol{q}_\phi^{'} \oplus \boldsymbol{\tau}_1 \oplus \boldsymbol{\tau}_2] \tag{19}$$

$$\boldsymbol{\tau}_1 = |\boldsymbol{s}_{i\phi}^j - \boldsymbol{q}_\phi^{'}|, \boldsymbol{\tau}_2 = \boldsymbol{s}_{i\phi}^j \odot \boldsymbol{q}_\phi^{'} \tag{20}$$

$$\boldsymbol{s}_{i\phi}^j = f_\phi(\boldsymbol{s}_i^j), \boldsymbol{q}_\phi^{'} = f_\phi(\boldsymbol{q}^{'}) \tag{21}$$

where f_ϕ is a linear layer, $|\cdot|$ is element-wise absolute value and $\odot$ is element-wise product, we use these two operation to get the difference information $\boldsymbol{\tau}_1$ and $\boldsymbol{\tau}_2$ between $\boldsymbol{s}_i^j$ and $\boldsymbol{q}^{'}$, then concatenate them all as the multi cross attention information mca, then $f_\varphi(\cdot)$ is a linear layer, $\sigma(\cdot)$ is a $tanh$ activation function, sum$\{\cdot\}$ means a sum operation of all elements in the vector. Finally, γ_i^j is the weight of j instance in support set $\boldsymbol{s}_i$, and we use a softmax function to nomalize it to β_i^j.

Through the multi cross attention mechanism, the prototype can pay more attention to those query-related support instances and improve the capacity of support set.

5 Experiments

In this section, we will introduce the experiment results of our model. Firstly, we evaluate our model on FewRel dataset and CSID dataset, and achieve state-of-the-art results, our model outperforms the best baselines models by 1.11% and 1.64% respectively on 10 way 5 shot setting. Then we will show how our model works by case study and visualization of attention layers. We further demonstrate that the hierarchical attention increases the augmentability of support set and the convergence speed of the model.

5.1 Datasets

FewRel Few-Shot Relation Classification (Han et al., 2018) is a new large-scale supervised dataset[1]. It consists of 70000 instances on 100 relations derived from Wikipedia, and each relation includes 700 instances. It also marks the head and tail entities in each instance, and the average number of tokens is 24.99. FewRel has 64 relations for training, 16 relations for validation, and 20 relations for test separately.

CSID Character Studio Intention Detection is a dataset extracted from a real-world open domain chatbot. In character studio platform, this chatbot should transform its character style sometime so it can adapt to different user group and environment, thus dialog query intention detection turns into an important task. CSID consists of 24596 instances for 128 intentions, and each intention includes 30 to 260 instances, the average number of tokens in each instance is 11.52. We use 80, 18 and 30 intentions for training, validation, and test respectively.

Table 2: Accuracies (%) of different models on the CSID dataset on four different settings.

5.2 Baselines

Firstly, we compare our model with several traditional models such as Finetune and kNN, Then we compare our model with five state-of-the-art few-shot learning models based on neural networks, they are MetaN (Munkhdalai and Yu, 2017), GNN (Garcia and Bruna, 2018), SNAIL (Mishra et al., 2018), Proto (Snell et al., 2017) and PHATT (Gao et al., 2019) respectively.

5.3 Implementation details

We compare our models with seven baselines, and the implementation details are as follows.

For FewRel dataset, we cite the results reported by Snell et al. (2017) which includes Finetune, kNN, MetaN, GNN, and SNAIL, then we cite the results reported by Gao et al. (2019) which includes Proto and PHATT. For a fair comparison, in our model, we use the same word embeddings and hyperparameters of instance encoder as PHATT proposed. In detail, we use the Glove (Pennington et al., 2014) consisting of 6B tokens and 400K vocabulary as our initialized word representation, and each word has a 50 dimensions vector. In addition, the position embedding dimension of a word is 10, the max length of each instance is 40. Finally, we evaluate all models on 5 way 5 shot and 10 way 5 shot settings.

For CSID dataset, we implement all above seven baseline models and our models. we use the Baidu Encyclopedia (Li et al., 2018) as our initialized word representation, it includes 745M tokens and 5422K vocabulary, and each word has a 300d dimensions vector, the max length of each instance is 20. Finally, we evaluate all models on 5 way 5 shot, 5 way 10 shot, 10 way 5 shot and 10 way 10 shot settings.

For the Finetune and kNN baselines, they learn the parameters on the support set with the CNN encoder. For the neural networks based baselines, we use the same hyper parameters as Han et al. (2018) proposed.

For our hierarchical attention prototypical networks, the window size of the CNN instance encoder is 3, the dimension of the hidden layer is 230, the learning rate is 0.1, the learning rate decay step is 3000 and the decay rate is 0.1. In addition, we train our model 12000 episodes and each episode consists of 20 classes.

In order to study the effects of different components, we refer to our models as HAPN-{FA,WA, IMCA}, FA indicates feature level attention, WA indicates word level attention and IMCA indicates instance level multi cross attention.

5.4 Results and analysis

The experimental accuracies on CSID and FewRel are shown in Tabel 2 and Table 4 respectively. In this subsection, we will show the effects of hierarchical attention and support set augmentability of three Proto-based models and the convergence speed comparison.

5.4.1 Effects of hierarchical attention

Benefit from hierarchical attention, our model achieves excellent performance.

The case study of word level attention and instance level multi cross attention are shown in Table 3, this is a 2 way 3 shot task on FewRel dataset. The query instance is an instance of “mother” class in fact, and our model should classify it into “mother” class or “child” class. It is a difficult

Class	Word Attention	IMCAS
	Support Set	
(1) mother	**Cherie Gil** is the daughter of Filipino actors Eddie Mesa and **Rosemarie Gil**, and sister of fellow actors, Michael de Mesa and the late Mark Gil.	
	When they reached adulthood, Pelias and **Neleus** found their mother **Tyro** and then killed her stepmother, Sidero, for having mistreated her.	
	It was here that the Queen Consort **Jetsun Pema** gave birth to a son on 5 February 2016, **Jigme Namgyel Wangchuck**.	
(2) child	In 1421 **Mehmed** died and his son **Murad II** refused to honour his father's obligations to the Byzantines.	
	Henry Norreys was a lifelong friend of Queen Elizabeth and was the father of six sons, who included Sir **John Norreys**, a famous English soldier.	
	Jim Henson and his son **Brian** were impressed enough with Barron's style to offer him a job directing the pilot episode of "The Storyteller".	
	Query	
(1) or (2)	From 1922 to 1963, **Princess Dagmar of Demark**, the daughter of Frederick VIII of Denmark and **Louise of Sweden**, lived on Kongestlund.	

Table 3: Visualization of word level and instance level multi cross attention scores (IMCAS) for 2 way 3 shot setting, the bold words are head entities and tail entities.

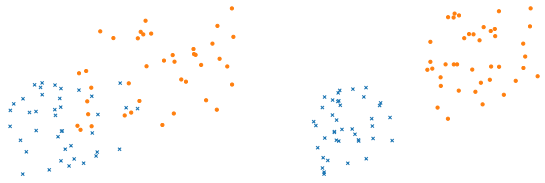
HAPN	**91.02 ± 0.11**	**84.16 ± 0.18**

Table 4: Accuracies (%) for 5 way 5 shot and 10 way 5 shot settings on FewRel test set. * reported by Han et al. (2018) and ◇ reported by Gao et al. (2019).

task because of there are many similarities between the expressions of two classes. With the help of word level attention, we highlight the importance of the word "daughter", which appears in the query instance and the first support instance of class "mother" at the same time, then this support instance get the highest attention score and contributes more to the prototype vector of "mother" class, finally our model can classify the query instance into the correct class in this confusing task.

As shown in Figure 2, by using the feature level attention, we also get the feature attention scores of "mother" class and "child" class respectively. The features with high scores have deep color, and the features with low scores have light color. Obviously, different classes may have different feature score vector, in other words, the same feature of different classes have different importance. So our feature level attention can highlight importance of the useful features and weaken the importance of the noise features, then the distance between the prototype vector and the query vector will measure the difference between them more efficiently.

(a) Feature attention scores of "mother" class



(b) Feature attention scores of "child" class

Figure 2: Feature attention scores of different classes

We treat the final prototype embedding vector as the features of each instance, then we can get the distribution of features by principal pomponent analysis in feature space as shown in Figure 3. As we can see, the instances without hierarchical attention are more distributed and may cross with each other, but the instances with hierarchical attention are more centralized and discriminative, which proves that our model learns a better semantic space, which helps to distinguish confus-

ing data..

(a) Instances without hierarchical attention

(b) Instances with hierarchical attention

Figure 3: Instances distribution of embedding vector without hierarchical attention (a) and with hierarchical attention (b). The left blue points marked × are instances of "mother" class and the right orange points marked • are instances of "child" class.

5.4.2 Augmentability of support set

More support instances can contribute more useful information to the prototype vector, meanwhile, more noise will be added in.

In this section, we define the support set augmentability (SSA) as the additive value of accuracy when we increase the same number of the support set for different models. So we compare our model's SSA with other models such as Proto and PHATT on the 10 way FewRel task, and the shot number ranges from 5 to 25.

By using the hierarchical attention, our model obtaines a strong robustness and can pay more attention to the important information of support set and reduce those negative effects of noisy data, thus as shown in Figure 4, the support set augmentability of our model is larger than other models. Benefit from the above advantages, we can deploy our model in the cold start stage, and gradually accumulate labeled support data in practical applications, then improve the performance of the model day by day, and thus improve the utilization rate of few data in realistic settings.

5.4.3 Convergence speed comparison

At the training stage, we also compare the convergence speed between Proto, PHATT, and HAPN on the 10 way 5 shot and 10 way 15 shot FewRel task. As shown in Figure 5, our model can be optimized more quickly than the other models. From 10 way 5 shot task to 10 way 15 shot settings, the Proto model takes almost twice time to achieve 70% accuracy on validation set, in other words, the convergence speed will decrease sharply when we increase the number of support instances, but this problem can be effectively alleviated when we use hierarchical attention mechanism.

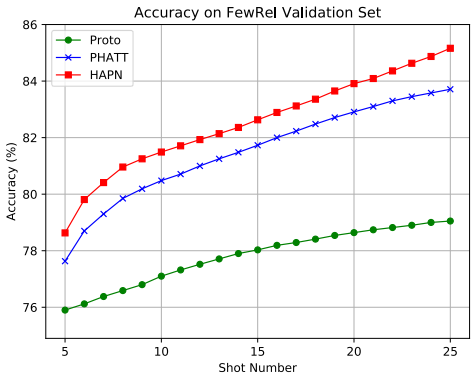


Figure 4: Support set augmentability of Proto, PHATT and HAPN on FewRel validation set.

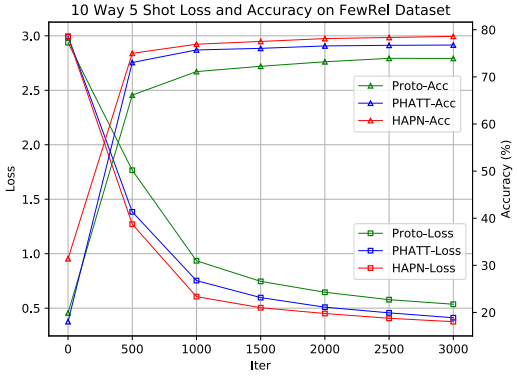

Figure 5: Training Proto, PHATT and HAPN on FewRel dataset. Lines marked □ denote loss on the training set and lines marked △ denote accuracy on the validation set.

6 Conclusion

Previous few-shot learning models for text classification roughly apply text representations or neglect the noisy information. We propose to do hierarchical attention prototypical networks consisting of feature level, word level and instance level multi cross attention, which highlight the important information of few data and learn a more discriminative prototype representation. In the experiments, our model achieves the state-of-the-art performance on FewRel and CSID datasets. HAPN not only increases support set augmentability but also accelerates convergence speed in the training stage.

In the future, we will contribute new text dataset to few-shot learning, explore better feature extrac-

tor networks and do some industrial application.

Acknowledgements

We would like to thank Sawyer Zeng and Yue Liu for providing valuable hardware support and useful advice, and thank Xuexiang Xu and Yang Bai for helping us test online FewRel dataset. Many Faces of Feature Importance: Comparing Built-in and Post-hoc Feature Importance in Text Classification

Abstract

Feature importance is commonly used to explain machine predictions. While feature importance can be derived from a machine learning model with a variety of methods, the consistency of feature importance via different methods remains understudied. In this work, we systematically compare feature importance from built-in mechanisms in a model such as attention values and post-hoc methods that approximate model behavior such as LIME. Using text classification as a testbed, we find that 1) no matter which method we use, important features from traditional models such as SVM and XGBoost are more similar with each other, than with deep learning models; 2) post-hoc methods tend to generate more similar important features for two models than built-in methods. We further demonstrate how such similarity varies across instances. Notably, important features do *not* always resemble each other better when two models agree on the predicted label than when they disagree.

1 Introduction

As machine learning models are adopted in societally important tasks such as recidivism prediction and loan approval, explaining machine predictions has become increasingly important (Doshi-Velez and Kim, 2017; Lipton, 2016). Explanations can potentially improve the trustworthiness of algorithmic decisions for decision makers, facilitate model developers in debugging, and even allow regulators to identify biased algorithms.

A popular approach to explaining machine predictions is to identify important features for a particular prediction (Luong et al., 2015; Ribeiro et al., 2016; Lundberg and Lee, 2017). Typically, these explanations assign a value to each feature (usually a word in NLP), and thus enable visualizations such as highlighting top k features.

In general, there are two classes of methods: 1) built-in feature importance that is embedded in the machine learning model such as coefficients in linear models and attention values in attention mechanisms; 2) post-hoc feature importance through credit assignment based on the model such as LIME. It is well recognized that robust evaluation of feature importance is challenging (Jain and Wallace, 2019; Nguyen, 2018, inter alia), which is further complicated by different use cases of explanations (e.g., for decision makers vs. for developers). Throughout this work, we refer to machine learning models that learn from data as *models* and methods to obtain local explanations (i.e., feature importance in this work) for a prediction by a model as *methods*.

While prior research tends to focus on the internals of models in designing and evaluating methods of explanations, e.g., how well explanations reflect the original model (Ribeiro et al., 2016), we view feature importance itself as a subject of study, and aim to provide a systematic characterization of important features obtained via different methods for different models. This view is particularly important when explanations are used to support decision making because they are the only exposure to the model for decision makers. It would be desirable that explanations are consistent across different instances. In comparison, debugging represents a distinct use case where developers often know the mechanism of the model beyond explanations. Our view also connects to studying explanation as a *product* in cognitive studies of explanations (Lombrozo, 2012), and is complementary to the model-centric perspective.

Given a wide variety of models and methods to generate feature importance, there are basic open questions such as how similar important features are between models and methods, how important features distribute across instances, and what lin-

Table 1: 10 most important features (separated by comma) identified by different methods for different models for the given review. In the interest of space, we only show built-in and LIME here.

guistic properties important features tend to have. We use text classification as a testbed to answer these questions. We consider built-in importance from both traditional models such as linear SVM and neural models with attention mechanisms, as well as post-hoc importance based on LIME and SHAP. Table 1 shows important features for a Yelp review in sentiment classification. Although most approaches consider "fresh" and "favorite" important, there exists significant variation.

We use three text classification tasks to characterize the overall similarity between important features. Our analysis reveals the following insights:

- (Comparison between approaches) Deep learning models generate more different important features from traditional models such as SVM and XGBoost. Post-hoc methods tend to reduce the dissimilarity between models by making important features more similar than the built-in method. Finally, different approaches do not generate more similar important features even if we focus on the most important features (e.g., top one feature).
- (Heterogeneity between instances) Similarity between important features is not always greater when two models agree on the predicted label, and longer instances are less likely to share important features.
- (Distributional properties) Deep models generate more diverse important features with higher entropy, which indicates lower consistency across instances. Post-hoc methods bring the POS distribution closer to background distributions.

In summary, our work systematically compares important features from different methods for different models, and sheds light on how different models/methods induce important features. Our work takes the first step to understand important features as a product and helps inform the adoption of feature importance for different purposes. Our code is available at https://github.com/BoulderDS/feature-importance.

2 Related Work

To provide further background for our work, we summarize current popular approaches to generating and evaluating explanations of machine predictions, with an emphasis on feature importance.

Approaches to generating explanations. A battery of approaches have been recently proposed to explain machine predictions (see Guidotti et al. (2019) for an overview), including example-based approaches that identifies "informative" examples in the training data (e.g., Kim et al., 2016) and rule-based approaches that reduce complex models to simple rules (e.g., Malioutov et al., 2017). Our work focuses on characterizing properties of feature-based approaches. Feature-based approaches tend to identify important features in an instance and enable visualizations with important features highlighted. We discuss several directly related post-hoc methods here and introduce the built-in methods in §3. A popular approach, LIME, fits a sparse linear model to approximate model predictions locally (Ribeiro et al., 2016); Lundberg and Lee (2017) present a unified framework based on Shapley values, which can be computed with different approximation methods for different models. Gradients are popular for identifying important features in deep learning models since these models are usually differentiable (Shrikumar et al., 2017), for instance, Li et al. (2016) uses gradient-based saliency to compare LSTMs with simple recurrent networks.

Definition and evaluation of explanations. De-

spite a myriad of studies on approaches to explaining machine predictions, explanation is a rather overloaded term and evaluating explanations is challenging. Doshi-Velez and Kim (2017) lays out three levels of evaluations: functionally-grounded evaluations based on proxy automatic tasks, human-grounded evaluations with laypersons on proxy tasks, and application-grounded based on expert performance in the end task. In text classification, Nguyen (2018) shows that automatic evaluation based on word deletion moderately correlate with human-grounded evaluations that ask crowdworkers to infer machine predictions based on explanations. However, explanations that help humans infer machine predictions may not actually help humans make better decisions/predictions. In fact, recent studies find that feature-based explanations alone have limited improvement on human performance in detecting deceptive reviews and media biases (Lai and Tan, 2019; Horne et al., 2019).

In another recent debate, Jain and Wallace (2019) examine attention as an explanation mechanism based on how well attention values correlate with gradient-based feature importance and whether they exclusively lead to the predicted label, and conclude that attention is not explanation. Similarly, Serrano and Smith (2019) show that attention is not a fail-safe indicator for explaining machine predictions based on intermediate representation erasure. However, Wiegreffe and Pinter (2019) argue that attention can be explanation depending on the definition of explanations (e.g., plausibility and faithfulness).

In comparison, we treat feature importance itself as a subject of study and compare different approaches to obtaining feature importance from a model. Instead of providing a normative judgment with respect to what makes good explanations, our goal is to allow decision makers or model developers to make informed decisions based on properties of important features using different models and methods.

3 Approach

In this section, we first formalize the problem of obtaining feature importance and then introduce the models and methods that we consider in this work. Our main contribution is to compare important features identified for a particular instance through different methods for different models.

Feature importance. For any instance t and a machine learning model $m : t \rightarrow y \in \{0, 1\}$, we use method h to obtain feature importance on an interpretable representation of t, $\mathcal{I}_t^{m,h} \in \mathbb{R}^d$, where d is the dimension of the interpretable representation. In the context of text classification, we use unigrams as the interpretable representation. Note that the machine learning model does not necessarily use the interpretable representation. Next, we introduce the models and methods in this work.

Models (m). We include both recent deep learning models for NLP and popular machine learning models that are not based on neural networks. In addition, we make sure that the chosen models have some built-in mechanism for inducing feature importance and describe the built-in feature importance as we introduce the model.[1]

- Linear SVM with ℓ_2 (or ℓ_1) regularization. Linear SVM has shown strong performance in text categorization (Joachims, 1998). The absolute value of coefficients in these models is typically considered a measure of feature importance (e.g., Ott et al., 2011). We also consider ℓ_1 regularization because ℓ_1 regularization is often used to induce sparsity in the model.

- Gradient boosting tree (XGBoost). XGBoost represents an ensembled tree algorithm that shows strong performance in competitions (Chen and Guestrin, 2016). We use the default option in XGBoost to measure feature importance with the average training loss gained when using a feature for splitting.

- LSTM with attention (often shortened as LSTM in this work). Attention is a commonly used technique in deep learning models for NLP (Bahdanau et al., 2015). The intuition is to assign a weight to each token before aggregating into the final prediction (or decoding in machine translation). We use the dot product formulation in Luong et al. (2015). The weight on each token has been commonly used to visualize the importance of each token. To compare with the previous bag-of-words models, we use the average weight of each type (unique token) in this work to measure feature importance.

- BERT. BERT represents an example architecture based on Transformers, which could show different behavior from LSTM-style recurrent

[1] For instance, we do not consider LSTM as a model here due to the lack of commonly-accepted built-in mechanisms.

networks (Devlin et al., 2019; Vaswani et al., 2017; Wolf, 2019). It also achieves state-of-the-art performance in many NLP tasks. Similar to LSTM with attention, we use the average attention values of 12 heads used by the first token at the final layer (the representation passed to fully connected layers) to measure feature importance for BERT.[2] Since BERT uses a subword tokenizer, for each word, we aggregate the attention on related subparts. BERT also requires special processing due to the length constraint; please refer to the supplementary material for details. As a result, we focus on presenting LSTM with attention in the main paper for ease of understanding.

Methods (h). For each model, in addition to the built-in feature importance that we described above, we consider the following two popular methods for extracting post-hoc feature importance (see the supplementary material for details of using the post-hoc methods).

- LIME (Ribeiro et al., 2016). LIME generates post-hoc explanations by fitting a local sparse linear model to approximate model predictions. As a result, the explanations are sparse.
- SHAP (Lundberg and Lee, 2017). SHAP unifies several interpretations of feature importance through Shapley values. The main intuition is to account the importance of a feature by examining the change in prediction outcomes for all the combinations of other features. Lundberg and Lee (2017) propose various approaches to approximate the computation for different classes of models (including gradient-based methods for deep models).

Note that feature importances obtained via all approaches are all local, because the top features are conditioned on an instance (i.e., words present in an instance) even for the built-in method for SVM and XGBoost.

Comparing feature importance. Given $\mathcal{I}_t^{m,h}$ and $\mathcal{I}_t^{m',h'}$, we use Jaccard similarity based on the top k features with the greatest absolute feature importance, $\frac{|\text{TopK}(\mathcal{I}_t^{m,h}) \cap \text{TopK}(\mathcal{I}_t^{m',h'})|}{|\text{TopK}(\mathcal{I}_t^{m,h}) \cup \text{TopK}(\mathcal{I}_t^{m',h'})|}$, as our main similarity metric for two reasons. First, the most typical way to use feature importance for interpretation purposes is to show the most important features (Lai and Tan, 2019; Ribeiro et al., 2016; Horne et al., 2019). Second, some models and methods inherently generate sparse feature importance, so most feature importance values are 0.

It is useful to discuss the implication of similarity before we proceed. On the one hand, it is possible that different models/methods identify the same set of important features (high similarity) and the performance difference in prediction is due to how different models weigh these important features. If this were true, the choice of model/method would have mattered little for visualizing important features. On the other hand, a low similarity poses challenges for choosing which model/method to use for displaying important features. In that case, this work aims to develop an understanding of how the similarity varies depending on models and methods, instances, and features. We leave it to future work for examining the impact on human interaction with feature importance. Low similarity may enable model developers to understand the differences between models, but may lead to challenges for decision makers to get a consistent picture of what the model relies on.

4 Experimental Setup and Hypotheses

Our goal is to characterize the similarities and differences between feature importances obtained with different methods and different models. In this section, we first present our experimental setup and then formulate our hypotheses.

Experimental setup. We consider the following three text classification tasks in this work. We choose to focus on classification because classification is the most common scenario used for examining feature importance and the associated human interpretation (e.g., Jain and Wallace, 2019).

- Yelp (Yelp, 2019). We set up a binary classification task to predict whether a review is positive (rating $\geq$ 4) or negative (rating $\leq$ 2). As the original dataset is huge, we subsample 12,000 reviews for this work.
- SST (Socher et al., 2013). It is a sentence-level sentiment classification task and represents a common benchmark. We only consider the binary setup here.
- Deception detection (Ott et al., 2013, 2011).

[2] We also tried to use the max of 12 heads and previous layers, and the average of the final layer is more similar to SVM (ℓ_2) than the average of first layer. Results are in the supplementary material. Vig (2019) show that attention in BERT tends to be on first words, neighboring words, and even separators. The complex choices for BERT further motivate our work to view feature importance as a subject of study.

Model	Yelp	SST	Deception
SVM (ℓ_2)	92.3	80.8	86.3
SVM (ℓ_1)	91.5	79.2	84.4
XGBoost	88.8	75.9	83.4
LSTM w/ attention	93.9	82.6	88.4
BERT	95.5	92.2	90.9

Table 2: Accuracy on the test set.

This dataset was created by extracting genuine reviews from TripAdvisor and collecting deceptive reviews using Turkers. It is relatively small with 1,200 reviews and represents a distinct task from sentiment classification.

For all the tasks, we use 20% of the dataset as the test set. For SVM and XGBoost, we use cross validation on the other 80% to tune hyperparameters. For LSTM with attention and BERT, we use 10% of the dataset as a validation set, and choose the best hyperparameters based on the validation performance. We use spaCy to tokenize and obtain part-of-speech tags for all the datasets (Honnibal and Montani, 2017). Table 2 shows the accuracy on the test set and our results are comparable to prior work. Not surprisingly, BERT achieves the best performance in all three tasks. For important features, we use $k \leq 10$ for Yelp and deception detection, and $k \leq 5$ for SST as it is a sentence-level task. See supplementary materials for details of preprocessing, learning, and dataset statistics.

Hypotheses. We aim to examine the following three research questions in this work: 1) How similar are important features between models and methods? 2) What factors relate to the heterogeneity across instances? 3) What words tend to be chosen as important features?

Overall similarity. Here we focus on discussing comparative hypotheses, but we would like to note that it is important to understand to what extent important features are similar across models (i.e., the value of similarity score). First, as deep learning models and XGBoost are non-linear, we hypothesize that built-in feature importance is more similar between SVM (ℓ_1) and SVM (ℓ_2) than other model pairs (**H1a**). Second, LIME generates more similar important features to SHAP than to built-in feature importance because both LIME and SHAP make additive assumptions, while built-in feature importance is based on drastically different models (**H1b**). It also follows that post-hoc explanations of different models show higher similarity than built-in explanations across models. Third, the similarity with small k is higher (**H1c**) because hopefully, all models and methods agree what the most important features are.

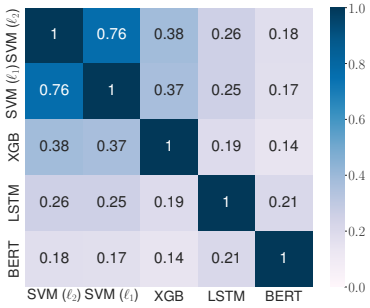

Figure 1: Jaccard similarity between the top 10 features of different models based on built-in feature importance on Yelp. The similarity is the greatest between SVM (ℓ_2) and SVM (ℓ_1), while LSTM with attention and BERT pay attention to quite different features from other models.

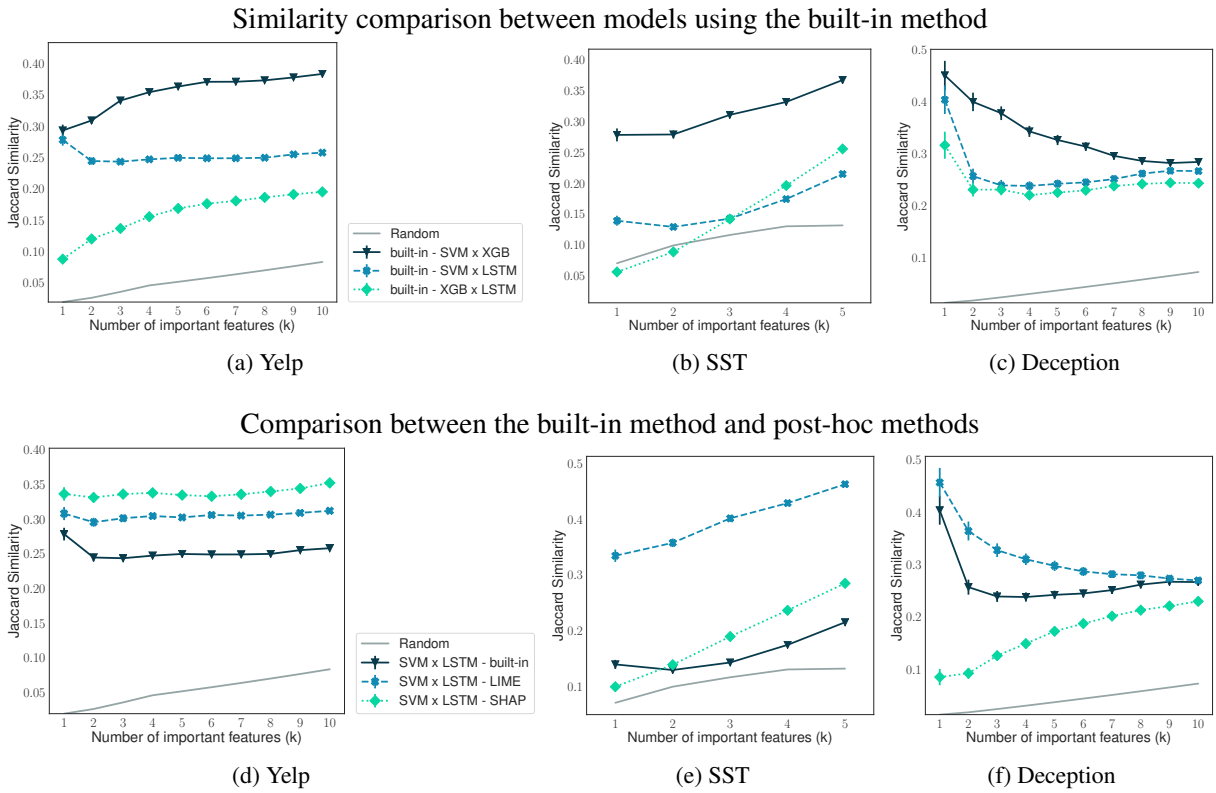
Heterogeneity between instances. Given a pair of (model, method) combinations, our second question is concerned with how instance-level properties affect the similarity in important features between different combinations. We hypothesize that 1) when two models agree on the predicted label, the similarity between important features is greater (**H2a**); 2) longer instances are less likely to share similar important features (**H2b**). 3) instances with higher type-token ratio,[3] which might be more complex, are less likely to share similar important features (**H2c**).

Distribution of important features. Finally, we examine what words tend to be chosen as important features. This question certainly depends on the nature of the task, but we would like to understand how consistent different models and methods are. We hypothesize that 1) deep learning models generate more diverse important features (**H3a**); 2) adjectives are more important in sentiment classification, while pronouns are more important in deception detection as shown in prior work (**H3b**).

5 Similarity between Instance-level Feature Importance

We start by examining the overall similarity between different models using different methods. In a nutshell, we compute the average Jaccard similarity of top k features for each pair of (m, h) and

[3]Type-token ratio is defined as the number of unique tokens divided by the number of tokens.



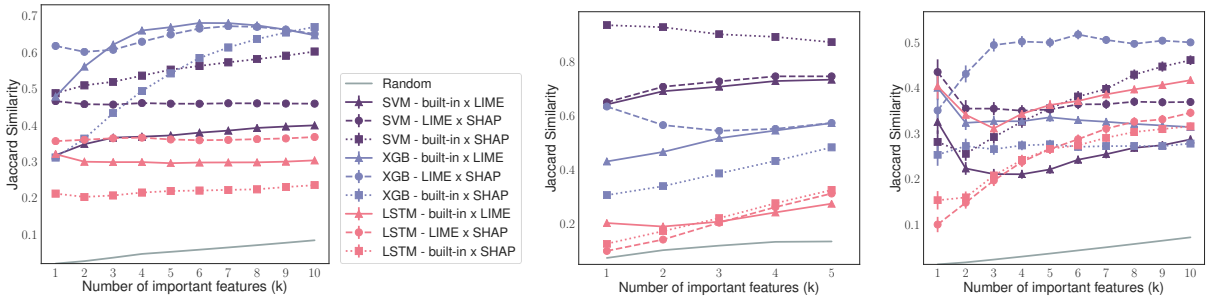


Figure 2: Similarity comparison between models with the same method. x-axis represents the number of important features that we consider, while y-axis shows the Jaccard similarity. *Error bars represent standard error throughout the paper.* The top row compares three pairs of models using the built-in method, while the second row compares three methods on SVM and LSTM with attention (LSTM in figure legends always refers to LSTM with attention in this work). The random line is derived using the average similarity between two random samples of k features from 100 draws.

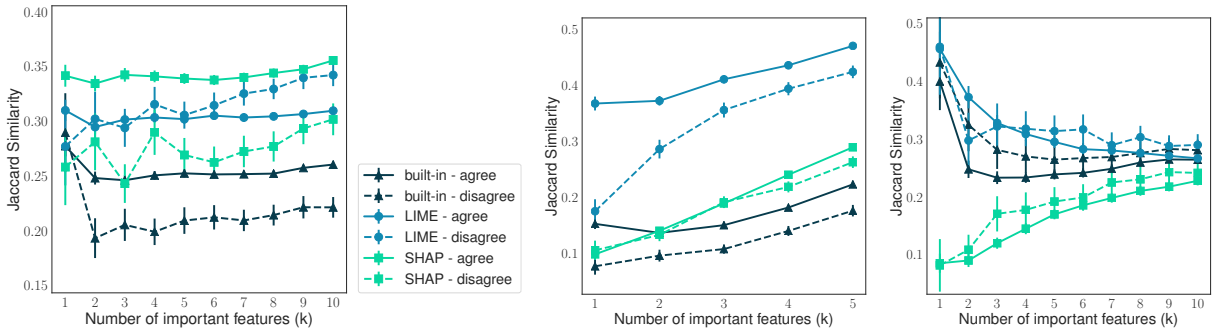
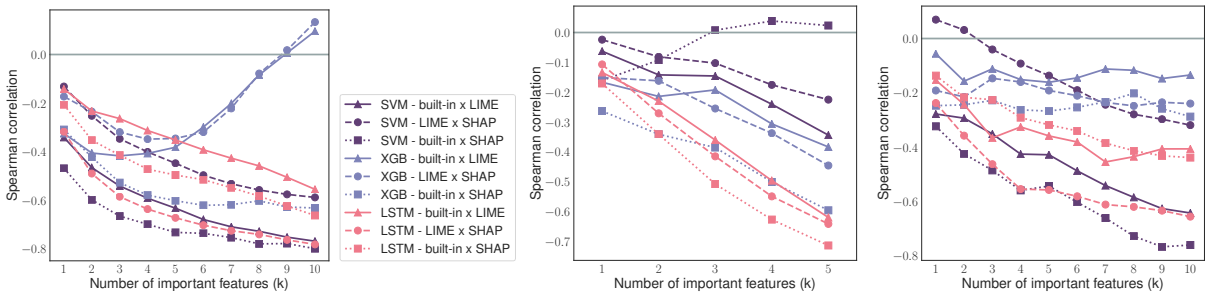
(m', h'). To facilitate effective comparisons, we first fix the method and compare the similarity of different models, and then fix the model and compare the similarity of different methods. Figure 1 shows the similarity between different models using the built-in feature importance for the top 10 features in Yelp ($k = 10$). Consistent with **H1a**, SVM (ℓ_2) and SVM (ℓ_1) are very similar to each other, and LSTM with attention and BERT clearly lead to quite different top 10 features from the other models. As the number of important features (k) can be useful for evaluating the overall trend, we thus focus on line plots as in Figure 2 in the rest of the paper. This heatmap visualization represents a snapshot for $k = 10$ using the built-in method. Also, we only include SVM (ℓ_2) in the main paper for ease of visualization and sometimes refer to it in the rest of the paper as SVM.



No matter which method we use, important features from SVM and XGBoost are more similar with each other, than with deep learning models (Figure 2). First, we compare the similarity of feature importance between different models using the same method. Using the built-in method (first row in Figure 2), the solid line (SVM x XGBoost) is always above the other lines, usually by a significant margin, suggesting that deep learning models such as LSTM with attention are less similar to traditional models. In fact, the similarity between XGBoost and LSTM with attention is lower than random samples for $k = 1, 2$ in SST. Similar results also hold for BERT (see supplementary materials). Another interesting observation is that post-hoc methods tend to generate greater similarity than built-in methods, especially for LIME (the dashed line (LIME) is always above the solid line (built-in) in the second row of Figure 2). This is likely because LIME only depends on the model behavior (i.e., what the model predicts) and does not account for how the model works.

The similarity between important features from different methods tends to be lower for LSTM with attention (Figure 3). Second, we compare the similarity of feature importance derived from the same model with different methods. For deep learning models such as LSTM with at-

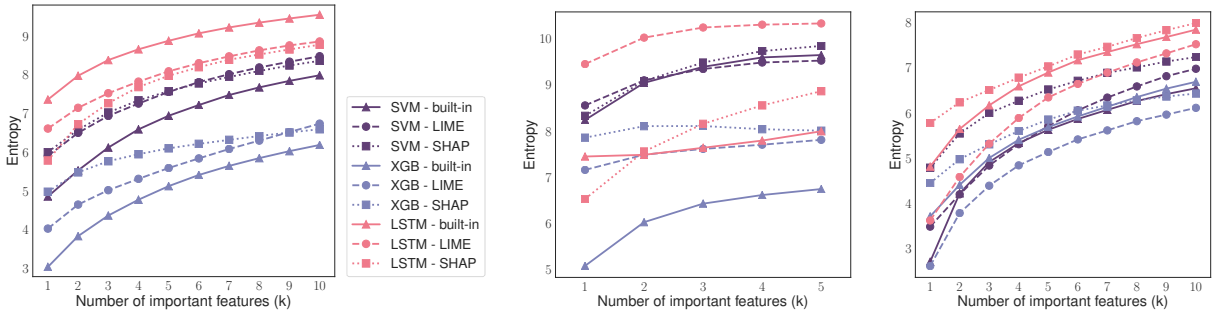


(a) Yelp (b) SST (c) Deception

Figure 3: Similarity comparison between methods using the same model. The similarity between different methods based on LSTM with attention is generally lower than other methods. Similar results hold for BERT (see the supplementary material).

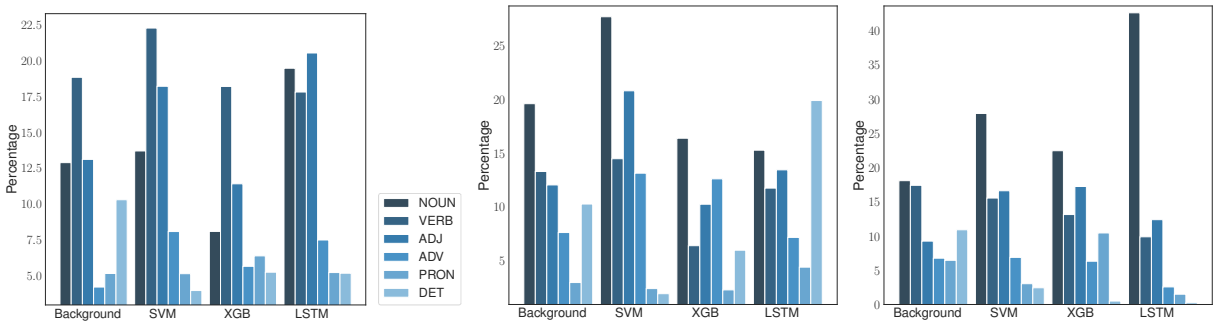
(a) Yelp (b) SST (c) Deception

Figure 4: Similarity between SVM (ℓ_2) and LSTM with attention with different methods grouped by whether these two models agree on the predicted label. The similarity is not always greater when they agree on the predicted labels than when they disagree.



(a) Yelp (b) SST (c) Deception

Figure 5: In most cases, the similarity between feature importance is negatively correlated with length. Here we only show the comparison between different methods based on the same model. Similar results hold for comparison between different models using the same method. For ease of comparison, the gray line marks the value 0. Generally as k grows, relationship becomes even more negatively correlated.



tention, the similarity between feature importance generated by different methods is the lowest, especially comparing LIME with SHAP. Notably, the results are much more cluttered in deception detection. Contrary to **H1b**, we do not observe that LIME is more similar to SHAP than built-in. The order seems to depend on both the task and the model: even within SST, the similarity between built-in and LIME can rank as third, second, or first. In other words, post-hoc methods generate more similar important features when we compare different models, but that is not the case when we fix the model. It is reassuring that that similarity between any pairs is above random, with a sizable margin in most cases (BERT on SHAP is an exception; see supplementary materials).

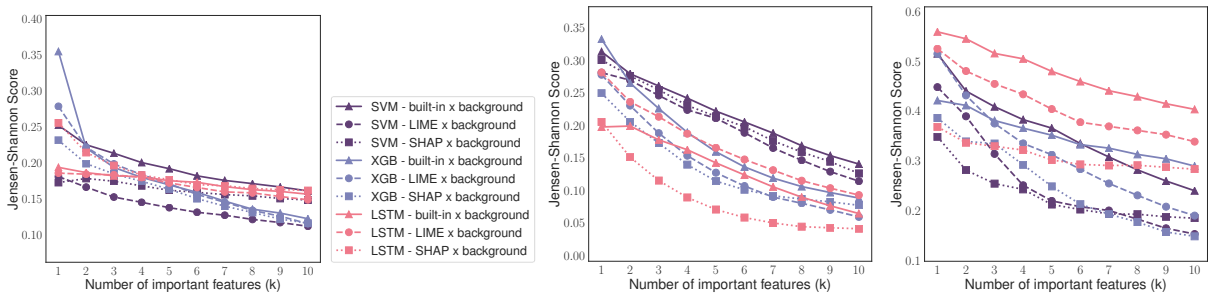
Relation with k. As the relative order between different approaches can change with k, we have

(a) Yelp (b) SST (c) Deception

Figure 6: The entropy of important features. LSTM with attention generates more diverse important features than SVM and XGBoost.

(a) Yelp (b) SST (c) Deception

Figure 7: Part-of-speech tag distribution with the built-in method. "Background" shows the distribution of all words in the test set. LSTM with attention puts a strong emphasis on nouns in deception detection, but is not necessarily more different from the background than other models.



so far only focused on relatively consistent patterns over k and classification tasks. Contrary to **H1c**, the similarity between most approaches is not drastically greater for small k, which suggests that different approaches may not even agree on the most important features. In fact, there is no consistent trend as k grows: similarity mostly *increases* in SST (while our hypothesis is that it decreases), increases or stays level in Yelp, and shows varying trends in deception detection.

6 Heterogeneity between Instances

Given the overall low similarity between different methods/models, we next investigate how the similarity may vary across instances.

The similarity between models is not always greater when two models agree on the predicted label (Figure 4). One hypothesis for the overall low similarity between models is that different models tend to give different predictions therefore they choose different features to support their decisions. However, we find that the similarity between models is not particularly high when they agree on the predicted label, and are sometimes even lower than when they disagree. This is true for LIME in Yelp and for all methods in deception detection. In SST, the similarity when the models agree on the predicted label is generally greater than when they disagree. We show the comparison between SVM (ℓ_2) and LSTM here, and similar results hold for other combinations (see supplementary materials). This observation suggests that feature importance may not connect with the predicted labels: different models agree for different reasons and also disagree for different reasons.

The similarity between models and methods is generally negatively correlated with length but positively correlated with type-token ratio (Figure 5). Our results support **H2b**: Spearman correlation between length and similarity is mostly below 0, which indicates that the longer an instance is, the less similar the important features are. The negative correlation becomes stronger as k grows, indicating that length has a stronger effect on similarity when we consider more top features. However, this is not true in the case of LIME and SHAP where the correlation between length and similarity are occasionally above 0 and sometimes even

(a) Yelp (b) SST (c) Deception

Figure 8: Distance of the part-of-speech tag distributions between important features and all words (background). Distance is generally smaller with post-hoc methods for all models, although some exceptions exist for LSTM with attention and BERT.

the declining relationship with k does not hold. Our result on type-token ratio is opposite to **H2c**: the greater the type-token ratio, the higher the similarity (see supplementary materials). We believe that the reason is that type-token ratio is strongly negatively correlated with length (the Spearman correlation for Yelp, SST and deception dataset is -0.92, -0.59 and -0.84 respectively). In other words, type-to-token ratio becomes redundant to length and fails to capture text complexity beyond length.

7 Distribution of Important Features

Finally, we examine the distribution of important features obtained from different approaches. These results may partly explain our previously observed low similarity in feature importance.

Important features show higher entropy using LSTM with attention and lower entropy with XGBoost (Figure 6). As expected from **H3a**, LSTM with attention (the pink lines) are usually at the top (similar results for BERT in the supplementary material). Such a high entropy can contribute to the low similarity between LSTM with attention and other models. However, as the order in similarity between SVM and XGBoost is less stable, entropy cannot be the sole cause.

Distribution of POS tags (Figure 7 and Figure 8). We further examine the linguistic properties of important words. Consistent with **H3b**, adjectives are more important in sentiment classification than in deception detection. On the contrary to our hypothesis, we found that pronouns do not always play an important role in deception detection. Notably, LSTM with attention puts a strong emphasis on nouns in deception detection. In all cases, determiners are under-represented among important words. With respect to the distance of part-of-speech tag distributions between important features and all words (background), post-hoc methods tend to bring important words closer to the background words, which echoes the previous observation that post-hoc methods tend to increase the similarity between important words (Figure 8).

8 Concluding Discussion

In this work, we provide the first systematic characterization of feature importance obtained from different approaches. Our results show that different approaches can sometimes lead to very different important features, but there exist some consistent patterns between models and methods. For instance, deep learning models tend to generate diverse important features that are different from traditional models; post-hoc methods lead to more similar important features than built-in methods.

As important features are increasingly adopted for varying use cases (e.g., decision making vs. model debugging), we hope to encourage more work in understanding the space of important features, and how they should be used for different purposes. While we focus on consistent patterns across classification tasks, it is certainly interesting to investigate how properties related to tasks and data affect the findings. Another promising direction is to understand whether more concentrated important features (lower entropy) lead to better human performance in supporting decision making.

Abstract

For text classification, traditional local feature driven models learn long dependency by deeply stacking or hybrid modeling. This paper proposes a novel Encoder1-Encoder2 architecture, where global information is incorporated into the procedure of local feature extraction from scratch. In particular, Encoder1 serves as a global information provider, while Encoder2 performs as a local feature extractor and is directly fed into the classifier. Meanwhile, two modes are also designed for their interactions. Thanks to the awareness of global information, our method is able to learn better instance specific local features and thus avoids complicated upper operations. Experiments conducted on eight benchmark datasets demonstrate that our proposed architecture promotes local feature driven models by a substantial margin and outperforms the previous best models in the fully-supervised setting.

1 Introduction

Text classification is a fundamental task in natural language processing, which is widely used in various applications such as spam detection, sentiment analysis and topic classification. One of the mainstream approaches firstly utilizes explicit local extractors to identity key local patterns and classifies based on them afterwards. In this paper, we call this line of research as *local feature driven models*.

Lots of proposed methods can be grouped into this scope. Ngrams have been traditionally exploited in statistical machine learning approaches (Pang et al., 2002; Wang and Manning, 2012). For deep neural networks, encoding local features into low-dimensional distributed ngrams embeddings (Joulin et al., 2016; Qiao et al., 2018) and simply bagging of them have been proved effective and highly efficient. Convolutional Neural Networks (CNN) (LeCun et al., 2010) are promising methods for their strong capacities in capturing local invariant regularities (Kim, 2014). More recently, Wang (2018) proposes the Disconnected Recurrent Neural Network (DRNN), which utilizes RNN to extract local features for larger windows and has reported best results on several benchmarks.

Case1: ***Apple*** *is really amazing! I am fed up to carry my clunky camera.*
Case2: ***Apple*** *is famous around world and deserves to be called "nutritional powerhouses".*

Table 1: Topic classification examples for *Technology* and *Health*, where ***Apple*** is ambiguous within local context.

Despite having good interpretability and remarkable performance, current local feature extraction still has one shortcoming. As shown in Table 1, the real meaning of *Apple* can only be correctly recognized from overall view instead of narrow window. If the local extractor in charge of *Apple* cannot receive *camera* and *nutritional* from the very beginning, it would require complicated and costly upper structures to help revise the imprecisely local representation and create newer high-level features, such as deeply stacking (Johnson and Zhang, 2017; Conneau et al., 2016) and hybrid integration (Xiao and Cho, 2016). To a certain extend, it is inefficient and hard to train especially in the case of insufficient corpus.

To address this issue, we believe a more efficient approach is to optimize the local extraction process directly. In this paper, we propose

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 496–506, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

a novel architecture named Encoder1-Encoder2[1], which innovatively contains two encoders for the identical input sequence respectively, instead of using only one single encoder in previous work. Concretely, the Encoder1 can be any kind of neural network models designed for briefly grasping global background, while the Encoder2 should be a typical local feature driven model. The key point is, the earlier generated global representations from Encoder1 is then incorporated into the local extraction procedure of Encoder2. In this way, local extractors can notice more long-range information on the basis of its natural advantages. As a result, better instance specific local features can be captured and directly utilized for classification owing to global awareness, which means further upper complicated operations can be avoided.

We conduct experiments on eight public text classification datasets introduced by Zhang et al. (2015). The experimental results show that our proposed architecture promotes local feature driven models by a substantial margin. In fully-supervised settings, our best models achieves new state-of-the-art performances on all benchmark datasets. We further demonstrate the ability and generalization of our architecture in the semi-supervised domain.

Our contributions can be concluded as follows:

1. We propose a novel Encoder1-Encoder2 architecture, where better instance specific local features are captured by incorporating global representations into local extraction procedure.

2. Our architecture has great flexibility. Different associations among Encoder1, Encoder2 and Interaction Modes are studied, where any kind of combination promotes vanilla CNN or DRNN significantly.

3. Our architecture is more robust to the window size of local extractors and the corpus scale.

2 Related Work

Local Feature Driven Models FastText uses bag of n-grams embeddings as text representation (Joulin et al., 2016), which has been proved effective and efficient. Qiao et al. (2018) propose a new method of learning and utilizing task specific n-grams embeddings to conquer data sparsity.

CNN (LeCun et al., 2010) are representative methods of this category. Convolution operators are performed at every window based location to extract local features, interleaved with pooling layer for capturing invariant regularities. From Kim (2014), CNN are widely used in text classification. In addition to shallow structure, very deep and more complex CNN based models have also been studied to establish long distance association. Examples are deep character-level CNNs Zhang et al. (2015); Conneau et al. (2016), deep pyramid CNN Johnson and Zhang (2017) and convolution-recurrent networks Xiao and Cho (2016), in which recurrent layers are designed on top of convolutional layers for learning long-term dependencies between local features.

CNN use simple linear operations on n-gram vectors of each window, which enlightens researchers to capture higher order local non-linear feature using RNN. Shi et al. (2016) first replace convolution filters with LSTM for query classification. Wang (2018) proposes DRNN, which exploits large window size equipped with GRU.

To make full use of local and global information, Zhao et al. (2018) propose a sandwich network by carding a CNN in the middle of two LSTM layers, where the output of CNN provides local semantic representations while the top LSTM supplies global structure representations. However, the global information they mainly focus on is the syntax part, which is produced by reorganizing the already obtained local features. Besides, both of them are directly used for final classification, while we use pre-acquired global representations to help capture better local features. To the best of our knowledge, we are the first to incorporate global representation into the extraction procedure of local features for text classification.

Other Neural Network Models Recurrent Neural Networks (RNN) are naturally good at modeling variable-length sequential data and capturing long-term dependencies (Hochreiter and Schmidhuber, 1997; Chung et al., 2014). Global features are encoded by semantically synthesizing each word in the sequence in turn and there is no explicit small regions feature extraction procedure in this process. Lai et al. (2015) equip RNN with max-pooling to tackle the bias problem where later words are more dominant than earlier words. Tang et al. (2015) utilize LSTM to encode semantics of sentences and their relations in doc-

[1]Our code will be available at https://github.com/PaddlePaddle/models/tree/develop/PaddleNLP/Research/EMNLP2019-GELE. "GELE" is the abbreviation for Global Encoder and Local Encoder, i.e., Encoder1 and Encoder2 respectively.

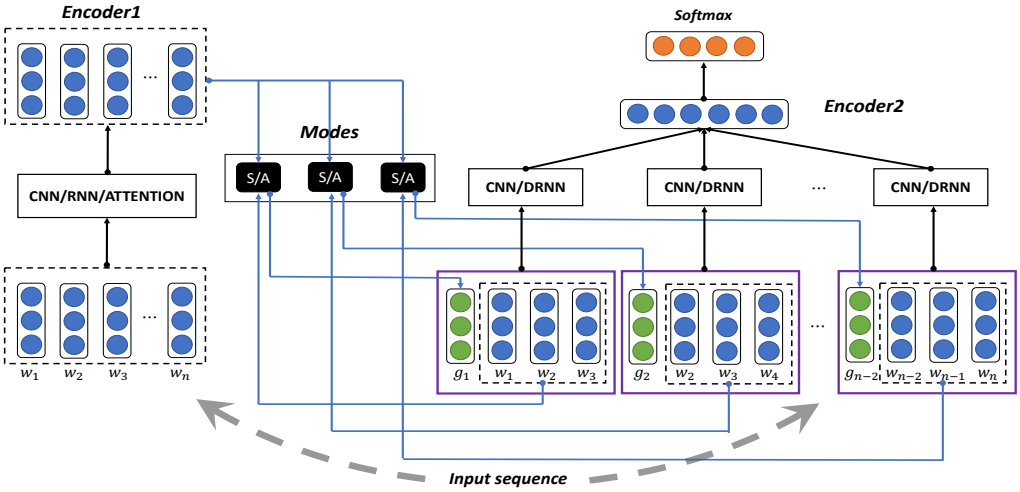

Figure 1: Encoder1-Encoder2 architecture mainly contains three components. (1) Encoder1 serves as a global information provider. (2) Encoder2 is a local feature driven model whose output is directly fed into the classifier. (3) Mode is the interaction manner between them. S and A are abbreviation of SAME and ATTEND respectively.

ument representation. Tai et al. (2015) introduce a tree-structured LSTM for sentiment classification.

The attention mechanism proposed by Bahdanau et al. (2014) has achieved great success in machine translation (Vaswani et al., 2017). For text classification which only has single input sequence, attention based models mainly focus on applying attention mechanism on top of CNN or RNN for selecting the more important information (Yang et al., 2016; Er et al., 2016). Letarte et al. (2018) and Shen et al. (2018) also explore self-attention networks which is CNN/RNN free.

3 Encoder1-Encoder2 Architecture

3.1 Overview

In this paper, we propose a novel neural network architecture named Encoder1-Encoder2 for text classification, which is illustrated in Figure 1. The identical input sequence will be encoded twice by two encoders respectively, but only the output of Encoder2 is used directly for the classifier. In particular, the Encoder1 serves as a pioneer for providing global information, while the Encoder2 focuses on extracting better local features by incorporating the former into the local extraction procedure. Besides, two Interaction Modes are developed for more targeted absorption of global information.

3.2 Encoder1: Global Information Provider

Without loss of generality, we introduce three types of models for Encoder1 in our architecture, each of which can be an independent global information provider and they are compared in our experiments.

CNN Let $\mathbf{x}_t$ be the d-dimensional word vector corresponding to the t-th word in a sequence of length n, $\mathbf{x}_{t-h+1:t}$ refers to the concatenation of words $\mathbf{x}_{t-h+1}, \mathbf{x}_{t-h+2}, \ldots, \mathbf{x}_t$ with size h and k number of filters are applied to the input sequence to generate features. Formally, filters $\mathbf{W}_f$ are applied to window $\mathbf{x}_{t-h+1:t}$ to compute $\mathbf{h}_t$:

$$\mathbf{h}_t = Conv(\mathbf{x}_{t-h+1}, \mathbf{x}_{t-h+2}, \ldots, \mathbf{x}_t) \quad (1)$$

$$= relu(\mathbf{W}_f \mathbf{x}_{t-h+1:t} + \mathbf{b}_f) \quad (2)$$

By same padding, filters are applied to n possible windows in the sequence and the global representation can be represented as $\mathbf{enc}_1$:

$$\mathbf{enc}_1 = [\mathbf{h}_1; \mathbf{h}_2; \ldots; \mathbf{h}_n] \quad (3)$$

GRU Gated recurrent units (GRU) are a gating mechanism in RNN (Cho et al., 2014). Two types of gates are used in GRU: reset gate decides how much new information is updated, while update gate controls the flow of previous information. The hidden state $\mathbf{h}_t$ is computed iteratively based on $\mathbf{h}_{t-1}$ and $\mathbf{x}_t$. As a result, the all previous information can be encoded. For saving space, here we abbreviate it as:

$$\mathbf{h}_t = GRU(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_t) \quad (4)$$

The global representation produced by GRU is hidden states of all time steps:

$$\mathbf{enc}_1 = [\mathbf{h}_1; \mathbf{h}_2; \ldots; \mathbf{h}_n] \quad (5)$$

Attention We also introduce attention mechanism on GRU for enhancing valuable information following Zhou et al. (2016). Define a context vector $\mathbf{u}_w$ to measure the importance of each hidden state $\mathbf{h}_t$ in GRU, which is randomly initialized and learned during training. A normalized importance weight α_t is obtained through a softmax function:

$$\alpha_t = \frac{\exp(\tanh(\mathbf{h}_t)^\top \mathbf{u}_w)}{\sum_t \exp(\tanh(\mathbf{h}_t)^\top \mathbf{u}_w)} \quad (6)$$

The global representation produced by this attention mechanism is expressed as:

$$\mathbf{enc}_1 = [\alpha_1 \mathbf{h}_1; \alpha_2 \mathbf{h}_2; \ldots; \alpha_n \mathbf{h}_n] \quad (7)$$

3.3 Encoder2: Variant Local Extractor

Vanilla local feature extractor strictly focuses on a limited size region. Here we propose a variant method. Apart from the expected local context, global information distilled by Encoder1 is also absorbed by a local extractor. In this way, the local features extracted by Encoder2 can notice the global background while still maintaining the position-invariant local patterns.

For Encoder2, we introduce two kinds of local feature driven models, i.e., CNN and DRNN. The former is good at capturing local spatial structure, while the latter is highlighted in capturing local temporal part. Set $\mathbf{g_t}$ as the required global information for a certain size window starting from $\mathbf{x}_t$, which will be introduced in 3.4 in detail.

CNN Here we treat each $\mathbf{g_t} \in \mathbb{R}^d$ as a faked extra global word, and do convolution with window words together. Based on Equation 1, features produced by filters for window $\mathbf{x}_{t-h+1:t}$ can be represented as:

$$\mathbf{h}_t = Conv(\mathbf{g_t}, \mathbf{x}_{t-h+1}, \mathbf{x}_{t-h+2}, \ldots, \mathbf{x}_t) \quad (8)$$

DRNN Different from CNN, DRNN utilizes RNN to extract local features for each window (Wang, 2018). To introduce global information into DRNN, faked global word $\mathbf{g_t}$ is filled in the head of each window like CNN does. Because of the sequential nature of RNN, even for a limited window, global information can be encoded into RNN from scratch and motivate the latter words. Here we use GRU as the local feature extractor, and features produced for window $\mathbf{x}_{t-h+1:t}$ can be represented as:

$$\mathbf{h}_t = GRU(\mathbf{g_t}, \mathbf{x}_{t-h+1}, \mathbf{x}_{t-h+2}, \ldots, \mathbf{x}_t) \quad (9)$$

To maintain translation invariant, a max-over-time pooling layer is then applied to CNN or DRNN layer, the pooling result is regarded as the output of Encoder2:

$$\mathbf{enc}_2 = maxpool([\mathbf{h}_1; \mathbf{h}_2; \ldots; \mathbf{h}_n]) \quad (10)$$

3.4 Interaction Modes between Encoders

Set $\mathbf{enc}_1$ as the global representation produced by Encoder1, required information for a certain window $\mathbf{x}_{t-h+1:t}$ with size h is defined as $\mathbf{g_t}$:

$$\mathbf{g_t} = G(\mathbf{enc}_1, \mathbf{x}_{t-h+1}, \mathbf{x}_{t-h+2}, \ldots, \mathbf{x}_t) \quad (11)$$

where G is a function of interaction mode. Two modes are devised from different point of views.

SAME Treat $\mathbf{enc}_1$ as a "reference book" provided by Encoder1. The basic idea of SAME Mode is each window in Encoder2 will get indiscriminate guidance regardless of the local information itself. For this purpose, max-over-time pooling is operated on $\mathbf{enc}_1$ directly to extract the most important information:

$$\hat{\mathbf{g}}_\mathbf{t} = maxpool(\mathbf{enc}_1) \quad (12)$$

ATTEND Mode ATTEND utilizes global information from another perspective. According to different local contexts, the guidances from Encoder1 can be be more targeted. Specifically, we use attention mechanism.

For window $\mathbf{x}_{t:t+h-1}$ with size h, the context vector is the average pooling of local words embeddings and the importance weight α_t for each hidden state $\mathbf{h}_t$ in Encoder1 can be computed as:

$$\alpha_t = \frac{\exp(\tanh(\mathbf{h}_t)^\top avg(\mathbf{x}_{t:t+h-1}))}{\sum_t \exp(\tanh(\mathbf{h}_t)^\top avg(\mathbf{x}_{t:t+h-1}))} \quad (13)$$

To maximize the profits obtained from Encoder1, we concatenate both of maxpooling results and attention results. Then $\hat{\mathbf{g}}_\mathbf{t}$ in ATTEND mode can be represented as:

$$\hat{\mathbf{g}}_\mathbf{t} = Concat(maxpool(\mathbf{enc}_1), \sum_t \alpha_t \mathbf{h}_t) \quad (14)$$

Finally, to keep consistent dimensions with words in the text, we compress $\hat{\mathbf{g}}_\mathbf{t}$ using MLP and formalized as $\mathbf{g_t}$, which can be easily embedded into the local feature extraction in Encoder2.

Sogou	56k	400	15
Yah. A.	400k	256	20
DBP	400k	128	15

Table 3: Model settings. We limit the vocabulary size and set maximum sequence length. We also show the window size in DRNN following Wang (2018).

3.5 Classification Layer

After incorporating the global information obtained from Encoder1 into the local feature extraction of Encoder2, the output vector of latter can be regarded as the representation of the entire text. The vector is then fed into a softmax classifier to predict the probability of each category and cross entropy is used as loss function:

$$\hat{y} = softmax(\mathbf{W}_c\mathbf{enc}_2 + \mathbf{b}_c) \quad (15)$$

$$H(y, \hat{y}) = \sum_i y_i \log \hat{y}_i \quad (16)$$

where $\hat{y}_i$ is the predicted probability and y_i is the true probability of class i.

4 Experiments

We report experiments with proposed models in comparison with previous methods.

4.1 Experiments Settings

Datasets Publicly available datasets from Zhang et al. (2015) are used to evaluate our models. These datasets contain various domains and sizes, corresponding to sentiment analysis, news classification, question answering, and ontology extraction, which are summarized in Table 2.

Model Settings For data preprocessing, all the texts of datasets are tokenized by NLTKs tokenizer (Loper and Bird, 2002). For model hyperparameters, notations are following in 3.2 and 3.3. We adopt CNN, GRU and Attention for Encoder1. In CNN (Encoder1), we use filter windows (h) of $[3, 5, 7]$ with 128 feature maps (k) each. The hidden unit number is 128 in GRU (Encoder1) and Attention (Encoder1). For Encoder2, we conduct experiments based on two types of local feature extractor, corresponding to CNN and DRNN respectively. In CNN (Encoder2), window sizes of filters are of $[3, 5, 7]$ with 128 feature maps each. In DRNN (Encoder2), all the dimensions of hidden states are set to 300. Other settings are shown in Table 3, all trainable parameters including embeddings of words are initialized randomly without any pre-trained techniques (Mikolov et al., 2013; Peters et al., 2018; Devlin et al., 2018).

Training and Validation For each dataset, we randomly split the full training corpus into training and validation set, where the validation size is the same as the corresponding test size. Then the validation set is fixed for all models for fair comparison. The reported test accuracy is evaluated in the model which has lowest validation error.

AdaDelta (Zeiler, 2012) with $\rho = 0.95$ and $\epsilon = 1e - 6$ is chosen to optimize all the trainable parameters. Gradient norm clipping is employed to avoid the gradient explosion problem. L2 normalization is used in all models which include RNN structures. The batch size is set to 64 for Yelp P. and Yelp F. while 128 for other datasets. We train all the models using early stopping with timedelay 10.

4.2 Experimental Results and Analysis

Table 4 is the summary of the experimental results. We use underscores to represent the best published models, and bold the best records. Best models in our proposed architecture beat previous state-of-the-art models on all eight text classification benchmarks.

For published models, best results are achieved almost all by local feature driven models including Region-emb, VDCNN and DRNN. Self-Attention model SANet performs well, but does not achieve advantageous results as in sequence to sequence

Model	Yelp P.	Yelp F.	Amz. P.	Amz. F.	AG	Sogou	Yah. A.	DBP
bigram-FastText (Joulin et al., 2016)	95.7	63.9	94.6	60.2	92.5	96.8	72.3	98.6

Table 4: Test accuracy [%] on several Datasets. We use Encoder1-Encoder2-Mode to represent our architecture, where S indicates mode SAME while A indicates ATTEND. For each specialized Encoder2, we test three different Encoder1. For the sake of brevity, *Encoder1* here does not specifically refer to a certain model but the best performance of the three combinations. Detailed experiments results for all combinations of Encoder1-Encoder2-Mode are further reported and compared in Table 5. For compared previous models, first block lists n-grams based models including bigram-FastText (Joulin et al., 2016) and region embedding (Qiao et al., 2018). Self-attention Networks SANet (Letarte et al., 2018) is reported in the second block. RNN based models LSTM (Zhang et al., 2015), D-LSTM (Yogatama et al., 2017) and CNN based models char-CNN (Zhang et al., 2015) and VDCNN (Conneau et al., 2016) are listed in third and forth block respectively. Strong local feature driven models CNN (Kim, 2014) and DRNN (Wang, 2018) are chosen as base model and directly compared with our architecture in last two blocks.

scenes, neither do RNN based methods. We argue that it is because key phrases and word order play an important role in text classification.

For our models, the experimental results show that enhanced local extractors with global encoder outperform vanilla local models by a advantageous margin. When CNN is chosen as local extractor, the performance gains are particularly significant for relatively difficult tasks such as Amz. F.(+2.4%) and Yah. A.(+2.0%). Encoder1-CNN performs even better than VDCNN with 29 convolutional layers. The results are satisfying considering that our CNN used as local extractor here is a shallow model with only one layer. Moreover, complicated VDCNN performs best among published models on larger datasets Amz. P.(95.7%) and Amz. F.(63.0%) but not as expected on smaller AG(91.3%), while our Encoder1-CNN has stable superior performance on all datasets. When DRNN is chosen as local extractor, the bonus from the global encoder is not so big like CNN, but still considerable and stable. Encoder1-DRNN beats DRNN on all datasets with a highest gain up to 0.7%.

To better analyze the impact of specific Encoder1 (global encoder) and different Interaction Modes on architecture performance, Table 5 details all combinations results of Encoder1-Encoder2-Mode on three datasets. We find the local extractor benefits quite a lot for any introduced global encoders. Overall, RNN and Attention based global encoders perform well-matched for local extractor, and both of them often perform better than CNN based global encoder. For example, Attention-CNN wins CNN-CNN 1.0% on Yelp F. and RNN-DRNN wins CNN-DRNN 0.4% on Yah. A. This is intuitive since RNN and Attention are more appropriate in capturing global information compared with CNN, which is critical for local extractor. The structures which specialize in modeling long-term dependency are more recommended as the global encoder.

For two Interaction Modes, we find ATTEND performs slightly better than SAME up to 0.4%, which can verify the differentiated motivation. Encoder1 (global encoder) can be viewed as a "reference book" about the whole text. Two Modes utilize the information from different perspectives to

(a) Experiments on Yelp F.

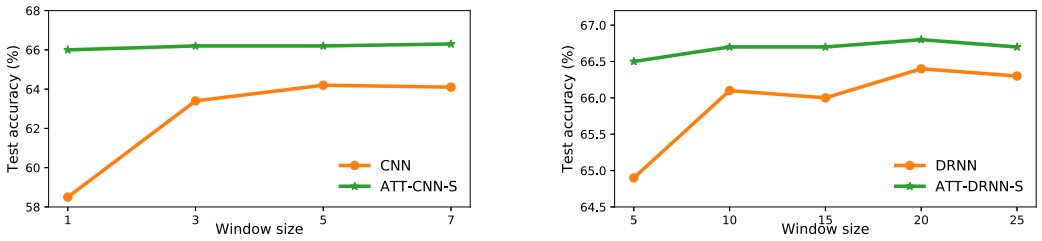
assist the local extractor. SAME Mode selects the most important information of global encoder and provides same guidance for each window in Encoder2, while the ATTEND Mode tends to make use of the "reference" with purpose based on different local contexts as if we refer to a reference book with initiative questions.

4.3 Model Ablation

In addition to introducing another encoder into vanilla local feature driven models, the greatest novelty of our architecture lies in that the global encoding is used to generate local features directly. Based on this motivation, the local features have the global awareness from the very beginning. To verify that our novel architecture makes key contribution to the performance improvement, we carry out model ablation experiments.



Without loss of generality, we use CNN as local extractor here and validate on Yelp F. and Yah. A. datasets. The results are illustrated in Figure 2.

Firstly, we list the results of Vanilla CNN, which is regarded as the most primitive state. Secondly, another additional encoder is introduced but they both process inputs independently and then their output representations are concatenated for classification. We call it "Concat", abbreviated as "C". For example, RNN-CNN-C stands for concatenating another RNN. Finally, we upgrade the way to use the introduced encoder as our proposed architecture. Here we list Mode SAME, abbreviated as "S".

We find CNN-CNN-C loses 0.5% on Yelp P. but wins 0.4% on Yah. A. compared with vanilla CNN. CNN-CNN-C can be viewed as doubling convolution filters and we can observe that introducing more parameters does not always perform better. Meanwhile, RNN-CNN-C wins vanilla CNN 0.7% on Yelp P. and 0.9% on Yah. A. It makes sense since the classifier could use features from CNN and RNN simultaneously and different model structures complement each other for classification. In particular, our architecture performs best for both cases. CNN-CNN-S wins CNN-CNN-C 1.3% and 0.8%, and RNN-CNN-S wins RNN-CNN-C 0.6% and 1.0% on Yelp P. and Yah. A. respectively. In fact, CNN-CNN-S does not introduce new model structure or complicated operations and the number of parameters are almost the same. We attribute the great improvement to our novel mechanism where the global representation conduces to the local extraction.

4.4 Effect of Window Size

As an important hyperparameter, window size determines how much information can be seen in a specific window and often requires carefully tun-

Table 6: Visualization of chosen samples on AG News and Yelp Review Polarity dataset. We use SAME Interaction Mode in ATT-CNN where ATT is the abbreviation of Attention.

ing in traditional method. Small window sizes may result in the loss of some critical information whereas large windows result in an enormous parameter space, which could be difficult to train (Lai et al., 2015). In this section, we analyze the impact of different window sizes on model performances.

As shown in Figure 3, both CNN and DRNN are very sensitive to window size, the optimal window size in DRNN can be much larger than CNN due to the sequential memory in RNN structure. Tuning these models is often challenging. In contrast, our Encoder1-Encoder2 architecture is insensitive to the parameter and achieves stable satisfied performance in various window sizes. We believe it is because the local extraction has been enhanced by global information and not strictly dependent on large windows to capture long range information.

4.5 Case Study and Visualization

To investigate how our architecture makes a difference in details, we visualize the attending phrases by the neural model in Table 6. Qualitatively, we display the contribution of phrases in Encoder2 to classification via max-pooling. The most important phrases are highlighted red where the intensity of the color indicates the contribution. Meanwhile, we use waves to roughly indicate the key phrases with high attention scores in Encoder1. Detailed visualization techniques have been introduced in Li et al. (2015).

The first two lines compare CNN with our Attention-CNN on an example from AG News. CNN wrongly captures key phrases *British Energy* and *the nuclear generator* and thus misclassifies the example into *World*. In contrast, our Attention-CNN is able to correctly classify it into *Business*. The Encoder1 firstly captures the global description by *Energy deal*, *nuclear*, and *rescue plan*. Informed with these global information, Encoder2 reduces its attention to *nuclear*, which implies label *World* while captures key phrases *British Energy deal* and *5bn rescue plan*. Accordingly the model makes a correct prediction labeled as *Business*. For the second example, the global representations include phrases *high price* and conjunction *Overall*, making Encoder2 activate *I would rather* while reduce its sensitivity to *highly recommend them* compared with CNN.

In short, the global representations learned by Encoder1 provide a brief overall grasp of the whole text, which includes both semantic and structure information. It effectively helps Encoder2 capture better instance specific local features and improve model performance.

4.6 Comparison to Pre-trained Models

As shown above, our paper mainly focuses on fully-supervised domain where all model parameters are trained from scratch. Alternatively, substantial work has shown that pre-trained models are beneficial for various NLP tasks. Typically, they first pre-train neural networks on large-scale unlabeled text corpora, and then finetune the models or representations on downstream tasks.

One kind of pre-trained models is the word embeddings, such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). More recently, by utilizing larger-scale unsupervised corpus and deeper architecture, pre-trained language models have shown to be effective in learning common language representations and have achieved great success. Among them, OpenAI GPT (Radford et al., 2018), BERT (Devlin et al., 2018), XLNet (Yang et al., 2019) and ERNIE 2.0 (Sun et al., 2019) are the most remarkable examples.

In this section, we generalize our architecture to semi-supervised domain which is equipped with pre-trained word embeddings and then compare with popular pre-trained based models. Specifically, we use GloVe vectors[2] with 300 dimensions to initialize the word embeddings in our architecture. BERT$_{BASE}$[3] and ERNIE 2.0$_{BASE}$[4] with 12-layer Transformer (Vaswani et al., 2017) are chosen for comparison. Here we report best model for each specialized Encoder2 with SAME Mode. Results on three datasets are listed in Table 7.

Overall, our architecture can be further boosted a lot by utilizing pre-trained word embeddings. For example, *Encoder1*-DRNN-S obtains a new score of 76.2%(+1.4%) on Yah. A. and *Encoder1*-CNN-S gets 94.1%(+1.6%) on AG. Vanilla local extractors also achieve better performance as expected in most instances while our models are still much better than them. *Encoder1*-CNN-S outperforms CNN by 0.9%, 1.8% and 2.0% on three datasets respectively, and *Encoder1*-DRNN-S outperforms DRNN by 0.4%, 0.6% and 0.7%. It shows that our architecture is well generalized and compatible with pre-training techniques.

It is interesting to compare with stronger pre-trained models. Although we obtain close scores on AG, BERT and ERNIE 2.0 indeed achieve more advanced results on others and the latter performs best on all three datasets. Despite their superb accuracy, we argue that the huge models are resource-hungry in practice. Lightweight models still have advantages under some circumstances such as limited memory, longer text data to be processed and requirements of faster inference time.

Model	Yelp F.	AG	Yah. A.
CNN(n/y)	64.7/64.5	91.9/92.3	72.6/73.7
Encoder1-CNN-S(n/y)	66.2/66.6	92.5/94.1	74.5/75.7
DRNN(n/y)	66.4/66.8	92.9/93.6	74.3/75.5
Encoder1-DRNN-S(n/y)	66.8/67.2	93.0/94.2	74.8/76.2
BERT$_{BASE}$	67.9	94.2	76.4
ERNIE 2.0$_{BASE}$	**69.1**	**94.3**	**77.0**

Table 7: Semi-supervised generalization of our architecture and comparison with popular pre-trained models. Here "n" and "y" stand for initializing word embeddings randomly and with pre-trained GloVe vectors separately.

5 Conclusion

In this work, we demonstrate the local feature extraction can be significantly enhanced with global information. Instead of traditionally exploiting deeper and complicated operations in upper neural layers, our work innovatively provides another lightweight way for improving the ability of neural model. Specifically, we propose a novel architecture named Encoder1-Encoder2 with two Interaction Modes for their interacting. The architecture has high flexibility and our best models achieve new state-of-the-art performance in fully-supervised setting on all benchmark datasets. We also find that our architecture is insensitive to window size and enjoy a better robustness. In future work, we plan to validate its effectiveness for multi-label classification. Besides, we are interested in incorporating more powerful unsupervised methods into our architecture.

xiaoanding@uchicago.edu, kgimpel@ttic.edu

Abstract

Generative classifiers offer potential advantages over their discriminative counterparts, namely in the areas of data efficiency, robustness to data shift and adversarial examples, and zero-shot learning (Ng and Jordan, 2002; Yogatama et al., 2017; Lewis and Fan, 2019). In this paper, we improve generative text classifiers by introducing discrete latent variables into the generative story, and explore several graphical model configurations. We parameterize the distributions using standard neural architectures used in conditional language modeling and perform learning by directly maximizing the log marginal likelihood via gradient-based optimization, which avoids the need to do expectation-maximization. We empirically characterize the performance of our models on six text classification datasets. The choice of where to include the latent variable has a significant impact on performance, with the strongest results obtained when using the latent variable as an auxiliary conditioning variable in the generation of the textual input. This model consistently outperforms both the generative and discriminative classifiers in small-data settings. We analyze our model by using it for controlled generation, finding that the latent variable captures interpretable properties of the data, even with very small training sets.

1 Introduction

The most widely-used neural network classifiers are **discriminative**, that is, they are trained to explicitly favor the gold standard label over others. The alternative is to design classifiers that are **generative**; these follow a generative story that includes predicting the label and then the data conditioned on the label. Discriminative classifiers are preferred because they generally outperform their generative counterparts on standard benchmarks. These benchmarks typically assume large annotated training sets, little mismatch between training and test distributions, relatively clean data, and a lack of adversarial examples (Zue et al., 1990; Marcus et al., 1993; Deng et al., 2009; Lin et al., 2014).

However, when conditions are not ideal for discriminative classifiers, generative classifiers can actually perform better. Ng and Jordan (2002) showed theoretically that linear generative classifiers approach their asymptotic error rates more rapidly than discriminative ones. Based on this finding, Yogatama et al. (2017) empirically characterized the performance of RNN-based generative classifiers, showing advantages in sample complexity, zero-shot learning, and continual learning. Recent work in generative question answering models (Lewis and Fan, 2019) demonstrates better robustness to biased training data and adversarial testing data than state-of-the-art discriminative models.

In this paper, we focus on settings with small amounts of annotated data and improve generative text classifiers by introducing discrete latent variables into the generative story. Accordingly, the training objective is changed to log marginal likelihood of the data as we marginalize out the latent variables during learning. We parameterize the distributions with standard neural architectures used in conditional language models and include the latent variable by concatenating its embedding to the RNN hidden state before computing the softmax over words. While traditional latent variable learning in NLP uses the expectation-maximization (EM) algorithm (Dempster et al., 1977), we instead simply perform direct optimization of the log marginal likelihood using gradient-based methods. At inference time, we similarly marginalize out the latent variables while maximizing over the label.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 507–517, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

We characterize the performance of our latent-variable generative classifiers on six text classification datasets introduced by Zhang et al. (2015). We observe that introducing latent variables leads to large and consistent performance gains in the small-data regime, though the benefits of adding latent variables reduce as the training set becomes larger.

To better understand the modeling space of latent variable classifiers, we explore several graphical model configurations. Our experimental results demonstrate the importance of including a direct dependency between the label and the input in the model. We study the relationship between the label, latent, and input variables in our strongest latent generative classifier, finding that the label and latent capture complementary information about the input. Some information about the textual input is encoded in the latent variable to help with generation.

We analyze our latent generative model by generating samples when controlling the label and latent variables. Even with small training data, the samples capture the salient characteristics of the label space while also conforming to the values of the latent variable, some of which we find to be interpretable. While discriminative classifiers excel at separating examples according to labels, generative classifiers offer certain advantages in practical settings that benefit from a richer understanding of the data-generating process.

2 Discriminative and Generative Text Classifiers

We begin by defining our baseline generative and discriminative text classifiers for document classification. Our models are essentially the same as those from Yogatama et al. (2017); we describe them in detail here because our latent-variable models will extend them.[1] Our classifiers are trained on datasets D of annotated documents. Each instance $\langle x, y \rangle \in D$ consists of a textual input $x = \{x_1, x_2, ..., x_T\}$, where T is the length of the document, and a label $y \in \mathcal{Y}$.

[1]The main difference between our baselines and the models in Yogatama et al. (2017) are: (1) their discriminative classifier uses an LSTM with "peephole connections"; (2) they evaluate a label-based generative classifier ("Independent LSTMs") that uses a separate LSTM for each label. They also evaluate the model we described here, which they call "Shared LSTMs". Their Independent and Shared LSTMs perform similarly across training set sizes.

The discriminative classifier is trained to maximize the conditional probability of labels given documents: $\sum_{\langle x,y \rangle \in D} \log p(y \mid x)$. For our discriminative model, we encode a document x using an LSTM (Hochreiter and Schmidhuber, 1997), and use the average of the LSTM hidden states as the document representation. The classifier is built by adding a softmax layer on top of the LSTM state average to get a probability distribution over labels.

The generative classifier is trained to maximize the joint probability of documents and labels: $\sum_{\langle x,y \rangle \in D} \log p(x, y)$. The generative classifier uses the following factorization:

$$p(x, y) = p(x \mid y)p(y) \tag{1}$$

We parameterize $\log p(x \mid y)$ as a conditional LSTM language model using the standard sequential factorization:

$$\log p(x \mid y) = \sum_{t=1}^{T} \log p(x_t \mid x_{<t}, y) \tag{2}$$

We define a label embedding matrix $V_{\mathcal{Y}} \in \mathbb{R}^{d_1 \times |\mathcal{Y}|}$. To predict the next word x_{t+1}, we concatenate the LSTM hidden state h_t with the label embedding v_y (a column of $V_{\mathcal{Y}}$), and feed it to a softmax layer to get the probability distribution over the vocabulary. More details about the factorization and parameterization are discussed in Section 3. The label prior $p(y)$ is acquired via maximum likelihood estimation and fixed during training of the remaining parameters.

At inference time, the prediction is made by maximizing $p(y \mid x)$ with respect to y for the discriminative classifier and maximizing $p(x \mid y)p(y)$ for the generative classifier.

3 Latent-Variable Generative Classifiers

We now introduce discrete latent variables into the standard generative classifier as shown in Figure 1. We refer to the latent-variable model as an auxiliary latent generative model, as we expect the latent variable to contain auxiliary information that can help with the generation of the input.

Following the graphical model structure in Figure 1(b), we factorize the joint probability $p(x, y, c)$ as follows:

$$p(x, y, c) = p_\Theta(x \mid c, y)p_\Phi(c)p_\Psi(y) \tag{3}$$

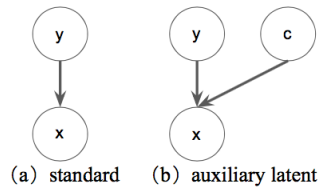

Figure 1: Graphical models of (a) standard generative classifier and (b) auxiliary latent generative classifier.

We parameterize $p_\Theta(x \mid c, y)$ as a conditional LSTM language model using the same factorization as above:

$$\log p_\Theta(x \mid c, y) = \sum_{t=1}^{T} \log p_\Theta(x_t \mid x_{<t}, c, y) \quad (4)$$

where Θ is the set of parameters of the language model. As in the generative classifier, we use a label embedding matrix $V_\mathcal{Y}$. In addition, we define a latent variable embedding matrix $V_\mathcal{C} \in \mathbb{R}^{d_2 \times |\mathcal{C}|}$ where $\mathcal{C}$ is the set of values for the discrete latent variable. Also like the generative classifier, we use an LSTM to predict each word with a softmax layer:

$$p_\Theta(x_t \mid x_{<t}, c, y) \propto \exp\{u_{x_t}^\top([h_t; v_y; v_c]) + b_{x_t}\} \quad (5)$$

where h_t is the hidden representation of $x_{<t}$ from the LSTM, v_y and v_c are the embeddings for the label and the latent variable, respectively, $[u; v]$ denotes vertical concatenation, u_{x_t} is the output word embedding, and b_{x_t} is a bias parameter.

The prior distribution of the latent variable is parameterized as follows:

$$p_\Phi(c) \propto \exp\{w_c^\top v_c + b_c\} \quad (6)$$

where Φ is the set of parameters for this distribution which includes the vector w_c and scalar b_c for each c.

As in the standard generative model, the label prior $p_\Psi(y)$ is acquired from the empirical label distribution in the training data and remains fixed during training.

Training. As is standard in latent-variable modeling, we train our models by maximizing the log marginal likelihood:

$$\max_{\Theta,\Phi,V_\mathcal{C},V_\mathcal{Y}} \sum_{\langle x,y\rangle \in \mathcal{D}} \log \sum_{c \in \mathcal{C}} p_\Theta(x \mid c, y) p_\Phi(c) p_\Psi(y) \quad (7)$$

In NLP, these sorts of optimization problems are traditionally solved with the EM algorithm. However, we instead directly optimize the above quantity using automatic differentiation. This is natural because we use softmax-transformed parameterizations; a more traditional parameterization would assign parameters directly to individual probabilities, which then requires constrained optimization.

Inference. The prediction is made by marginalizing out the latent variables as follows:

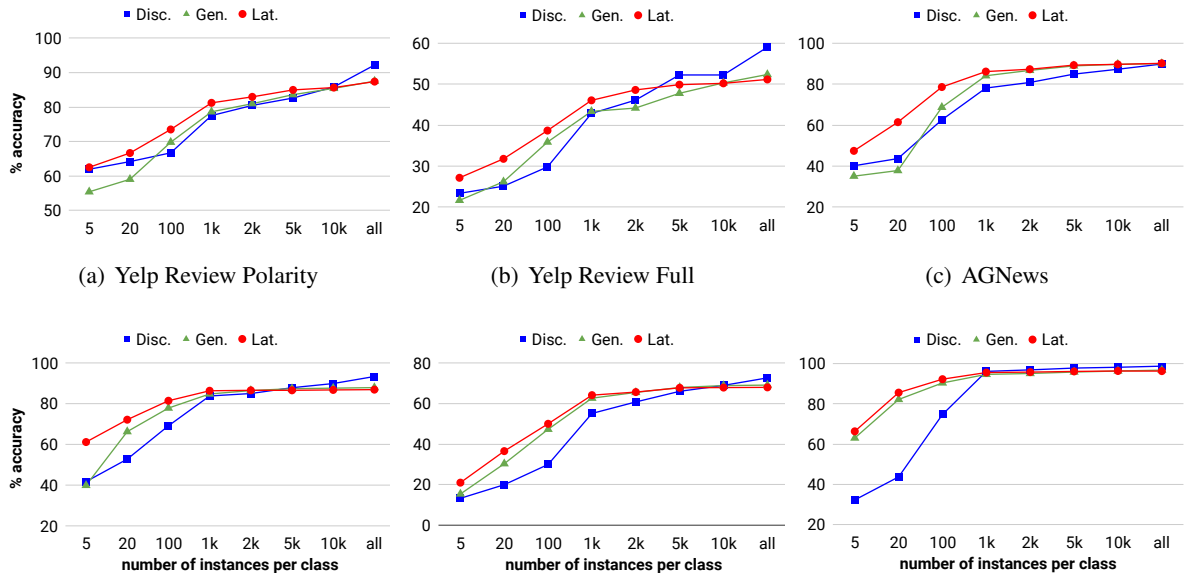
$$\hat{y} = \operatorname*{argmax}_{y \in \mathcal{Y}} \sum_{c \in \mathcal{C}} p_\Theta(x \mid c, y) p_\Phi(c) p_\Psi(y) \quad (8)$$

We experimented with other inference objectives and found similar results. More details can be found in Appendix C.

Differences with ensembles. Our latent-variable model resembles an ensemble of multiple generative classifiers, but there are two main differences. First, all parameters in the latent generative classifier are trained jointly, while a standard ensemble combines predictions from multiple, independently-trained models. Joint training leads to complementary information being captured by latent variable values, as shown in our analysis. Moreover, a standard ensemble will lead to far more parameters (10, 30, or 50 times as many in our experimental setup) since each generative classifier is a completely separate model. Our approach simply conditions on the embedding of the latent variable value and therefore does not add many parameters.

4 Experiments

4.1 Datasets



We present our results on six publicly available text classification datasets introduced by Zhang et al. (2015), which include news categorization, sentiment analysis, question/answer topic classification, and article ontology classification.[2]

To compare classifiers across training set sizes, we follow the setup of Yogatama et al. (2017) and construct multiple training sets by randomly sampling 5, 20, 100, 1k, 2k, 5k, and 10k instances per label from each dataset.

4.2 Training Details

In all experiments, the word embedding dimension and the LSTM hidden state dimension are set to

[2] A more detailed dataset description is in Appendix E.

(d) Sogou (e) Yahoo (f) DBpedia

Figure 2: Comparison of classification accuracy of the discriminative (**Disc.**), standard generative (**Gen.**), and latent generative (**Lat.**) classifiers training across training set sizes.

100. All LSTMs use one layer and are unidirectional. The label dimensionality of all generative classifiers is set to 100. We adopt the same parameter settings as Yogatama et al. (2017) to ensure the results are comparable. For the latent-variable generative classifiers, we choose 10 or 30 latent variable values with embeddings of dimensionality 10, 50, or 100.

For optimization, we use Adam (Kingma and Ba, 2015) with learning rate 0.001. We do early stopping by evaluating the classification accuracy on the development set.

Due to memory limitations and computational costs, we truncate the length of the input sequences to 80 tokens before adding <s> and </s> to indicate the start and end of the document. Though truncation decreases the performance of the models, all models use the same truncated inputs, so the comparison is still fair.[3]

4.3 Baselines

To confirm we have built strong baselines, we first compare our implementation of the generative and discriminative classifiers to prior work. Our results in Appendix A show that our baselines are comparable to those of Yogatama et al. (2017).

[3]In other experiments, we compared performance with different truncation limits across training set sizes, finding the trends to be consistent with those presented here.

5 Results

5.1 Data Efficiency

Figure 2 shows results for the discriminative, generative, and latent generative classifiers in terms of data efficiency. Data efficiency is measured by comparing the accuracies of the classifiers when trained across varying sizes of training sets. Numerical comparisons on two datasets are shown in Table 1.

With small training sets, the latent generative classifier consistently outperforms both the generative and discriminative classifiers. When the generative classifier is better than the discriminative one, as in DBpedia, the latent classifier resembles the generative classifier. When the discriminative classifier is better, as in Yelp Polarity, the latent classifier patterns after the discriminative classifier. However, when the number of training examples is in the range of approximately 5,000 to 10,000 per class, the discriminative classifier tends to perform best.

With small training sets, the generative classifier outperforms the discriminative one in most cases except the very smallest training sets. For example, in the Yelp Review Polarity dataset, the first two points are from classifiers trained with only 10 and 40 instances in total. The other case in which generative classifiers underperform is when training over large training sets, which

agrees with the theoretical and empirical findings in prior work (Yogatama et al., 2017; Ng and Jordan, 2002).

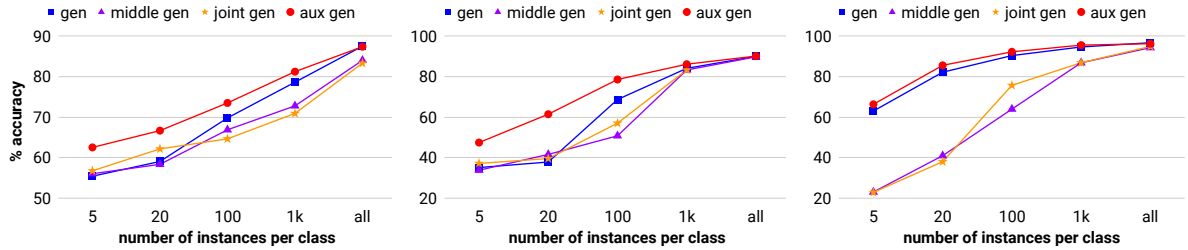
5.2 Effect of Graphical Model Structure

There are multiple choices to factorize the joint probability of the variables x, y, and c, which correspond to different graphical models. Here we consider other graphical model structures, namely those shown in Figure 3. We refer to the model in Figure 3(b) as the "joint" latent generative classifier since it uses the latent variable to jointly generate x and y. We refer to the model in Figure 3(c) as the "middle" latent generative classifier as the latent variable separates the textual input from the label. We use similar parameterizations for these models as for the auxiliary latent classifier, with conditional language models to generate x where the embedding of the latent variable is concatenated to the hidden state as in Section 3.

Figure 4 shows the comparison of the standard and the three latent generative classifiers on Yelp Review Polarity, AGNews, and DBpedia.[4] We observe that the auxiliary model consistently performs best, while the other two latent generative classifiers do not consistently improve over the standard generative classifier. On DBpedia, we see surprisingly poor performance when adding latent variables suboptimally. This suggests that the choice of where to include latent variables has a significant impact on performance.

Dependency between label and input variable. We observe that the most prominent difference between the auxiliary and the other two latent-variable models is that the label variable y is directly linked to the input variable x in the auxiliary model, which is also the case in the standard generative model.

In order to verify the importance of this direct dependency between the label and input, we create a new latent-variable model by adding a directed edge between y and x to the middle latent generative model. We refer to this model as the "hierarchical" latent generative classifier, which is shown in Figure 3(d). The results in Table 2 show the performance gains after adding this edge, which are all positive and sometimes very large. The resulting hierarchical model is very close in performance to the auxiliary model, which is unsurprising because these two models differ only in the presence of the edge from y to c.



5.3 Effect of Latent Variables

We conduct a comparison to demonstrate that the performance gains are due to the latent-variable structure instead of an increased number of parameters when adding the latent variables.[5]

For the latent generative classifier, we choose 10 latent variable values with embeddings of di-

[4] Similar trends are observed for all datasets, so we only show three for brevity.

[5] The results in the preceding sections use the models with configurations tuned on the development sets. We follow the practice of Yogatama et al. (2017) and fix label dimensionality to 100, as described in Section 4.2. The only tuned hyperparameters are the number of latent variable values and the dimensions of their embeddings.

Table 4: Comparison of the classification accuracy and convergence speed of the classifiers trained with direct optimization (**Direct**) of the log marginal likelihood and the EM algorithm (**EM**). The numbers inside the parentheses are the numbers of epochs required to reach the classification accuracies listed outside the parentheses.

mensionality 10, and a label dimensionality of 100 (**Lat. PC** in Table 3). For the standard generative classifier, we choose a label dimensionality of 110 (**Gen. PC** in Table 3). So, the numbers of parameters are comparable, since we ensure the same number of parameters in the "output" word embeddings in the softmax layer of the language model, which is the decision that most strongly affects the number of parameters.

Table 3 shows the results with different configurations, including the choices mentioned above as well as the results from earlier configurations mentioned in the paper. We observe that the latent generative classifiers still perform better in terms of data efficiency, which shows that the latent-variable structure accounts for the performance gains.

5.4 Learning via Expectation-Maximization

The results reported before are evaluated on the classifiers trained by directly maximizing the log marginal likelihood via gradient-based optimization. In addition, we train our latent generative classifiers with the EM algorithm (Salakhutdinov et al., 2003). More training details can be found in Appendix B.

To speed convergence, we use a mini-batch version of EM, updating the parameters after each mini-batch. Our results in Table 4 show that the direct approach and the EM algorithm have similar performance in terms of classification accuracy and convergence speed in optimizing the parameters of our latent models. Similar trends appear for the other datasets.

6 Analysis

6.1 Interpretation of Latent Variables

We take the strongest latent-variable model, the auxiliary latent generative classifier, and analyze the relationship among the latent, input, and label variables. We use the AGNews dataset, which contains 4 categories: world, sports, business, and sci/tech. The classifier we analyze has 10 values for the latent variable and is trained on a training set containing 1k instances per class.

We first investigate the relationship between

the latent variable and the label by counting co-occurrences. For each instance in the development set, we calculate the posterior probability distribution over the latent variable, and pick the value with the highest probability as the preferred latent variable value for that instance. This is reasonable since in our trained model, the posterior distribution over latent variable values is peaked. Then we categorize the data by their preferred latent variable values and count the gold standard labels in each group. We observe that the labels are nearly uniformly distributed in each latent variable value, suggesting that the latent variables are not obviously being used to encode information about the label.

Thus, we hypothesize there should be information other than that pertaining to the label that causes the data to cluster into different latent variable values. We study the differences of the input texts among the 10 clusters by counting frequent words, manually scanning through instances, and looking for high-level similarities and differences. We report our manual labeling for the latent variable values in Table 5.

For example, value 1 is mostly associated with future and progressive tenses; the words "will", "next", and "new" appear frequently. Value 2 tends to contain past and perfect verb tenses (the phrases "has been" and "have been" appear frequently). Value 3 contains region names like "VANCOUVER", "LONDON", and "New Brunswick", while value 7 contains country-oriented terms like "Indian", "Russian", "North Korea", and "Ireland". Our choice of only 10 latent variable values causes them to capture the coarse-grained patterns we observe here. It is possible that more fine-grained differences would appear with a larger number of values.

6.2 Generation with Latent Variables

Another advantage of generative models is that they can be used to generate data in order to better understand what they have learned, especially in seeking to understand latent variables. We use our auxiliary latent generative classifier to generate multiple samples by setting the latent variable and the label. Instead of the soft mixture of discrete latent variable values that is used in classification (since we marginalize over the latent variable at test time), here we choose a single latent variable value when generating a textual sample.

To increase generation diversity, we use temperature-based sampling when choosing the next word, where higher temperature leads to higher variety and more noise. We set the temperature to 0.6. Note that the latent-variable model here is trained on only 4000 instances (1k for each label) from AGNews, so the generated samples do suffer from the small size of data used in training the language model. Table 6 shows some generated examples. We observe that different combinations of the latent variable and label lead to generations that comport with both the labels and our interpretations of the latent variable values.

We speculate that the reason our generative classifiers perform well in the data-efficient setting is that they are better able to understand the data via language modeling rather than directly optimizing the classification objective. Our generated samples testify to the ability of generative classifiers to model the underlying data distribution even with only 4000 instances.

7 Related Work

Supervised Generative Models. Generative models have traditionally been used in supervised settings for many NLP tasks, including naive Bayes and other models for text classification (Maron, 1961; Yogatama et al., 2017), Markov models for sequence labeling (Church, 1988; Bikel et al., 1999; Brants, 2000; Zhou and Su, 2002), and probabilistic models for parsing (Magerrnan and Marcus, 1991; Black et al., 1993; Eisner, 1996; Collins, 1997; Dyer et al., 2016). Recent work in generative models for question answering (Lewis and Fan, 2019) learns to generate questions instead of directly penalizing prediction errors, which encourages the model to better understand the input data. Our work is directly inspired by that of Yogatama et al. (2017), who build RNN-based generative text classifiers and show scenarios where they can be empirically useful.

Text Classification. Traditionally, linear classifiers (McCallum and Nigam, 1998; Joachims, 1998; Fan et al., 2008) have been used for text classification. Recent work has scaled up text classification to larger datasets with models based on logistic regression (Joulin et al., 2017), convolutional neural networks (Kim, 2014; Zhang et al., 2015; Conneau et al., 2017), and recurrent neural networks (Xiao and Cho, 2016; Yogatama et al.,

2017), the latter of which is most closely-related to our models.

Latent-variable Models. Latent variables have been widely used in both generative and discriminative models to learn rich structure from data (Petrov and Klein, 2007, 2008; Blunsom et al., 2008; Yu and Joachims, 2009; Morency et al., 2008). Recent work in neural networks has shown that introducing latent variables leads to higher representational capacity (Kingma and Welling, 2014; Chung et al., 2015; Burda et al., 2016; Ji et al., 2016). However, unlike variational autoencoders (Kingma and Ba, 2015) and related work that use continuous latent variables,

our model is more similar to recent efforts that combine neural architectures with discrete latent variables and end-to-end training (Ji et al., 2016; Kim et al., 2017; Kong et al., 2017; Chen and Gimpel, 2018; Wiseman et al., 2018, *inter alia*).

8 Discussion and Future Work

An alternative solution to the small-data setting is to use language representations pretrained on large, unannotated datasets (Mikolov et al., 2013; Pennington et al., 2014; Devlin et al., 2019). In other experiments not reported here, we found that using pretrained word embeddings leads to larger performance improvements for the discriminative classifiers than the generative ones.

Future work will explore the performance of latent generative classifiers in other challenging experimental conditions, including testing robustness to data shift and adversarial examples as well as zero-shot learning. Another thread of future work is to explore the performance of discriminative models with latent variables, and investigate combining pretrained representations with both generative and discriminative classifiers.

9 Conclusion

We focused in this paper on improving the data efficiency of generative text classifiers by introducing discrete latent variables into the generative story. Our experimental results demonstrate that, with small annotated training data, latent generative classifiers have larger and more stable performance gains over discriminative classifiers than their standard generative counterparts. Analysis reveals interpretable latent variable values and generated samples, even with very small training sets.

Acknowledgments

We would like to thank Lingyu Gao, Qingming Tang, and Lifu Tu for helpful discussions, Michael Maire and Janos Simon for their useful feedback, the anonymous reviewers for their comments that improved this paper, and Google for a faculty research award to K. Gimpel that partially supported this research.

Abstract

Finding the right reviewers to assess the quality of conference submissions is a time consuming process for conference organizers. Given the importance of this step, various automated reviewer-paper matching solutions have been proposed to alleviate the burden. Prior approaches, including bag-of-words models and probabilistic topic models have been inadequate to deal with the vocabulary mismatch and partial topic overlap between a paper submission and the reviewer's expertise. Our approach, the common topic model, jointly models the topics common to the submission and the reviewer's profile while relying on abstract topic vectors. Experiments and insightful evaluations on two datasets demonstrate that the proposed method achieves consistent improvements compared to available state-of-the-art implementations of paper-reviewer matching.

1 Introduction

The peer review mechanism constitutes the bedrock of today's academic research landscape spanning submissions to conferences, journals, and funding bodies across numerous disciplines. Matching a paper (or a proposal) to an expert in the topic presented in the paper requires the knowledge of diverse topics of both the submission as well as that of the reviewer's expertise in addition to knowing recent affiliations and co-authorship to resolve conflict of interest. Considering the scale of current conference submissions, performing the task of paper-reviewer matching manually incurs significant overheads to the program committee (PC) and calls for automating the process. Faced with record number of paper submissions essentially interdisciplinary in nature, the inadequacy of available reviewer matching systems to scale to the current needs is being expressed by many conference program committees. It is also notable that the approaches to address the challenges seem ad-hoc and non-scalable, as described in a few of the PC blogs; "Looking at the abstracts for many of the submissions it also quickly became clear that there was disparity in how authors chose topic keywords for submissions with many only using a single keyword and others using over half a dozen keywords. As such relying on the keywords for submissions became difficult. The combined effect of these problems made any automatic or semi-automatic assignment using HotCRP suboptimal...So, we chose to hand assign the papers." (Falsafi et al., 2018), and again in "Our plan was to rely on the Toronto Paper Matching System (TPMS) in allocating papers to reviewers. Unfortunately, this system didnt prove as useful as we had hoped for (it requires more extensive reviewer profiles for optimal performance than what we had available) and the work had to rely largely on the manual effort..." (ACL, 2019). Noting the urgent need to advance research to address this problem, we study this challenge of matching a paper with a reviewer from a list of potential reviewers for the purpose of assessing the quality of the submission.

Aside from the long precedence of research in the related area of expertise retrieval – that of expert finding and expert profiling (Balog et al., 2012), several recent attempts have been made to automate the process (Price and Flach, 2017). These include, the Toronto paper matching system (Laurent and Zemel, 2013), the IEEE INFOCOM review assignment system (Li and Hou, 2016), and the online reviewer recommendation system (Qian et al., 2018). Central to these systems is a module that performs the paper-reviewer assignment, which can be broken down into its matching and constraint satisfaction constituents. The constraint

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 518–528, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

satisfaction component typically handles the constraints that each paper be reviewed by at least a few reviewers, each reviewer be assigned no more than a few papers, and thaat reviewers not be assigned papers for which they have a conflict of interest. A second constituent is that of finding a reviewer from a list of reviewers based on the relevance of the person's expertise with the topic of the submission. This latter aspect will be the focus of our study.

Available approaches to solve this matching problem can be broadly classified into the following categories (Price and Flach, 2017): a) Feature-based matching, where a set of topic keywords are collected for each paper and each reviewer. The reviewers are then ranked in order of the number of keyword matches with the paper; b) Automatic feature construction with profile-based matching, where the relevance is decided by building automatic topic representations of both papers and reviewers; c) Bidding, a more recent method, involves giving the reviewers access to all the papers and asking them to bid on papers of their choice. The approaches used in this study are of the profile-based matching kind, where we rely on the use of abstract topic vectors and word embeddings (Mikolov et al., 2013b) to derive the semantic representations of the paper and the expertise area of the reviewer. This is a departure from the bag-of-words approach taken in related prior approaches, e.g. (Laurent and Zemel, 2013), relying on automatic topic extraction using keywords – a ranked list of terms taken from the paper and the reviewer's profile.

In general, we assume that a reviewer can be represented by a collection of the abstracts of her past publications (termed as the reviewer's profile) and a submission by its abstract. While attempting to match the paper with the reviewer via their profile representations, the obvious difference in the document lengths gives rise to a mismatch due to the small overlap in vocabulary and a consequent scarcity of shared contexts of these overlapping terms. This is because, while past publications of a reviewer may be sufficient to provide a reasonable context for a topical word, a submission abstract provides a very limited context for that topical word.

To alleviate this problem of mismatched 'profiles', we use the idea of a shared topic space between the submission and the reviewer's profile. In our experiments we compare our approach to match the profiles using abstract vectors with that using the hidden topic model (also a set of abstract topic vectors) (Gong et al., 2018). The two approaches primarily differ in the way the shared topic space is constructed, which we describe in Section 4. We also include other baseline comparisons where the matching is done on the basis of common topic words (keywords) and word- or document-embeddings.

This study makes the following contributions:
(1) Instead of relying on a collection of topic words (keywords chosen by the authors or experts), our approach relies on abstract topic vectors to represent the common topics shared by the submission and the reviewer.
(2) We propose a model that outperforms state-of-the-art approaches in the task of paper-reviewer matching on a benchmark dataset (Mimno and McCallum, 2007). Additionally, a field evaluation of our approach performed by the program committee of a tier-1 conference showed that it was highly useful.

2 Related Work

The paper-reviewer matching task lays the basis for the peer review process ubiquitous in academic conferences and journals. Existing automatic approaches can be broadly categorized into the following types according to the type of models for comparing documents: *feature-based models*, *probabilistic models*, *embedding-based models*, *graph models* and *neural network models*.

Feature-based models. A list of keywords which summarizes the topics of a submission is used as informative features in the matching process (Dumais and Nielsen, 1992; Basu et al., 1999). Automatic extraction of these features achieves higher efficiency and one commonly-used feature is a bag-of-words weighted by the words' TF-IDF scores (Jin et al., 2018; Tang et al., 2010; Li and Hou, 2016; Nguyen et al., 2018).

Probabilistic models. The Latent Dirichlet Allocation (LDA) model is the most commonly used probabilistic model in expertise matching, where each topic is represented as a distribution over a given vocabulary and each document is a mixture of hidden topics (Blei et al., 2003). The popular Toronto Paper Matching System (TPMS) (Laurent and Zemel, 2013) uses LDA to generate the similarity score between a reviewer and a submis-

sion (Li and Hou, 2016). One limitation of LDA is that it does not make use of the potential semantic relatedness between words in a topic because of its assumption that words are generated independently (Xie et al., 2015). Variants of LDA have been proposed to incorporate notions of semantic coherence for more effective topic modeling (Hu and Tsujii, 2016; Das et al., 2015; Xun et al., 2017). Beyond having probabilistic models for topics, Jin et al. sought to capture the temporal changes of reviewer interest as well as the stability of their interest trend with probabilistic modeling (Jin et al., 2017).

In addition to their inherent limiting assumptions such as independence of semantically related words, probabilistic models, including LDA, require a large corpus to accurately identify the topics and topic distribution in each document, which can be problematic when applied to short documents, such as abstracts.

Embedding-based models. Latent Semantic Indexing (LSI) proposes to represent a document as a single dense vector (Deerwester et al., 1990). The documents corresponding to reviewers and submissions can thus be transformed into their respective vector representations. The relevance of a reviewer to a given submission would then be measured using a distance metric in the vector space, such as the cosine similarity. Other approaches have used word or document embeddings as document representations in order to compare two documents.

Kou et al. derived topic vectors by treating each topic as a distribution of words (Kou et al., 2015). In comparison, the key improvement in our work is that the topics are derived based on word embeddings instead of word distributions. Moreover, we derive common topics for each submission-reviewer pair, and as a result, the topics can vary from pair to pair.

Another approach to capture similarity between documents is by the use of the Word Mover's Distance (WMD). It relies on the alignment of word pairs from two texts, and the textual dissimilarity is measured as the total distance between the vectors of the word pairs (Kusner et al., 2015). More recently, a hidden topic model has been used to compare two documents via extracted abstract topic vectors, which showed a strong performance in comparing document for semantic similarity (Gong et al., 2018).

Extending the models in this category, we propose the common topic model. Similar to the hidden topic model, we extract topic vectors using word embeddings and match documents at the topic level. The hidden topic model extracts topics purely relying on the reviewer profile, so the topic vectors can be regarded as a summary of the reviewers' research interest. In contrast, the common topic vectors are selected based on the knowledge of both the submission and the reviewer's profile, which are expected to capture the topical overlap between the two. As we will show in the qualitative evaluation, the hidden topic model is likely to miss some important topics when a reviewer has broad research interests, resulting in an underestimation of the paper-reviewer relevance. The common topic model is able to overcome this limitation by extracting topics with reference to submissions.

Graph models. All of the models mentioned above only assume access to the texts of submissions and reviewers' publications. Some works also make use of external information such as coauthorship to improve the matching performance. For instance, Liu et al. capture academic connections between reviewers using a graph model, and show that such information improves the matching quality. Each node in their graph model represents a reviewer (Liu et al., 2014). There is an edge between two nodes if the corresponding reviewers have co-authored papers, and the edge weight is the number of publications. This work also uses LDA to measure the similarity between the submission and the reviewer.

Neural network models. Dense vectors are learned by neural networks as the semantic representation of documents (Socher et al., 2011; Le and Mikolov, 2014; Lin et al., 2015; Lau and Baldwin, 2016). When it comes to the task of expertise matching, the reviewer-submission relevance can thus be measured by the similarity of the vector representations of their textual descriptions.

3 System Overview

The different stages of our system, together called PaRe, are briefly explained as below:

Data collection. At this stage, we collect previous publications from one or more tier-1 conferences in the same domain as the one to which reviewer-submission matching is applied. This data is used to create our pool of candidate reviewers and do-

main knowledge of the research area. The source of the data is Microsoft Academic Graph (MSG) (Sinha et al., 2015). All the abstracts of a reviewer are concatenated as one document, which is then used to profile the reviewer. Reviewers' profiles reflect their research topics, which are later used in the reviewer-submission matching process.

Data processing. Since our proposed model is based on word embeddings, we pre-train embeddings using CBOW model of word2vec on the collected publications (Mikolov et al., 2013a). The dense word representations are intended to capture domain-specific lexical semantics. The data collection and processing are detailed in Section 5.

Reviewer-submission matching. A common topic modeling approach is proposed in this work to match reviewers with submissions. The model compares the abstracts of submissions and reviewers' past abstracts during the matching process to decide the reviewer-submission relevance by finding their common research topics. The algorithm is described in Section 4.

4 Modeling

For the purpose of our study, we consider a reviewer's profile to be the concatenation of the abstracts from their previous publications. Let m be the number of words in the reviewer's profile and let the *normalized* word embeddings of these words be stacked as a reviewer matrix $\mathbf{R} \in \mathbb{R}^{\mathbf{d}\times\mathbf{m}}$, where d is the embedding dimension. Since the embedding is normalized, we have $\|\mathbf{R_i}\|_\mathbf{2} = \mathbf{1}$ for each column in $\mathbf{R}$. Next suppose that the submission is represented by an $n-$word sequence of its abstract. Similar to the case of the reviewer, we stack its normalized embeddings as a submission matrix $\mathbf{S} \in \mathbb{R}^{\mathbf{d}\times\mathbf{n}}$. Also we have for each column $\|\mathbf{S_j}\|_\mathbf{2} = \mathbf{1}, \forall \mathbf{1} \leq \mathbf{j} \leq \mathbf{n}$.

Common topic selection. Inspired by the compositionality of embeddings (Gong et al., 2017) and the hidden topic model in document matching (Gong et al., 2018), our intention is to extract topics from reviewer profiles and submissions to summarize their topical overlap. We would like to remind the reader that the topics extracted are neither words nor distributions, but only abstractions and constitute a set of numeric vectors that do not necessarily have a textual representation. To establish the connection between topics, reviewer profiles and submissions, we assume that the topic vectors can be written as a linear combination of the embeddings of component words in either the reviewer profiles or the submissions. This assumption is supported by the geometric property of word embeddings that the weighted sum of the component word embeddings have been shown to be a robust and efficient representation of sentences and documents (Mikolov et al., 2013b). Intuitively, the extracted common topics would be highly correlated with the subset of the words in the reviewer profile or that of the submission in terms of semantic similarity.

Let both the reviewer and the submission have K research topics, with each topic represented by a $d-$dimensional vector. This vector is an abstract topic vector and does not necessarily correspond to a specific word or a word distribution as in LDA (Blei et al., 2003). Suppose that these topic vectors of the reviewer are stacked as a matrix $\mathbf{P} \in \mathbb{R}^{d\times K}$, and those of the submission as $\mathbf{Q} \in \mathbb{R}^{d\times K}$. Therefore, these matrices can be represented as a linear combination of the underlying word vectors.

$$\begin{aligned} \mathbf{P} &= \mathbf{Ra}, \\ \mathbf{Q} &= \mathbf{Sb}, \end{aligned} \tag{1}$$

where $\mathbf{a} \in \mathbb{R}^{m\times K}, \mathbf{b} \in \mathbb{R}^{n\times K}$ are the coefficients in the linear combinations.

Our goal is to find the common topics shared by a given reviewer and a given submission, to account for the overlap of their research areas. We consider a pair of topics from a reviewer and a submission respectively to constitute a pair of common topics if they are semantically similar. For example, if the reviewer's research areas are *machine learning* and *theory of computation*, and the submission is about *classification* in *natural language processing*, then (*machine learning, classification*) can be regarded as a pair of common topics, while the other pairs corresponding to the areas *theory of computation* and *natural language processing* are much less similar. We used cosine similarity to measure the semantic similarity of two topic vectors [*]. The similarity $\text{sim}(\mathbf{P}_k, \mathbf{Q}_k)$ between reviewer topic $\mathbf{P}_k$ and submission topic $\mathbf{Q}_k$ is shown below.

$$\text{sim}(\mathbf{P}_k, \mathbf{Q}_k) = \frac{\mathbf{P}_k^T \mathbf{Q}_k}{\|\mathbf{P}_k\| \cdot \|\mathbf{Q}_k\|}. \tag{2}$$

[*]We leave it to future work to experiment with other useful measures of semantic similarity.

For K pairs of topic vectors $\{\mathbf{P_k}, \mathbf{Q_k}\}_{k=1}^{K}$, their similarity is the sum of the pairwise similarities:

$$\text{sim}(\mathbf{P}, \mathbf{Q}) = \sum_{k=1}^{K} \text{sim}(\mathbf{P}_k, \mathbf{Q}_k). \quad (3)$$

This in turn translates to identifying the common research topics between the reviewer and the submission, i.e., we need to find K such pairs of topics that have the maximum similarity. Based on our discussions above, the approach of common topic extraction can be formulated as an optimization problem:

$$\begin{aligned} &\max_{\mathbf{a},\mathbf{b}} \text{sim}(\mathbf{P}, \mathbf{Q}) \\ \text{s.t.} \quad &\mathbf{P} = \mathbf{R}\mathbf{a}, \\ &\mathbf{Q} = \mathbf{S}\mathbf{b}, \\ &\mathbf{P}^T\mathbf{P} = \mathbf{Q}^T\mathbf{Q} = \mathbf{I} \end{aligned} \quad (4)$$

The first two constraints are based on the linear assumption shown in Eq. 1. Without loss of generality, we add the third constraint that the topic vectors are orthogonal as shown in Eq. 4 to avoid generating multiple similar topic vectors. The closed-form solution to this optimization problem can be derived via singular value decomposition on the correlation matrix of $\mathbf{R}$ and $\mathbf{S}$ (Wegelin, 2000).

Let topic vectors $\mathbf{P}^*$ and $\mathbf{Q}^*$ be the optimal solution, both describing the common topics shared by the reviewer and the submission. In the following discussions, we use $\mathbf{P}^*$ as the common topic vectors.

Common topic scoring. To further quantify the reviewer-submission relevance, we need to evaluate how significant these common topics are for the reviewer and the submission respectively. Reusing the example where a reviewer's area are *machine learning* and *theory of computation*, we know that *machine learning* is the common topic between the reviewer and the submission. If the topic of *machine learning* were only a small part of the reviewer's publications, the reviewer may not be a good match for the submission since reviewer is more of an expert in *theory of computation* than in *machine learning*.

To evaluate how well the topics reflect a reviewer's expertise, we define the importance of common topics $\mathbf{P}^*$ for both the reviewer and the submission. Consider the vector of the $i-$th word in the reviewer's profile, $\mathbf{R}_i$, and the k-th topic vector $\mathbf{P}_k^*$. The relevance between $\mathbf{R}_i$ and $\mathbf{P}_k^*$ is defined as the their squared cosine similarity.

$$\text{rel}(\mathbf{R}_i, \mathbf{P}_k^*) = \cos^2(\mathbf{R}_i, \mathbf{P}_k^*) = (\mathbf{R}_i^T\mathbf{P}_k^*)^2. \quad (5)$$

Note that we do not use cosine similarity as is, since $\mathbf{R}_i$ and $\mathbf{P}_k^*$ might be negatively correlated and the cosine similarity can be negative. Instead, we use the square of the cosine similarity to reflect the strength of their correlation.

The relevance between word $\mathbf{R}_i$ and a set of topic vectors $\mathbf{P}^*$ is defined as the sum of the relevance between the word and each topic vector.

$$\text{rel}(\mathbf{R}_i, \mathbf{P}^*) = \sum_{k=1}^{K} \text{rel}(\mathbf{R}_i, \mathbf{P}_k^*). \quad (6)$$

We can think of word vector $\mathbf{R}_i$ to be projected along the K dimensions of a linear subspace spanned by topic vectors in $\mathbf{P}^*$. If $\mathbf{R}_i$ lies in this linear subspace, then it can be represented as a linear combination of the topic vectors. In this case, $\text{rel}(\mathbf{R}_i, \mathbf{P})$ achieves the maximum of 1. If the word vector is orthogonal to all topic vectors in $\mathbf{P}^*$, the relevance results in the minimum relevance of 0. Thus, the range of $\text{rel}(\mathbf{R}_i, \mathbf{P})$ is from 0 to 1.

Furthermore, we define the relevance between the reviewer and the topics as the average of the relevance between the words and the topics.

$$\text{rel}(\mathbf{R}, \mathbf{P}^*) = \frac{1}{m} \sum_{i=1}^{m} \text{rel}(\mathbf{R}_i, \mathbf{P}^*). \quad (7)$$

The reviewer-topic relevance $\text{rel}(\mathbf{R}, \mathbf{P})$ also ranges from 0 to 1.

Similarly, we measure the relevance between a submission and a set of common topics, $\text{rel}(\mathbf{S}, \mathbf{P}^*)$ by measuring the relevance between words in the submission and common topics. The submission-topic relevance reflects the importance of the common topics for a submission. We define the reviewer-submission matching score as a harmonic mean (f-measure) of the reviewer-topic and submission-topic relevance (Powers, 2015).

$$\text{rel}(\mathbf{R}, \mathbf{S}) = \frac{2 \cdot \text{rel}(\mathbf{R}, \mathbf{P}^*) \cdot \text{rel}(\mathbf{S}, \mathbf{P}^*)}{\text{rel}(\mathbf{R}, \mathbf{P}^*) + \text{rel}(\mathbf{S}, \mathbf{P}^*)}. \quad (8)$$

The reviewer-submission relevance is high when the common topic vectors $\mathbf{P}^*$ are highly relevant to both the reviewer and the submission.

It indicates that the submission has a substantial overlap with reviewer's research area, and that the reviewer is considered to be a good match for the submission.

5 Experiments and Results

In this section, we empirically compare our proposed common topic model approach against a variety of models in the task of expertise matching.

5.1 Dataset

For our experiments, we use the two datasets described below.

NIPS dataset. This is a benchmark dataset described in (Mimno and McCallum, 2007) and commonly used in the evaluation of expertise matching. It consists of 148 NIPS papers accepted in 2006 and abstracts from the publications of 364 reviewers. It includes annotations from 9 annotators on the relevance of 650 reviewer-paper pairs. Each pair is rated on a scale from 0 to 3. Here "0" means irrelevant, "1" means slightly relevant, "2" means relevant and "3" means very relevant.

A new dataset. Our proposed paper-reviewer matching system is applied to a tier-1 conference in the area of computer architecture. We created a new dataset for the evaluation of expertise matching from the submissions to this conference. We first collected a pool of 2284 candidate reviewers with publications in top conferences of computer architecture. A reviewer selection policy was adopted by the conference program committee to select reviewers still active in relevant areas. Reviewers were excluded if

1) they started publishing 40 years ago, but had no publications for the last ten years;

2) they did not have publications for the last ten years and have fewer than three papers before that.

The publications of these reviewers were collected from Microsoft Academic Graph (Sinha et al., 2015). Each reviewer had at least one publication, and some reviewers had as many as 34 publications. Again the abstracts were used as reviewers' profile.

We then used our proposed common topic model to assist the program committee of the conference on computer architecture, and recommended most relevant reviewers to all submissions in the conference. We randomly selected 20 submissions and with the help of the committee, we collected feedbacks from 33 reviewers on their relevance to the assigned submissions. These 33 reviewers were among the top reviewers recommended by our system for each of 20 submissions. The relevance was rated on a scale from 1 to 5, where a score of "1" meant that the paper was not relevant at all, "2" meant that the reviewer had passing familiarity with the topic of the submission, "3" meant that the reviewer knew the material well, "4" meant that the reviewer had a deep understanding of the submission, and "5" means that the reviewer was a champion candidate for the submission.

5.2 Baselines

We include previous approaches to paper-reviewer matching as our baselines.

- **APT 200**. Author-Person-Topic (Mimno and McCallum, 2007) is a generative probabilistic topic model which groups documents of an author into different clusters with the author's topic distribution. Clusters represent different areas of a reviewer's research.
- **Single Doc**. The Single Doc model is a probabilistic model which takes the idea of language modeling and estimates the likelihood that a submission is assigned to a reviewer given the reviewer's previous works (Mimno and McCallum, 2007).
- **Latent Dirichlet Allocation (LDA)**: LDA and its variants are the most popular topic models in expertise matching systems (Blei et al., 2003). LDA models assume that each document is a mixture of topics where each topic is a multinomial distribution over the words.
- **Hierarchical Dirichlet Process (HDP)**. HDP model is an extension of LDA (Teh et al., 2006). It is a non-parametric mixed-membership Bayesian model with variable number of topics. It is effective in choosing the number of topics to characterize a given corpus.
- **Random Walk with Restart (RWR)**. RWR is a graph model with sparsity constraints in expertise matching (Liu et al., 2014). It relies on LDA to capture reviewer-submission relevance and also takes diversity into consideration in the matching process.
- **Word Mover's Distance (WMD)**. WMD is a distance metric between two documents on the basis of pre-trained word embeddings (Kusner et al., 2015). It calculates the dissmilarity be-

Method	Number of Topics	P@5	P@10	P@5	P@10	P@5	P@10

tween two documents, which is measured by the embedding distance of aligned words in these documents.

- **Hidden Topic Model**. This model proposes to learn hidden topic vectors to measure document similarity based on word embeddings (Gong et al., 2018).
- **Doc2Vec**. Doc2Vec is a neural network model which trains document embeddings to predict component words in the documents (Le and Mikolov, 2014). In expertise matching, the Doc2Vec model is pre-trained on the corpus consisting of reviewers' previous publications. We use the trained model to generate representations for reviewers and submissions respectively. The reviewer-submission relevance is quantified by the cosine similarity of their embeddings.

Setting. Since our model relies on word embeddings, we pre-train embeddings on all papers published in the NIPS conference until 2017 for the matching task in NIPS dataset. Similarly for our new dataset, we collected a corpus of publications until 2018 from top computer architecture conferences for embedding training. The embedding dimension was set as 100, and these word embeddings were also used in two embedding-based baselines: word mover's distance and hidden topic model. For a fair comparison, the corpora used for word embedding training were also used to train Doc2Vec model to generate document embeddings.

5.3 Results on NIPS Data

The NIPS dataset provides ground truth relevance for reviewer-submission pairs, and the relevance scales from 0 to 3. A score of 0 is assigned when that the reviewer is considered to be *not relevant* and a score of 3 is assigned when the reviewer is considered to be *highly relevant*. We set a relevance threshold of 2, and considered reviewers with a score equal to or higher than this threshold to be relevant reviewers to the given submission. In our matching system, we sorted reviewers in decreasing order of the predicted relevance score for a given submission.

Evaluation Metric. Precision at k (P@k) is a commonly-used ranking metric on NIPS dataset. P@k is defined to be the percentage of relevant reviewers in the top-k recommendations made by the model to a submission. It is likely that the top-k recommendations made by the model contain reviewers whose relevance information is not available in the ground truth. To address this issue, we first discard reviewers that do not have a relevance information prior to calculating P@k. In our experiments, we set k to be 5 and 10. We report the average P@k over all submissions in Table 1.

We note that not all submissions in NIPS dataset have the same number of relevant reviewers and a

failure to account for this discrepancy would negatively impact the performance of a system. For example, a submission with only one relevant reviewer would result in a P@5 no higher than 20% for any model. In order to take this discrepancy into consideration, we report the performance only on submissions with at least two relevant reviewers in the columns of "GT2", and on submissions with at least three relevant reviewers in column "GT3". In "GT1", we report the performance without making this distinction.

The reviewer-submission matching results of our model on the NIPS dataset are presented in Table 1 alongside those of our chosen baselines. We note that the results for APT 200 and Single Doc were only available for GT1 and we report them as such. Some approaches including Common Topic Model, Hidden Topic Model and LDA required a hyperparameter (number of topics) to be specified. We performed experiments on NIPS data with different number of topics in Table 1. As is shown, our proposed approach consistently outperforms the strong baselines. We also note that Hidden Topic Model and Doc2Vec are competitive approaches in expertise matching compared against probabilistic models.

Expertise Level	% of Reviewers Predicted by the System
$\geq$5	15.2
$\geq$4	63.6
$\geq$3	87.9
$\geq$2	100

Table 2: Percentage of reviewers in levels of expertise to the submissions recommended by our model.

5.4 Results on the New Dataset

Our proposed approach has been used to assist in the paper-reviewer matching process in a tier-1 conference of computer architecture. We evaluated our approach on a new dataset constructed with reviewers' feedbacks on their assigned submissions. Based on the optimal number of topics on the NIPS dataset, we set the number of common topics to be 10 in this experiment.

We report the percentage of reviewers whose reported expertise level falls in the given range in Table 2. We note that all recommendations made by our system are reasonable considering that all reviewers had expertise levels no lower than 2. The majority (87.9%) of reviewers reported that they were familiar with the topics of the submissions assigned to them, and 63.6% of the reviewers had deep understanding of the submissions.

6 Error Analysis

We perform a qualitative analysis on NIPS dataset to analyze the difference of different algorithms on expertise matching. For the clarity of our discussion, we sample a submission whose abstract is shown in Table 4. We consider five models: common topic modeling (CT), hidden topic modeling (HT), LDA, Doc2Vec and WMD. We list reviewers who were considered as top candidates for this submission by the five models in Table 3. For the analyses, we used research topics from the publications of the reviewers as well as their relevance scores assigned by human annotators (i.e., their TREC scores in NIPS dataset). Reviewers are sorted in decreasing order of their relevance to the submission by five models. For example, rank 1 corresponds to the highest relevance. In Table 3, We also present the rank of each reviewer given by the models.

Common topic model. According to the common topic model, reviewer 3, 4 and 5 are included as its top 3 recommendations. But we note that it ranks reviewer 3 higher than reviewer 4 and 5. The relevance scoring of common topic model is based on the relevance between the common topic "Bayesian method" and reviewers' profile. Since reviewer 3 is more focused on Bayesian model, it's topic-reviewer relevance is higher than reviewer 4 and 5 who have broader research interests beyond Bayesian model and more publications. One limitation of common topic model reflected in this case is that it does not capture the authority and experience of reviewers.

Hidden topic model. It incorrectly considered reviewer 1 more relevant to the submission compared to reviewer 5. We note that reviewer 5 works on a broad set of research topics ranging from Bayesian model to active learning. Since the hidden topic model extracts reviewer's topics based on the topic importance without any knowledge of the submission, it is likely that Bayesian model was not selected into representative hidden topics, which results in low relevance of reviewer 5 to the given submission.

LDA model. LDA assigns higher relevance to reviewer 1 than reviewer 4. Reviewer 1 used

Reviewer	TREC	Research topics	CT	HT	LDA	Doc2Vec	WMD
1	1	Speech recognition with Bayesian approach, Neural network	6	2	4	1	7
2	0	Online learning, Sequential prediction, Bayes point machine	10	10	8	9	1
3	2	Bayesian network, Variational Bayes estimation, Mixture models	1	4	3	2	9
4	3	Variational method, Bayesian learning, Markov model	2	3	9	4	8
5	3	Bayesian learning, Variational method, Active learning	3	5	1	7	6

Table 3: Examples of reviewers and their relevance to the submission ranked by different algorithms.

Dirichlet Process (DP) mixture models are candidates for clustering applications where the number of clusters is unknown a priori. [...] The speedup is achieved by incorporating kd-trees into a variational Bayesian algorithm for DP mixture [...]

Table 4: An example of abstract from a submission.

Bayesian approach, whereas it was not his research focus according to his publications. Reviewer 4 had done extensive research in general graphical models including Bayesian model. We observed that LDA fails to capture the relevance between graph model and Bayesian model since it ignores the semantic similarity between words.

Doc2Vec model. Doc2Vec assigned the highest relevance to reviewer 1 among all reviewers. The document representation it generates for reviewer 1's profile is similar to the representation for the submission, possibly because the key word "Bayesian" and "mixture" in the submission also occurs frequently in the profile. It suggests that Doc2Vec model might be limited to lexical overlap.

WMD. Reviewer 2 is included as WMD's top recommendation, whereas the research focus of reviewer 2 is sequential prediction which is irrelevant to the submission. Moreover, actually relevant reviewers 4 and 5 were excluded from WMD's top recommendations. This may have resulted from WMD's word-level similarity measure. Reviewer 2's publications had some lexical overlap with the submission (e.g., words "Bayes", "algorithm" and "learning", which have high frequency in the submission). WMD tends to assign high relevance scores due to such lexical overlap.

7 Future Work

This study used a basic version of a reviewer's profile to be the concatenation of the abstracts from their previous publications. A concrete direction for future work would be to consider enhancements in representing reviewers' profiles. Such efforts could consider, for instance, the temporal variation of research interests in order to capture the relevance of a given reviewer to a given topic based on the recency of the contributions to a given area. Other efforts could involve the use of a variable number of research topics for each reviewer and exploring ways to render reviewer profiles human interpretable.

8 Conclusion

We proposed an automated reviewer-paper matching algorithm via jointly finding the common research topics between submissions and reviewers' publications. Our model is based on word embeddings and efficiently captures the reviewer-paper relevance. It is robust to cases of vocabulary mismatch and partial topic overlap between submissions and reviewers – factors that have posed problems for previous approaches. The common topic model showed strong empirical performance on a benchmark and a newly collected dataset.

Linking artificial and human neural representations of language

Abstract

What information from an act of sentence understanding is robustly represented in the human brain? We investigate this question by comparing sentence encoding models on a brain decoding task, where the sentence that an experimental participant has seen must be predicted from the fMRI signal evoked by the sentence. We take a pre-trained BERT architecture as a baseline sentence encoding model and fine-tune it on a variety of natural language understanding (NLU) tasks, asking which lead to improvements in brain-decoding performance.

We find that none of the sentence encoding tasks tested yield significant increases in brain decoding performance. Through further task ablations and representational analyses, we find that tasks which produce syntax-light representations yield significant improvements in brain decoding performance. Our results constrain the space of NLU models that could best account for human neural representations of language, but also suggest limits on the possibility of decoding fine-grained syntactic information from fMRI human neuroimaging.

What are the neural representations which support human language understanding? Language neuroscience has converged on a set of reliable physiological markers related to language processing (Kutas and Federmeier, 2011), and a picture of where in the brain different aspects of language processing take place (Fedorenko et al., 2010). But we still largely lack a coherent picture of the *structure* and *format* of the neural representations driving language understanding.

Part of this struggle is due to a scarcity of candidate representational structures in the first place. While there are certainly enough representational theories of language understanding, many are specified at too high a level of analysis to plausibly map onto neural structures without serious further revision (Poeppel, 2012).

Studies which draw on these high-level representations must therefore also assume some link between such representations and measures of neural activity — for example, that the magnitude of neural activations should match up with the probability values derived from a computational model (Brennan et al., 2016), or measures derived from syntactic representations of the input (Pallier et al., 2011). While the success of these mapping studies demonstrates that specific summary statistics of linguistic representations have correlates in the mind, these summary statistics are not themselves candidate representations for the fundamental operations underlying language understanding.

In the meantime, research in natural language processing has produced neural network models that capture many different sorts of intelligent language understanding behavior (Collobert et al., 2011; Goldberg, 2016). These models accomplish this behavior in an implementation better matched with that of the brain, with information about their inputs distributed across a high-dimensional continuous space. Could these models be taken seriously as candidate hypotheses of how language processing could be implemented in neural hardware? Under the assumption that both human brain and neural network representations are optimally suited to solve some *task* (Anderson et al., 1990), linking these two computational systems should reveal parallel task-optimal structure shared within their representations.

This paradigm linking brain and machine has already seen substantial success in vision science. Yamins et al. (2013) first demonstrated that the activations of a convolutional neural network trained on ImageNet in response to natural images could

predict activations in a macaque monkey's visual cortex in response to the same images. This result and others have led to an increasingly detailed understanding of the contents of brain representations (Schrimpf et al., 2018) and novel artificial neural network architectures (Kubilius et al., 2018) in the domain of vision.

In language understanding, several authors have exploited neural network representations as proxies for sentence meaning, and demonstrated that human brain activations in response to sentences can match with these meaning representations at well above chance performance (see e.g. Mitchell et al., 2008; Wehbe et al., 2014; Huth et al., 2016; Pereira et al., 2018). Our aim in this paper is to further understand why these mappings are successful, uncovering the parallel *representational contents* shared between human brains and neural networks.

We evaluate the link between human brain activity and neural network models as the models are optimized for different tasks. We find that neural network models quickly diverge in their capacity to match human brain activations as they are optimized for different NLU objectives. We further locate correlates of these changes in representational content, finding that the granularity of a model's *syntactic* representations is at least partially responsible for their differences in brain decoding performance. Overall, this approach allows us to generate and validate hypotheses about the representational contents of both human brain and neural network activity.

1 Related work

Several papers have begun to explore the brain–machine link in language understanding, asking whether human brain activations can be matched with the activations of computational language models. Mitchell et al. (2008) first demonstrated that distributional word representations could be used to predict human brain activations, when subjects were presented with individual words in isolation. Huth et al. (2016) replicated and extended these results using distributed word representations, and Pereira et al. (2018) extended these results to sentence stimuli. Wehbe et al. (2014), Qian et al. (2016), Jain and Huth (2018), and Abnar et al. (2019) next introduced more complex word and sentence meaning representations, demonstrating that neural network language models could better account for brain activation by incorporating representations of longer-term linguistic context. Gauthier and Ivanova (2018) and Sun et al. (2019) further demonstrated that optimizing model representations for different objectives yielded substantial differences in brain decoding performance. This paper extends the neural network brain decoding paradigm both in **breadth**, studying a wide class of different task-optimal models, and in **depth**, exploring the particular representational contents of each model responsible for its brain decoding performance.

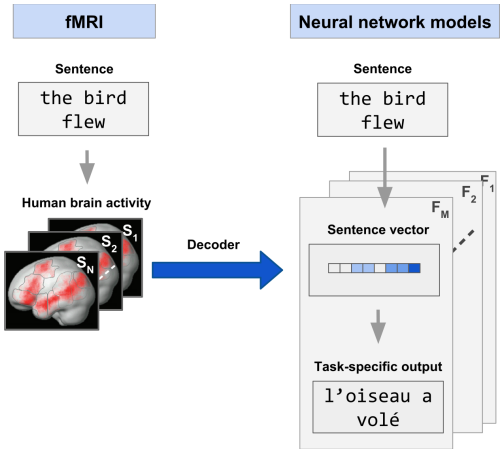

Figure 1: Brain decoding methodology. We use human brain activations in response to sentences to predict how neural networks represent those same sentences.

2 Methods

Figure 1 describes the high-level design of our experiments, which attempt to match human neuroimaging data with different candidate model representations of sentence inputs. Using a dataset of human brain activations recorded in response to complete sentences, we learn linear regression models which map from human brain activity to representations of the same sentences produced by different natural language understanding models.

To the extent that this linear decoding is successful, it can reveal parallel structure between brain and model representations. Consider a softmax neural network classifier model optimized for some task T, mapping input sentences $\mathbf{x}$ to class outputs y. We can factor this neural network classifier into the composition of two operations, a representational function $r(\mathbf{x})$, and an affine operator A:

$$p(y \mid \mathbf{x}) \propto \exp(A(r(\mathbf{x}))) \quad (1)$$

Under this factorization, $r(\mathbf{x})$ must compute representations which are linearly separable with respect

to the classes of the task T.

Research in cognitive neuroscience has shown that surprisingly many features of perceptual and cognitive states are likewise linearly separable from images of human brain activity, even at the coarse spatial and temporal resolution afforded by functional magnetic resonance imaging (fMRI; see e.g. Haxby et al., 2001; Kriegeskorte et al., 2006). However, the full power of linear decoding with fMRI remains unknown within language neuroscience and elsewhere. One possibility (1) is that the representational distinctions intrinsically required to describe language understanding behavior are linearly decodable from fMRI data. If this were the case, we could use performance in brain decoding to gauge the similarity between the mental representations underlying human language understanding and those deployed within artificial neural network models. Conversely (2), if the representations supporting language understanding in the brain are not linearly decodable from fMRI, we should be able to demonstrate this fact by showing specific ablations of sentence representation models do not degrade in brain decoding performance. Thus, the brain decoding framework offers possibilities both for (1) discriminating among NLU tasks as faithful characterizations of human language understanding, and for (2) understanding potential limitations of fMRI imaging and linear decoding methods. We explore both of these possibilities in this paper.

Section 2.1 describes the human neuroimaging data used as the source of this learned mapping. Section 2.2 next describes how we derive the target representations of sentence inputs from different natural language understanding models. Finally, Section 2.3 describes our method for deriving and evaluating mappings between the two representational spaces.

2.1 Human neuroimaging data

We use the human brain images collected by Pereira et al. (2018, experiment 2).[1] Pereira et al. visually presented 384 natural-language sentences to 8 adult subjects. The sentences (examples in Table 1) consisted of simple encyclopedic statements about natural kinds, written by the authors. The subjects were instructed to carefully read each sentence, presented one at a time, and think about its meaning. As they read the sentences, the subjects' brain activity was recorded with functional magnetic resonance imaging (fMRI). For each subject and each sentence, the fMRI images consist of a $\sim 200,000$-dimensional vector describing the approximate neural activity within small 3D patches of the brain, known as voxels.[2] We collect these vectors in a single matrix and compress them to $d_B = 256$ dimensions using PCA, yielding a matrix $B_i \in \mathbb{R}^{384 \times d_B}$ for each subject i.[3]

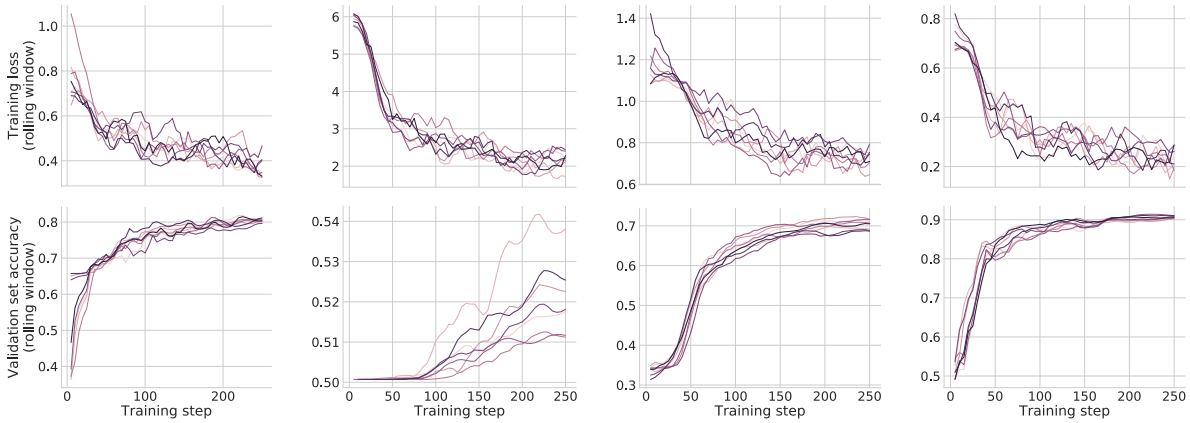
Table 2: Details of the tasks used for fine-tuning.

2.2 Sentence representation models



We will match the human brain activation data described above with a suite of different sentence representations. Our primary concern in this evaluation is to compare alternative *tasks* and the representational contents they demand, rather than comparing neural network architectures. For this reason, we draw sentence representations from a unified neural network architecture — the bidirectional Transformer model BERT (Devlin et al., 2018) — as we optimize it to perform different tasks.

The BERT model uses a series of multi-head attention operations to compute context-sensitive representations for each token in an input sentence. The model is pre-trained on two tasks: (1) a cloze language modeling task, where the model is given a complete sentence containing several masked words and asked to predict the identity of a particu-

[1] This dataset is publicly available at https://osf.io/crwz7/.

[2] For more information on data collection and fMRI analysis, please see Pereira et al. (2018).

[3] The PCA projections retain more than 95% of the variance among sentence responses within each subject.

(a) QQP (b) SQuAD (c) MNLI (d) SST

Figure 2: Learning curves (training set loss and evaluation set accuracy) for NLU model fine-tuning.

lar masked word; and (2) a next-sentence prediction task, where the model is given two sentences and asked to predict whether the sentences are immediately adjacent in the original language modeling data.[4] For our purposes, this pre-training process produces a set of BERT parameters Θ_{LM} jointly optimized for these two objectives, consisting of word embeddings and attention mechanism parameters.

For an input token sequence $w_1, \ldots, w_T$, the output of the BERT model is a corresponding sequence of contextualized representations of each token. We derive a single sentence representation vector by prepending a constant token $w_0 = \texttt{[CLS]}$, and extracting its corresponding output vector at the final layer, following Devlin et al. (2018).[5]

We first extract sentence representations from the pre-trained model parameterized by Θ_{LM}. We let $C_{\text{LM}} \in \mathbb{R}^{384 \times d_H}$ refer to the matrix of sentence representations drawn from this pre-trained BERT model, where d_H is the dimensionality of the BERT hidden layer representation.

2.2.1 Fine-tuned models

We use the code and pre-trained weights released by Devlin et al. (2018) to fine-tune the BERT model on a suite of natural language processing classification tasks, shown in Table 2.[6] This fine-tuning process jointly optimizes the pre-trained word embeddings and attention weights drawn from Θ_{LM}, along with a task-specific classification model which accepts the sentence representations produced by the BERT model (the vector corresponding to the prepended `[CLS]` token) as input.

We fine-tune the pretrained BERT model on a set of popular shared NLU tasks, shown in Table 2, with fixed hyperparameters across tasks (available in Appendix B). Each fine-tuning operation is run for 250 iterations, before which all models show substantial improvements on the fine-tuning task. Figure 2 shows the learning curves for each of the models fine-tuned by this procedure.

We execute 8 different runs for each fine-tuning task. Each run ℓ of each fine-tuning task j produces a set of final parameters $\Theta_{j\ell}$. We can derive a set of sentence representations $C_{j\ell}$ from each fine-tuned model by the same logic as above, feeding in each sentence with a prepended `[CLS]` token and extracting the contextualized `[CLS]` representation.

For our purposes, the product of each fine-tuning run is a set of sentence representations $C_{j\ell} \in \mathbb{R}^{384 \times d_H}$.

Custom tasks In order to better understand *why* models might fail or succeed at brain decoding, we also produced several custom fine-tuning tasks. Each task was a modified form of the standard BERT cloze language modeling task, manipulated to strongly select for or against some particular aspect of linguistic representation.[7]

[4] See Devlin et al. (2018); Vaswani et al. (2017) for further details on model architecture and training.

[5] We also repeated the experiments of this paper using sentence representations computed by uniformly averaging BERT's contextualized token representations of each input sentence, and found similar qualitative results as will be presented below.

[6] Details on the fine-tuning procedure are available in Devlin et al. (2018).

[7] The training and test data for these tasks were generated from the Toronto Books Corpus (Zhu et al., 2015), a subset of the data used to train the original BERT model. Further details and examples for these tasks are given in Appendix C.

Scrambled language modeling We first design two language modeling tasks to select against fine-grained syntactic representation of inputs. We randomly shuffle words from the corpus samples used for language modeling, to remove all first-order cues to syntactic structure. Our first custom task, `LM-scrambled`, deals with sentence inputs where words are shuffled within sentences; our second task, `LM-scrambled-para`, uses inputs where words are shuffled within their containing paragraphs in the corpus. [8]

By shuffling inputs in this way, we effectively turn the cloze task into a bag-of-words language modeling task: given a set of words from a sentence or a random draw of words from a paragraph, the model must predict a missing word. After optimizing models on these scrambled tasks, we design a probe to validate the effects of the task on the model's syntactic representations. This probe is detailed in Section 3.2.2.

Part-of-speech language modeling We next design a task, `LM-pos`, to select against fine-grained semantic representation of inputs. We do this by requiring a model to predict only the *part of speech* of a masked word, rather than the word itself. This manipulation removes pressure for the model to distinguish predictions between target words in the same syntactic class.

We repeat fine-tuning runs on each of these custom tasks 4 times per task, and see substantial improvements in held-out task performance for each of these custom tasks after just 250 steps of training. After fine-tuning, we extract sentence representation matrices $C_{j\ell}$ from each run ℓ of each these models.

Language modeling control As a control, we also continue training on the original BERT language modeling objectives using text drawn from the Books Corpus (Zhu et al., 2015). We run 4 fine-tuning runs of this task, yielding representations $C_{\text{LM},\ell}$.

2.2.2 Word vector baseline

As a baseline comparison, we also include sentence representations computed from GloVe word vectors (Pennington et al., 2014). Unlike BERT's word representations, these word vectors are insensitive to their surrounding sentential context. These word vectors have nevertheless successfully served as sentence meaning representations in prior studies (Pereira et al., 2018; Gauthier and Ivanova, 2018). We let $C_{\text{GloVe}}(w_1, \ldots, w_T) = \frac{1}{T} e(w_t)$, where $e(w_i)$ retrieves the GloVe embedding for word w_i.[9]

2.3 Brain decoding

We next learn a suite of *decoders*: regression models mapping from descriptions of human brain activation to model activations in response to sentences. Let $B_i \in \mathbb{R}^{384 \times d_B}$ represent the brain activations of subject i in response to the 384 sentences in our evaluation set. For each subject and each sentence representation available (including both language model representations C_{LM} and fine-tuned model representations $C_{j\ell}$), we learn a linear map $G_{i \to j\ell} : \mathbb{R}^{d_H \times d_B}$ between the two spaces which minimizes the regularized regression loss

$$J_{ij\ell} = ||G_{i \to j\ell} B_i - C_{j\ell}||_2^2 + \beta \, ||G_{i \to j\ell}||_2^2 \quad (2)$$

where β is a regularization hyperparameter. For each subject's collection of brain images and each target model representation, we train and evaluate the above regression model with nested 8-fold cross-validation (Cawley and Talbot, 2010). The regression models are evaluated under two metrics: mean squared error (MSE) in prediction of model activations, and average rank (AR):

$$\text{AR}(i, j, \ell) = \frac{1}{384} \sum_k \text{rank}((G_{i \to j\ell} B_i)[k], C_{j\ell}[k]) \quad (3)$$

where $\text{rank}((G_{i \to j\ell} B_i)[k], C_{j\ell}[k])$ gives the rank of a ground-truth sentence representation $C_{j\ell}[k]$ in the list of nearest neighbors of a predicted sentence representation $(G_{i \to j\ell} B_i)[k]$, ordered by increasing cosine distance.

These two metrics serve complementary roles: the MSE metric strictly evaluates the ability of human brain activations to exactly match the representational geometry of model activations, while the AR metric simply requires that the brain activations be able to support the relevant meaning contrasts between the 384 sentences tested.

[8] This shuffling method removes first-order cues to constituency: for example, the fact that *the table* appears directly to the right of *on* suggests that they are members of a single constituent. It is still possible that the model can exploit second-order cues to structure. For example, if two nouns *ranch* and *rancher* appear in the same sentence as *dressing*, we can still guess that *ranch* is more likely to modify *dressing*.

[9] We use publicly available GloVe vectors computed on Common Crawl, available in the spaCy toolkit as `en_vectors_web_lg`.

3 Results

We first present the performance of all of the BERT models tested and the GloVe baseline in Figure 3. This figure makes apparent a number of surprising findings, which we validate by paired t-tests.[10]

1. On average, fine-tuning on the standard NLU tasks yields *increased error* in brain decoding under both metrics relative to the BERT baseline (MSE, $t \approx 14.8, p < 3 \times 10^{-36}$; AR, $t \approx 17, p < 3 \times 10^{-42}$). This trend is significant for each model individually, except QQP (MSE, $t \approx -2.2, p > 0.03$; AR, $t \approx 0.79, p > 0.4$).

2. Fine-tuning on the LM-scrambled-para custom task yields *decreased error* in brain decoding under both metrics relative to the BERT baseline (MSE, $t \approx -33.6, p < 3 \times 10^{-45}$; AR, $t \approx -26.9, p < 5 \times 10^{-39}$) and GloVe vectors (MSE, $t \approx -23.4, p < 4 \times 10^{-35}$; AR, $t \approx -12.1, p < 6 \times 10^{-19}$).

3. Fine-tuning on both the control language-modeling task and the LM-pos custom task yields ambiguous results: *decreased MSE* and *no significant change in AR* relative to the BERT baseline (LM-pos: MSE, $t \approx -2.90, p < 0.007$; AR, $t \approx 2.10, p > 0.04$; LM: MSE, $t \approx -5.68, p < 4 \times 10^{-7}$; AR, $t \approx -2.36, p > 0.02$).

3.1 Learning dynamics

When during training do these models diverge in brain decoding performance? We repeat our brain decoding evaluation on model snapshots taken every 5 steps during fine-tuning, and chart brain decoding performance over time for each model in Figure 4. We find that models rapidly diverge in brain decoding performance, but remain mostly stable after about 100 fine-tuning steps. This phase of rapid change in brain decoding performance is generally matched with a phase of rapid change in task performance (compare each line in Figure 4 with the learning curves in Figure 2).

[10]Each sample in our statistical tests compares the brain decoding performance matching a subject's brain image with model representations before and after fine-tuning on a particular task. See Figures 8 and 9 of Appendix A for further visualizations. Results are reported throughout with a significance level $\alpha = 0.01$.

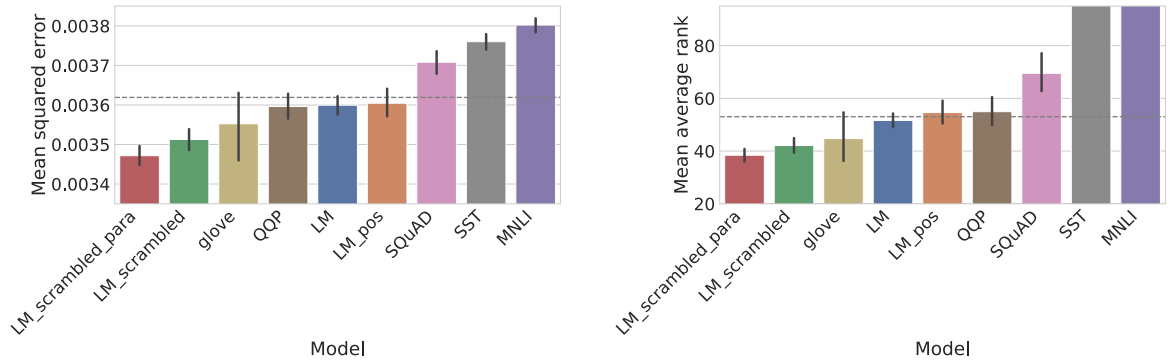
3.2 Representational analysis

We next investigate the structure of the model representations, and find that differing fidelity of *syntactic* representation can explain some major qualitative differences between the models in brain decoding performance.

3.2.1 Representational similarity

We first investigate coarse-grained model similarity with representational similarity analysis (Kriegeskorte et al., 2008), which measures models' pairwise distance judgments as a proxy for how well the underlying representations are aligned in their contents. For each fine-tuning run ℓ on each task j, we compute pairwise cosine similarities between each pair of sentence representation rows in $C_{j\ell}$, yielding a vector $D_{j\ell} \in \mathbb{R}^{(384 \text{ choose } 2)}$.

We measure the similarity between the representations derived from a run (j, ℓ) and some other run (j', ℓ') by computing the Spearman correlation coefficient $\rho(D_{j\ell}, D_{j'\ell'})$. These correlation values are graphed as a heatmap in Figure 5, where each cell averages over different runs of the two corresponding models. This heatmap yields several clear findings:

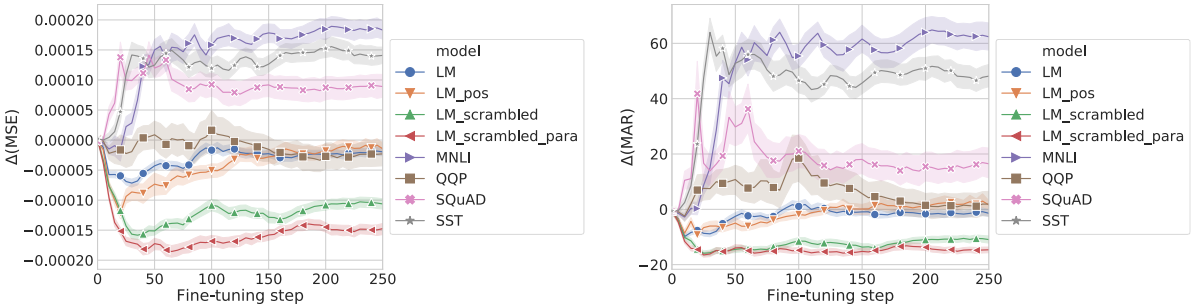


1. The language modeling fine-tuning runs (especially the two LM-scrambled tasks) are the only models which have reliable high correlations between one another.

2. Language modeling tasks yield representations which make similar sentence-sentence distance predictions between different runs on the same task, while the rest of the models are less coherent across runs (see matrix diagonal).

The scrambled LM tasks produce sentence representations which are reliably coherent across runs (Figure 5), and produce reliable improvements in brain decoding performance (Figure 3). What is it about this task which yields such reliable results? We attempt to answer this question in the following section.

3.2.2 Syntactic probe



Because the scrambled LM tasks were designed to remove all first-order cues to syntactic constituency from the input, we hypothesized that the models trained on this task were succeeding due to their resulting coarse syntactic representations. We tested

(a) Mean squared error metric

(b) Average rank metric

Figure 3: Brain decoding performance for fine-tuned BERT models and the GloVe baseline. Error bars are bootstrapped 95% confidence intervals, pooling across decoders matching different subjects (8 total) and different BERT fine-tuning runs (up to 8 runs per model). Dashed gray line shows the average brain decoding performance of the pretrained BERT language model.

(a) Mean squared-error metric

(b) Average rank metric

Figure 4: Brain decoding performance trajectories over fine-tuning time, graphed relative to the brain decoding performance of the pre-trained BERT language model. Performance rapidly diverges and then stabilizes within tens of fine-tuning steps. Shaded regions represent 95% confidence intervals, pooling across 8 subjects and up to 8 fine-tuning runs per model.

this idea using the structural probe method of Hewitt and Manning (2019). This method measures the degree to which word representations can reproduce syntactic analyses of sentences. We used dependency-parsed sentences from the Universal Dependencies (UD) English Web Treebank corpus (Silveira et al., 2014) to evaluate the performance of each fine-tuned BERT model with a structural probe.

For each fine-tuned BERT model (task j, fine-tuning run ℓ) and each sentence $w_1, \ldots, w_T$, let $\tilde{w}_i$ denote the context-sensitive representation of word w_i under the model parameters $\Theta_{j\ell}$. The structural probe method attempts to derive a distance measure between context-sensitive word representations, parameterized by a transformation matrix B, which approximates the number of grammatical dependencies separating the two words (Hewitt and Manning, 2019). Concretely, for any two words w_i, w_j in a parsed sentence, we learn a parameter matrix B such that

$$\left((B(\tilde{w}_i - \tilde{w}_j))^T (B(\tilde{w}_i - \tilde{w}_j))\right)^2 \approx |w_i \leftrightarrow w_j| \quad (4)$$

where $|w_i \leftrightarrow w_j|$ denotes the number of edges separating w_i and w_j in a dependency parse of the sentence.

We learn this parameter matrix B for a set of training sentences randomly sampled from the UD corpus, and then apply the distance measure above to model representations for a set of held-out test sentences. For any sentence $w_1, \ldots, w_T$, the measure induces a $T \times T$ pairwise distance matrix, where each entry (i, j) predicts the distance (in grammatical dependencies) between words i and j. By applying a minimum spanning tree algorithm to this matrix, we derive an (undirected) parse tree for

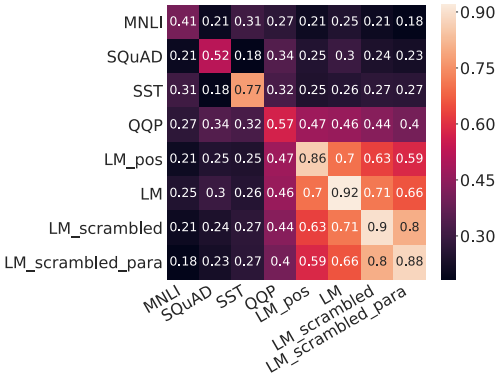


Figure 5: Representational similarity of the sentence encodings produced by each model (between -1 and 1; higher is more similar). See Section 3.2.1 for details.

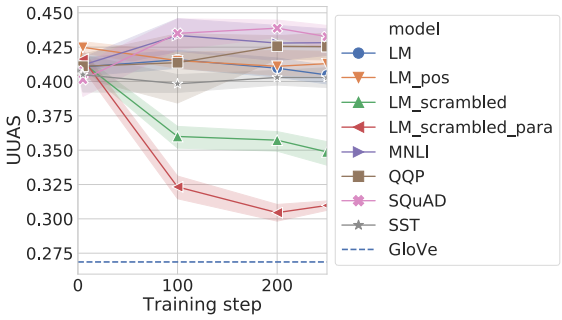

Figure 6: Syntactic probe evaluation across fine-tuning time (section 3.2.2).

the sentence which best matches the predictions of the distance measure. We measure the accuracy of the reconstructed tree by calculating its unlabeled attachment score (UAS) relative to ground-truth parses from the UD corpus.

We apply the probe described above to every fine-tuning run of each model, and to baseline GloVe representations. We expected the GloVe representations to perform worst, since they cannot encode any context-sensitive features of input words. The probe results are graphed over fine-tuning time in Figure 6, relative to a probe induced from the GloVe representations (dashed blue line). This analysis shows that the models optimized for LM-scrambled and LM-scrambled-para — the models which improve in brain decoding performance — progressively worsen under this syntactic probe measure during fine-tuning. Their probe performance remains well above the performance of the GloVe baseline, however.

Figure 7 shows a representative sample sentence with parses induced from the syntactic probes of

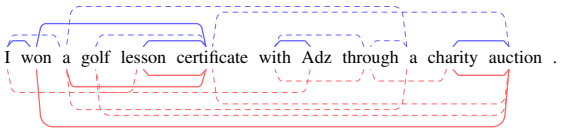

Figure 7: Example sentence with undirected syntactic probe parses induced from LM-scrambled representations (blue, above) and GloVe representations (red, below). Solid arcs represent correct dependency predictions; dashed lines represent errors.

LM-scrambled (after 250 fine-tuning steps) and the GloVe baseline. While both parses make many mistaken attachments (dashed arcs), the parse induced from LM-scrambled (blue arcs) makes better guesses about local attachment decisions than the parse from GloVe (red arcs), which seems to simply link identical and thematically related words. This is the case even though LM-scrambled is never able to exploit information about the relative positions of words during its training. Overall, this suggests that much (but not all) of the syntactic information initially represented in the baseline BERT model is *discarded* during training on the scrambled language modeling tasks. Surprisingly, this loss of syntactic information seems to yield improved performance in brain decoding.

4 Discussion

The brain decoding paradigm presented in this paper has led us to a set of scrambled language modeling tasks which best match the structure of brain activations among the models tested. Optimizing for these scrambled LM tasks produces a rapid but stable divergence in representational contents, yielding improvements in brain decoding performance (Figures 3 and 4) and reliably coherent predictions in pairwise sentence similarity (Figure 5). These changes are matched with a clear loss of syntactic information (Figure 6), though some minimal information about local grammatical dependencies is decodable from the model's context-sensitive word representations (Figure 7).

We do not take these results to indicate that human neural representations of language do not encode syntactic information. Rather, we see several possible explanations for these results:

Limitations of fMRI. Functional magnetic resonance imaging — the brain imaging method used to collect the dataset studied in this paper — may be too temporally coarse to detect traces of the syntac-

tic computations powering language understanding in the human brain.

This idea may conflict with several findings in the neuroscience of language. For example, Brennan et al. (2016) compared how language models with different granularities of syntactic representation map onto human brain activations during passive listening of English fiction. They derived word-level surprisal estimates from n-gram models (which have no explicit syntactic representation) and PCFG models (which explicitly represent syntactic constituency). In a stepwise regression analysis, they demonstrated that the surprisal estimates drawn from the PCFG model explain variance in fMRI measures of brain activation not already explained by estimates drawn from the n-gram model.

Pallier et al. (2011) examined a different hypothesis linking mental and neural representations of language. They presented subjects with strings of words which contain valid syntactic constituents of different lengths. They assumed that, since subjects will attempt to construct syntactic analyses of the word strings, the length of the possible syntactic constituents in any stimulus should have some correlate in subjects' neural activations. They found a reliable relationship between the size of the available constituents in the input and region-specific brain activations as measured by fMRI.

Our results are compatible with the idea that *specific syntactic features* like those discussed above are still represented in the brain at the time scale of fMRI. Figures 6 and 7 demonstrate, in fact, that the `LM-scrambled` models still retain some syntactic information (or correlates thereof), in that they clearly outperform a baseline model in predicting the syntactic parses of sentences.

While these brain mapping studies have detected particular summary features of syntactic computation in the brain, these summary features do not constitute complete proposals of syntactic processing. In contrast, each of the models trained in this paper constitutes an independent candidate algorithmic description of sentence representation. These candidate descriptions can be probed (as in Section 3.2.2) to reveal exactly *why* brain decoding fails or succeeds in any case.

Our paradigm thus enables us to next ask: what specific syntactic features are responsible for the improved performance of the `LM-scrambled` models? By further probing the models and designing ablated datasets, we plan to narrow down the particular phenomena responsible for the findings presented here. These results should act as a source of finer-grained hypotheses about what sort of syntactic information is preserved at coarse temporal resolutions, and allow us to resolve the conflict between our results those of Pallier et al. (2011) and Brennan et al. (2016), among others.

Limitations of the linking hypothesis. Our linear linking hypothesis (presented in Section 2.3) that representations of syntactic structure are encoded entirely in the linear geometry of both neural networks and human brains. It is likely that some syntactic information — among other features of the input — *are* conserved in the fMRI signal, but not readable by a linear decoder. Future work should investigate how more complex transforms linking brain and machine can reveal parallel structure between the two systems.

Limitations of the data. The fMRI data used in this study (presented in Section 2.1) was collected as subjects read sentences and were asked to simply think about their meaning. This vague task specification may have led subjects to engage only superficially with the sentences. If this were the case, these shallow mental representations might present us with correspondingly shallow neural representations — just the sort of representations which might be optimal for the simple tasks such as `LM-scrambled` and `LM-scrambled-para`. Future work should integrate brain images derived from different behavioral tasks, and study which model–brain relationships are conserved across these behaviors. Such studies could illuminate the degree to which there are genuinely task-general language representations in the mind.

Our broader framework of analysis promises to reveal further insights about the parallel contents between artificial and human neural representations of language. In this spirit, we have released our complete analysis framework as open source code for the research community, available at `http://bit.ly/nn-decoding`.

Abstract

Text summarization aims at compressing long documents into a shorter form that conveys the most important parts of the original document. Despite increased interest in the community and notable research effort, progress on benchmark datasets has stagnated. We critically evaluate key ingredients of the current research setup: datasets, evaluation metrics, and models, and highlight three primary shortcomings: 1) automatically collected datasets leave the task underconstrained and may contain noise detrimental to training and evaluation, 2) current evaluation protocol is weakly correlated with human judgment and does not account for important characteristics such as factual correctness, 3) models overfit to layout biases of current datasets and offer limited diversity in their outputs.

1 Introduction

Text summarization aims at compressing long textual documents into a short, human readable form that contains the most important information from the source. Two strategies of generating summaries are *extractive* (Dorr et al., 2003; Nallapati et al., 2017), where salient fragments of the source document are identified and directly copied into the summary, and *abstractive* (Rush et al., 2015; See et al., 2017), where the salient parts are detected and paraphrased to form the final output.

The number of summarization models introduced every year has been increasing rapidly. Advancements in neural network architectures (Sutskever et al., 2014; Bahdanau et al., 2015; Vinyals et al., 2015; Vaswani et al., 2017) and the availability of large scale data (Sandhaus, 2008; Nallapati et al., 2016a; Grusky et al., 2018) enabled the transition from systems based on expert knowledge and heuristics to data-driven approaches powered by end-to-end deep neural models. Current approaches to text summarization utilize advanced attention and copying mechanisms (See et al., 2017; Tan et al., 2017; Cohan et al., 2018), multi-task and multi-reward training techniques (Guo et al., 2018; Pasunuru and Bansal, 2018; Kryściński et al., 2018), reinforcement learning strategies (Paulus et al., 2017; Narayan et al., 2018b; Dong et al., 2018; Wu and Hu, 2018), and hybrid extractive-abstractive models (Liu et al., 2018; Hsu et al., 2018; Gehrmann et al., 2018; Chen and Bansal, 2018). Many of the introduced models are trained on the CNN/DailyMail (Nallapati et al., 2016a) news corpus, a popular benchmark for the field, and are evaluated based on n-gram overlap between the generated and target summaries with the ROUGE package (Lin, 2004).

Despite substantial research effort, the progress on these benchmarks has stagnated. State-of-the-art models only slightly outperform the Lead-3 baseline, which generates summaries by extracting the first three sentences of the source document. We argue that this stagnation can be partially attributed to the current research setup, which involves uncurated, automatically collected datasets and non-informative evaluations protocols. We critically evaluate our hypothesis, and support our claims by analyzing three key components of the experimental setting: datasets, evaluation metrics, and model outputs. Our motivation is to shift the focus of the research community into developing a more robust research setup for text summarization.

2 Related Work

2.1 Datasets

To accommodate the requirements of modern data-driven approaches, several large-scale datasets have been proposed. The majority of

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 540–551,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

available corpora come from the news domain. Gigaword (Graff and Cieri, 2003) is a set of articles and corresponding titles that was originally used for headline generation (Takase et al., 2016), but it has also been adapted to single-sentence summarization (Rush et al., 2015; Chopra et al., 2016). NYT (Sandhaus, 2008) is a collection of articles from the New York Times magazine with abstracts written by library scientists. It has been primarily used for extractive summarization (Hong and Nenkova, 2014; Li et al., 2016) and phrase-importance prediction (Yang and Nenkova, 2014; Nye and Nenkova, 2015). The CNN/DailyMail (Nallapati et al., 2016a) dataset consists of articles with summaries composed of highlights from the article written by the authors themselves. It is commonly used for both *abstractive* (See et al., 2017; Paulus et al., 2017; Kryściński et al., 2018) and *extractive* (Dong et al., 2018; Wu and Hu, 2018; Zhou et al., 2018) neural summarization. The collection was originally introduced as a Cloze-style QA dataset by Hermann et al. (2015). XSum (Narayan et al., 2018a) is a collection of articles associated with one, single-sentence summary targeted at abstractive models. Newsroom (Grusky et al., 2018) is a diverse collection of articles sourced from 38 major online news outlets. This dataset was released together with a leaderboard and held-out testing split.

Outside of the news domain, several datasets were collected from open discussion boards and other portals offering structure information. Reddit TIFU (Kim et al., 2018) is a collection of posts scraped from Reddit where users post their daily stories and each post is required to contain a Too Long; Didn't Read (TL;DR) summary. WikiHow (Koupaee and Wang, 2018) is a collection of articles from the WikiHow knowledge base, where each article contains instructions for performing procedural, multi-step tasks covering various areas, including: arts, finance, travel, and health.

2.2 Evaluation Metrics

Manual and semi-automatic (Nenkova and Passonneau, 2004; Passonneau et al., 2013) evaluation of large-scale summarization models is costly and cumbersome. Much effort has been made to develop automatic metrics that would allow for fast and cheap evaluation of models.

The ROUGE package (Lin, 2004) offers a set of automatic metrics based on the lexical overlap between candidate and reference summaries. Overlap can be computed between consecutive (n-grams) and non-consecutive (skip-grams) subsequences of tokens. ROUGE scores are based on exact token matches, meaning that computing overlap between synonymous phrases is not supported.

Many approaches have extended ROUGE with support for synonyms and paraphrasing. ParaEval (Zhou et al., 2006) uses a three-step comparison strategy, where the first two steps perform optimal and greedy paraphrase matching based on paraphrase tables before reverting to exact token overlap. ROUGE-WE (Ng and Abrecht, 2015) replaces exact lexical matches with a soft semantic similarity measure approximated with the cosine distances between distributed representations of tokens. ROUGE 2.0 (Ganesan, 2018) leverages synonym dictionaries, such as WordNet, and considers all synonyms of matched words when computing token overlap. ROUGE-G (ShafieiBavani et al., 2018) combines lexical and semantic matching by applying graph analysis algorithms to the WordNet semantic network. Despite being a step in the direction of a more comprehensive evaluation protocol, none of these metrics gained sufficient traction in the research community, leaving ROUGE as the default automatic evaluation toolkit for text summarization.

2.3 Models

Existing summarization models fall into three categories: *abstractive*, *extractive*, and *hybrid*.

Extractive models select spans of text from the input and copy them directly into the summary. Non-neural approaches (Neto et al., 2002; Dorr et al., 2003; Filippova and Altun, 2013; Colmenares et al., 2015) utilized domain expertise to develop heuristics for summary content selection, whereas more recent, neural techniques allow for end-to-end training. In the most common case, models are trained as word- or sentence-level classifiers that predict whether a fragment should be included in the summary (Nallapati et al., 2016b, 2017; Narayan et al., 2017; Liu et al., 2019; Xu and Durrett, 2019). Other approaches apply reinforcement learning training strategies to directly optimize the model on task-specific, non-differentiable reward functions (Narayan et al., 2018b; Dong et al., 2018; Wu and Hu, 2018) .

Abstractive models paraphrase the source doc-

uments and create summaries with novel phrases not present in the source document. A common approach in *abstractive* summarization is to use attention and copying mechanisms (See et al., 2017; Tan et al., 2017; Cohan et al., 2018). Other approaches include using multi-task and multi-reward training (Paulus et al., 2017; Jiang and Bansal, 2018; Guo et al., 2018; Pasunuru and Bansal, 2018; Kryściński et al., 2018), and unsupervised training strategies (Chu and Liu, 2018; Schumann, 2018).

Hybrid models (Hsu et al., 2018; Liu et al., 2018; Gehrmann et al., 2018; Chen and Bansal, 2018) include both *extractive* and *abstractive* modules and allow to separate the summarization process into two phases – content selection and paraphrasing.

For the sake of brevity we do not describe details of different models, we refer interested readers to the original papers.

2.4 Analysis and Critique

Most summarization research revolves around new architectures and training strategies that improve the state of the art on benchmark problems. However, it is also important to analyze and question the current methods and research settings.

Zhang et al. (2018) conducted a quantitative study of the level of abstraction in *abstractive* summarization models and showed that word-level, copy-only *extractive* models achieve comparable results to fully *abstractive* models in the measured dimension. Kedzie et al. (2018) offered a thorough analysis of how neural models perform content selection across different data domains, and exposed data biases that dominate the learning signal in the news domain and architectural limitations of current approaches in learning robust sentence-level representations. Liu and Liu (2010) examine the correlation between ROUGE scores and human judgments when evaluating meeting summarization data and show that the correlation strength is low, but can be improved by leveraging unique meeting characteristics, such as available speaker information. Owczarzak et al. (2012) inspect how inconsistencies in human annotator judgments affect the ranking of summaries and correlations with automatic evaluation metrics. The results showed that system-level rankings, considering all summaries, were stable despite inconsistencies in judgments, however, summary-level rankings and automatic metric correlations benefit from improving annotator consistency. Graham (2015) compare the fitness of the BLEU metric (Papineni et al., 2002) and a number of different ROUGE variants for evaluating summarization outputs. The study reveals superior variants of ROUGE that are different from the commonly used recommendations and shows that the BLEU metric achieves strong correlations with human assessments of generated summaries. Schulman et al. (2015) study the problems related to using ROUGE as an evaluation metric with respect to finding optimal solutions and provide proof of NP-hardness of global optimization with respect to ROUGE.

Similar lines of research, where the authors put under scrutiny existing methodologies, datasets, or models were conducted by Callison-Burch et al. (2006, 2007); Tan et al. (2015); Post (2018) in machine translation, (Gkatzia and Mahamood, 2015; Reiter and Belz, 2009; Reiter, 2018) in natural language generation, Lee et al. (2016); Chen et al. (2016); Kaushik and Lipton (2018) in reading comprehension, Gururangan et al. (2018); Poliak et al. (2018); Glockner et al. (2018) in natural language inference, Goyal et al. (2017) in visual question answering, and Xian et al. (2017) in zero-shot image classification. Comments on the general state of scholarship in the field of machine learning were presented by Sculley et al. (2018); Lipton and Steinhardt (2019) and references therein.

3 Datasets

3.1 Underconstrained task

The task of summarization is to compress long documents by identifying and extracting the most important information from the source documents. However, assessing the importance of information is a difficult task in itself, that highly depends on the expectations and prior knowledge of the target reader.

We show that the current setting in which models are simply given a document with one associated reference summary and no additional information, leaves the task of summarization underconstrained and thus too ambiguous to be solved by end-to-end models.

To quantify this effect, we conducted a human study which measured the agreement between different annotators in selecting important sentences

Article	
The glowing blue letters that once lit the Bronx from above Yankee stadium failed to find a buyer at an auction at Sotheby's on Wednesday. While the 13 letters were expected to bring in anywhere from $300,000 to $600,000, the only person who raised a paddle - for $260,000 - was a Sotheby's employee trying to jump start the bidding. The current owner of the signage is Yankee hall-of-famer Reggie Jackson, who purchased the 10-feet-tall letters for an undisclosed amount after the stadium saw its final game in 2008. No love: 13 letters that hung over Yankee stadium were estimated to bring in anywhere from $300,000 to $600,000, but received no bids at a Sotheby's auction Wednesday. The 68-year-old Yankee said he wanted 'a new generation to own and enjoy this icon of the Yankees and of New York City.', The letters had beamed from atop Yankee stadium near grand concourse in the Bronx since 1976, the year before Jackson joined the team. (...)	
Summary Questions	
When was the auction at Sotheby's? Who is the owner of the signage? When had the letters been installed on the stadium?	
Constrained Summary A	**Unconstrained Summary A**
Glowing letters that had been hanging above the Yankee stadium from 1976 to 2008 were placed for auction at Sotheby's on Wednesday, but were not sold, The current owner of the sign is Reggie Jackson, a Yankee hall-of-famer.	There was not a single buyer at the auction at Sotheby's on Wednesday for the glowing blue letters that once lit the Bronx's Yankee Stadium. Not a single non-employee raised their paddle to bid. Jackson, the owner of the letters, was surprised by the lack of results. The venue is also auctioning off other items like Mets memorabilia.
Constrained Summary B	**Unconstrained Summary B**
An auction for the lights from Yankee Stadium failed to produce any bids on Wednesday at Sotheby's. The lights, currently owned by former Yankees player Reggie Jackson, lit the stadium from 1976 until 2008.	The once iconic and attractive pack of 13 letters that was placed at the Yankee stadium in 1976 and later removed in 2008 was unexpectedly not favorably considered at the Sotheby's auction when the 68 year old owner of the letters attempted to transfer its ownership to a member the younger populace. Thus, when the minimum estimate of $300,000 was not met, a further attempt was made by a former player of the Yankees to personally visit the new owner as an

Table 1: Example summaries collected from human annotators in the *constrained* (left) and *unconstrained* (right) task. In the *unconstrained* setting, annotators were given a news article and asked to write a summary covering the parts they considered most important. In the *constrained* setting, annotators were given a news article with three associated questions and asked to write a summary that contained the answers to the given questions.

from a fragment of text. We asked workers to write summaries of news articles and highlight sentences from the source documents that they based their summaries on. The experiment was conducted in two settings: *unconstrained*, where the annotators were instructed to summarize the content that they considered most important, and *constrained*, where annotators were instructed to write summaries that would contain answers to three questions associated with each article. This is similar to the construction of the TAC 2008 Opinion Summarization Task [1]. The questions associated with each article where collected from human workers through a separate assignment. Experiments were conducted on 100 randomly sampled articles, further details of the human study can be found in Appendix A.1.

Table 2 shows the average number of sentences, per-article, that annotators agreed were important. The rows show how the average changes with the human vote threshold needed to reach consensus about the importance of any sentence. For example, if we require that three or more human votes are necessary to consider a sentence important, annotators agreed on average on the importance of 0.627 and 1.392 sentences per article in the *unconstrained* and *constrained* settings respectively. The average length (in sentences) of sampled articles was 16.59, with a standard deviation of 5.39. The study demonstrates the difficulty and ambiguity of content selection in text summarization.

We also conducted a qualitative study of summaries written by annotators. Examples comparing summaries written in the *constrained* and *unconstrained* setting are shown in Table 1. We noticed that in both cases the annotators correctly identified the main topic and important fragments of the source article. However, *constrained* summaries were more succinct and targeted, without sacrificing the natural flow of sentences. *Un-*

Human vote threshold	Sent. per article considered important	
	Unconstrained	*Constrained*
$= 5$	0.028	0.251
≥ 4	0.213	0.712
≥ 3	0.627	1.392
≥ 2	1.695	2.404
≥ 1	5.413	4.524

Table 2: Average number of sentences, per-article, which annotators agreed were important. The human vote threshold investigates how the average agreement changes with the threshold of human votes required to consider any sentence important. Rows $= 5$ and ≥ 1 correspond to the set intersection and union of selected sentences accordingly.

constrained writers tended to write more verbose summaries that did not add information. The study also highlights the *abstractive* nature of human written summaries in that similar content can be described in unique ways.

3.2 Layout bias in news data

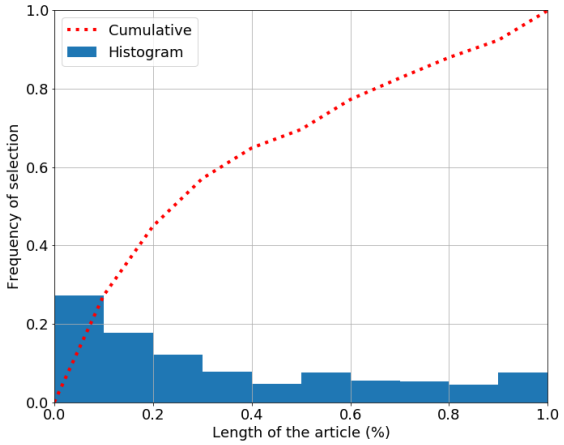

Figure 1: The distribution of important sentences over the length of the article according to human annotators (blue) and its cumulative distribution (red).

News articles adhere to a writing structure known in journalism as the "Inverted Pyramid" (PurdueOWL, 2019). In this form, initial paragraphs contain the most newsworthy information, which is followed by details and background information.

To quantify how strongly articles in the CNN/DM corpus follow this pattern we conducted a human study that measured the importance of different sections of the article. Annotators read news articles and selected sentences they found most important. Experiments were conducted on 100 randomly sampled articles, further details of the human study are described in Appendix A.3. Figure 1 presents how annotator selections were distributed over the length of the article. The distribution is skewed towards the first quarter of the length of articles. The cumulative plot shows that nearly 60% of the important information was present in the first third of the article, and approximately 25% and 15% of selections pointing to the second and last third, respectively.

It has become standard practice to exploit such biases during training to increase performance of models (See et al., 2017; Paulus et al., 2017; Kryściński et al., 2018; Gehrmann et al., 2018; Jiang and Bansal, 2018; Pasunuru and Bansal, 2018), but the importance of these heuristics has been accepted without being quantified. These same heuristics would not apply to books or legal documents, which lack the Inverted Pyramid layout so common in the news domain, so it is important that these heuristics be part of ablation studies rather than accepted as default pre-processing step.

3.3 Noise in scraped datasets

Given the data requirements of deep neural networks and the vast amounts of diverse resources available online, automatically scraping web content is a convenient way of collecting data for new corpora. However, adapting scraped content to the needs of end-to-end models is problematic. Given that manual inspection of data is infeasible and human annotators are expensive, data curation is usually limited to removing any markup structure and applying simple heuristics to discard obviously flawed examples. This, in turn, makes the quality of the datasets heavily dependent on how well the scraped content adheres to the assumptions made by the authors about its underlying structure.

This issue suggests that available summarization datasets would be filled with noisy examples. Manual inspection of the data, particularly the reference summaries, revealed easily detectable, consistent patterns of flawed examples Many such examples can be isolated using simple regular expressions and heuristics, which allows approximation of how widespread these flaws are in the dataset.

We investigated this issue in two large summarization corpora scraped from the internet:

CNN/DM (Nallapati et al., 2016a) and the Newsroom (Grusky et al., 2018). The problem of noisy data affects 0.47%, 5.92%, and 4.19% of the training, validation, and test split of the CNN/DM dataset, and 3.21%, 3.22%, and 3.17% of the respective splits of the Newsroom dataset. Examples of noisy summaries are shown in Table 3. Flawed examples contained links to other articles and news sources, placeholder texts, unparsed HTML code, and non-informative passages in the reference summaries.

4 Evaluation Metrics

4.1 Weak correlation with human judgment

The effectiveness of ROUGE was previously evaluated (Lin, 2004; Graham, 2015) through statistical correlations with human judgment on the DUC datasets (Over and Yen, 2001, 2002, 2003). However, their setting was substantially different from the current environment in which summarization models are developed and evaluated.

To investigate the robustness of ROUGE in the setting in which it is currently used, we evaluate how its scores correlate with the judgment of an average English-speaker using examples from the CNN/DM dataset. Following the human evaluation protocol from Gehrmann et al. (2018), we asked annotators to rate summaries across four dimensions: *relevance* (selection of important content from the source), *consistency* (factual alignment between the summary and the source), *fluency* (quality of individual sentences), and *coherence* (collective quality of all sentences). Each summary was rated by 5 distinct judges with the final score obtained by averaging the individual scores. Experiments were conducted on 100 randomly sampled articles with the outputs of 13 summarization systems provided by the original authors. Correlations were computed between all pairs of Human-, ROUGE-scores, for all systems. Additional summaries were collected from annotators to inspect the effect of using multiple ground-truth labels on the correlation with automatic metrics. Further details of the human study can be found in Appendix A.2.

Results are shown in Table 5. The left section of the table presents Pearson's correlation coefficients and the right section presents Kendall rank correlation coefficients. In terms of Pearsons's coefficients, the study showed minimal correlation with any of the annotated dimensions for both *abstractive* and *extractive* models together and for *abstractive* models individually. Weak correlation was discovered for *extractive* models primarily with the *fluency* and *coherence* dimensions.

We hypothesized that the noise contained in the fine-grained scores generated by both human annotators and ROUGE might have affected the correlation scores. We evaluated the relation on a higher level of granularity by means of correlation between rankings of models that were obtained from the fine-grained scores. The study showed weak correlation with all measured dimensions, when evaluated for both *abstractive* and *extractive* models together and for *abstractive* models individually. Moderate correlation was found for *extractive* models across all dimensions. A surprising result was that correlations grew weaker with the increase of ground truth references.

Our results align with the observations from Liu and Liu (2010) who also evaluated ROUGE outside of its original setting. The study highlights the limited utility in measuring progress of the field

solely by means of ROUGE scores.

4.2 Insufficient evaluation protocol

The goal of text summarization is to automatically generate succinct, fluent, relevant, and factually consistent summaries. The current evaluation protocol depends primarily on the exact lexical overlap between reference and candidate summaries measured by ROUGE. In certain cases, ROUGE scores are complemented with human studies where annotators rate the *relevance* and *fluency* of generated summaries. Neither of the methods explicitly examines the factual consistency of summaries, leaving this important dimension unchecked.

To evaluate the factual consistency of existing models, we manually inspected randomly sampled articles with summaries coming from randomly chosen, *abstractive* models. We focused exclusively on factual incorrectness and ignored any other issues, such as low fluency. Out of 200 article-summary pairs that were reviewed manually, we found that 60 (30%) contained consistency issues. Table 4 shows examples of discovered inconsistencies. Some of the discovered inconsistencies, despite being factually incorrect, could be rationalized by humans. However, in many cases, the errors were substantial and could have severe repercussions if presented as-is to target readers.

5 Models

5.1 Layout bias in news data

We revisit the problem of layout bias in news data from the perspective of models. Kedzie et al. (2018) showed that in the case of news articles, the layout bias dominates the learning signal for neural models. In this section, we approximate the degree with which generated summaries rely on the leading sentences of news articles.

We computed ROUGE scores for collected models in two settings: first using the CNN/DM reference summaries as the ground-truth, and second where the leading three sentences of the source article were used as the ground-truth, i.e. the Lead-3 baseline. We present the results in Table 6.

For all examined models we noticed a substantial increase of overlap across all ROUGE variants. Results suggest that performance of current models is strongly affected by the layout bias of news corpora. Lead-3 is a strong baseline that exploits the described layout bias. However, there is still a large gap between its performance and an upper bound for extractive models (extractive oracle).

5.2 Diversity of model outputs

Models analyzed in this paper are considerably different from each other in terms of architectures, training strategies, and underlying approaches. We inspected how the diversity in approaches translates into the diversity of model outputs.

We computed ROUGE-1 and ROUGE-4 scores between pairs of model outputs to compare them by means of token and phrase overlap. Results are visualized in Figure 2, where the values above and below the diagonal are ROUGE-1 and -4 scores accordingly, and model names (M-) follow the order from Table 6.

Table 6: ROUGE (R-) scores computed for different models on the test set of the CNN/DM dataset. Left: Scores computed with the original reference summaries. Right: Scores computed with Lead-3 used as the reference.

We notice that the ROUGE-1 scores vary considerably less than ROUGE-4 scores. This suggests that the models share a large part of the vocabulary on the token level, but differ on how they organize the tokens into longer phrases.

Comparing results with the n-gram overlap between models and reference summaries (Table 6) shows a substantially higher overlap between any model pair than between the models and reference summaries. This might imply that the training data contains easy to pick up patterns that all models overfit to, or that the information in the training signal is too weak to connect the content of the source articles with the reference summaries.

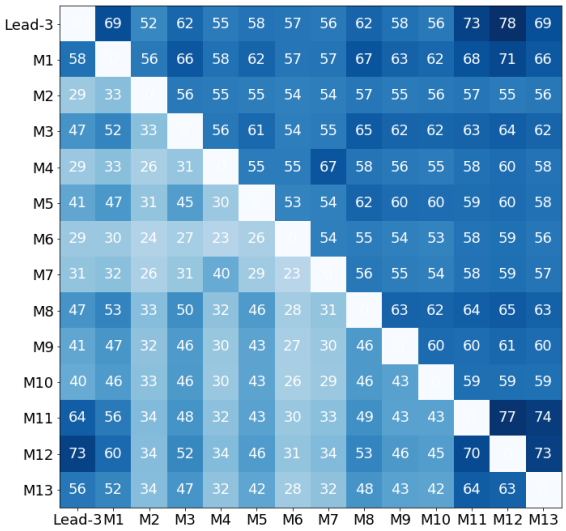

Figure 2: Pairwise similarities between model outputs computed using ROUGE. Above diagonal: Unigram overlap (ROUGE-1). Below diagonal: 4-gram overlap (ROUGE-4). Model order (M-) follows Table 6.

6 Conclusions

This critique has highlighted the weak points of the current research setup in text summarization. We showed that text summarization datasets require additional constraints to have well-formed summaries, current state-of-the-art methods learn to rely too heavily on layout bias associated with the particular domain of the text being summarized, and the current evaluation protocol reflects human judgments only weakly while also failing to evaluate critical features (e.g. factual correctness) of text summarization.

We hope that this critique provides the summarization community with practical insights for future research directions that include the construction of datasets, models less fit to a particular domain bias, and evaluation that goes beyond current metrics to capture the most important features of summarization.

7 Acknowledgements

We thank all the authors listed in Table 6 for sharing their model outputs and thus contributing to this work. We also thank Shafiq Rayhan Joty for reviewing this manuscript and providing valuable feedback.

Abstract

Traditionally, most data-to-text applications have been designed using a modular pipeline architecture, in which non-linguistic input data is converted into natural language through several intermediate transformations. By contrast, recent neural models for data-to-text generation have been proposed as end-to-end approaches, where the non-linguistic input is rendered in natural language with much less explicit intermediate representations in between. This study introduces a systematic comparison between neural pipeline and end-to-end data-to-text approaches for the generation of text from RDF triples. Both architectures were implemented making use of the encoder-decoder Gated-Recurrent Units (GRU) and Transformer, two state-of-the art deep learning methods. Automatic and human evaluations together with a qualitative analysis suggest that having explicit intermediate steps in the generation process results in better texts than the ones generated by end-to-end approaches. Moreover, the pipeline models generalize better to unseen inputs. Data and code are publicly available.[1]

1 Introduction

Data-to-text Natural Language Generation (NLG) is the computational process of generating meaningful and coherent natural language text to describe non-linguistic input data (Gatt and Krahmer, 2018). Practical applications can be found in domains such as weather forecasts (Mei et al., 2016), health care (Portet et al., 2009), feedback for car drivers (Braun et al., 2018), diet management (Anselma and Mazzei, 2018), election results (Leppänen et al., 2017) and sportscasting news (van der Lee et al., 2017).

Traditionally, most of data-to-text applications have been designed in a modular fashion, in which the non-linguistic input data (be it, say, numerical weather information or game statistics) are converted into natural language (e.g., weather forecast, game report) through several explicit intermediate transformations. The most prominent example is the 'traditional' pipeline architecture (Reiter and Dale, 2000) that performs tasks related to document planning, sentence planning and linguistic realization in sequence. Many of the traditional, rule-based NLG systems relied on modules because (a) these modules could be more easily reused across applications, and (b) because going directly from input to output using rules was simply too complex in general (see Gatt and Krahmer 2018 for a discussion of different architectures).

The emergence of neural methods changed this: provided there is enough training data, it does become possible to learn a direct mapping from input to output, as has also been shown in, for example, neural machine translation. As a result, in NLG more recently, neural end-to-end data-to-text models have been proposed, which directly learn input-output mappings and rely much less on explicit intermediate representations (Wen et al., 2015; Dušek and Jurcicek, 2016; Mei et al., 2016; Lebret et al., 2016; Gehrmann et al., 2018).

However, the fact that neural end-to-end approaches are *possible* does not necessarily entail that they are *better* than (neural) pipeline models. On the one hand, cascading of errors is a known problem of pipeline models in general (an error in an early module will impact all later modules in the pipeline), which (almost by definition) does not apply to end-to-end models. On the other hand, it is also conceivable that developing dedicated neural modules for specific tasks leads to better performance on each of these successive tasks, and combining them might lead to better,

and more reusable, output results. In fact, this has never been systematically studied, and this is the main goal of the current paper.

We present a systematic comparison between neural pipeline and end-to-end data-to-text approaches for the generation of output text from RDF input triples, relying on an augmented version of the WebNLG corpus (Gardent et al., 2017b). Using two state-of-the-art deep learning techniques, GRU (Cho et al., 2014) and Transformer (Vaswani et al., 2017), we develop both a neural pipeline and an end-to-end architecture. The former, which also makes use of the NeuralREG approach (Castro Ferreira et al., 2018a), tackles standard NLG tasks (discourse ordering, text structuring, lexicalization, referring expression generation and textual realization) in sequence, while the latter does not address these individual tasks, but directly tries to learn how to map RDF triples into corresponding output text.

Using a range of evaluation techniques, including both automatic and human measures, combined with a qualitative analysis, we provide answers to our two main research questions: (RQ1) How well do deep learning methods perform as individual modules in a data-to-text pipeline architecture? And (RQ2) How well does a neural pipeline architecture perform compared to a neural end-to-end one? Our results show that adding supervision during the data-to-text generation process, by distinguishing separate modules and combining them in a pipeline, leads to better results than full end-to-end approaches. Moreover, the pipeline architecture offers somewhat better generalization to unseen domains and compares favorably to the current state-of-the-art.

2 Data

The experiments presented in this work were conducted on the WebNLG corpus (Gardent et al., 2017a,b), which consists of sets of ⟨ Subject, Predicate, Object ⟩ RDF triples and their target texts. In comparison with other popular NLG benchmarks (Belz et al., 2011; Novikova et al., 2017; Mille et al., 2018), WebNLG is the most semantically varied corpus, consisting of 25,298 texts describing 9,674 sets of up to 7 RDF triples in 15 domains. Out of these domains, 5 are exclusively present in the test set, being unseen during the training and validation processes. Figure 1 depicts an example of a set of 3 RDF triples and its related text.

A.C._Cesena	**manager**	Massimo_Drago
Massimo_Drago	**club**	S.S.D._Potenza_Calcio
Massimo_Drago	**club**	Calcio_Catania

↓

Massimo Drago played for the club SSD Potenza Calcio and his own club was Calcio Catania. He is currently managing AC Cesena.

Figure 1: Example of a set of triples (top) and the corresponding text (bottom).

To evaluate the intermediate stages between the triples and the target text, we use the augmented version of the WebNLG corpus (Castro Ferreira et al., 2018b), which provides gold-standard representations for traditional pipeline steps, such as discourse ordering (i.e., the order in which the source triples are verbalized in the target text), text structuring (i.e., the organization of the triples into paragraph and sentences), lexicalization (i.e., verbalization of the predicates) and referring expression generation (i.e., verbalization of the entities).

3 Pipeline Architecture

Based on Reiter and Dale (2000), we propose a pipeline architecture which converts a set of RDF triples into text in 5 sequential steps.

3.1 Discourse Ordering

Originally designed to be performed when the document is planned, Discourse Ordering is the process of determining the order in which the communicative goals should be verbalized in the target text. In our case, the communicative goals are the RDF triples received as input by the model.

Given a set of linearized triples, this step determines the order in which they should be verbalized. For example, given the triple set in Figure 1 in the linearized format:

<TRIPLE> A.C._Cesena **manager** Massimo_Drago </TRIPLE> <TRIPLE> Massimo_Drago **club** S.S.D._Potenza_Calcio </TRIPLE> <TRIPLE> Massimo_Drago **club** Calcio_Catania </TRIPLE>

Our discourse ordering model would ideally return the set `club club manager`, which later is used to retrieve the input triples on the predicted order. In case of triples with the same predicates, as `club`, our implementation will randomly retrieve the triples.

3.2 Text Structuring

Text Structuring is the step which intends to organize the ordered triples into paragraphs and sentences. Since the WebNLG corpus only contains single-paragraph texts, this step will be only evaluated on sentence planning, being closer to the Aggregation task of the original architecture (Reiter and Dale, 2000). However, it can be easily extended to predict paragraph structuring in multi-paragraph datasets.

Given a linearized set of ordered triples, this step works by generating the predicates segmented by sentences based on the tokens <SNT> and </SNT>. For example, given the ordered triple set in Figure 1 in the same linearized format as in Discourse Ordering, the module would generate <SNT> club club </SNT> <SNT> manager </SNT>, where predicates are replaced by the proper triples for the next step.

3.3 Lexicalization

Lexicalization involves finding the proper phrases and words to express the content to be included in each sentence (Reiter and Dale, 2000). In this study, given a linearized ordered set of triples segmented by sentences, the Lexicalization step aims to predict a template which verbalizes the predicates of the triples. For our example based on Figure 1, given the ordered triple set segmented by sentences in the following format:

<SNT> <TRIPLE> Massimo_Drago **club** S.S.D._Potenza_Calcio </TRIPLE> <TRIPLE> Massimo_Drago **club** Calcio_Catania </TRIPLE> </SNT> <SNT> <TRIPLE> A.C._Cesena **manager** Massimo_Drago </TRIPLE> </SNT>

This step would ideally return a template like:

ENTITY-1 VP[*aspect=simple, tense=past, voice=active, person=null, number=null*] play for DT[*form=defined*] the club **ENTITY-2** and **ENTITY-1** own club VP[*aspect=simple, tense=past, voice=active, person=null, number=singular*] be **ENTITY-3** . **ENTITY-1** VP[*aspect=simple, tense=present, voice=active, person=3rd, number=singular*] be currently VP[*aspect=progressive, tense=present, voice=active, person=null, number=null*] manage **ENTITY-4** .

The template format not only selects the proper phrases and words to verbalize the predicates, but also does indications for the further steps. The general tags ENTITY-[0-9] indicates where references should be realized. The number in an entity tag indicates the entity to be realized based on its occurrence in the ordered triple set. For instance, ENTITY-3 refers to the entity Calcio_Catania, the third mentioned entity in the ordered triple set.

Information for the further textual realization step is stored in the tags VP, which contains the aspect, mood, tense, voice and number of the subsequent lemmatized verb, and DT, which depicts the form of the subsequent lemmatized determiner.[2]

3.4 Referring Expression Generation

Referring Expression Generation (REG) is the pipeline task responsible for generating the references to the entities of the discourse (Krahmer and van Deemter, 2012). As previously explained, the template created in the previous step depicts where and to which entities such references should be generated. Given our example based in Figure 1, the result of the REG step for the template predicted in the previous step would be:

Massimo Drago VP[...] play for DT[...] the club **SSD Potenza Calcio** and **his** own club VP[...] be **Calcio Catania** . **He** VP[...] be currently VP[...] manage **AC Cesena** .

To perform the task, we used the NeuralREG algorithm (Castro Ferreira et al., 2018a). Given a reference to be realized, this algorithm works by encoding the template before (pre-context) and after (post-contex) the reference using two different Bidirectional LSTMs (Hochreiter and Schmidhuber, 1997). Attention vectors are then computed for both vectors and concatenated together with the embedding of the entity. Finally, this representation is decoded into the referring expression to the proper entity in the given context.[3]

3.5 Textual Realization

Textual Realization aims to perform the last steps of converting the non-linguistic data into text. In our pipeline architecture this includes setting the verbs (e.g., *VP[aspect=simple, tense=past, voice=passive, person=3rd, number=singular] locate → was located*) and determiners (*DT[form=undefined] a American national → an American national*) to their right formats. Both verbs and determiners are solved in a

[2]Both kind of tags with their respective information are treated as a single token.

[3]NeuralREG works with the Wikipedia representation of the entities (e.g., Massimo_Drago) in the templates instead of general tags (e.g., ENTITY-1).

rule-based strategy, where the implications are extracted from the training set. This step will not be individually evaluated as the other ones.

4 End-to-End Architecture

Our end-to-end architecture is similar to novel data-to-text models (Wen et al., 2015; Dušek and Jurcicek, 2016; Mei et al., 2016; Lebret et al., 2016; Gehrmann et al., 2018), which aim to convert a non-linguistic input into natural language without explicit intermediate representations, making use of Neural Machine Translation techniques. In this study, our end-to-end architecture intends to directly convert an unordered (linearized) set of RDF triples into text.

5 Models Set-Up

Both pipeline steps and the end-to-end architecture were modelled using two deep learning encoder-decoder approaches: Gated-Recurrent Units (GRU; Cho et al. 2014) and Transformer (Vaswani et al., 2017). These models differ in the way they encode their input. GRUs encode the input data by going over the tokens one-by-one, while Transformers (which do not have a recurrent structure) may encode the entire source sequence as a whole, using position embeddings to keep track of the order. We are particularly interested in the capacity of such approaches to learn order and structure in the process of text generation. The model settings are explained in the supplementary materials.

6 Experiment 1: Learning the pipeline

Most of the data-to-text pipeline applications have their steps implemented using rule-based or statistical data-driven models. However, these techniques have shown to be outperformed by deep neural networks in other Computational Linguistics subfields and in particular pipeline steps like Referring Expression Generation. NeuralREG (Castro Ferreira et al., 2018a), for instance, outperforms other techniques in generating references and co-references along a single-paragraph text. Given this context, our first experiment intends to analyze how well deep learning methods perform particular steps of the pipeline architecture, like Discourse Ordering, Text Structuring, Lexicalization and Referring Expression Generation, in comparison with simpler data-driven baselines.

6.1 Data

We used version 1.5 of the augmented WebNLG corpus (Castro Ferreira et al., 2018b)[4] to evaluate the steps of our pipeline approach. Based on its intermediate representations, we extracted gold-standards to train and evaluate the different steps.

Discourse Ordering We used pairs of RDF triple sets and their ordered versions to evaluate our Discourse Ordering approaches. For the cases in the training set where a triple set was verbalized in more than one order, we added one entry per verbalization taking the proper order as the target. To make sure the source set followed a pattern, we ordered the input according to the alphabetic order of its predicates, followed by the alphabetical order of its subjects and objects in case of similar predicates. In total, our Discourse Ordering data consists of 13,757, 1,730 and 3,839 ordered triple sets for 5,152, 644 and 1,408 training, development and test input triple sets, respectively.

Text Structuring 14,010, 1,752 and 3,955 structured triple sets were extracted for 10,281, 1,278 and 2,774 training, development and test ordered triple sets, respectively.

Lexicalization 18,295, 2,288 and 5,012 lexicalization templates were used for 12,814, 1,601 and 3,463 training, development and test structured triple sets, respectively.

Referring Expression Generation To evaluate the performance of the REG models, we extracted 67,144, 8,294 and 19,210 reference instances from training, development and test part of the corpus. Each instance consists of the cased tokenized referring expression, the identifier of the target entity and the uncased tokenized pre- and post-contexts.

6.2 Metrics

Discourse Ordering and Text Structuring approaches were evaluated based on their accuracy to predict one of the gold-standards given the input (many of the RDF triple sets in the corpus were verbalized in more than one order and structure). Referring Expression Generation approaches were also evaluated based on their accuracy to predict the uncased tokenized gold-standard referring expressions. Lexicalization was evaluated based on the BLEU score of the predicted templates in their uncased tokenized form.

[4] https://github.com/ThiagoCF05/webnlg

6.3 Baselines

We proposed *random* and *majority* baselines for the steps of Discourse Ordering, Text Structuring and Lexicalization. In comparison with NeuralREG, we used the *OnlyNames* baseline, also introduced in Castro Ferreira et al. (2018a).

Discourse Ordering The random baseline returns the triple set in a random order, whereas the majority one returns the most frequent order of the input predicates in the training set. For unseen sets of predicates, the *majority* model returns the triple set in the same order as the input.

Text Structuring The random baseline for this step chooses a random split of triples in sentences, inserting the tags <SNT> and </SNT> in aleatory positions among them. The majority baseline returns the most frequent sentence intervals in the training set based on the input predicates. In case of an unseen set, the model looks for sentence intervals in subsets of the input.

Lexicalization Algorithm 1 depicts our baseline approach for Lexicalization. As in Text Structuring, given a set of input triples structured in sentences, the random and majority models return a random and the most frequent template that describes the input predicates, respectively (line 6). If the set of predicates is unseen, the model returns a template that describes a subset of the input.

Algorithm 1 Lexicalization Pseudocode

```
Require: struct, model
 1: start, end ← 0, |struct|
 2: template ← ∅
 3: while start < |struct| do
 4:     snts ← struct[start,end)
 5:     if snts ∈ model then
 6:         template ← template ∪ model[snts]
 7:         start ← end
 8:         end ← |struct|
 9:     else
10:         end ← end −1
11:         if start = end then
12:             start ← start + 1
13:             end ← |struct|
14:         end if
15:     end if
16: end while
17: return template
```

Referring Expression Generation We used *OnlyNames*, a baseline introduced in Castro Ferreira et al. (2018a), in contrast to NeuralREG. Given an entity to be referred to, this model returns the entity Wikipedia identifier with underscores replaced by spaces (`Massimo_Drago` → `Massimo Drago`).

	All	Seen	Unseen
Discourse Ordering			
Random	0.31	0.29	0.35

Table 1: Accuracy of Discourse Ordering, Text Structuring and Referring Expression models, as well as BLEU score of Lexicalization approaches.

6.4 Results

Table 1 shows the results for our models for each of the 4 evaluated pipeline steps. In general, the results show a clear pattern in all of these steps: both neural models (GRU and Transformer) introduced higher results on domains seen during training, but their performance drops substantially on unseen domains in comparison with the baselines (Random and Majority). The only exception is found in Text Structuring, where the neural models outperforms the Majority baseline on unseen domains, but are still worse than the Random baseline. Between both neural models, recurrent networks seem to have an advantage over the Transformer in Discourse Ordering and Text Structuring, whereas the latter approach performs better than the former one in Lexicalization.

7 Experiment 2: Pipeline vs. End-to-End

In this experiment, we contrast our pipeline with our end-to-end implementation and state-of-the-art models for RDF-to-text. The models were evaluated in automatic and human evaluations, followed by a qualitative analysis.

7.1 Approaches

Pipeline We evaluated 4 implementations of our pipeline architecture, where the output of the previous step is fed into the next one. We call these implementations *Random*, *Majority*, *GRU* and *Transformer*, where each one has its steps solved by one of the proposed baselines or deep learning implementations. In Random and Majority, the referring expressions were generated by the *OnlyNames* baseline, whereas for GRU and Transformer, NeuralREG was used for the seen entities, *OnlyNames* for the unseen ones and special rules to realize dates and numbers.

End-to-End We aimed to convert a set of RDF-triples into text using a GRU and a Transformer implementation without explicit intermediate representations in-between.

7.2 Models for Comparison

To ground this study with related work, we compared the performance of the proposed approaches with 4 state-of-the-art RDF-to-text models.

Melbourne is the approach which obtained the highest performance in the automatic evaluation of the WebNLG Challenge. The approach consists of a neural encoder-decoder approach, which encodes a linearized triple set, with predicates split on camel case (e.g. `floorArea` → `floor area`) and entities represented by general (e.g., `ENTITY-1`) and named entity recognition (e.g., `PERSON`) tags, into a template where references are also represented with general tags. The referring expressions are later generated in the template simply by replacing these general tags with an approach similar to *OnlyNames*.

UPF-FORGe obtained the highest ratings in the human evaluation of the WebNLG challenge, having a performance similar to texts produced by humans. It also follows a pipeline architecture, which maps predicate-argument structures onto sentences by applying a series of rule-based graph-transducers (Mille et al., 2019).

Marcheggiani and Perez (2018) proposed a graph convolutional network that directly encodes the input triple set in contrast with previous model that first linearize the input to then decode it into text.

Moryossef et al. (2019) proposed an approach which converts an RDF triple set into text in two steps: text planning, a non-neural method where the input will be ordered and structured, followed by a neural realization step, where the ordered and structured input is converted into text.

7.3 Evaluation

Automatic Evaluation We evaluated the textual outputs of each system using the BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007) metrics. The evaluation was done on the entire test data, as well as only in their seen and unseen domains.

Human Evaluation We conducted a human evaluation, selecting the same 223 samples used in the evaluation of the WebNLG challenge (Gardent et al., 2017b). For each sample, we used the original texts and the ones generated by our 6 approaches and by the Melbourne and UPF-FORGe reference systems, totaling 2,007 trials. Each trial displayed the triple set and the respective text. The goal of the participants was to rate the trials based on the fluency (i.e., does the text flow in a natural, easy to read manner?) and semantics (i.e., does the text clearly express the data?) of the text in a 1-7 Likert scale.

We recruited 35 raters from Mechanical Turk to participate in the experiment. We first familiarized them with the set-up of the experiment, depicting a trial example in the introduction page accompanied by an explanation. Then each participant had to rate 60 trials, randomly chosen by the system, making sure that each trial was rated at least once.[5]

Qualitative Analysis To have a better understanding of the positive and negative aspects of each model, we also performed a qualitative analysis, where the second and third authors of this study analyzed the original texts and the ones generated by the previous 8 models for 75 trials extracted from the human evaluation sample for each combination between size and domain of the corpus. The trials were displayed in a similar way to the human evaluation, where the annotators did not know which model produced the text. The only difference was the additional display of the predicted structure by the pipeline approaches (a

[5]The raters had an average age of 32.29 and 40% were female. 17 participants indicated they were fluent in English, while 18 were native. The experiment, which obtained ethical clearance from the university, took around 20-30 minutes to be completed and each rater received a pay in U.S. dollars for participation.

Table 3: Qualitative analysis. The first part shows the percentage of trials that keeps the input predicates over Discourse Ordering (Ord.), Text Structuring (Struct.) and in the final text (Txt.). It also shows the ratio of text trials with more predicates than in the input (Ovr.) and the pipeline texts which keep the decisions of previous steps (Keep.). The second part shows the number of trials without verb, determiner and reference mistakes.

fake structure was displayed for the other models). Both annotators analyzed grammaticality aspects, like whether the texts had mistakes involving the determiners, verbs and references, and semantic ones, like whether the text followed the predicted order and structure, and whether it verbalizes less or more information than the input triples.[6]

7.4 Results

Table 2 depicts the results of automatic and human evaluations, whereas Table 3 shows the results of the qualitative analysis.

Automatic Evaluation In terms of BLEU, our neural pipeline models (GRU and Transformer) outperformed all the reference approaches in all domains, whereas our end-to-end GRU and Random pipeline obtained the best results on seen and unseen domains, respectively.

Regarding METEOR, which includes synonymy matching to score the inputs, reference methods introduced the best scores in all domains. In seen and unseen domains, our neural GRU pipeline and reference approach UPF-FORGe obtained the best results, respectively.

[6]Inter-annotator agreement for the evaluated aspects ranged from 0.26 (Reference) to 0.93 (Input Triples), with an average Krippendorff α of 0.67.

Human Evaluation In all domains, neural GRU pipeline and UPF-FORGe were rated the highest in fluency by the participants of the evaluation. In seen ones, both our neural pipeline approaches (GRU and Transformer) were rated the best, whereas UPF-FORGe was considered the most fluent approach in unseen domains.

UPF-FORGe was also rated the most semantic approach in all domains, followed by neural GRU and Majority pipeline approaches. For seen domains, similar to the fluency ratings, both our neural pipeline approaches were rated the highest, whereas UPF-FORGe was considered the most semantic approach in unseen domains.

Qualitative Analysis In general, UPF-FORGe emerges as the system which follows the input the best: 91% of the evaluated trials verbalized the input triples. Moreover, the annotators did not find any grammatical mistakes in the output of this approach.

When focusing on the neural pipeline approaches, we found that in all the steps up to Text Structuring, the recurrent networks retained more information than the Transformer. However, 68% of the Transformer's text trials contained all the input triples, against 67% of the GRU's trials. As in Experiment 1, we see that recurrent networks as GRUs are better in ordering and structuring the discourse, but is outperformed by the Transformer in the Lexicalization step. In terms of fluency, we did not see a substantial difference between both kinds of approaches.

Regarding our end-to-end trials, different from the pipeline ones, less than a half verbalized all the input triples. Moreover, the end-to-end outputs also constantly contained more information than there were in the non-linguistic input.

8 Discussion

This study introduced a systematic comparison between pipeline and end-to-end architectures for data-to-text generation, exploring the role of deep neural networks in the process. In this section we answer the two introduced research questions and additional topics based on our findings.

How well do deep learning methods perform as individual modules in a data-to-text pipeline? In comparison with Random and Majority baselines, we observed that our deep learning implementations registered a higher performance in the pipeline steps on domains seen during training, but their performance dropped considerably on unseen domains, being lower than the baselines.

In the comparison between our GRU and Transformer, the former seems to be better at ordering and structuring the non-linguistic input, whereas the latter performs better in verbalizing an ordered and structured set of triples. The advantage of GRUs over the Transformer in Discourse Ordering and Text Structuring may be its capacity to implicitly take order information into account. On the other hand, the Transformer could have had difficulties caused by the task's design, where triples and sentences were segmented by tags (e.g. `<TRIPLE>` and `<SNT>`), rather than positional embeddings, which suits this model better. In sum, more research needs to be done to set this point.

How well does a neural pipeline architecture perform compared to a neural end-to-end one? Our neural pipeline approaches were superior to the end-to-end ones in most tested circumstances: the former generates more fluent texts which better describes data on all domains of the corpus. The difference is most noticeable for unseen domains, where the performance of end-to-end approaches drops considerably. This shows that end-to-end approaches do not generalize as well as the pipeline ones. In the qualitative analysis, we also found that end-to-end generated texts have the problem of describing non-linguistic representations which are not present in the input, also known as Hallucination (Rohrbach et al., 2018).

The example in Figure 2 shows the advantage of our pipeline approaches in comparison with the end-to-end ones. It depicts the texts produced by the proposed approaches for an unseen set during training of 4 triples, where 2 out of the 4 predicates are present in the WebNLG training set (e.g., *birthPlace* and *occupation*). In this context, the pipeline approaches managed to generate a semantic text based on the two seen predicates, whereas the end-to-end approaches hallucinated texts which have no semantic relation with the non-linguistic input.

Related Work We compared the proposed approaches with 4 state-of-the-art RDF-to-text systems. Except for Marcheggiani and Perez (2018), all the others are not end-to-end approaches, already directing the field to pipeline architectures. UPF-FORGe is a proper pipeline system with sev-

Ace_Wilder	**background**	"solo_singer"
Ace_Wilder	***birthPlace***	Sweden
Ace_Wilder	**birthYear**	1982
Ace_Wilder	***occupation***	Songwriter

↓

GRU	Ace Wilder, born in Sweden, performs as Songwriter.
Transformer	Ace Wilder (born in Sweden) was Songwriter.
E2E GRU	The test pilot who was born in Willington, who was born in New York, was born in New York and is competing in the competing in the U.S.A. The construction of the city is produced in Mandesh.
E2E Trans.	Test pilot Elliot See was born in Dallas and died in St. Louis.

Figure 2: Example of a set of triples from an unseen domain during training (top) and the corresponding texts produced by our pipeline (e.g., GRU and Transformer) and end-to-end approaches (e.g., E2E GRU and E2E Trans.) (bottom). In the top set of triples, predicates seen during training are highlighted in *italic*, whereas the unseen ones are underlined.

eral sequential steps, Melbourne first generates a delexicalized template to later realize the referring expressions, and Moryossef et al. (2019) splits the process up into Planning, where ordering and structuring are merged, and Realization.

Besides the approach of Marcheggiani and Perez (2018), the ADAPT system, introduced in the WebNLG challenge (Gardent et al., 2017b), is another full end-to-end approach to the task. It obtained the highest results in the seen part of the WebNLG corpus (BLEU = 60.59; METEOR = 0.44). However, the results drastically dropped on the unseen part of the dataset (BLEU = 10.53; METEOR = 0.19). Such results correlate with our findings showing the difficult of end-to-end approaches to generalize to new domains.

By obtaining the best results in almost all the evaluated metrics, UPF-FORGe emerges as the best reference system, showing again the advantage of generating text from non-linguistic data in several explicit intermediate representations. However, it is important to observe that the advantage of UPF-FORGe over our pipeline approaches is the fact that it was designed taking the seen and unseen domains of the corpus into account. So in practice, there was no "unseen" domains for UPF-FORGe. In a fair comparison between this reference system with our neural pipeline approaches in only seen domains, we may see that ours are rated higher in almost all the evaluated metrics.

General Applicability Besides our findings, the results for other benchmarks, such as Elder et al. (2019), suggest that pipeline approaches can work well in the context of neural data-to-text generation. Concerning our pipeline approach specifically, although it was designed to convert RDF triples to text, we assume it can be adapted to other domains (and languages) where communicative goals can be linearized and split in units, as in the E2E dataset (Novikova et al., 2017). In future work, we plan to study this in more detail.

Conclusion In a systematic comparison, we show that adding supervision during the data-to-text process leads to more fluent text that better describes the non-linguistic input data than full end-to-end approaches, confirming the trends in related work in favor of pipeline architectures.

Abstract

A robust evaluation metric has a profound impact on the development of text generation systems. A desirable metric compares system output against references based on their semantics rather than surface forms. In this paper we investigate strategies to encode system and reference texts to devise a metric that shows a high correlation with human judgment of text quality. We validate our new metric, namely MoverScore, on a number of text generation tasks including summarization, machine translation, image captioning, and data-to-text generation, where the outputs are produced by a variety of neural and non-neural systems. Our findings suggest that metrics combining contextualized representations with a distance measure perform the best. Such metrics also demonstrate strong generalization capability across tasks. For ease-of-use we make our metrics available as web service.[1]

1 Introduction

The choice of evaluation metric has a significant impact on the assessed quality of natural language outputs generated by a system. A desirable metric assigns a single, real-valued score to the system output by comparing it with one or more reference texts for content matching. Many natural language generation (NLG) tasks can benefit from robust and unbiased evaluation, including text-to-text (*machine translation* and *summarization*), data-to-text (*response generation*), and image-to-text (*captioning*) (Gatt and Krahmer, 2018). Without proper evaluation, it can be difficult to judge on system competitiveness, hindering the development of advanced algorithms for text generation.

It is an increasingly pressing priority to develop better evaluation metrics given the recent advances in neural text generation. Neural models provide the flexibility to copy content from source text as well as generating unseen words (See et al., 2017). This aspect is hardly covered by existing metrics. With greater flexibility comes increased demand for unbiased evaluation. Diversity-promoting objectives make it possible to generate diverse natural language descriptions (Li et al., 2016; Wiseman et al., 2018). But standard evaluation metrics including BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) compute the scores based primarily on n-gram co-occurrence statistics, which are originally proposed for diagnostic evaluation of systems but not capable of evaluating text quality (Reiter, 2018), as they are not designed to measure if, and to what extent, the system and reference texts with distinct surface forms have conveyed the same meaning. Recent effort on the applicability of these metrics reveals that while compelling text generation system ascend on standard metrics, the text quality of system output is still hard to be improved (Böhm et al., 2019).

Our goal in this paper is to devise an automated evaluation metric assigning a single holistic score to any system-generated text by comparing it against human references for content matching. We posit that it is crucial to provide a holistic measure attaining high correlation with human judgments so that various neural and non-neural text generation systems can be compared directly. Intuitively, the metric assigns a perfect score to the system text if it conveys the same meaning as the reference text. Any deviation from the reference content can then lead to a reduced score, e.g., the system text contains more (or less) content than the reference, or the system produces ill-formed text that fails to deliver the intended meaning.

We investigate the effectiveness of a spectrum of distributional semantic representations to encode system and reference texts, allowing them to be compared for semantic similarity across

multiple natural language generation tasks. Our new metric quantifies the semantic distance between system and reference texts by harnessing the power of contextualized representations (Peters et al., 2018; Devlin et al., 2018) and a powerful distance metric (Rubner et al., 2000) for better content matching. Our contributions can be summarized as follows:

- We formulate the problem of evaluating generation systems as measuring the semantic distance between system and reference texts, assuming powerful continuous representations can encode any type of semantic and syntactic deviations.
- We investigate the effectiveness of existing contextualized representations and Earth Mover's Distance (Rubner et al., 2000) for comparing system predictions and reference texts, leading to our new automated evaluation metric that achieves high correlation with human judgments of text quality.
- Our metric outperforms or performs comparably to strong baselines on four text generation tasks including summarization, machine translation, image captioning, and data-to-text generation, suggesting this is a promising direction moving forward.

2 Related Work

It is of fundamental importance to design evaluation metrics that can be applied to natural language generation tasks of similar nature, including summarization, machine translation, data-to-text generation, image captioning, and many others. All these tasks involve generating texts of sentence or paragraph length. The system texts are then compared with one or more reference texts of similar length for semantic matching, whose scores indicate how well the systems perform on each task. In the past decades, however, evaluation of these natural language generation tasks has largely been carried out independently within each area.

Summarization A dominant metric for summarization evaluation is ROUGE (Lin, 2004), which measures the degree of lexical overlap between a system summary and a set of reference summaries. Its variants consider overlap of unigrams (-1), bigrams (-2), unigrams and skip bigrams with a maximum gap of 4 words (-SU4), longest common subsequences (-L) and its weighted version (-W-1.2), among others. Metrics such as Pyramid (Nenkova and Passonneau, 2004) and BE (Hovy et al., 2006; Tratz and Hovy, 2008) further compute matches of content units, e.g., (head-word, modifier) tuples, that often need to be manually extracted from reference summaries. These metrics achieve good correlations with human judgments in the past. However, they are not general enough to account for the relatedness between abstractive summaries and their references, as a system abstract can convey the same meaning using different surface forms. Furthermore, large-scale summarization datasets such as CNN/Daily Mail (Hermann et al., 2015) and Newsroom (Grusky et al., 2018) use a *single reference* summary, making it harder to obtain unbiased results when only lexical overlap is considered during summary evaluation.

Machine Translation A number of metrics are commonly used in MT evaluation. Most of these metrics compare system and reference translations based on surface forms such as word/character n-gram overlaps and edit distance, but not the meanings they convey. BLEU (Papineni et al., 2002) is a precision metric measuring how well a system translation overlaps with human reference translations using n-gram co-occurrence statistics. Other metrics include SentBLEU, NIST, chrF, TER, WER, PER, CDER, and METEOR (Lavie and Agarwal, 2007) that are used and described in the WMT metrics shared task (Bojar et al., 2017; Ma et al., 2018). RUSE (Shimanaka et al., 2018) is a recent effort to improve MT evaluation by training sentence embeddings on large-scale data obtained in other tasks. Additionally, preprocessing reference texts is crucial in MT evaluation, e.g., normalization, tokenization, compound splitting, etc. If not handled properly, different preprocessing strategies can lead to inconsistent results using word-based metrics (Post, 2018).

Data-to-text Generation BLEU can be poorly suited to evaluating data-to-text systems such as dialogue response generation and image captioning. These systems are designed to generate texts with lexical and syntactic variation, communicating the same information in many different ways. BLEU and similar metrics tend to reward systems that use the same wording as reference texts, causing repetitive word usage that is deemed undesirable to humans (Liu et al., 2016). In a similar vein, evaluating the quality of image captions can be challenging. CIDEr (Vedantam et al., 2015) uses tf-idf weighted n-grams for similarity estimation; and SPICE (Anderson et al., 2016) incorporates

synonym matching over scene graphs. Novikova et al. (2017) examine a large number of word- and grammar-based metrics and demonstrate that they only weakly reflect human judgments of system outputs generated by data-driven, end-to-end natural language generation systems.

Metrics based on Continuous Representations Moving beyond traditional metrics, we envision a new generation of automated evaluation metrics comparing system and reference texts based on semantics rather than surface forms to achieve better correlation with human judgments. A number of previous studies exploit static word embeddings (Ng and Abrecht, 2015; Lo, 2017) and trained classifers (Peyrard et al., 2017; Shimanaka et al., 2018) to improve semantic similarity estimation, replacing lexical overlaps.

In contemporaneous work, Zhang et al. (2019) describe a method comparing system and reference texts for semantic similarity leveraging the BERT representations (Devlin et al., 2018), which can be viewed as a special case of our metrics and will be discussed in more depth later. More recently, Clark et al. (2019) present a semantic metric relying on sentence mover's similarity and the ELMo representations (Peters et al., 2018) and apply them to summarization and essay scoring. Mathur et al. (2019) introduce unsupervised and supervised metrics based on the BERT representations to improve MT evaluation, while Peyrard (2019a) provides a composite score combining redundancy, relevance and informativeness to improve summary evaluation.

In this paper, we seek to accurately measure the (dis)similarity between system and reference texts drawing inspiration from contextualized representations and Word Mover's Distance (WMD; Kusner et al., 2015). WMD finds the "traveling distance" of moving from the word frequency distribution of the system text to that of the reference, which is essential to capture the (dis)similarity between two texts. Our metrics differ from the contemporaneous work in several facets: (i) we explore the granularity of embeddings, leading to two variants of our metric, word mover and sentence mover; (ii) we investigate the effectiveness of diverse pretrained embeddings and finetuning tasks; (iii) we study the approach to consolidate layer-wise information within contextualized embeddings; (iii) our metrics demonstrate strong generalization capability across four tasks, oftentimes outperforming the supervised ones. We now describe our method in detail.

3 Our MoverScore Meric

We have motivated the need for better metrics capable of evaluating disparate NLG tasks. We now describe our metric, namely MoverScore, built upon a combination of (i) contextualized representations of system and reference texts and (ii) a distance between these representations measuring the semantic distance between system outputs and references. It is particularly important for a metric to not only capture the amount of *shared content* between two texts, i.e., intersect(A,B), as is the case with many semantic textual similarity measures (Peters et al., 2018; Devlin et al., 2018); but also to accurately reflect to what extent the system text has *deviated* from the reference, i.e., union(A,B) - intersect(A,B), which is the intuition behind using a distance metric.

3.1 Measuring Semantic Distance

Let $\boldsymbol{x} = (\mathrm{x}_1, \ldots, \mathrm{x}_m)$ be a sentence viewed as a sequence of words. We denote by $\boldsymbol{x}^n$ the sequence of n-grams of $\boldsymbol{x}$ (i.e., $\boldsymbol{x}^1 = \boldsymbol{x}$ is the sequence of words and $\boldsymbol{x}^2$ is the sequence of bigrams). Furthermore, let $\boldsymbol{f}_{\boldsymbol{x}^n} \in \mathbb{R}_+^{|\boldsymbol{x}^n|}$ be a vector of weights, one weight for each n-gram of $\boldsymbol{x}^n$. We can assume $\boldsymbol{f}_{\boldsymbol{x}^n}^\intercal \mathbf{1} = 1$, making $\boldsymbol{f}_{\boldsymbol{x}^n}$ a distribution over n-grams. Intuitively, the effect of some n-grams like those including function words can be downplayed by giving them lower weights, e.g., using Inverse Document Frequency (IDF).

Word Mover's Distance (WMD) (Kusner et al., 2015), a special case of Earth Mover's Distance (Rubner et al., 2000), measures semantic distance between texts by aligning semantically similar words and finding the amount of flow traveling between these words. It was shown useful for text classification and textual similarity tasks (Kusner et al., 2015). Here, we formulate a generalization operating on n-grams. Let $\boldsymbol{x}$ and $\boldsymbol{y}$ be two sentences viewed as sequences of n-grams: $\boldsymbol{x}^n$ and $\boldsymbol{y}^n$. If we have a distance metric d between n-grams, then we can define the *transportation cost* matrix $\boldsymbol{C}$ such that $\boldsymbol{C}_{ij} = d(\mathrm{x}_i^n, \mathrm{y}_j^n)$ is the distance between the i-th n-gram of $\boldsymbol{x}$ and the j-th n-gram of $\boldsymbol{y}$. The WMD between the two sequences of n-grams $\boldsymbol{x}^n$ and $\boldsymbol{y}^n$ with associated n-gram weights $\boldsymbol{f}_{\boldsymbol{x}^n}$ and $\boldsymbol{f}_{\boldsymbol{y}^n}$ is then given by:

$$\mathrm{WMD}(\boldsymbol{x}^n, \boldsymbol{y}^n) := \min_{\boldsymbol{F} \in \mathbb{R}^{|\boldsymbol{x}^n| \times |\boldsymbol{y}^n|}} \langle \boldsymbol{C}, \boldsymbol{F} \rangle,$$
$$\text{s.t. } \boldsymbol{F}\mathbf{1} = \boldsymbol{f}_{\boldsymbol{x}^n}, \quad \boldsymbol{F}^\intercal \mathbf{1} = \boldsymbol{f}_{\boldsymbol{y}^n}.$$

where $\boldsymbol{F}$ is the *transportation flow* matrix with $\boldsymbol{F}_{ij}$ denoting the amount of flow traveling from the i-th n-gram x_i^n in $\boldsymbol{x}^n$ to the j-th n-gram y_j^n in $\boldsymbol{y}^n$. Here, $\langle \boldsymbol{C}, \boldsymbol{F} \rangle$ denotes the sum of all matrix entries of the matrix $\boldsymbol{C} \odot \boldsymbol{F}$, where $\odot$ denotes element-wise multiplication. Then $\mathrm{WMD}(\boldsymbol{x}^n, \boldsymbol{y}^n)$ is the minimal transportation cost between $\boldsymbol{x}^n$ and $\boldsymbol{y}^n$ where n-grams are weighted by $\boldsymbol{f}_{\boldsymbol{x}^n}$ and $\boldsymbol{f}_{\boldsymbol{y}^n}$.

In practice, we compute the Euclidean distance between the embedding representations of n-grams: $d(\mathrm{x}_i^n, \mathrm{y}_j^n) = ||E(\mathrm{x}_i^n) - E(\mathrm{y}_j^n)||_2$ where E is the embedding function which maps an n-gram to its vector representation. Usually, *static* word embeddings like word2vec are used to compute E but these cannot capture word order or compositionality. Alternatively, we investigate contextualized embeddings like ELMo and BERT because they encode information about the whole sentence into each word vector.

We compute the n-gram embeddings as the weighted sum over its word embeddings. Formally, if $\boldsymbol{x}_i^n = (\mathrm{x}_i, \ldots, \mathrm{x}_{i+n-1})$ is the i-th n-gram from sentence $\boldsymbol{x}$, its embedding is given by:

$$E(\boldsymbol{x}_i^n) = \sum_{k=i}^{i+n-1} \mathrm{idf}(\mathrm{x}_k) \cdot E(\mathrm{x}_k) \qquad (1)$$

where $\mathrm{idf}(\mathrm{x}_k)$ is the IDF of word x_k computed from all sentences in the corpus and $E(\mathrm{x}_k)$ is its word vector. Furthermore, the weight associated to the n-gram $\boldsymbol{x}_i^n$ is given by:

$$\boldsymbol{f}_{\boldsymbol{x}_i^n} = \frac{1}{Z} \sum_{k=i}^{i+n-1} \mathrm{idf}(\mathrm{x}_k) \qquad (2)$$

where Z is a normalizing constant s.t. $\boldsymbol{f}_{\boldsymbol{x}^n}^\top \mathbf{1} = 1$,

In the limiting case where n is larger than the sentence's size, $\boldsymbol{x}^n$ contains only one n-gram: the whole sentence. Then $\mathrm{WMD}(\boldsymbol{x}^n, \boldsymbol{y}^n)$ reduces to computing the distance between the two sentence embeddings, namely Sentence Mover's Distance (SMD), denoted as:

$$\mathrm{SMD}(\boldsymbol{x}^n, \boldsymbol{y}^n) := ||E(\boldsymbol{x}_1^{l_x}) - E(\boldsymbol{y}_1^{l_y})||$$

where l_x and l_y are the size of sentences.

Hard and Soft Alignments In contemporaneous work, BERTScore (Zhang et al., 2019) also models the semantic distance between system and reference texts for evaluating text generation systems. As shown in Figure 1, BERTScore (precision/recall) can be intuitively viewed as hard alignments (one-to-one) for words in a sentence pair, where each word in one sequence travels to the most semantically similar word in the other sequence. In contrast, MoverScore goes beyond BERTScore as it relies on soft alignments (many-to-one) and allows to map semantically related words in one sequence to the respective word in the other sequence by solving a constrained optimization problem: finding the minimum effort to transform between two texts.

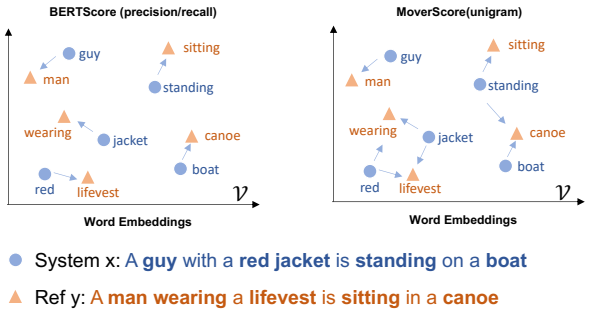

Figure 1: An illustration of MoverScore and BERTScore.

The formulation of Word Mover's Distance provides an important possibility to bias the metric towards precision or recall by using an asymmetric transportation cost matrix, which bridges a gap between MoverScore and BERTScore:

Proposition 1 *BERTScore (precision/recall) can be represented as a (non-optimized) Mover Distance $\langle \boldsymbol{C}, \boldsymbol{F} \rangle$, where $\boldsymbol{C}$ is a transportation cost matrix based on BERT and $\boldsymbol{F}$ is a uniform transportation flow matrix.*[2]

3.2 Contextualized Representations

The task formulation naturally lends itself to deep contextualized representations for inducing word vectors $E(\mathrm{x}_i)$. Despite the recent success of multi-layer attentive neural architectures (Devlin et al., 2018; Peters et al., 2018), consolidating layer-wise information remains an open problem as different layers capture information at disparate scales and task-specific layer selection methods may be limited (Liu et al., 2018, 2019). Tenney et al. (2019) found that a scalar mix of output layers trained from task-dependent supervisions would be effective in a deep transformer-based model. Instead, we investigate aggregation functions to consolidate layer-wise information, forming stationary representations of words without supervision.

Consider a sentence $\boldsymbol{x}$ passed through contextualized encoders such as ELMo and BERT with L layers. Each layer of the encoders produces a vec-

[2] See the proof in the appendix.

tor representation for each word x_i in $\boldsymbol{x}$. We denote by $\boldsymbol{z}_{i,l} \in \mathbb{R}^d$ the representation given by layer l, a d-dimensional vector. Overall, x_i receives L different vectors $(\boldsymbol{z}_{i,1}, \ldots, \boldsymbol{z}_{i,L})$. An aggregation ϕ maps these L vectors to one final vector:

$$E(x_i) = \phi(\boldsymbol{z}_{i,1}, \ldots, \boldsymbol{z}_{i,L}) \quad (3)$$

where $E(x_i)$ is the aggregated representation of the word x_i.

We study two alternatives for ϕ: (i) the concatenation of power means (Rücklé et al., 2018) as a generalized pooling mechanism, and (ii) a routing mechanism for aggregation (Zhao et al., 2018, 2019). We relegate the routing method to appendix, as it does not yield better results than power means.

Power Means Power means is an effective generalization of pooling techniques for aggregating information. It computes a non-linear average of a set of values with an exponent p (Eq. (4)). Following Rücklé et al. (2018), we exploit power means to aggregate vector representations $(\boldsymbol{z}_{i,l})_{l=1}^{L}$ pertaining to the i-th word from all layers of a deep neural architecture. Let $p \in \mathbb{R} \cup \{\pm\infty\}$, the p-mean of $(\boldsymbol{z}_{i,1}, \ldots, \boldsymbol{z}_{i,L})$ is:

$$\boldsymbol{h}_i^{(p)} = \left(\frac{\boldsymbol{z}_{i,1}^p + \cdots + \boldsymbol{z}_{i,L}^p}{L} \right)^{1/p} \in \mathbb{R}^d \quad (4)$$

where exponentiation is applied elementwise. This generalized form can induce common named means such as arithmetic mean ($p = 1$) and geometric mean ($p = 0$). In extreme cases, a power mean reduces to the minimum value of the set when $p = -\infty$, and the maximum value when $p = +\infty$. The concatenation of p-mean vectors we use in this paper is denoted by:

$$E(x_i) = \mathbf{h}_i^{(p_1)} \oplus \cdots \oplus \mathbf{h}_i^{(p_K)} \quad (5)$$

where $\oplus$ is vector concatenation; $\{p_1, \ldots, p_K\}$ are exponent values, and we use $K = 3$ with $p = 1, \pm\infty$ in this work.

3.3 Summary of MoverScore Variations

We investigate our MoverScore along four dimensions: (i) the granularity of embeddings, i.e., the size of n for n-grams, (ii) the choice of pretrained embedding mechanism, (iii) the fine-tuning task used for BERT[3] (iv) the aggregation technique (p-means or routing) when applicable.

[3]ELMo usually requires heavy layers on the top, which restricts the power of fine-tuning tasks for ELMo.

Granularity We used $n = 1$ and $n = 2$ as well as full sentences ($n =$ size of the sentence).

Embedding Mechanism We obtained word embeddings from three different methods: *static* embedding with word2vec as well as contextualized embedding with ELMo and BERT. If $n > 1$, n-gram embeddings are calculated by Eq. (1). Note that they represent sentence embeddings when $n =$ size of the sentence.

Fine-tuning Tasks Natural Language Inference (NLI) and paraphrasing pose high demands in understanding sentence meaning. This motivated us to fine-tune BERT representations on two NLI datasets, MultiNLI and QANLI, and one Paraphrase dataset, QQP—the largest datasets in GLUE (Wang et al., 2018). We fine-tune BERT on each of these, yielding different contextualized embeddings for our general evaluation metrics.

Aggregation For ELMo, we aggregate word representations given by all three ELMo layers, using p-means or routing (see the appendix). Word representations in BERT are aggregated from the last five layers, using p-means or routing since the representations in the initial layers are less suited for use in downstream tasks (Liu et al., 2019).

4 Empirical Evaluation

In this section, we measure the quality of different metrics on four tasks: *machine translation*, *text summarization*, *image captioning* and *dialogue generation*. Our major focus is to study the correlation between different metrics and human judgment. We employ two text encoders to embed n-grams: $\text{BERT}_{\text{base}}$, which uses a 12-layer transformer, and $\text{ELMO}_{\text{original}}$, which uses a 3-layer BiLSTM. We use Pearson's r and Spearman's ρ to measure the correlation. We consider two variants of MoverScore: *word mover* and *sentence mover*, described below.

Word Mover We denote our word mover notation containing four ingredients as: *WMD-Granularity+Embedding+Finetune+Aggregation*. For example, WMD-1+BERT+MNLI+PMEANS represents the semantic metric using word mover distance where unigram-based word embeddings fine-tuned on MNLI are aggregated by p-means.

Sentence Mover We denote our sentence mover notation with three ingredients as: *SMD+Embedding+Finetune+Aggregation*. For example, SMD+W2V represents the semantic

metric using sentence mover distance where two sentence embeddings are computed as the weighted sum over their word2vec embeddings by Eq. (1).

Baselines We select multiple strong baselines for each task for comparison: SentBLEU, METEOR++ (Guo et al., 2018), and a supervised metric RUSE for machine translation; ROUGE-1 and ROUGE-2 and a supervised metric S^3_{best} (Peyrard et al., 2017) for text summarization; BLEU and METEOR for dialogue response generation, CIDEr, SPICE, METEOR and a supervised metric LEIC (Cui et al., 2018) for image captioning. We also report BERTScore (Zhang et al., 2019) for all tasks (see §2). Due to the page limit, we only compare with the strongest baselines, the rest can be found in the appendix.

4.1 Machine Translation

Data We obtain the source language sentences, their system and reference translations from the WMT 2017 news translation shared task (Bojar et al., 2017). We consider 7 language pairs: from German (de), Chinese (zh), Czech (cs), Latvian (lv), Finnish (fi), Russian (ru), and Turkish (tr), resp. to English. Each language pair has approximately 3,000 sentences, and each sentence has one reference translation and multiple system translations generated by participating systems. For each system translation, at least 15 human assessments are independently rated for quality.

Results Table 1: In all language pairs, the best correlation is achieved by our word mover metrics that use a BERT pretrained on MNLI as the embedding generator and PMeans to aggregate the embeddings from different BERT layers, i.e., WMD-1/2+BERT+MNLI+PMeans. Note that our unsupervised word mover metrics even outperforms RUSE, a supervised metric. We also find that our word mover metrics outperforms the sentence mover. We conjecture that important information is lost in such a sentence representation while transforming the whole sequence of word vectors into one sentence embedding by Eq. (1).

4.2 Text Summarization

We use two summarization datasets from the Text Analysis Conference (TAC)[4]: TAC-2008 and TAC-2009, which contain 48 and 44 *clusters*, respectively. Each cluster includes 10 news articles (on the same topic), four reference summaries, and 57 (in TAC-2008) or 55 (in TAC-2009) system summaries generated by the participating systems. Each summary (either reference or system) has fewer than 100 words, and receives two human judgment scores: the *Pyramid* score (Nenkova and Passonneau, 2004) and the *Responsiveness* score. Pyramid measures how many important semantic content units in the reference summaries are covered by the system summary, while Responsiveness measures how well a summary responds to the overall quality combining both content and linguistic quality.

Results Tables 2: We observe that lexical metrics like ROUGE correlate above-moderate on TAC 2008 and 2009 datasets. In contrast, these metrics perform poorly on other tasks like Dialogue Generation (Novikova et al., 2017) and Image Captioning (Anderson et al., 2016). Apparently, strict matches on surface forms seems reasonable for *extractive* summarization datasets. However, we still see that our word mover metrics, i.e., WMD-1+BERT+MNLI+PMeans, perform better than or come close to even the supervised metric S^3_{best}.

4.3 Data-to-text Generation

We use two task-oriented dialogue datasets: BAGEL (Mairesse et al., 2010) and SFHOTEL (Wen et al., 2015), which contains 202 and 398 instances of Meaning Representation (MR). Each MR instance includes multiple references, and roughly two system utterances generated by different neural systems. Each system utterance receives three human judgment scores: *informativeness*, *naturalness* and *quality* score (Novikova et al., 2017). Informativeness measures how much information a system utterance provides with respect to an MR. Naturalness measures how likely a system utterance is generated by native speakers. Quality measures how well a system utterance captures fluency and grammar.

Results Tables 3: Interestingly, no metric produces an even moderate correlation with human judgments, including our own. We speculate that current contextualizers are poor at representing named entities like hotels and place names as well as numbers appearing in system and reference texts. However, best correlation is still achieved by our word mover metrics combining contextualized representations.

Table 2: Pearson r and Spearman ρ correlations with summary-level human judgments on TAC 2008 and 2009.

4.4 Image Captioning

We use a popular image captioning dataset: MS-COCO (Lin et al., 2014), which contains 5,000 images. Each image includes roughly five reference captions, and 12 system captions generated by the participating systems from 2015 COCO Captioning Challenge. For the system-level human correlation, each system receives five human judgment scores: M1, M2, M3, M4, M5 (Anderson et al., 2016). The M1 and M2 scores measure overall quality of the captions while M3, M4 and M5 scores measure correctness, detailedness and saliency of the captions. Following Cui et al. (2018), we compare the Pearson correlation with two system-level scores: M1 and M2, since we focus on studying metrics for the overall quality of the captions, leaving metrics understanding captions in different aspects (correctness, detailedness and saliency) to future work.

Results Table 4: Word mover metrics outperform all baselines except for the supervised metric LEIC, which uses more information by considering *both* images and texts.

4.5 Further Analysis

Hard and Soft Alignments BERTScore is the harmonic mean of BERTScore-Precision and BERTScore-Recall, where both two can be decomposed as a combination of "Hard Mover Distance" (HMD) and BERT (see Prop. 1).

We use the representations in the 9-th BERT layer for fair comparison of BERTScore and MoverScore and show results on the machine translation task in Table 5. MoverScore outperforms both asymmetric HMD factors, while if they are combined via harmonic mean, BERTScore is on par with MoverScore. We conjecture that BERT softens hard alignments of BERTScore as contextualized embeddings encode information about the whole sentence into each word vector. We also observe that WMD-BIGRAMS slightly outperforms WMD-UNIGRAMS on 3 out of 4 language pairs.

Table 5: Comparison on hard and soft alignments.

Distribution of Scores In Figure 2, we take a closer look at sentence-level correlation in MT. Results reveal that the lexical metric SENTBLEU can correctly assign lower scores to system translations of low quality, while it struggles in judging system translations of high quality by assigning them lower scores. Our finding agrees with the observations found in Chaganty et al. (2018); Novikova et al. (2017): lexical metrics correlate better with human judgments on texts of low quality than high quality. Peyrard (2019b) further show that lexical metrics cannot be trusted because

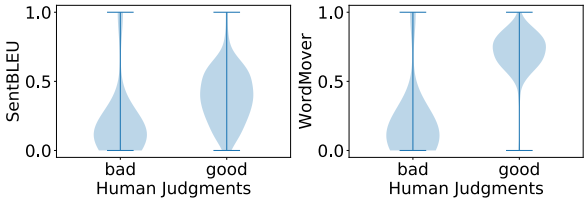

Figure 2: Score distribution in German-to-English pair.

they strongly disagree on high-scoring system outputs. Importantly, we observe that our word mover metric combining BERT can clearly distinguish texts of two polar qualities.

Correlation Analysis In Figure 3, we observe existing metrics for MT evaluation attaining medium correlations (0.4-0.5) with human judgments but high inter-correlations between themselves. In contrast, our metrics can attain high correlations (0.6-0.7) with human judgments, performing robust across different language pairs. We believe that our improvements come from clearly distinguishing translations that fall on two extremes.

Impact of Fine-tuning Tasks Figure 4 com-

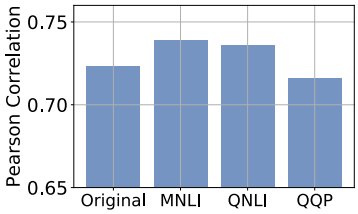

Figure 4: Correlation is averaged over 7 language pairs.

pares Pearson correlations with our word mover metrics combining BERT fine-tuned on three different tasks. We observe that fine-tuning on closely related tasks improves correlations, especially fine-tuning on MNLI leads to an impressive improvement by 1.8 points on average.

4.6 Discussions

We showed that our metric combining contextualized embeddings and Earth Mover's Distance outperforms strong unsupervised metrics on 3 out of 4 tasks, i.e., METEOR++ on machine translation by 5.7 points, SPICE on image captioning by 3.0 points, and METEOR on dialogue response generation by 2.2 points. The best correlation we achieved is combining contextualized word embeddings and WMD, which even rivals or exceeds SOTA task-dependent *supervised* metrics across different tasks. Especially in machine translation, our word mover metric pushes correlations in machine translation to 74.3 on average (5.8 points over the SOTA supervised metric and 2.4 points over contemporaneous BERTScore). The major improvements come from contextualized BERT embeddings rather than word2vec and ELMo, and from fine-tuning BERT on large NLI datasets. However, we also observed that soft alignments (MoverScore) marginally outperforms hard alignments (BERTScore). Regarding the effect of n-grams in word mover metrics, unigrams slightly outperforms bigrams on average. For the effect of aggregation functions, we suggested effective techniques for layer-wise consolidations, namely p-means and routing, both of which are close to the performance of the best layer and on par with each other (see the appendix).

5 Conclusion

We investigated new unsupervised evaluation metrics for text generation systems combining contextualized embeddings with Earth Mover's Distance. We experimented with two variants of our metric, sentence mover and word mover. The latter has demonstrated strong generalization ability across four text generation tasks, oftentimes even outperforming supervised metrics. Our metric provides a promising direction towards a holistic metric for text generation and a direction towards more 'human-like' (Eger et al., 2019) evaluation of text generation systems.

In future work, we plan to avoid the need for costly human references in the evaluation of text generation systems, and instead base evaluation scores on source texts and system predictions only, which would allow for 'next-level', unsupervised (in a double sense) and unlimited evaluation (Louis and Nenkova, 2013; Böhm et al., 2019).

Acknowledgments

We thank the anonymous reviewers for their comments, which greatly improved the final version of the paper. This work has been supported by the German Research Foundation as part of the Research Training Group Adaptive Preparation of Information from Heterogeneous Sources (AIPHES) at the Technische Universität Darmstadt under grant No. GRK 1994/1. A Supplemental Material

A.1 Proof of Prop. 1

In this section, we prove Prop. 1 in the paper about viewing BERTScore (precision/recall) as a (non-optimized) Mover Distance.

As a reminder, the WMD formulation is:

$$\text{WMD}(\boldsymbol{x}^n, \boldsymbol{y}^n) := \min_{\boldsymbol{F} \in \mathbb{R}^{|\boldsymbol{x}^n| \times |\boldsymbol{y}^n|}} \sum_{i,j} \boldsymbol{C}_{ij} \cdot \boldsymbol{F}_{ij}$$
$$\text{s.t. } \mathbf{1}^\intercal \boldsymbol{F}^\intercal \mathbf{1} = 1, \quad \mathbf{1}^\intercal \boldsymbol{F} \mathbf{1} = 1.$$

where $\boldsymbol{F}^\intercal \mathbf{1} = \boldsymbol{f}_x^n$ and $\boldsymbol{F}\mathbf{1} = \boldsymbol{f}_y^n$. Here, $\boldsymbol{f}_x^n$ and $\boldsymbol{f}_y^n$ denote vectors of weights for each n-gram of $\boldsymbol{x}^n$ and $\boldsymbol{y}^n$.

BERTScore is defined as:

$$R_{\text{BERT}} = \frac{\sum_{y_i^1 \in \boldsymbol{y}^1} \text{idf}(y_i^1) \max_{x_j^1 \in \boldsymbol{x}^1} E(x_j^1)^\intercal E(y_i^1)}{\sum_{y_i^1 \in \boldsymbol{y}^1} \text{idf}(y_i^1)}$$
$$P_{\text{BERT}} = \frac{\sum_{x_j^1 \in \boldsymbol{x}^1} \text{idf}(x_j^1) \max_{y_i^1 \in \boldsymbol{y}^1} E(y_i^1)^\intercal E(x_j^1)}{\sum_{x_j^1 \in \boldsymbol{x}^1} \text{idf}(x_j^1)}$$
$$F_{\text{BERT}} = 2\frac{P_{\text{BERT}} \cdot R_{\text{BERT}}}{P_{\text{BERT}} + R_{\text{BERT}}} \quad .$$

Then, R_{BERT} can be formulated in a "quasi" WMD form:

$$R_{\text{BERT}}(\boldsymbol{x}^1, \boldsymbol{y}^1) := \sum_{i,j} \boldsymbol{C}_{ij} \cdot \boldsymbol{F}_{ij}$$
$$\boldsymbol{F}_{ij} = \begin{cases} \frac{1}{M} & \text{if } x_j = \arg\max_{\hat{x}_j^1 \in \boldsymbol{x}^1} E(y_i^1)^\intercal E(\hat{x}_j^1) \\ 0 & \text{otherwise} \end{cases}$$
$$\boldsymbol{C}_{ij} = \begin{cases} \frac{M}{Z} \text{idf}(y_i^1) E(x_j^1)^\intercal E(y_i^1) & \text{if } x_j = \arg\max_{\hat{x}_j^1 \in \boldsymbol{x}^1} E(y_i^1)^\intercal E(\hat{x}_j^1) \\ 0 & \text{otherwise} \end{cases}$$

where $Z = \sum_{y_i^1 \in \boldsymbol{y}^1} \text{idf}(y_i^1)$ and M is the size of n-grams in $\boldsymbol{x}^1$. Similarly, we can have P_{BERT} in a quasi WMD form (omitted). Then, F_{BERT} can be formulated as harmonic-mean of two WMD forms of P_{BERT} and R_{BERT}.

A.2 Routing

In this section, we study the aggregation function ϕ with a routing scheme, which has achieved good results in other NLP tasks (Zhao et al., 2018, 2019). Specifically, we introduce a nonparametric clustering with Kernel Density Estimation (KDE) for routing since KDE bridges a family of kernel functions with underlying empirical distributions, which often leads to computational efficiency (Zhang et al., 2018), defined as:

$$\min_{\boldsymbol{v}, \gamma} f(\boldsymbol{z}) = \sum_{i=1}^{L} \sum_{j=1}^{T} \gamma_{ij} k(d(\boldsymbol{v}_j - \boldsymbol{z}_{i,j}))$$
$$\textit{s.t.} \quad \forall i, j : \gamma_{ij} > 0, \sum_{j=1}^{L} \gamma_{ij} = 1.$$

where $d(\cdot)$ is a distance function, γ_{ij} denotes the underlying closeness between the aggregated vector $\boldsymbol{v}_j$ and vector $\boldsymbol{z}_i$ in the i-th layer, and k is a kernel function. Some instantiations of $k(\cdot)$ (Wand and Jones, 1994) are:

$$Gaussian: k(x) \triangleq \exp\left(-\frac{x}{2}\right), \quad Epanechnikov: k(x) \triangleq \begin{cases} 1-x & x \in [0,1) \\ 0 & x \geq 1. \end{cases}$$

One typical solution for KDE clustering to minimize $f(\boldsymbol{z})$ is taking Mean Shift (Comaniciu and Meer, 2002), defined as:

$$\nabla f(\boldsymbol{z}) = \sum_{i,j} \gamma_{ij} k'(d(\boldsymbol{v}_j, \boldsymbol{z}_{i,j})) \frac{\partial d(\boldsymbol{v}_j, \boldsymbol{z}_{i,j})}{\partial \boldsymbol{v}}$$

Firstly, $\boldsymbol{v}_j^{\tau+1}$ can be updated while $\gamma_{ij}^{\tau+1}$ is fixed:

$$\boldsymbol{v}_j^{\tau+1} = \frac{\sum_i \gamma_{ij}^{\tau} k'(d(\boldsymbol{v}_j^{\tau}, \boldsymbol{z}_{i,j}))\boldsymbol{z}_{i,j}}{\sum_{i,j} k'(d(\boldsymbol{v}_j^{\tau}, \boldsymbol{z}_{i,j}))}$$

Intuitively, $\boldsymbol{v}_j$ can be explained as a final aggregated vector from L contextualized layers. Then, we adopt SGD to update $\gamma_{ij}^{\tau+1}$:

$$\gamma_{ij}^{\tau+1} = \gamma_{ij}^{\tau} + \alpha \cdot k(d(\boldsymbol{v}_j^{\tau}, \boldsymbol{z}_{i,j}))$$

where α is a hyperparameter to control step size. The routing process is summarized in Algorithm 1.

Algorithm 1 Aggregation by Routing

procedure ROUTING($\boldsymbol{z}_{ij}, \ell$)
Initialize $\forall i, j : \gamma_{ij} = 0$
while true **do**
  foreach representation i and j in layer ℓ and $\ell+1$ **do** $\gamma_{ij} \leftarrow softmax(\gamma_{ij})$
  foreach representation j in layer $\ell+1$ **do**
    $\boldsymbol{v}_j \leftarrow \sum_i \gamma_{ij} k'(\boldsymbol{v}_j, \boldsymbol{z}_i)\boldsymbol{z}_i / \sum_i k'(\boldsymbol{v}_i, \boldsymbol{z}_i)$
  foreach representation i and j in layer ℓ and $\ell+1$ **do** $\gamma_{ij} \leftarrow \gamma_{ij} + \alpha \cdot k(\boldsymbol{v}_j, \boldsymbol{z}_i)$
  loss $\leftarrow \log(\sum_{\mathrm{i,j}} \gamma_{\mathrm{ij}} \mathrm{k}(\boldsymbol{v}_{\mathrm{j}}, \boldsymbol{z}_{\mathrm{i}}))$
  if $|\text{loss} - \text{preloss}| < \epsilon$ **then**
    break
  else
    preloss $\leftarrow$ loss
return v_j

Best Layer and Layer-wise Consolidation Table 6 compares our word mover based metric combining BERT representations on different layers with stronger BERT representations consolidated from these layers (using p-means and routing). We often see that which layer has best performance is task-dependent, and our word mover based metrics (WMD) with p-means or routing schema come close to the oracle performance obtained from the best layers.

Experiments Table 7, 8 and 9 show correlations between metrics (all baseline metrics and word mover based metrics) and human judgments on machine translation, text summarization and dialogue response generation, respectively. We find that word mover based metrics combining BERT fine-tuned on MNLI have highest correlations with humans, outperforming all of the unsupervised metrics and even supervised metrics like RUSE and S^3_{full}. Routing and p-means perform roughly equally well.

Abstract

Many text generation tasks naturally contain two steps: content selection and surface realization. Current neural encoder-decoder models conflate both steps into a black-box architecture. As a result, the content to be described in the text cannot be explicitly controlled. This paper tackles this problem by decoupling content selection from the decoder. The decoupled content selection is human interpretable, whose value can be manually manipulated to control the content of generated text. The model can be trained end-to-end without human annotations by maximizing a lower bound of the marginal likelihood. We further propose an effective way to trade-off between performance and controllability with a single adjustable hyperparameter. In both data-to-text and headline generation tasks, our model achieves promising results, paving the way for controllable content selection in text generation.[1]

1 Introduction

Many text generation tasks, e.g., data-to-text, summarization and image captioning, can be naturally divided into two steps: content selection and surface realization. The generations are supposed to have two levels of diversity: (1) content-level diversity reflecting multiple possibilities of content selection (what to say) and (2) surface-level diversity reflecting the linguistic variations of verbalizing the selected contents (how to say) (Reiter and Dale, 2000; Nema et al., 2017). Recent neural network models handle these tasks with the encoder-decoder (Enc-Dec) framework (Sutskever et al., 2014; Bahdanau et al., 2015), which simultaneously performs selecting and verbalizing in a black-box way. Therefore, both levels of diversity are entangled within the generation. This entanglement, however, sacrifices the controllability and interpretability, making it diffifcult to specify the content to be conveyed in the generated text (Qin et al., 2018; Wiseman et al., 2018).

Table 1: Headline generation examples from our model. We can generate text describing various contents by sampling different content selections. The selected source word and its corresponding realizations in the text are highlighted with the same color.

With this in mind, this paper proposes decoupling content selection from the Enc-Dec framework to allow finer-grained control over the generation. Table 1 shows an example. We can easily modify the content selection to generate text with various focuses, or sample multiple paraphrases by fixing the content selection.

Though there has been much work dealing with content selection for the Enc-Dec, none of them is able to address the above concerns properly. Current methods can be categorized into the following three classes and have different limits:

1. **Bottom-up**: Train a separate content selector to constrain the attention to source tokens (Gehrmann et al., 2018), but the separate training of selector/generator might lead to

*Work mostly done while at RIKEN AIP. Correspondence to xshen@mpi-inf.mpg.de

discrepancy when integrating them together.

2. **Soft-select**: Learn a soft mask to filter useless information (Mei et al., 2016; Zhou et al., 2017). However, the mask is *deterministic* without any probabilistic variations, making it hard to model the content-level diversity.

3. **Reinforce-select**: Train the selector with reinforcement learning (Chen and Bansal, 2018), which has high training variance and low diversity on content selection.

In this paper, we treat the content selection as latent variables and train with amortized variational inference (Kingma and Welling, 2014; Mnih and Gregor, 2014). This provides a lower training variance than Reinforce-select. The selector and generator are co-trained within the same objective, the generations are thus more faithful to the selected contents than Bottom-up methods. Our model is task-agnostic, end-to-end trainable and can be seamlessly inserted into any encoder-decoder architecture. On both the data-to-text and headline generation task, we show our model outperforms others regarding content-level diversity and controllability while maintaining comparable performance. The performance/controllability trade-off can be effectively adjusted by adjusting a single hyperparameter in the training stage, which constrains an upper bound of the conditional mutual information (CMI) between the selector and generated text (Alemi et al., 2018; Zhao et al., 2018). A higher CMI leads to stronger controllability with a bit more risk of text disfluency.

In summary, our contributions are **(1)** systematically studying the problem of controllable content selection for Enc-Dec text generation, **(2)** proposing a task-agnostic training framework achieving promising results and **(3)** introducing an effective way to achieve the trade-off between performance and controllability.

2 Background and Notation

Let X, Y denote a source-target pair. X is a sequence of $x_1, x_2, \ldots, x_n$ and can be either some structured data or unstructured text/image depending on the task. Y corresponds to $y_1, y_2, \ldots, y_m$ which is a text description of X. The goal of text generation is to learn a distribution $p(Y|X)$ to automatically generate proper text.

The Enc-Dec architecture handles this task with an encode-attend-decode process (Bahdanau et al., 2015; Xu et al., 2015). The encoder first encodes each x_i into a vector h_i. At each time step, the decoder pays attentions to some source embeddings and outputs the probability of the next token by $p(y_t|y_{1:t-1}, C_t)$. C_t is a weighted average of source embeddings:

$$C_t = \sum_i \alpha_{t,i} h_i$$
$$\alpha_{t,i} = \frac{e^{f(h_i, d_t)}}{\sum_j e^{f(h_j, d_t)}} \quad (1)$$

d_t is the hidden state of the decoder at time step t. f is a score function to compute the similarity between h_i and d_t (Luong et al., 2015).

3 Content Selection

Our goal is to decouple the content selection from the decoder by introducing an extra content selector. We hope the content-level diversity can be fully captured by the content selector for a more interpretable and controllable generation process. Following Gehrmann et al. (2018); Yu et al. (2018), we define content selection as a sequence labeling task. Let $\beta_1, \beta_2, \ldots, \beta_n$ denote a sequence of binary selection masks. $\beta_i = 1$ if h_i is selected and 0 otherwise. β_i is assumed to be independent from each other and is sampled from a bernoulli distribution $\mathbf{B}(\gamma_i)$[2]. γ_i is the bernoulli parameter, which we estimate using a two-layer feedforward network on top of the source encoder. Text are generated by first sampling β from $\mathbf{B}(\gamma)$ to decide which content to cover, then decode with the conditional distribution $p_\theta(Y|X, \beta)$. The text is expected to faithfully convey all selected contents and drop unselected ones. Fig. 1 depicts this generation process. Note that the selection is based on the token-level *context-aware* embeddings h and will maintain information from the surrounding contexts. It encourages the decoder to stay faithful to the original information instead of simply fabricating random sentences by connecting the selected tokens. For each source-target pair, the ground-truth selection mask is unknown, so training is challenging. In the following session, we discuss several training possibilities and introduce the proposed model in detail.

[2]Devlin et al. (2019) have shown that excellent performance can be obtained by assuming such conditionally independence given a sufficiently expressive representation of x, though modelling a richer inter-label dependency is for sure beneficial (Lei et al., 2016; Nallapati et al., 2017).

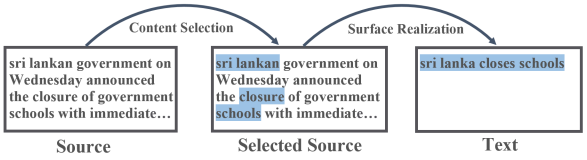

Figure 1: Model will select contents based on $\mathbf{B}(\gamma)$, then decode with $p_\theta(Y|X,\beta)$. Source-text pairs are available for training, but the ground-truth content selection for each pair is unknown.

3.1 Bottom-up

The most intuitive way is training the content selector to target some heuristically extracted contents. For example, we can train the selector to select overlapped words between the source and target (Gehrmann et al., 2018), sentences with higher tf-idf scores (Li et al., 2018) or identified image objects that appear in the caption (Wang et al., 2017). A standard encoder-decoder model is independently trained. In the testing stage, the prediction of the content selector is used to hard-mask the attention vector to guide the text generation in a bottom-up way. Though easy to train, Bottom-up generation has the following two problems: **(1)** The heuristically extracted contents might be coarse and cannot reflect the variety of human languages and **(2)** The selector and decoder are independently trained towards different objectives thus might not adapt to each other well.

***β* as Latent Variable:** Another way is to treat β as a latent variable and co-train selector and generator by maximizing the marginal data likelihood. By doing so, the selector has the potential to automatically explore optimal selecting strategies best fit for the corresponding generator component.

With this in mind. We design $p_\theta(Y|X,\beta)$ by changing the original decoder in the following way: (1) We initialize hidden states of the decoder from a mean pooling over selected contents to inform the decoder which contents to cover and (2) Unselected contents will be prohibited from being attended to:

$$d_0 = \text{MLP}\left(\frac{1}{n}\left(\sum_i^n \beta_i h_i\right)\right)$$
$$\alpha_{t,i} = \frac{e^{f(h_i,d_t)}\beta_i}{\sum_j e^{f(h_j,d_t)}\beta_j} \quad (2)$$

d_0 is the initial decoder hidden state and MLP denotes multi-layer-perceptron.

Since computing the exact marginal likelihood $\log \mathbb{E}_{\beta\sim\mathbf{B}(\gamma)} p_\theta(Y|X,\beta)$ requires enumerating over all possible combinations of β (complexity $\mathbf{O}(2^n)$), we need some way to efficiently estimate the likelihood.

3.2 Soft-Select

Soft-select falls back on a *deterministic* network to output the likelihood function's first-order Taylor series approximation expanded at $\mathbb{E}_{\beta\sim\mathbf{B}(\gamma)}\beta$:

$$\begin{aligned}&\log \mathbb{E}_{\beta\sim\mathbf{B}(\gamma)} p_\theta(Y|X,\beta)\\ \approx &\log[p_\theta(Y|X,\gamma) + \mathbb{E}_{\beta\sim\mathbf{B}(\gamma)}(\beta-\gamma)p'_\theta(Y|X,\gamma)]\\ = &\log p_\theta(Y|X,\gamma)\end{aligned}$$

By moving the expectation into the decoding function, we can deterministically compute the likelihood by setting $\beta_i = \gamma_i$, reducing complexity to $\mathbf{O}(1)$. Each attention weight will first be "soft-masked" by γ before being passed to the decoder. soft-select is fully differentiable and can be easily trained by gradient descent. However, this soft-approximation is normally inaccurate, especially when $\mathbf{B}(\gamma)$ has a high entropy, which is common in one-to-many text generation tasks. The gap between $\log \mathbb{E}_{\beta\sim\mathbf{B}(\gamma)} p_\theta(Y|X,\beta)$ and $\log p_\theta(Y|X,\mathbb{E}_{\beta\sim\mathbf{B}(\gamma)})$ will be large (Ma et al., 2017; Deng et al., 2018). In practice, this would lead to unrealistic generations when sampling β from the deterministically trained distribution.

3.3 Reinforce-Select

Reinforce-select (RS) (Ling and Rush, 2017; Chen and Bansal, 2018) utilizes reinforcement learning to approximate the marginal likelihood. Specifically, it is trained to maximize a lower bound of the likelihood by applying the Jensen inequalily:

$$\log \mathbb{E}_{\beta\sim\mathbf{B}(\gamma)} p_\theta(Y|X,\beta) \geq \mathbb{E}_{\beta\sim\mathbf{B}(\gamma)} \log p_\theta(Y|X,\beta)$$

The gradient to γ is approximated with Monte-Carlo sampling by applying the REINFORCE algorithm (Williams, 1992; Glynn, 1990). To speed up convergence, we pre-train the selector by some distant supervision, which is a common practice in reinforcement learning. REINFORCE is unbiased but has a high variance. Many research have proposed sophisticated techniques for variance reduction (Mnih and Gregor, 2014; Tucker et al., 2017; Grathwohl et al., 2018). In text generation, the high-variance problem is aggravated because there exists multiple valid selections. Accurately estimating the likelihood becomes difficult. Another

issue is its tendency to avoid stochasticity (Raiko et al., 2015), which we will show in Sec 5.2 that it results in low content-level diversity.

3.4 Variational Reinforce-Select

We propose Variational Reinforce-Select (VRS) which applies variational inference (Kingma and Welling, 2014) for variance reduction. Instead of directly integrating over $\mathbf{B}(\gamma)$, it imposes a proposal distribution q_ϕ for importance sampling. The marginal likelihood is lower bounded by:

$$\begin{aligned}
&\log \mathbb{E}_{\beta\sim\mathbf{B}(\gamma)} p_\theta(Y|X,\beta) \\
&= \log \mathbb{E}_{\beta\sim q_\phi} \frac{p_\theta(Y,\beta|X)}{q_\phi(\beta)} \\
&\geq \mathbb{E}_{\beta\sim q_\phi} \log \frac{p_\theta(Y,\beta|X)}{q_\phi(\beta)} \\
&= \mathbb{E}_{\beta\sim q_\phi} \log p_\theta(Y|X,\beta) - KL(q_\phi||\mathbf{B}(\gamma))
\end{aligned} \tag{3}$$

By choosing a proper q_ϕ, the bound will be improved and the variance can be largely reduced compared with REINFORCE. If q_ϕ equals the posterior distribution $p_\theta(\beta|X,Y)$, the bound is tight and the variance would be zero (Mnih and Rezende, 2016). We define $q_\phi(\beta|X,Y)$ as a mean-field distribution parameterized by a set of global parameters ϕ to approach the true posterior distribution. ϕ, θ and γ are simultaneously trained by minimizing the last tine of Eq. 3. $q_\phi(\beta|X,Y)$ also allows us to further perform posterior inference: Given an arbitrary text Y for a source X, we can infer which source contents are included in Y (An example is given in Appendix C).

In Eq.3, the KL divergence term can be computed analytically. As for the independence assumption, it can be summed over each individual β_i. The likelihood term is differentiable to θ but not to ϕ, we estimate the gradient to ϕ in Eq 3 by applying the REINFORCE estimator:

$$\nabla_\phi \mathbb{E}_{\beta\sim q_\phi} \log p_\theta(Y|X,\beta) =$$
$$\mathbb{E}_{\beta\sim q_\phi} \nabla_\phi \log q_\phi(\beta|X,Y)(\log p_\theta(Y|X,\beta) - B)$$

B is the control variate (Williams, 1992). The optimal B would be (Weaver and Tao, 2001):

$$B^* = \mathbb{E}_{\beta\sim q_\phi} \log p_\theta(Y|X,\beta)$$

which we set as a soft-select approximation:

$$B = \log p_\theta(Y|X, \mathbb{E}_{\beta\sim q_\phi}\beta)$$

We estimate Eq. 3.4 with a single sample from q_ϕ for efficiency. Though multiple-sample could potentially further tighten the bound and reduce the variance (Burda et al., 2016; Lawson et al., 2018; Tucker et al., 2019), it brings significant computational overhead, especially in text generation tasks where the whole sentence needs to be decoded.

3.5 Degree of Controllability

In practice, when treating content selection as latent variables, the model tends to end up with a trivial solution of always selecting all source tokens (Shen et al., 2018a; Ke et al., 2018). This behavior is understandable since Eq. 2 strictly masks unselected tokens. Wrongly unselecting one token will largely deteriorate the likelihood. Under the maximum likelihood (MLE) objective, this high risk pushes the selector to take a conservative strategy of always keeping all tokens, then the whole model degenerates to the standard Enc-Dec and the selection mask loses effects on the generation. Usually people apply a penalty term to the selecting ratio when optimizing the likelihood:

$$\mathcal{L} + \lambda\big|(\bar{\gamma} - \alpha)\big| \tag{4}$$

$\mathcal{L}$ is the MLE loss function, $\bar{\gamma}$ is the mean of γ and α is the target selecting ratio. This forces the selector to select the most important α tokens for each source input instead of keeping all of them.

In our VRS model, we can easily adjust the degree of controllability by limiting an upper bound of the conditional mutual information (CMI) $I(\beta, Y|X)$ (Zhao et al., 2018). Specifically, we can change our objective into:

$$\begin{aligned}
&\max_{\phi,\theta,\gamma} \mathbb{E}_{\beta\sim q_\phi} \log p_\theta(Y|X,\beta) \\
&\quad -\lambda\big|KL(q_\phi||\mathbf{B}(\gamma)) - \epsilon)\big|
\end{aligned} \tag{5}$$

λ is a fixed lagrangian multiplier. Eq. 5 can be proved equal to maximum likelihood with the constraint $I(\beta, Y|X) = \epsilon$ given proper λ (Alemi et al., 2018). A higher ϵ indicates β has more influences to Y (higher controllability) while always safely selecting all tokens will lead $I(\beta, Y|X) = 0$.[3] It is preferred over Eq. 4 because (a) CMI directly considers the dependency between the selection and *multiple*-possible text while limiting the ratio aims at finding the *single* most salient parts for each source. (b) Unlike CMI, limiting the ratio is coarse. It considers only the total selected size and ignores its internal distribution.

[3] We also tried adding a coverage constraint to ensure the decoder covers all the selected tokens (Wen et al., 2015; Wang et al., 2019), but we find it brings no tangible help since a higher CMI can already discourage including redundant tokens into the selection.

Algorithm 1 Variational Reinforce-Select (VRS)

Parameters: θ, ϕ, γ
$pretrain \leftarrow$ TRUE
repeat
  Sample X,Y from the corpus;
  Encode X into $(h_1, h_2, \ldots, h_n)$;
  if $pretrain$ **then**
    Update ϕ with distant supervision;
    Update θ, γ by $\nabla_{\theta,\gamma}$Eq. 3;
  else
    Update θ, γ, ϕ by $\nabla_{\theta,\gamma,\phi}$Eq. 5;
  end if
  $pretrain \leftarrow$ FALSE if Eq. 3 degrades
until convergence and $pretrain$ is False

In practice, we can set ϵ to adjust the degree of controllability we want. Later we will show it leads to a trade-off with performance. The final algorithm is detailed in Algorithm 1. To keep fairness, we trian RS and VRS with the same control variate and pre-training strategy.[4]

4 Related Work

Most content selection models train the selector with heuristic rules (Hsu et al., 2018; Li et al., 2018; Yu et al., 2018; Gehrmann et al., 2018; Yao et al., 2019; Moryossef et al., 2019), which fail to fully capture the relation between selection and generation. Mei et al. (2016); Zhou et al. (2017); Lin et al. (2018); Li et al. (2018) "soft-select" word or sentence embeddings based on a gating function. The output score from the gate is a deterministic vector without any probabilistic variations, so controlling the selection to generate diverse text is impossible. Very few works explicitly define a bernoulli distribution for the selector, then train with the REINFORCE algorithm (Ling and Rush, 2017; Chen and Bansal, 2018), but the selection targets at a high recall regardless of the low precision, so the controllability over generated text is weak. Fan et al. (2018) control the generation by manually concatenating entity embeddings, while our model is much more flexible by explicitly defining the selection probability over all source tokens.

Our work is closely related with learning discrete representations with variational inference (Wen et al., 2017; van den Oord et al., 2017; Kaiser et al., 2018; Lawson et al., 2018), where we treat content selection as the latent representation. Limiting the KL-term is a common technique to deal with the "posterior collapse" problem (Kingma et al., 2016; Yang et al., 2017; Shen et al., 2018b). We adopt a similar approach and use it to further control the selecting strategy.

[4]The only extra parameter of VRS is ϕ which is a simple MLP structure. The actual training complexity is similar to RS because they both use the REINFORCE algorithm for gradient estimation.

5 Experiments

For the experiments, we focus on comparing (1) Bottom-up generation (Bo.Up.), (2) soft-select (SS), (3) Reinforce-select (RS) and (4) Variational-Reinforce-select (VRS) regarding their performance on content selection. SS and RS are trained with the selecting ratio constraint in Eq. 4. For the SS model, we further add a regularization term to encourage the maximum value of γ to be close to 1 as in Mei et al. (2016). We first briefly introduce the tasks and important setup, then present the evaluation results.

5.1 Tasks and Setup

We test content-selection models on the headline and data-to-text generation task. Both tasks share the same framework with the only difference of source-side encoders.

Headline Generation: We use English Gigaword preprocessed by Rush et al. (2015), which pairs first sentences of news articles with their headlines. We keep most settings same as in Zhou et al. (2017), but use a vocabulary built by byte-pair-encoding (Sennrich et al., 2016). We find it speeds up training with superior performance.

Data-to-Text Generation: We use the Wikibio dataset (Lebret et al., 2016). The source is a Wikipedia infobox and the target is a one-sentence biography description. Most settings are the same as in Liu et al. (2018), but we use a bi-LSTM encoder for better performance.

Heuristically extracted content: This is used to train the selector for bottom up models and pretrain the RS and VRS model. For wikibio, we simply extract overlapped words between the source and target. In Gigaword, as the headline is more abstractive, we select the closest source word for each target word in the embedding space. Stop words and punctuations are prohibited from being selected.

Choice of α/ϵ: As seen in Sec 3.5, we need to set the hyperparameter α for RS/SS and ϵ for

Gigaword	Oracle upper bound of			% unique	% unique	% Effect of	Entropy of

VRS	**52.41**	**55.03**	**11.89**	57.62	77.83	**74.03**	0.181

Table 2: Diversity of content selection. The % effect of selector is defined as the ratio of unique generation and mask, which reflects the rate that changing the selector will lead to corresponding changes of the generated text.

VRS. α corresponds to the selecting ratio. We set them as $\alpha = 0.35$ for Wikibio and 0.25 for Gigaword. The value is decided by running a human evaluation to get the empirical estimation. To keep comparison fairness, we tune ϵ to make VRS select similar amount of tokens with RS. The values we get are $\epsilon = 0.15n$ for Wikibio and $\epsilon = 0.25n$ for Gigaword. n is the number of source tokens. [5]

5.2 Results and Analysis

Ideally we would expect the learned content selector to (1) have reasonable diversity so that text with various contents can be easily sampled, (2) properly control the contents described in the generated text and (3) not hurt performance. The following section will evaluate these three points in order.

Diversity: We first look into the diversity of content selection learned by different models. For each test data, 50 selection masks are randomly sampled from the model's learned distribution. Greedy decoding is run to generate the text for each mask. We measure the entropy of the selector, proportion of unique selection masks and generated text in the 50 samples. We further define the "effect" of the selector as the ratio of sampled unique text and mask. This indicates how often changing the selection mask will also lead to a change in the generated text. The results are averaged over all test data. Following Rush et al. (2015) and Lebret et al. (2016), we measure the quality of generated text with ROUGE-1, 2, L F-score for Gigaword and ROUGE-4, BLEU-4, NIST for Wikibio. As there is only one reference text for each source, we report an oracle upper bound of these scores by assuming an "oracle" that can choose the best text among all the candidates (Mao et al., 2015; Wang et al., 2017). Namely, out of each 50 sampled text, we pick the one with the maximum metric score. The final metric score is evaluated on these "oracle" picked samples. The intuition is that if the content selector is properly trained, at least one out of the 50 samples should describe similar contents with the reference text, the metric score between it and the reference text should be high. Table 2 lists the results. We can have the following observations:

- RS model completely fails to capture the content-level diversity. Its selector is largely deterministic, with a lowest entropy value among all models. In contrast, the selector from SS, VRS and Bo.Up. have reasonable diversity, with over 90% and 75% unique selection masks for Gigaword and Wikibio respectively.

- The selector from VRS has the strongest effect to the generator, especially on the Gigaword data where modifying the content selection changes the corresponding text in more than 95% of the cases. RS has the lowest effect value, which indicates that even with the selecting ratio constraint, its generator still ignores the selection mask to a large extent.

- The oracle metric score of VRS is much higher than the other two. This is beneficial when people want to apply the model to generate a few candidate text then hand-pick the suitable one. VRS has more potential than the other three to contain the expected text. SS performs worst. The gap between the

[5] ϵ corresponds to the KL divergence of the selection mask, which scales linearly with the number of source tokens, so we set it proportinally w.r.t. n.

soft approximation and the real distribution, as mentioned before, indeed results in a large drop of performance.

In short, compared with others, the content selector of VRS is *(1) diverse, (2) has stronger effect on the text generation and (3) with a larger potential of producing an expected text*.

Controllability: We have shown the content selector of VRS is diverse and has strong effect on the text generation. This section aims at examining whether such effect is desirable, i.e., whether the selector is able to properly control the contents described in the text. We measure it based on the self-bleu metric and a human evaluation.

The self-bleu metric measures the controllability by evaluating the "intra-selection" similarity of generated text. Intuitively, by fixing the selection mask, multiple text sampled from the decoder are expected to describe the same contents and thereby should be highly similar to each other. The decoder should only model surface-level diversity without further modifying the selected contents. With this in mind, for each test data, we randomly sample a selection mask from the selector's distribution, then fix the mask and run the decoder to sample 10 different text. The self-BLEU-1 score (Zhu et al., 2018) on the sampled text is reported, which is the average BLEU score between each text pair. A higher self-BLEU score indicates the sampled text are more similar with each other. The results are shown in Table 3. We can see generations from VRS have a clearly higher intra-selection similarity. SS performs even worse than RS, despite having a high effect score in Table 2. The selector from SS affects the generation in an undesirable way, which also explain why SS has a lowest oracle metric score though with a high score on content diversity and effect.

Method	Bo.Up.	SS	RS	VRS
Gigaword	46.58	37.20	48.13	**61.14**
Wikibio	38.30	13.92	25.99	**43.81**

Table 3: Self-Bleu score by fixing selection mask. Higher means better controllability of content selection

We further run a human evaluation to measure the text-content consistency among different models. 100 source text are randomly sampled from the human-written DUC 2004 data for task 1&2 (Over et al., 2007). Bo.Up, SS, RS and VRS are applied to generate the target text by first sampling a selection mask, then run beam search decoding with beam size 10. We are interested in seeing (1) if multiple generations from the same selection mask are paraphrases to each other (intra-consistent) and (2) if generations from different selection masks do differ in the content they described (inter-diverse). The results in Table 4 show that VRS significantly outperforms the other two in both intra-consistency and inter-diversity. RS has the lowest score on both because the selector has very weak effects on the generation as measured in the last section. Bo.Up and SS lay between them. Overall VRS is able to *maintain the highest content-text consistency* among them.

Performance & **Trade-off**: To see if the selector affects performance, we also ask human annotators to judge the text fluency. The fluency score is computed as the average number of text being judged as fluent. We include generations from the standard Enc-Dec model. Table 4 shows the best fluency is achieved for Enc-Dec. Imposing

Table 6: Wikibio best-select results.

a content selector always affects the fluency a bit. The main reason is that when the controllability is strong, the change of selection will directly affect the text realization so that a tiny error of content selection might lead to unrealistic text. If the selector is not perfectly trained, the fluency will inevitably be influenced. When the controllability is weaker, like in RS, the fluency is more stable because it will not be affected much by the selection mask. For SS and Bo.Up, the drop of fluency is significant because of the gap of soft approximation and the independent training procedure. In general, VRS does properly decouple content selection from the enc-dec architecture, with only tiny degrade on the fluency.

Table 5/6 further measure the metric scores on Gigaword/Wikibio by decoding text from the best selection mask based on the selector's distribution (set $\beta_i = 1$ if $\mathbf{B}(\gamma_i) > 0.5$ and 0 otherwise). We include results from VRS model with $\epsilon = 0$, which puts no constraint on the mutual information. We further report the score by generating the best selection mask from the learned posterior distribution $q_\phi(\beta|X, Y)$ for VRS model. Two current SOTA results from Zhou et al. (2017) and Liu et al. (2018) and the proportion of selected source words for each model are also included. We have the following observations:

- As the value of ϵ decreases, the performance of VRS improves, but the selector loses more controllability because the model tends to over-select contents (over 75% source words selected). The text-content consistency will become low.

- Increasing ϵ sacrifices a bit performance, but still comparable with SOTA. Especially on Wikibio where the performance drop is minor. The reason should be that Wikibio is relatively easier to predict the selection but Gigaword has more uncertainty.

- Increasing ϵ improves the accuracy of the posterior selection. This would be useful when we want to perform posterior inference for some source-target pair.

- Setting $\epsilon = 0$ can actually outperform SOTA seq2seq which keeps all tokens, suggesting it is still beneficial to use the VRS model even if we do not care about the controllability.

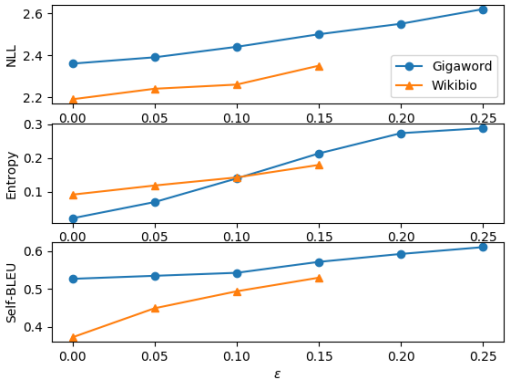

Figure 2: Negative log likelihood (NLL), selection entropy and self-BLEU as ϵ changes. NLL and self-bleu on Wikibio are added by 1 for better visualization. Lower NLL suggests higher performance. Higher entropy/self-BLEU means higher diversity/controllability.

Figure 2 visualizes how changing the value of ϵ affects the negative log likelihood (NLL), entropy of the selector and self-bleu score, which roughly correlates with performance, diversity and controllability. NLL is evaluated based on the lower bound in Eq 3 (Sohn et al., 2015). We can see as ϵ increases, the performance decreases gradually but the content selection gains more diversity and controllability. In practice we can tune the ϵ value to achieve a trade-off.

Generation Example: Figure 3 shows some examples from Gigaword. As can be seen, decodings from the VRS model are largely consistent with each other, in most cases only replacing one or two words with corresponding synonyms. Samples are able to faithfully convey all selected contents. In contrast, generations from SS. Bo.Up. and RS are unpredictable, differing in both selected

contents and also the way of saying. SS and Bo.Up also suffer more from the text disfluency. The generations from them are largely uncertain.

6 Conclusion

In this paper, we tackle the unaddressed problem of controllable content selection in text generation. We propose a general framework based on variational inference that can be potentiall applied to arbitrary tasks. On both the headline generation and data-to-text tasks, our model outperforms state-of-the-art models regarding the diversity and controllability of content selection. We further introduce an effective way to achieve a performance/controllability trade-off, which can be easily tuned to meet specific requirement.

Sentence-Level Content Planning and Style Specification for Neural Text Generation

Xinyu Hua and **Lu Wang**
Khoury College of Computer Sciences
Northeastern University
Boston, MA 02115
hua.x@husky.neu.edu luwang@ccs.neu.edu

Abstract

Building effective text generation systems requires three critical components: content selection, text planning, and surface realization, and traditionally they are tackled as separate problems. Recent all-in-one style neural generation models have made impressive progress, yet they often produce outputs that are incoherent and unfaithful to the input. To address these issues, we present an end-to-end trained two-step generation model, where a sentence-level content planner first decides on the keyphrases to cover as well as a desired language style, followed by a surface realization decoder that generates relevant and coherent text. For experiments, we consider three tasks from domains with diverse topics and varying language styles: persuasive argument construction from Reddit, paragraph generation for normal and simple versions of Wikipedia, and abstract generation for scientific articles. Automatic evaluation shows that our system can significantly outperform competitive comparisons. Human judges further rate our system generated text as more fluent and correct, compared to the generations by its variants that do not consider language style.

1 Introduction

Automatic text generation is a long-standing challenging task, as it needs to solve at least three major problems: (1) *content selection* ("what to say"), identifying pertinent information to present, (2) *text planning* ("when to say what"), arranging content into ordered sentences, and (3) *surface realization* ("how to say it"), deciding words and syntactic structures that deliver a coherent output based on given discourse goals (McKeown, 1985). Traditional text generation systems often handle each component separately, thus requiring extensive effort on data acquisition and system engineering (Reiter and Dale, 2000). Recent progress has been made by developing end-to-end trained neural models (Rush et al., 2015; Yu et al., 2018; Fan et al., 2018), which naturally excel at producing fluent text. Nonetheless, limitations of model structures and training objectives make them suffer from low interpretability and substandard generations which are often incoherent and unfaithful to the input material (See et al., 2017; Wiseman et al., 2017; Li et al., 2017).

Topic: **US should cut off foreign aid completely.**

`/r/ChangeMyView` *Counter-argument:* It can be a useful **political bargaining chip**. A few years ago, the US **cut financial aid** to **Uganda** due to its plans to **make homosexuality a crime** punishable by death. *Please consider changing your mind!*

Topic: **Artificial Intelligence**

English Wikipedia: … **Computer science** defines **AI research** as … any **device** that **perceives its environment** and **takes actions** that **maximize its chance** of successfully **achieving its goals**. ...

Simple Wikipedia: **Artificial Intelligence** is **the ability** of a **computer program** or **a machine** to **think and learn**. ...

Figure 1: [Upper] Sample counter-argument from Reddit. Argumentative stylistic language for persuasion is in italics. [Bottom] Excerpts from Wikipedia, where sophisticated concepts and language of higher complexity used in the standard version are not present in the corresponding simplified version. Both: key concepts are in bold.

To address the problems, we believe it is imperative for neural models to gain adequate control on content planning (i.e., content selection and ordering) to produce coherent output, especially for long text generation. We further argue that, in order to achieve desired discourse goals, it is beneficial to enable style-controlled surface realization by explicitly modeling and specifying proper linguistic styles. Consider the task of producing counter-arguments to the topic "US should cut off foreign aid completely". A sample argument in Figure 1 demonstrates how human selects

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 591–602, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

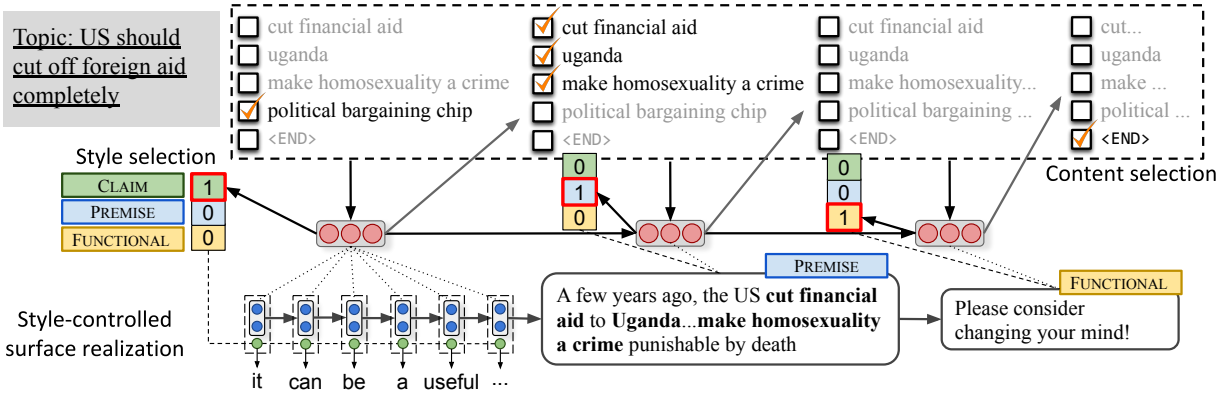

Figure 2: Overview of our framework. The LSTM content planning decoder (§ 3.2) first identifies a set of keyphrases from the memory bank conditional on previous selection history, based on which, a style is specified. During surface realization, the hidden states of the planning decoder and the predicted style encoding are fed into the realizer, which generates the final output (§ 3.3). Best viewed in color.

a series of talking points and a proper style based on the argumentative function for each sentence. For instance, the argument starts with a *proposition* on "foreign aid as a political bargaining chip", followed by a concrete *example* covering several key concepts. It ends with *argumentative stylistic language*, which differs in both content and style from the previous sentences. Figure 1 shows another example on Wikipedia articles: compared to a topic's standard version where longer sentences with complicated concepts are constructed, its simplified counterpart tends to explain the same subject with plain language and simpler concepts, indicating the interplay between content selection and language style.

We thus present an end-to-end trained neural text generation framework that includes the modeling of traditional generation components, to promote the control of content and linguistic style of the produced text.[1] Our model performs *sentence-level content planning* for information selection and ordering, and *style-controlled surface realization* to produce the final generation. We focus on conditional text generation problems (Lebret et al., 2016; Colin et al., 2016; Dušek et al., 2018): As shown in Figure 2, the input to our model consists of a topic statement and a set of keyphrases. The output is a relevant and coherent paragraph to reflect the salient points from the input. We utilize two separate decoders: for each sentence, (1) a planning decoder selects relevant keyphrases and a desired style conditional on previous selections, and (2) a realization decoder produces the text in the specified style.

We demonstrate the effectiveness of our framework on three challenging datasets with diverse topics and varying linguistic styles: persuasive argument generation on Reddit ChangeMyView (Hua and Wang, 2018); introduction paragraph generation on a *newly* collected dataset from Wikipedia and its simple version; and scientific paper abstract generation on AGENDA dataset (Koncel-Kedziorski et al., 2019).

Experimental results on all three datasets show that our models that consider content planning and style selection achieve significantly better BLEU, ROUGE, and METEOR scores than non-trivial comparisons that do not consider such information. Human judges also rate our model generations as more fluent and correct compared to the outputs produced by its variants without style modeling.

2 Related Work

Content selection and text planning are critical components in traditional text generation systems (Reiter and Dale, 2000). Early approaches separately construct each module and mainly rely on hand-crafted rules based on discourse theory (Scott and de Souza, 1990; Hovy, 1993) and expert knowledge (Reiter et al., 2000), or train statistical classifiers with rich features (Duboue and McKeown, 2003; Barzilay and Lapata, 2005). Advances in neural generation models have alleviated human efforts on system engineering, by combining all components into an end-to-end trained conditional text generation framework (Mei et al., 2016; Wiseman et al., 2017). However, without

[1]Data and code are available at xinyuhua.github.io/Resources/emnlp19/.

proper planning and control (Rambow and Korelsky, 1992; Stone and Doran, 1997; Walker et al., 2001), the outputs are often found to be incoherent and hallucinating. Recent work (Moryossef et al., 2019) separates content selection from the neural generation process and shows improved generation quality. However, their method requires an exhaustive search for content ordering and is therefore hard to generalize and scale. In this work, we improve the content selection by incorporating past selection history and directly feeding the predicted language style into the realization module.

Our work is also inline with concept-to-text generation, where sentences are produced from *structured* representations, such as database records (Konstas and Lapata, 2013; Lebret et al., 2016; Wiseman et al., 2017; Moryossef et al., 2019), knowledge base items (Luan et al., 2018; Koncel-Kedziorski et al., 2019), and AMR graphs (Konstas et al., 2017; Song et al., 2018; Koncel-Kedziorski et al., 2019). Shared tasks such as WebNLG (Colin et al., 2016) and E2E NLG challenges (Dušek et al., 2019) have been designed to evaluate single sentence planning and realization from the given structured inputs with a small set of fixed attribute types. Planning for multiple sentences in the same paragraph is nevertheless much less studied; it poses extra challenges for generating coherent long text, which is addressed in this work. Moreover, structured inputs are only available in a limited number of domains (Tanaka-Ishii et al., 1998; Chen and Mooney, 2008; Belz, 2008; Liang et al., 2009; Chisholm et al., 2017). The emerging trend is to explore less structured data (Kiddon et al., 2016; Fan et al., 2018; Martin et al., 2018). In our work, keyphrases are used as input to our generation system, which offer flexibility for concept representation and generalizability to broader domains.

3 Model

Our model tackles conditional text generation tasks where the input is comprised of two major parts: (1) a topic statement, $\mathbf{x} = \{x_i\}$, which can be an argument, the title of a Wikipedia article, or a scientific paper title, and (2) a keyphrase memory bank, $\mathcal{M}$, containing a list of talking points, which plays a critical role in content planning and style selection. We aim to produce a sequence of words, $\mathbf{y} = \{y_t\}$, to comprise the output, which can be a counter-argument, a paragraph as in Wikipedia articles, or a paper abstract.

3.1 Input Encoding

The input text $\mathbf{x}$ is encoded via a bidirectional LSTM (biLSTM), with its last hidden state used as the initial states for both content planning decoder and surface realization decoder. To encode keyphrases in the memory bank $\mathcal{M}$, each keyphrase is first converted into a vector $\boldsymbol{e}_k$ by summing up all its words' embeddings from GloVe (Pennington et al., 2014). A biLSTM-based *keyphrase reader*, with hidden states $\boldsymbol{h}^e_k$, is used to encode all keyphrases in $\mathcal{M}$. We also insert entries of <START> and <END> into $\mathcal{M}$ to facilitate learning to start and finish selection.

3.2 Sentence-Level Content Planning and Style Specification

Content Planning: Context-Aware Keyphrase Selection. Our content planner selects a set of keyphrases from the memory bank $\mathcal{M}$ for each sentence, indexed with j, conditional on keyphrases that have been selected in previous sentences, allowing topical coherence and content repetition avoidance. The decisions are denoted as a *selection vector* $\boldsymbol{v}_j \in \mathbb{R}^{|\mathcal{M}|}$, with each dimension $\boldsymbol{v}_{j,k} \in \{0, 1\}$, indicating whether the k-th phrase is selected for the j-th sentence generation. Starting with a <START> tag as the input for the first step, our planner predicts $\boldsymbol{v}_1$ for the first sentence, and recurrently makes predictions per sentence until <END> is selected, as depicted in Figure 2.

Formally, we utilize a sentence-level LSTM f, which consumes the summation embedding of selected keyphrases, $\boldsymbol{m}_j$, to produce a hidden state $\boldsymbol{s}_j$ for the j-th sentence step:

$$\boldsymbol{s}_j = f(\boldsymbol{s}_{j-1}, \boldsymbol{m}_j) \tag{1}$$

$$\boldsymbol{m}_j = \sum_{k=1}^{|\mathcal{M}|} \boldsymbol{v}_{j,k} \boldsymbol{h}^e_k \tag{2}$$

where $\boldsymbol{v}_{j,k} \in \{0, 1\}$ is the selection decision for the k-th keyphrase in the j-th sentence.

Our recent work (Hua et al., 2019) utilizes a similar formulation for sentence representations. However, the prediction of $\boldsymbol{v}_{j+1}$ is estimated by a bilinear product between $\boldsymbol{h}^e_k$ and $\boldsymbol{s}_j$, which is agnostic to what have been selected so far. While in reality, content selection for a new sentence should depend on previous selections. For in-

stance, keyphrases that have already been utilized many times are less likely to be picked again; topically related concepts tend to be mentioned closely. We therefore propose a vector $\boldsymbol{q}_j$ that keeps track of what keyphrases have been selected up to the j-th sentence:

$$\boldsymbol{q}_j = (\sum_{r=0}^{j} \boldsymbol{v}_r)^T \times \mathbb{E} \quad (3)$$

where $\mathbb{E} = [\boldsymbol{h}^e_1, \boldsymbol{h}^e_2, \dots \boldsymbol{h}^e_{|\mathcal{M}|}]^T \in \mathbb{R}^{|\mathcal{M}| \times H}$ is the matrix of keyphrase representations, H is the hidden dimension of the keyphrase reader LSTM.

Then $\boldsymbol{v}_{j+1}$ is calculated in an attentive manner with $\boldsymbol{q}_j$ as the attention query:

$$P(\boldsymbol{v}_{j+1,k} = 1 | \boldsymbol{v}_{1:j}) = \sigma(\mathbf{w}_v^T \boldsymbol{s}_j + \boldsymbol{q}_j \mathbf{W}^c \boldsymbol{h}^e_k) \quad (4)$$

where σ is the sigmoid funciton, and $\mathbf{w}_*$, $\mathbf{W}^*$, and $\mathbf{W}^{**}$ are trainable parameters throughout the paper. Bias terms are all omitted for simplicity.

As part of the learning objective, we utilize the binary cross-entropy loss with the gold-standard selection $\boldsymbol{v}^*_j$ as criterion over the training set D:

$$\mathcal{L}_{\text{sel}} = -\sum_{(\mathbf{x},\mathbf{y}) \in D} \sum_{j=1}^{J} (\sum_{k=1}^{|\mathcal{M}|} \log(P(\boldsymbol{v}^*_{j,k}))) \quad (5)$$

Style Specification. As discussed in § 1, depending on the content (represented as selected keyphrases in our model), humans often choose different language styles adapted for different discourse goals. Our model characterizes such stylistic variations by assigning a categorical style type $\boldsymbol{t}_j$ for each sentence, which is predicted as follows:

$$\hat{\boldsymbol{t}}_j = \text{softmax}(\mathbf{w}_s^T(\tanh(\mathbf{W}^s[\boldsymbol{m}_j; \boldsymbol{s}_j])) \quad (6)$$

$\hat{\boldsymbol{t}}_j$ is the estimated distribution over all types. We select the one with the highest probability and use a one-hot encoding vector, $\boldsymbol{t}_j$, as the input to our realization decoder (§ 3.3). The estimated distributions $\hat{\boldsymbol{t}}_j$ are compared against the gold-standard labels $\boldsymbol{t}^*_j$ to calculate the cross-entropy loss $\mathcal{L}_{\text{style}}$:

$$\mathcal{L}_{\text{style}} = -\sum_{(\mathbf{x},\mathbf{y}) \in D} \sum_{j=1}^{J} \boldsymbol{t}^*_j \log \hat{\boldsymbol{t}}_j \quad (7)$$

3.3 Style-Controlled Surface Realization

Our surface realization decoder is implemented with an LSTM with state calculation function g to get each hidden state $\boldsymbol{z}_t$ for the t-th generated token. To compute $\boldsymbol{z}_t$, we incorporate the content planning decoder hidden state $\boldsymbol{s}_{J(t)}$ for the sentence to be generated, with $J(t)$ as the sentence index, and previously generated token $\boldsymbol{y}_{t-1}$:

$$\boldsymbol{z}_t = g(\boldsymbol{z}_{t-1}, \tanh(\mathbf{W}^{ws}\boldsymbol{s}_{J(t)} + \mathbf{W}^{ww}\boldsymbol{y}_{t-1})) \quad (8)$$

For word prediction, we calculate two attentions, one over the input statement $\mathbf{x}$, which produces a context vector $\boldsymbol{c}^w_t$ (Eq. 10), the other over the keyphrase memory bank $\mathcal{M}$, which generates $\boldsymbol{c}^e_t$ (Eq. 11). To better reflect the control over word choice by language styles, we directly append the predicted style $\boldsymbol{t}_{J(t)}$ to the context vectors and hidden state $\boldsymbol{z}_t$, to compute the distribution over the vocabulary[2]:

$$P(y_t | y_{1:t-1}) = \text{softmax}(\tanh(\mathbf{W}^o[\boldsymbol{z}_t; \boldsymbol{c}^w_t; \boldsymbol{c}^e_t; \boldsymbol{t}_{J(t)}])) \quad (9)$$

$$\boldsymbol{c}^w_t = \sum_{i=1}^{L} \alpha^w_i \boldsymbol{h}_i, \quad \alpha^w_i = \text{softmax}(\boldsymbol{z}_t \mathbf{W}^{wa} \boldsymbol{h}_i) \quad (10)$$

$$\boldsymbol{c}^e_t = \sum_{k=1}^{|\mathcal{M}|} \alpha_k \boldsymbol{h}^e_k, \quad \alpha^e_k = \text{softmax}(\boldsymbol{z}_t \mathbf{W}^{we} \boldsymbol{h}^e_k) \quad (11)$$

We further adopt a copying mechanism from See et al. (2017) to enable direct reuse of words from the input $\mathbf{x}$ and keyphrase bank $\mathcal{M}$ to allow out-of-vocabulary words to be included.

3.4 Training Objective

We jointly learn to conduct content planning and surface realization by aggregating the losses over (i) word generation: $\mathcal{L}_{\text{gen}} = -\sum_D \sum_{t=1}^{T} \log P(y^*_t | \mathbf{x}; \theta)$, (ii) keyphrase selection: $\mathcal{L}_{\text{sel}}$ (Eq. 5), and (iii) style prediction $\mathcal{L}_{\text{style}}$ (Eq. 7):

$$\mathcal{L}(\theta) = \mathcal{L}_{\text{gen}}(\theta) + \gamma \cdot \mathcal{L}_{\text{style}}(\theta) + \eta \cdot \mathcal{L}_{\text{sel}}(\theta) \quad (12)$$

where θ denotes the trainable parameters. γ and η are set to 1.0 in our experiments for simplicity.

4 Tasks and Datasets

4.1 Task I: Argument Generation

Our first task is to generate a counter-argument for a given statement on a controversial issue. The input keyphrases are extracted from automatically retrieved and reranked passages with queries constructed from the input statement.

[2]The inclusion of style variables is different from our prior style-aware generation model (Hua et al., 2019), where styles are predicted but not encoded for word production.

	Argument	Wikipedia	AGENDA
	# Args (# Threads)	(Nor. / Sim.)	
# Train	272,147 (11,434)	125,136	38,720
# Dev	40,291 (1,784)	21,004	1,000
# Test	46,757 (1,706)	23,534	1,000
# Tokens	54.87	70.57 / 48.60	141.34
# Sent.	2.48	3.15 / 3.20	5.59
# KP (candidates)	55.80	23.56	12.23
# KP (selected)	11.61	16.01/11.11	12.23

Table 1: Statistics of the three datasets. Average numbers are reported. For argument dataset, number of unique threads is also shown. On AGENDA, entities are extracted from abstract as keyphrases, hence all candidates are "selected".

	CLAIM	PREMISE	FUNCTIONAL
# Arguments	29.1%	62.2%	8.7%
# Tokens	17.0	26.2	10.0

Length $\in$	(0, 10]	(10, 20]	(20, 30]	(30, ∞)
Normal Wikipedia	9.9%	40.5%	29.8%	19.8%
Simple Wikipedia	29.3%	51.7%	14.6%	4.4%

Table 2: Sentence style distribution for argument and Wikipedia datasets.

We reuse the dataset from our previous work (Hua et al., 2019), but annotate with newly designed style scheme. We first briefly summarize the procedures for data collection, keyphrase extraction and selection, and passage reranking; more details can be found in our prior work. Then we describe how to label argument sentences with style types that capture argumentative structures.

The dataset is collected from Reddit `/r/ChangeMyView` subcommunity, where each thread consists of a multi-paragraph original post (OP), followed by user replies with the intention to change the opinion of the OP user. Each OP is considered as the input, and the root replies awarded with delta (Δ), or with positive `karma` (# upvotes $>$ # downvotes) are target counter-arguments to be generated. A domain classifier is further adopted to select politics related threads. Since users often have separate arguments in different paragraphs, we treat each paragraph as one *target argument* by itself. Statistics are shown in Table 1.

Input Keyphrases and Label Construction. To obtain the input keyphrase candidates and their sentence-level selection labels, we first construct queries to retrieve passages from Wikipedia and news articles collected from `commoncrawl.org`.[3] For training, we construct a query per target argument sentence using its content words for retrieval, and keep top 5 passages per query. For testing, the queries are constructed from the sentences in OP (input statement).

We then extract keyphrases from the retrieved passages based on topic signature words (Lin and Hovy, 2000) calculated over the given OP. These words, together with their related terms from WordNet (Miller, 1994), are used to determine whether a phrase in the passage is a *keyphrase*. Specifically, a keyphrase is (1) a noun phrase or verb phrase that is shorter than 10 tokens; (2) contains at least one content word; (3) has a topic signature or a Wikipedia title. For each keyphrase candidate, we match them with the sentences in the target counter-argument, and we consider it to be "selected" for the sentence if there is any overlapping content word.

During test time, we further adopt a stance classifier from Bar-Haim et al. (2017) to produce a stance score for each passage. We retain passages that have a negative stance towards OP, and a greater than 5 stance score. They are further ordered based on the number of overlapping keyphrases with the OP. Top 10 passages are used to construct the input keyphrase bank, and as optional input to our model.

Sentence Style Label Construction. For argument generation, we define three sentence styles based on their argumentative discourse functions (Persing and Ng, 2016; Lippi and Torroni, 2016): CLAIM is a proposition, usually containing one or two talking points, e.g., "*I believe foreign aid is a useful bargaining chip*"; PREMISE contains supporting arguments with reasoning or examples; FUNCTIONAL is usually a generic statement, e.g., "*I understand what you said*". For training, we employ a list of rules extended from the claim detection method by Levy et al. (2018) to automatically construct a style label for each sentence. Statistics are displayed in Table 2, and sample rules are shown below, with the complete list in the Supplementary:

- CLAIM: must be shorter than 20 tokens and matches any of the following patterns: (a) `i (don't)? (believe|agree|...);` (b) `(anyone|all|everyone|nobody...) (should|could|need|must|might...);`

[3]The choice of news portals, statistics of the dataset, and preprocerssing steps are described in Hua et al. (2019), §4.1.

(c) `(in my opinion|my view|...)`

- PREMISE: must be longer than 5 tokens, contains at least one noun or verb content word, and matches any of the following patterns: (a) `(for (example|instance)|e.g.)`; (b) `(increase|reduce|improve|...)`
- FUNCTIONAL: contains fewer than 5 alphabetical words and no noun or verb content word

Paragraphs that only contain FUNCTIONAL sentences are removed from our dataset.

4.2 Task II: Paragraph Generation for Normal and Simple Wikipedia

The second task is generating introduction paragraphs for Wikipedia articles. The input consists of a title, a user-specified global style (normal or simple), and a list of keyphrases collected from the gold-standard paragraphs of both normal and simple Wikipedia. During training and testing, the global style is encoded as one extra bit appended to $\boldsymbol{m}_j$ (Eq. 2).

We construct a *new* dataset with topically-aligned paragraphs from normal and simple English Wikipedia.[4] For alignment, we consider it a match if two articles share exactly the same title with at most two non-English words. We then extract the first paragraphs from both and filter out the pair if one of the paragraphs is shorter than 10 words or is followed by a table.

Input Keyphrases and Label Construction. Similar to argument generation, we extract noun phrases and verb phrases and consider the ones with at least one content word as keyphrase candidates. After de-duplication, there are on average 5.4 and 3.7 keyphrases per sentence for the normal and simple Wikipedia paragraphs, respectively. For each sample, we merge the keyphrases from the aligned paragraphs as the input. The model is then trained to select the appropriate ones conditioned on the global style.

Sentence Style Label Construction. We distinguish sentence-level styles based on language complexity, which is approximated by sentence length. The distribution of sentence styles is displayed in Table 2.

4.3 Task III: Paper Abstract Generation

We further consider a task of generating abstracts for scientific papers (Ammar et al., 2018), where the input contains a paper title and scientific entities mentioned in the abstract. We use the AGENDA data processed by Koncel-Kedziorski et al. (2019), where entities and their relations in the abstracts are extracted by SciIE (Luan et al., 2018). All entities appearing in the abstract are included in our keyphrase bank. The state-of-the-art system (Koncel-Kedziorski et al., 2019) exploits the scientific entities, their relations, and the relation types. In our setup, we ignore the relation graph, and focus on generating the abstract with only entities and title as the input. Due to the dataset's relatively uniform language style and smaller size, we do not experiment with our style specification component.

[4] We download the dumps of 2019/04/01 for both dataset.

5 Experiments

5.1 Implementation Details

For argument generation, we truncate the input OP and retrieved passages to 500 and 400 words. Passages are optionally appended to OP as our encoder input. The keyphrase bank size is limited to 70 for argument, and 30 for Wikipedia and AGENDA data (based on the average numbers in Table 1), with keyphrases truncated to 10 words. We use a vocabulary size of 50K for all tasks.

Training Details. Our models use a two-layer LSTM for both decoders. They all have 512-dimensional hidden states per layer and dropout probabilities (Gal and Ghahramani, 2016) of 0.2 between layers. Wikipedia titles are encoded with the summation of word embeddings due to their short length. The learning process is driven by AdaGrad (Duchi et al., 2011) with 0.15 as the learning rate and 0.1 as the initial accumulator. We clip the gradient norm to a maximum of 2.0. The mini-batch size is set to 64. And the optimal weights are chosen based on the validation loss.

For argument generation, we also pre-train the encoder and the lower layer of realization decoder using language model losses. We collect all the OP posts from the training set, and an extended set of reply paragraphs, which includes additional counter-arguments that have non-negative `karma`. For Wikipedia, we consider the large collection of 1.9 million unpaired normal English Wikipedia paragraphs to pre-train the model for both normal and simple Wikipedia generation.

Beam Search Decoding. For inference, we utilize beam search with a beam size of 5. We disallow the repetition of trigrams, and replace the `UNK`

with the keyphrase of the highest attention score.

5.2 Baselines and Comparisons

For all three tasks, we consider a SEQ2SEQ with attention baseline (Bahdanau et al., 2015), which encodes the input text and keyphrase bank as a sequence of tokens, and generates the output.

For argument generation, we implement a RETRIEVAL baseline, which returns the highest reranked passage retrieved with OP as the query. We also compare with our prior model (Hua and Wang, 2018), which is a multi-task learning framework to generate both keyphrases and arguments.

For Wikipedia generation, a RETRIEVAL baseline obtains the most similar paragraph from the training set with input title and keyphrases as the query, measured with bigram cosine similarity. We further train a logistic regression model (LOGREGSEL), which takes the summation of word embeddings in a phrase and predicts its inclusion in the output for a normal or simple Wiki paragraph.

For abstract generation, we compare with the state-of-the-art system GRAPHWRITER (Koncel-Kedziorski et al., 2019), which is a transformer model enabled with knowledge graph encoding mechanism to handle both the entities and their structural relations from the input.

We also report results by our model variants to demonstrate the usefulness of content planning and style control: (1) with gold-standard[5] keyphrase selection for each sentence (Oracle Plan.), and (2) without style specification.

6 Results and Analysis

6.1 Automatic Evaluation

We report precesion-oriented BLEU (Papineni et al., 2002), recall-oriented ROUGE-L (Lin, 2004) that measures the longest common subsequence, and METEOR (Denkowski and Lavie, 2014), which considers both precision and recall.

Argument Generation. For each input OP, there can be multiple possible counter-arguments. We thus consider the best matched (i.e., highest scored) reference when reporting results in Table 3. Our models yield significantly higher BLEU and ROUGE scores than all comparisons while producing longer arguments than generation-based approaches. Furthermore, among our model variants, oracle content planning further improves the performance, indicating the importance of content selection and ordering. Taking out style specification decreases scores, indicating the influence of style control on generation.[6]

	BLEU	ROUGE	MTR	Len.
RETRIEVAL	7.81	15.68	**10.59**	150.0
SEQ2SEQ	3.64	19.00	9.85	51.7
H&W (2018)	5.73	14.44	3.82	36.5
OURS (Oracle Plan.)	16.30*	20.25*	11.61	65.5
OURS	**13.19***	20.15*	10.42	65.2
w/o Style	12.61*	**20.28***	10.15	64.5
w/o Passage	11.84*	19.90*	9.03	62.6

Table 3: Results on argument generation with BLEU (up to bigrams), ROUGE-L, and METEOR (MTR). Best systems without oracle planning are in **bold** per metric. Our models that are significantly better than all comparisons are marked with $*$ ($p < 0.001$, approximate randomization test (Noreen, 1989)).

Wikipedia Generation. Results on Wikipedia (Table 4) show similar trends, where our models almost always outperform all comparisons across metrics. The significant performance drop on ablated models without style prediction proves the effectiveness of style usage. Our model, if guided with oracle keyphrase selection per sentence, again achieves the best performance.

We further show the *effect of content selection on generation* on Wikipedia and abstract data in Figure 3, where we group the test samples into 10 bins based on F1 scores on keyphrase selection.[7] We observe a strong correlation between keyphrase selection and generation performance, e.g., for BLEU, Pearson correlations of 0.95 ($p < 10^{-4}$) and 0.85 ($p < 10^{-2}$) are established for Wikipedia and abstract. For ROUGE, the values are 0.99 ($p < 10^{-8}$) and 0.72 ($p < 10^{-1}$).

Abstract Generation. Lastly, we compare with the state-of-the-art GRAPHWRITER model on AGENDA dataset in Table 5. Although our model does not make use of the relational graph encod-

[5] "Gold-standard" indicates the keyphrases that have content word overlap with the reference sentence.

[6] We do not compare with our recent model in Hua et al. (2019) due to the training data difference caused by our new sentence style scheme. However, the newly proposed model generates arguments with lengths closer to human arguments, benefiting from the improved content planning module.

[7] We calculate F1 by aggregating the selections across all sentences. For argument generation, keyphrases are often paraphrased, making it difficult to calculate F1 reliably, therefore omitted here.

	BLEU	ROUGE	METEOR	Length	BLEU	ROUGE	METEOR	Length
	Normal Wikipedia				Simple Wikipedia			
RETRIEVAL	20.10	28.60	12.23	44.5	21.99	33.44	12.97	34.7
SEQ2SEQ	22.62	27.49	14.74	52.9	21.98	29.36	16.94	52.8
LOGREGSEL	29.28	28.65	**27.76**	34.3	5.59	23.21	13.27	13.0
OURS (Oracle Plan.)	37.70*	45.41*	31.65*	79.8	34.22*	45.48*	32.84*	70.5
OURS	**33.76***	**40.08***	25.70	65.4	**31.22***	**40.76***	**26.76***	58.7
w/o Style	31.06*	37.72*	24.56	71.0	27.94*	38.20*	25.87*	64.5

Table 4: Results on Wikipedia generation. Best results without oracle planning are in **bold**. $*$: Our models that are significantly better than all comparisons ($p < 0.001$, approximate randomization test).

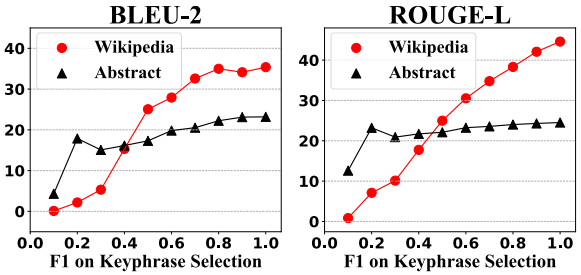

Figure 3: Effect of keyphrase selection (F1 score) on generation performance, measured by BLEU and ROUGE. Positive correlations are observed.

	BLEU	ROUGE	MTR	Len.
GRAPHWRITER	29.95	28.56	19.90	130.1
SEQ2SEQ	18.13	21.03	13.95	134.8
OURS (Oracle Plan.)	25.03	26.18	19.21	125.8
OURS	20.32	23.30	15.95	128.3

Table 5: Results on paper abstract generation. Notice that GRAPHWRITER models rich information about relations and relation types among entities, which is not utilized by our model.

ing, we achieve competitive ROUGE-L and METEOR scores given the oracle plans. Our model also outperforms the seq2seq baseline, which has the same input, indicating the applicability of our method across different domains.

6.2 Human Evaluation

We further ask three proficient English speakers to assess the quality of generated arguments and Wikipedia paragraphs. Human subjects are asked to rate on a scale of 1 (worst) to 5 (best) on **grammaticality**, **correctness** of the text (for arguments, the stance is also considered), and **content richness** (i.e., coverage of relevant points). Detailed guidelines for different ratings are provided to the raters (see Supplementary). For both tasks, we randomly choose 30 samples from the test set; outputs from two variants of our models and a human written text are presented in random order.

	Argument			Wikipedia		
	Gram.	Corr.	Cont.	Gram.	Corr.	Cont.
HUMAN	4.81	3.90	3.48	4.84	4.73	4.49
OURS	**3.99***	**2.78***	**2.61***	**3.38**	**3.24***	3.43
w/o Style	3.03	2.26	2.03	2.99	2.89	**3.50**
Krippendorff's α	0.75	0.69	0.33	0.70	0.56	0.55

Table 6: Human evaluation on argument generation (Upper) and Wikipedia generation (Bottom). Grammaticality (**Gram**), correctness (**Corr**), and content richness (**Cont**) are rated on Likert scale ($1-5$). We mark our model with $*$ to indicate statistically significantly better ratings over the variant without style specification ($p < 0.001$, approximate randomization test).

According to Krippendorff's α, the raters achieve substantial agreement on grammaticality and correctness, while the agreement on content richness is only moderate due to its subjectivity. As shown in Table 6, on both tasks, our models with style specification produce more fluent and correct generations, compared to the ones without such information. However, there is still a gap between system generations and human edited text.

We further show **sample outputs** in Figure 4. The first example is on the topic of abortion, our model captures the relevant concepts such as "*fetuses are not fully developed*" and "*illegal to kill*". It also contains fewer repetitions than the seq2seq baseline. For Wikipedia, our model is not only better at controlling the global simplicity style, but also more grammatical and coherent than the seq2seq output.

6.3 Further Analysis and Discussions

We further investigate the usage of different styles, and show the top frequent patterns for each argument style from human arguments and our system generation (Table 7). We first calculate the most

	Human	Our model
C	It doesn't mean that; everyone should be able to	I don't believe that it is necessary; don't need to be able to
P	have the freedom to; is leagal in the US; imagine for a moment if; Let's say (you/your partner/a friend)	have the right to (bear arms/cast a ballot vote); For example, (if you look at/let's look at/I don't think)
F	Why is that?; that's ok; Would it change your mind?	I'm not sure (why/if) this is; TLDR: I don't care about this

Table 7: Top frequent patterns captured in style CLAIM (C), PREMISE (P), and FUNCTIONAL (F) from arguments by human and our model.

frequent 4-grams per style, then extend it with context. We manually cluster and show the representative ones. For both columns, the popular patterns reflect the corresponding discourse functions: CLAIM is more evaluative, PREMISE lists out details, and FUNCTIONAL exhibits argumentative stylistic languages. Interestingly, our model also learns to paraphrase popular patterns, e.g., "*have the freedom to*" vs. "*have the right to*".

For Wikipedia, the sentence style is defined by length. To validate its effect on content selection, we calculate the average number of keyphrases per style type. The results on human written paragraphs are 2.0, 3.8, 5.8, and 9.0 from the simplest to the most complex. A similar trend is observed in our model outputs, which indicates the challenge of content selection in longer sentences.

For future work, improvements are needed in both model design and evaluation. As shown in Figure 4, system arguments appear to overfit on stylistic languages and rarely create novel concepts like humans do. Future work can lead to improved model guidance and training methods, such as reinforcement learning-based explorations, and better evaluation to capture diversity.

7 Conclusion

We present an end-to-end trained neural text generation model that considers sentence-level content planning and style specification to gain better control of text generation quality. Our content planner first identifies salient keyphrases and a proper language style for each sentence, then the realization decoder produces fluent text. We consider three tasks of different domains on persuasive argument generation, paragraph generation for normal and simple versions of Wikipedia, and abstract generation for scientific papers. Experimental results demonstrate the effectiveness of our model, where it obtains significantly better BLEU, ROUGE, and METEOR scores than non-trivial comparisons. Human subjects also rate our model generations as more grammatical and correct when language style is considered.

Topic: Aborting a fetus has some non-zero negative moral implications

Human: It's not the birthing process that changes things. It's the existence of the baby. Before birth, the baby only exists inside another human being. After birth, it exists on its own in the world like every other person in the world.

Seq2seq: i 'm not going to try to change your view here , but i do n't want to change your position . i do n't think it 's fair to say that a fetus is not a person . it 's not a matter of consciousness .

Our model: tl ; dr : i agree with you , but i think it 's important to note that fetuses are not fully developed . i do n't know if this is the case , but it does n't seem to be a compelling argument to me at all , so i 'm not going to try to change your view by saying that it should be illegal to kill

Topic: Moon Jae-in

Simple Wikipedia: Moon Jae-in is a South Korean politician. He is the 12th and current President of South Korea since 10 May 2017 after winning the majority vote in the 2017 presidential election.

Seq2seq: moon election park is a election politician who served as prime minister of korea from 2007 to 2013 . he was elected as a member of the house of democratic party in the moon 's the the moon the first serving president of jae-in , in office since 2010 .

Our model: moon jae-in is a south korean politician and current president of south korea from 2012 to 2017 and again from 2014 to 2017.

Normal Wikipedia: Moon Jae-in is a South Korean politician serving as the 19th and current President of South Korea since 2017. He was elected after the impeachment of Park Geun-hye as the candidate of the Democratic Party of Korea.

Seq2seq: moon winning current is a current politician who served as prime minister of korea from 2007 to 2013 . he was elected as a member of the house of democratic party in the moon 's the the current the first president of pakistan , in office . prior to that , he also served on the democratic republic of germany .

Our model: moon jae-in is a south korean politician serving as the 19th and current president of south korea , since 2019 to 2019 and 2019 to 2017 respectively he has been its current president ever since .

Abstract

We propose a Cross-lingual Encoder-Decoder model that simultaneously translates and generates sentences with Semantic Role Labeling annotations in a resource-poor target language. Unlike annotation projection techniques, our model does not need parallel data during inference time. Our approach can be applied in monolingual, multilingual and cross-lingual settings and is able to produce dependency-based and span-based SRL annotations. We benchmark the labeling performance of our model in different monolingual and multilingual settings using well-known SRL datasets. We then train our model in a cross-lingual setting to generate new SRL labeled data. Finally, we measure the effectiveness of our method by using the generated data to augment the training basis for resource-poor languages and perform manual evaluation to show that it produces high-quality sentences and assigns accurate semantic role annotations. Our proposed architecture offers a flexible method for leveraging SRL data in multiple languages.

1 Introduction

Semantic Role Labeling (SRL) extracts semantic predicate-argument structure from sentences. This has proven to be useful in Neural Machine Translation (NMT) (Marcheggiani et al., 2018), Multi-document-summarization (Khan et al., 2015), AMR parsing (Wang et al., 2015) and Reading Comprehension (Mihaylov and Frank, 2019). SRL consists of three steps: i) predicate detection, ii) argument identification and iii) role classification. In this work we focus on PropBank SRL (Palmer et al., 2005), which has proven its validity across languages (van der Plas et al., 2010). While former SRL systems rely on syntactic features (Punyakanok et al., 2008; Täckström et al., 2015), recent neural approaches learn to model both argument detection and role classification given a predicate (Marcheggiani et al., 2017; He et al., 2017), and even jointly predict predicates inside sentences (He et al., 2018; Cai et al., 2018). While these approaches alleviate the need for pipeline models, they require sufficient amounts of training data to perform adequately. To date, such models have been tested primarily for English, which offers a considerable amount of high-quality training data compared to other languages. The lack of sufficiently large SRL datasets makes it hard to straightforwardly apply the same architectures to other languages and calls for methods to augment the training data in lower-resource languages.

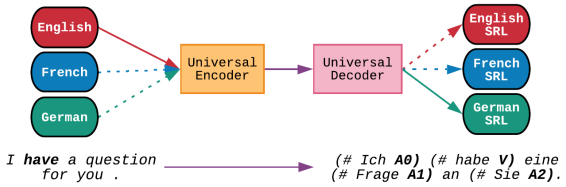

Figure 1: We propose an Encoder-Decoder model that translates a sentence into a target language and applies SRL labeling to the translated words. In this example we translate from English to German and label roles for the predicate *have*.

There is significant prior work on SRL data augmentation (Hartmann et al., 2017), annotation projection for monolingual (Fürstenau and Lapata, 2012; Hartmann et al., 2016), and cross-lingual SRL (Padó and Lapata, 2009; van der Plas et al., 2011; Akbik et al., 2015, 2016). A drawback of cross-lingual projection is that even at prediction time it requires parallel sentences, a semantic role labeler on the source side, as well as syntactic information for both language sides. Thus, it is desirable to design an architecture that can make use of existing annotations in more than one lan-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 603–615, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

guage and that learns to translate input sentences to another language while transferring semantic role annotations from the source to the target.

Techniques for low-resource Neural Machine Translation (NMT) show the positive impact on target predictions by adding more than one language during training, such as Multi-source NMT (Zoph and Knight, 2016) and Multilingual NMT (Johnson et al., 2017; Firat et al., 2016a), whereas Mulcaire et al. (2018) show the advantages of training a single polyglot SRL system that improves over monolingual baselines in lower-resource settings. In this work, we propose a general Encoder-Decoder (Enc-Dec) architecture for SRL (see Figure 1). We extend our previous Enc-Dec approach for SRL (Daza and Frank, 2018) to a cross-lingual model that translates sentences from a source language to a (lower-resource) target language, and during decoding jointly labels it with SRL annotations.[1]

Our contributions are as follows:

- We propose the first cross-lingual multilingual Enc-Dec model for PropBank SRL.
- We show that our cross-lingual model can generate new labeled sentences in a target language without the need of explicit syntactic or semantic annotations at inference time.
- Cross-lingual evaluation against a labeled gold standard achieves good performance, comparable to monolingual SRL results.
- Augmenting the training set of a lower-resource language with sentences generated by the cross-lingual model achieves improved F1 scores on the benchmark dataset.
- Our universal Enc-Dec model lends itself to monolingual, multilingual and crosslingual SRL and yields competitive performance.

2 An Extensible Model for SRL

2.1 One Model to Treat Them All

We define the SRL task as a sequence transduction problem: given an input sequence of tokens $X = x_1, ..., x_i$, the system is tasked to generate a sequence $Y = y_1, ..., y_j$ consisting of words interleaved with SRL annotations. Defining the task in this fashion allows X and Y to be of different lengths and therefore target sequences may also

[1]Code is available at: https://github.com/Heidelberg-NLP/SRL-S2S.

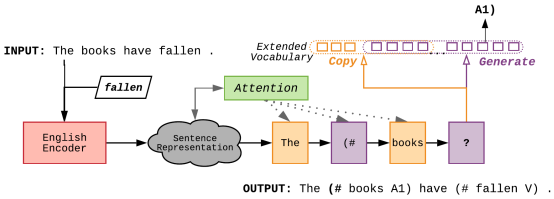

Figure 2: Monolingual Enc-Dec model for SRL with copying (Daza and Frank, 2018). We generalize this architecture to multilingual and cross-lingual SRL.

contain word tokens of different languages if desired. This means that we could train an Enc-Dec model that learns not only to label a sentence, but to jointly translate it while applying SRL annotations directly to the target language. Moreover, following conceptually the multilingual Enc-Dec model proposed by Johnson et al. (2017), we can train a single model that allows for joint training with multiple language pairs while sharing parameters among them. We apply a similar joint multilingual learning method to produce structured output sequences in the form of translations enriched with SRL annotations on the (lower-resource) target language (cf. Figure 3). We will apply this universal structure-inducing Enc-Dec model to the Semantic Role Labeling task, and show that it can be deployed in three different settings:

i) **monolingual**: encode a sentence in a given language and learn to decode a labeled sequence by reproducing the source words and inserting the appropriate structure-indicating labels in the output (cf. Figure 2). A copying mechanism (Gu et al., 2016) allows this model to reproduce the input sentence as faithfully as possible.

ii) **one-to-one multilingual**: train a single, joint model to generate n different structure-enriched target languages given inputs in the same language. For example: Labeled English (*EN-SRL*) given an *EN* sentence or Labeled German (*DE-SRL*) given a *DE* sentence. This multilingual model still relies on copying to relate each labeled output sentence to its corresponding input counterpart. However, unlike (i), it has the advantage of sharing parameters among languages.

iii) **cross-lingual**: generate outputs in n different target languages given inputs in m different source languages, for example: Labeled German (*DE-SRL*) and Labeled French (*FR-SRL*) given an *EN* sentence (see Figure 3). In this setting, we do not restrict the model to *copy* words from the

source sentence but train it to *translate* them.

In Section 2.2 we describe how the basic Enc-Dec model for SRL is constructed and in Section 2.3 we describe the additional components that allow us to generalize this architecture to the one-to-one multilingual and cross-lingual scenarios.

2.2 Encoder-Decoder Architecture

We reimplement and extend the Enc-Dec model with attention (Bahdanau et al., 2015) and copying (Gu et al., 2016) mechanisms for SRL proposed by Daza and Frank (2018). This model encodes the source sentence and decodes the input sequence of words (in the same language) interleaved with SRL labels.

Data Representation. Similar to other prior work (Liu et al., 2018) and our own (Daza and Frank, 2018), we linearize the SRL structure in order to process it as a sequence of symbols suitable for the Enc-Dec architecture. We restrict ourselves to argument identification and labeling of one predicate at a time. We feed the gold predicate in training and inference, and process each sentence as many times as it has predicates. An opening bracket *(#* indicates the start of a labeled-argument region; a closing labeled bracket, e.g. *A0)*, indicates the ending and the tag of the labeled region (see Figure 2).

Vocabulary. We define a shared vocabulary consisting of all source and target words $\mathcal{V} = \{v_1, ..., v_N\} \cup \{UNK\}$ and the SRL labels $\mathcal{L} = \{l_1, ..., l_M\}$. In addition, we employ a per-instance extension set $\mathcal{X} = \{x_1 ..., x_{T_x}\}$ containing all words from the source sequence. Our final vocabulary is $\mathcal{V} \cup \mathcal{L} \cup \mathcal{X}$.

Encoder. In our prior work (Daza and Frank, 2018) we used a 2-layer BiLSTM as encoder. In this paper, we adopt the Deep BiLSTM Encoder from He et al. (2017) which has been shown to work well for SRL models. Again following He et al. (2017), we define the encoder input vector x_i as the concatenation of a word embedding w_i and a binary predicate-feature embedding p_i indicating at each time-step whether the current word is a predicate or not [2]. The encoder outputs a series of hidden states $h_1, ..., h_{T_x}$ representing each token. We refer to this series of states as $\mathbf{H}$.

Attention. To improve the access to the source sentence representation, we include the attention mechanism proposed by Bahdanau et al. (2015), which computes a context vector at each time step *t* based on $\mathbf{H}$ and the current decoder state.

Decoder. We use a single-layer Decoder with LSTM cells (Hochreiter and Schmidhuber, 1997) and a copying mechanism. It emits an output token y_t from a learned score ψ_g over the vocabulary at each time step *t* given its state s_t, the previous output token y_{t-1}, and the attention context vector c_t. In addition, a copying score ψ_c is calculated. The decoder learns from these scores when to generate a new token and when to copy from the encoded hidden states $\mathbf{H}$. Formally we compute the scores as:

$$\begin{aligned} \psi_g(y_t = v_i) &= W_o[s_t; c_t], \quad v_i \, \epsilon \, \mathcal{V} \cup \mathcal{L} \\ \psi_c(y_t = x_j) &= \sigma(h_j^T W_c) s_t, \quad x_j \, \epsilon \, \mathcal{X} \end{aligned} \tag{1}$$

where $W_o \epsilon \mathbb{R}^{N \times 2d_s}$ and $W_c \epsilon \mathbb{R}^{d_h \times d_s}$ are learnable parameters and s_t, c_t are the current decoder state and context vector, respectively. These scores are used to compute two distributions: one for the likelihood of copying ($\mathbf{c}$) y_t and another for the likelihood of generating ($\mathbf{g}$) y_t. Formally:

$$\begin{aligned} p(y_t | s_t, y_{t-1}, c_t, \mathbf{H}) = p(y_t, \mathbf{g} | s_t, y_{t-1}, c_t) + \\ p(y_t, \mathbf{c} | s_t, y_{t-1}, \mathbf{H}) \end{aligned} \tag{2}$$

The two distributions are then normalized by a final *softmax* layer from which we compute a joint likelihood of y_t and choose the token with the highest score within this joint likelihood.

2.3 Multilingual Extensions

We generalize the monolingual Enc-Dec model for SRL to a multilingual SRL system by adding two main components:

Translation Token. Like Johnson et al. (2017), we prefix the source sequence with a special token that indicates the expected language of the target sequence. If the source is in *EN* and the target is a German sentence with SRL labels, the source sentence will be preceded by the token *<2DE-SRL>*.

Language Indicator Embeddings. We want the model to profit from the common role label inventory used across languages, yet at the same time there are subtle differences in role labeling and how roles are linguistically marked in the different languages[3]. Hence, we define *N* different language indicators (e.g., *FR, DE*) and represent

[2] These two additions already show improvements compared to the reported results in Daza and Frank (2018).

[3] e.g. the role A2 (Beneficiary) can be PP in *EN* and *FR*, but dative NP in *DE* (DativeNP)

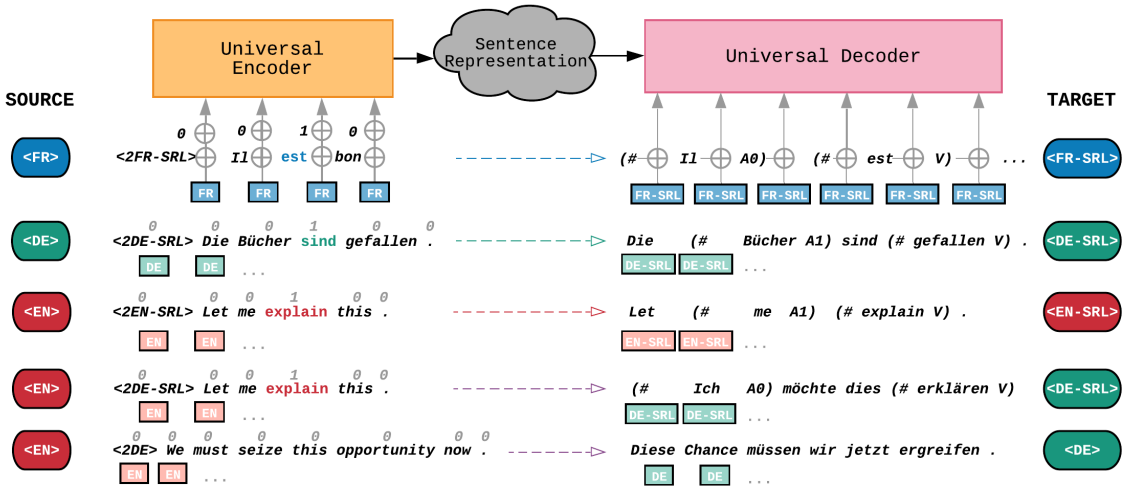

Figure 3: A universal structure-inducing Enc-Dec model with copying and sharing of parameters across languages that jointly translates and labels sentences. It can also be trained cross-lingually and be augmented with classic machine translation data (as shown in the two bottom rows of the figure).

each of them with a randomly initialized language indicator vector that we tune during training. The model can use these language indicator embedding vectors to leverage language-specific properties when generating SRL annotations. Also, by using these embeddings in the decoder, we can help it to stay consistent regarding the language it generates[4].

Thus, in all multilingual settings, at each time step t we feed the **Encoder** with a concatenation of the previous encoder state h_{t-1}, the word embedding w_t of the current token, the embedded predicate indicator p_t and the language indicator embedding l_t. The Encoder state update is defined as:

$$h_t = LSTM([h_{t-1}; w_t; p_t; l_t]) \quad (3)$$

Likewise, on the **Decoder** side we concatenate the representations for both word tokens and label tokens with the language indicator vector to produce tokens in a specific language. For SRL-labeled output sentences the indicator token for the language embedding is *DE-SRL, FR-SRL, ...* depending on the target language. Formally, at each time step the decoder updates its state by taking into account the previous decoder state s_{t-1}, the previous generated token[5] y_{t-1}, the language indicator embedding l_{t-1} and the attention context vector c_t:

$$s_t = LSTM([s_{t-1}; y_{t-1}; l_{t-1}; c_t]) \quad (4)$$

3 Data

3.1 SRL Monolingual Datasets

Two labeling schemes have been established for PropBank SRL: span-based and dependency-based. In the former, arguments are characterized as word-spans. This scheme was introduced in the CoNLL-05 Shared-task (Carreras and Màrquez, 2005) and is available only for English. In the dependency-based SRL format, only the syntactic heads of arguments are labeled. This format was defined in the CoNLL-09 Shared task (Hajič et al., 2009), which includes SRL labeled data for seven languages.[6]

We will use span-based and dependency-based data for English to benchmark the monolingual system. For the multilingual experiments, we use the dependency-based annotations, given that there is labeled data available in different languages on this format. Specifically, we use the English and German portions of CoNLL-09 and the automatically annotated French SRL corpus of van der Plas et al. (2011) for training and the human-labeled sentences from van der Plas et al. (2010) for testing. Both corpora contain a similar

[4] Johnson et al. (2017) only use a translation token, but our training data is significantly smaller than theirs.

[5] During training we use teacher forcing, feeding the gold target token instead of the previously generated token

[6] Note that CoNLL-09 is not a parallel corpus. All data was annotated independently and later ported to CoNLL.

Mono-lingual	Language	Train		Test
		# Sents	w/ 1-Pred	w/ 1-Pred
CoNLL-05	EN [Span]	75,187	94,497	5,476
CoNLL-09	EN [Dep]	39,279	180,446	10,626
CoNLL-09	DE [Dep]	36,020	39,138	2,044
v.d. Plas	FR [Dep]	40,075	73,094	2,036

Table 1: Train and Test Data for Monolingual Models. We show the original number of sentences and the size of the "expanded" data with one copy per predicate.

Cross-lingual Model	# Sentences
EN - DE-SRL (Akbik, 2015)	63,397
EN - FR-SRL (Akbik, 2015)	40,827
EN - FR (UN)	100,000
EN - DE (Europarl)	100,000

Table 2: Data used for Cross-lingual Models: From the SRL parallel data available we take 90% for training and use the rest as a *Dev* set for our experiments. We add the non-labeled data (from UN and Europarl) during training to enforce translation knowledge.

label set as the English PropBank[7]. For statistics on the size of the datasets see Table 1.

3.2 Datasets for Cross-lingual SRL

We use the dependency-based labeled German and French SRL corpus from Akbik et al. (2015) which was produced via annotation projection. These sentences are already pre-filtered to ensure that the predicate sense of the source predicate is preserved in the target sentence. Since the role labels are projected from automatically PropBank-parsed English sentences, all languages share the same label set. The underlying corpus for this dataset is composed of Machine Translation (MT) parallel corpora: Europarl (Koehn, 2005) for *EN-DE* (about 63K sents), and UN (Ziemski et al., 2016) for *EN-FR* (about 40K sents).

Since we only had access to the labeled sentences (target-side), we constructed our parallel training pairs *EN* to *FR-SRL* and *EN* to *DE-SRL* by finding the original source English counterparts. We use Flair (Akbik et al., 2018) to predict PropBank frames on the English source sentences and find the alignment to the labeled predicate on the target side using fast-align (Dyer et al., 2013).

In addition to the parallel SRL-labeled data, we choose a subset of 100K parallel (non-labeled) sentences for each language pair from the mentioned MT datasets (Europarl and UN corpora) to improve the translation quality of the model, we use 90% for training and the rest as a development set. The data is summarized in Table 2.

[7]French data was directly annotated using the English labelset but German CoNLL-09 contains additional core labels A5-A9 and does not contain *AM-* modifier labels

4 Experiments and Results

4.1 General Settings

We use the AllenNLP (Gardner et al., 2018) Enc-Dec model as a basis for our implementation. Our model is trained to minimize the negative log-likelihood of the next token. Hyperparameters and model sizes are provided in Supplement A.1. We use pre-trained word embeddings (fine-tuned during training) for the 3 languages: GloVe (Pennington et al., 2014) for *EN* and the pre-trained vectors from Grave et al. (2018) for *FR* and *DE*. We also train versions with contextual word representations: pre-trained English 1024-dimensional ELMo (Peters et al., 2018) and multilingual 768-dimensional BERT-small (Devlin et al., 2019) representations.

4.2 Monolingual Experiments and Results

We train three separate monolingual versions for *EN*, *DE* and *FR*. We first benchmark our system against a wide variety of English models (span- and dependency-based) that perform the role classification task with gold predicates to show that our labeling performance is competitive with the existent SOTA neural models for English. This is shown in Table 3. The performance of *DE* and *FR* is shown in Table 4 where we compare all monolingual systems for the three languages (top half), against the one-to-one multilingual versions (bottom half). Results for *EN* show that the Enc-Dec architecture is competitive with the GloVe-based models (although still 4 F1 points below SOTA in most cases), however it benefits more from ELMo, achieving SOTA results for span-based and dependency-based SRL.

4.3 Multilingual Experiments and Results

We train a single multilingual model with the concatenation of the training data for the three languages *EN*, *DE* and *FR* that we previously used on the monolingual experiments. We use a common vocabulary for the three languages and keep all tokens that occur more than 5 times in the combined dataset. We train the model with batches containing instances randomly chosen from the individual languages (this means that each batch might contain examples from different language pairs).

Table 4: F1 scores for role labeling on dependency-based SRL data. EN and DE Tests: CoNLL-09; FR-Test: van der Plas et al. (2011). State of the art (SOTA) models* are: Cai et al. (2018) [GloVe] for EN, Roth and Lapata (2016) [Dependency-path Embeddings] for DE and van der Plas et al. (2014) [Non-neural] for FR, respectively.

Multilingual training yields improvement on the three languages studied in this paper when compared to our monolingual baselines, particularly for German, which shows more than 6 points (F1) of improvement. In addition, we compare with the polyglot SRL system of Mulcaire et al. (2018) (which also leverages data from multiple languages during training), obtaining better results for English using GloVe. We then show that adding contextual representations to our model results in bigger improvements across the board.

4.4 Cross-Lingual Experiments and Results

Training. After validating the robustness of our architecture when handling different languages at the same time, we now train a cross-lingual SRL version. This setting differs from the previous two because the model needs to learn two tasks: besides generating appropriate SRL labels, it needs to translate from source into a target language. To do so, we train a single model using the concatenation of the parallel datasets listed in Table 2 and described in Section 3.2. We further include Machine Translation (MT) data to reinforce the translation knowledge of the model, so that it can generate fluent (labeled) target sentences. As in the multilingual experiments, we train the model with alternating batches of instances randomly chosen from the individual language pairs. Note that the amount of MT data that we can add is restricted: the labeled multilingual data is relatively small and labeling performance suffers when the MT data gets too dominant.

Evaluating Cross-lingual SRL. As in classical MT, evaluation is difficult, since the system outputs will approximate a target reference but will never be guaranteed to match it. Hence in this setting we do not have a proper gold standard to evaluate the labeled outputs, since we are generating labeled target sentences from scratch. Similar to MT research, we apply BLEU score (Papineni et al., 2002) to measure the closeness of the outputs against our *Dev* Set.

The upper part of Table 5 compares the scores of two versions of the Enc-Dec model trained on the cross-lingual data from Table 2 systems, one using GloVe embeddings and the second using BERT, respectively. To better distinguish translation vs. labeling quality, we compute BLEU scores for the system outputs against labeled reference sentences in three different ways: on *words only*, *labels only*, and on *full labeled sequences* (both word and label outputs). We see that the prediction of words is similar in the two languages, but labeling is more difficult for *DE* than for *FR* for both systems. Also we observe that adding multilingual BERT is very helpful to obtain even more fluent and correct labeled outputs (according to BLEU) resulting in ca. +9 points in German and +5 in French on the full sequences. This is very important given that we have a small training set compared to classic NMT scenarios.

The bottom part of Table 5 shows the scores when restricting the evaluation to sentences with score ≥ 10. We observed that this threshold[8] is a good trade-off in both the amount of kept sentences (above the threshold) and average BLEU

[8]We tried with thresholds of 5, 10, 20 and 30.

	German			French		
Model [Filter]	**F-Seq**	**Word**	**Label**	**F-Seq**	**Word**	**Label**
XL-GloVe [All]	18.86	17.17	25.52	28.99	17.36	32.76
XL-BERT [All]	27.22	27.36	29.59	33.59	22.48	37.17
XL-GloVe [$\geq$ 10]	30.58	36.71	51.68	38.99	43.79	61.73
XL-BERT [$\geq$ 10]	36.95	41.36	55.73	42.66	46.52	65.32

Table 5: Cross-lingual (XL) system results using BLEU score on individual languages inside the *Dev* set. We compute BLEU on labeled sequences (F-Seq), and separately for words and only labels. We also show scores when pre-filtering on F-Seq with BLEU $\geq$ 10.

score increase (presumably sentence quality). By keeping only the filtered subset of sentences we get an improvement on average of approx. 10 BLEU points on the full sequences (*F-Seq*), and almost double the score for *labels only*. This holds for GloVe and BERT versions on both languages.

Output Filtering and Data Generation. We use our cross-lingual model as a labeled data generator by applying it on *EN* sentences from Europarl (100K) and UN corpora (100K)[9] and let the model predict *DE-SRL* and *FR-SRL* as target languages. This results in *unseen* German and French labeled sentences. Since we cannot guarantee that the generated sentences preserve the source predicate meaning, we filter all outputs by keeping only those that come close to the original sentence meaning. We approximate this by back-translating the generated outputs (stripping the labels and keeping only the words) using the pre-trained *DE-EN* model from OpenNMT (Klein et al., 2017).

We compare the back-translations to the sentences that we originally presented to the system and, using the previously described filtering heuristic, we keep only those whose BLEU score is equal or greater than 10. The logic behind this is that if the back-translation is close enough to the source, the generated sentence preserves a fair amount of the original sentence meaning[10]. With this strategy, after applying the *BLEU filter*, we end up with a parallel dataset of 44K generated sentences for *(EN, DE-SRL)* and 32K for (*EN*, *FR-SRL*). In the next section we show more detailed evaluation measures of the system outputs, focusing on the filtered dataset that we just described.

[9]Note that these are taken from a different subset than the parallel sentences used during training.

[10]BLEU score is used as a naive approach to avoid excessively noisy data but we could also develop, for example, a semantic similarity metric to also keep sentences that are close enough to the original predicate sense meaning.

4.5 Cross-Lingual Detailed Evaluation

We are aware that BLEU score gives only a rough estimate of the actual quality of the outputs, therefore we propose to measure the performance of our system in two more detailed evaluation settings: (i) a small-scale **human evaluation** where we evaluate the assigned SRL labels against 226 sentences that were manually judged and annotated to give an estimation of the quality of the generated data, (ii) an **extrinsic evaluation** using labeled sentences generated by our system to augment the training set for a resource-poor language. We conduct the extrinsic evaluation on German and French and the manual evaluation only on the German data, which proved to be the more challenging language compared to French.

4.5.1 Human Evaluation

To provide an in-depth quality assessment of the generated sentences, we create a small-scale gold standard consisting of 226 sentences. To select a representative sample from our newly generated labeled sentences,[11] we analyze the distribution of labels in the data and apply stratified sampling to cover as many predicates as possible and as many role label variants as possible. We judge these sentences on the quality of the generated language and annotate them with PropBank roles.

SRL Gold Standard. As we are lacking trained PropBank annotators, we mimic the question-based role annotation method of He et al. (2015), who constructed QA pairs in order to label the predicate-argument structure of verbs. The annotation involves several subtasks: The first is to generate questions targeting a specific verb in a sentence and to mark as answers a subset of words from the same sentence. The next subtask is to choose the head word of each selected subset and to assign a PropBank label to this head according to a table that correlates WH-phrases with the most likely label.[12]

We ask two linguistically trained annotators to perform the whole task independently and compute Krippendorff's Alpha (Krippendorff, 1980) on the role labels, which results in an inter-annotator agreement score of 82.83. We resolved conflicting annotations through discussion among

[11]i.e., the generated sentences for which we measured a BLEU score $\geq$ 10 against the source using back-translation.

[12]We provide this correlation table and the full annotation guidelines in appendix A.2 in the Supplement.

the annotators. The resulting gold standard contains 737 annotated roles. Notably, the most prominent roles (as in the CoNLL datasets) are A0 and A1 which are normally related to the agent and the patient in sentences, but the annotated data also includes modifier roles such as temporal, modal, discourse markers, among others[13].

Translation Quality. We ask two different annotators to score each output sentence (they see only the words, not the labels) on a scale of 1-5 for *Quality* (1: 'is completely ungrammatical'; 5: 'is perfectly grammatical') and for *Naturalness* (1: 'The sentence is not what a native speaker would write'; 5: 'The sentence could have been written by a native speaker'). We obtain a high average score of 4.4 for *Quality* and 4.2 for *Naturalness*.

SRL Performance on Gold Standard. We use our human-annotated sentences to measure the automatic labeling performance of our cross-lingual SRL model which we call XL-BERT). We obtain 73.21 F1 score (73.33 precision, 73.1 recall). We also measure the performance of the ZAP label projection system of Akbik and Vollgraf (2018) on this data (we only consider arguments of the predicates that were annotated). ZAP obtains a low F1 score of 56.03 (42.65 precision, 81.7 recall). Thus, XL-BERT shows much better, and more precise results compared to this baseline and achieves overall very acceptable and stable labeling quality. This shows that the joint translation-labeling task is successful. ZAP, by contrast, shows more unstable results, which might be due to word alignment noise. Although we train on such data, our model can also loose some of this noise, given that the same model is trained to produce more than one labeled language, namely *FR-SRL* and *DE-SRL*.

4.5.2 Extrinsic Task: Data Augmentation

Finally, we augment the training sets of our two resource-poor languages *DE* and *FR*, in portions of 10K until we cover the complete generated data. We compare the increase in F1 score when training models with different amounts of additional data. We also add a comparison of the improvement achieved when adding the same amount of sentences produced by the labeled projection method of Akbik et al. (2015). We see in Table 6 that adding our German data shows improvement in F1 score, despite the fact that the CoNLL-09 label scheme has arguments not seen in our training data (namely A5-A9). Presumably we see this improvement because the frequency of the major roles is more prominent. In the case of French, we don't see significant improvement, however also here the addition of projected data shows a similar trend.

[13]The label distribution is given in the Supplement, A.3.

Model + Training Data	Data Size	F1 Test
DE [Mono] *(Original)*	39K	61.9
DE [Mono] + *LabelProj*	83K	62.37
DE [Mono] + OurGen10K	49K	62.4
DE [Mono] + OurGen20K	59K	62.46
DE [Mono] + OurGen30K	69K	62.81
DE [Mono] + OurGenALL	**83K**	**63.57**
FR [Mono] *(Original)*	73K	70.3
FR [Mono] + *LabelProj*	105K	70.45
FR [Mono] + OurGen10K	83K	70.33
FR [Mono] + OurGen20K	**93K**	**70.52**
FR [Mono] + OurGenALL	105K	70.39

Table 6: We retrain the monolingual systems *DE, FR* using the original training sets (BL: *Original*) shown in Table 1 and inject our generated data in different sizes. We also compare to the stronger baseline *LabelProj* where we add data created by label projection (Akbik et al., 2015).

5 Related Work

Encoder-Decoder Models. A wide range of NMT models are based on the Encoder-Decoder approach (Sutskever et al., 2014) with attention mechanism (Bahdanau et al., 2015; Luong et al., 2015). More recent architectures (Zoph and Knight, 2016; Firat et al., 2016a) show that training with multiple languages performs better than one-to-one NMT. Multilingual models have also been trained to perform Zero-shot translation (Johnson et al., 2017; Firat et al., 2016b). The Enc-Dec approach has been tested in many tasks that can be formulated as a sequence transduction problem: syntactic parsing (Vinyals et al., 2015), AMR and Semantic Parsing (Konstas et al., 2017; Dong and Lapata, 2016) and SRL (Daza and Frank, 2018). The most similar approach to ours is Zhang et al. (2017), who propose a cross-lingual Enc-Dec that produces OpenIE-annotated English given a Chinese sentence. However, their setup is easier than ours since they have a reliable labeler on the target side, facilitating the generation of more training data unlike us who are interested in labeling the resource-poor language.

Cross-lingual Annotation Projection. A common approach to address the lack of annotations is projecting labels from English to a lower-resource language of interest. This has shown good results in the transfer of semantic information to target languages. Kozhevnikov and Titov (2013) propose an unsupervised method to transfer SRL labels to another language by training on the source side and using shared feature representations for predicting on the target side. Padó and Lapata (2009) project FrameNet (Baker et al., 1998) SRL labels by searching for the best alignment in source and target constituent trees, defining label transfer as an optimization problem in a bipartite graph. van der Plas et al. (2011) use intersective word alignments between English and French with additional filtering heuristics to determine whether a PropBank label should be transferred and then use this to train a joint syntactic-semantic parser for both languages. Akbik et al. (2015) proposes a higher-confidence projection by first creating a system with high precision and low recall and then using a bootstrap approach to augment the labeled data.

Separately, Minard et al. (2016) generated a multilingual event and time parallel corpus including SRL annotations. Their corpus was manually annotated on the English side and automatically projected to Italian, Spanish, and Dutch based on the manual alignment of the annotated elements. Unfortunately, the authors do not report the performance of the SRL task, making it difficult for us to use their data for benchmarking.

Semantic Role Labeling. Span-based SRL only exists on English data (Zhou and Xu, 2015; He et al., 2018; Strubell et al., 2018; Ouchi et al., 2018). Dependency-based SRL models such as (Marcheggiani and Titov, 2017; Cai et al., 2018; Li et al., 2019) are the state-of-the-art for English. For French, we compare against van der Plas et al. (2014) since we did not find more recent work for that language. Roth and Lapata (2016) show a model based on dependency path embeddings that achieved SOTA in English and German. The Polyglot SRL model of Mulcaire et al. (2018) shows some improvement over monolingual baselines when aggregating all multilingual data available from CoNLL-09, while more refined integration did not show further improvement. Their system does not perform better than our multilingual models for English and German.

6 Conclusions

We presented the first cross-lingual SRL system that translates a sentence and concurrently labels it with PropBank roles. The proposed Enc-Dec architecture is flexible: as a *monolingual* system the model achieves SOTA for English PropBank role labeling, the *multilingual* SRL system shows that joining multiple languages improves SRL performance over the monolingual baselines, and a *cross-lingual* system can be used to generate SRL-labeled data for lower-resource languages. Evaluation of the cross-lingual system shows that the quality-filtered sentences are highly grammatical and natural, and that the generated PropBank labels can be more precise than label projection. Using our labeled data beats a label projection baseline when using it to augment the training set of a lower-resource language.

An advantage of our proposed model is that it does not need parallel data at inference time. Our current model can possibly be further improved by adding more automatically generated data in the data augmentation scenario, or by targeted selection in an active learning setting. Current limitations of the system may be alleviated by pretraining the model to acquire better translation knowledge from larger training data, and by developing more refined filtering methods.

In future work we also aim to make the system more flexible, by extending it to few-shot or zero-shot learning, to alleviate the need for an initial big annotated set, and thus to be able to generate SRL data for truly resource-poor languages. Further challenges for this novel architecture are to extend it to joint predicate and role labeling for more than one predicate at a time.

Syntax-Enhanced Self-Attention-Based Semantic Role Labeling

Yue Zhang, Rui Wang, Luo Si
Alibaba Group, China
{shiyu.zy, masi.wr, luo.si}@alibaba-inc.com

Abstract

As a fundamental NLP task, semantic role labeling (SRL) aims to discover the semantic roles for each predicate within one sentence. This paper investigates how to incorporate syntactic knowledge into the SRL task effectively. We present different approaches of encoding the syntactic information derived from dependency trees of different quality and representations; we propose a syntax-enhanced self-attention model and compare it with other two strong baseline methods; and we conduct experiments with newly published deep contextualized word representations as well. The experiment results demonstrate that with proper incorporation of the high quality syntactic information, our model achieves a new state-of-the-art performance for the Chinese SRL task on the CoNLL-2009 dataset.

1 Introduction

The task of semantic role labeling (SRL) is to recognize arguments for a given predicate in one sentence and assign labels to them, including "who" did "what" to "whom", "when", "where", etc. Figure 1 is an example sentence with both semantic roles and syntactic dependencies. Since the nature of semantic roles is more abstract than the syntactic dependencies, SRL has a wide range of applications in different areas, e.g., text classification (Sinoara et al., 2016), text summarization (Genest and Lapalme, 2011; Khan et al., 2015), recognizing textual entailment (Burchardt et al., 2007; Stern and Dagan, 2014), information extraction (Surdeanu et al., 2003), question answering (Shen and Lapata, 2007; Yih et al., 2016), and so on.

Traditionally, syntax is the bridge to reach semantics. However, along with the popularity of the end-to-end models in the NLP community, various recent studies have been discussing the necessity of syntax in the context of SRL. For instance, He et al. (2017) have observed that only good syntax helps with the SRL performance. Xia et al. (2019) have explored what kind of syntactic information or structure is better suited for the SRL model. Cai et al. (2018) have compared syntax-agnostic and syntax-aware approaches and claim that the syntax-agnostic model surpasses the syntax-aware ones.

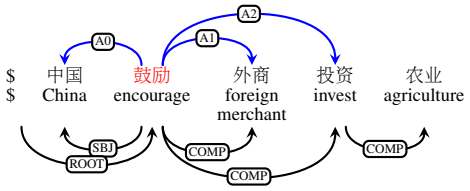

Figure 1: An example of one sentence with its syntactic dependency tree and semantic roles. Arcs above the sentence are semantic role annotations for the predicate "鼓励 (encourage)" and below the sentence are syntactic dependency annotations of the whole sentence. The meaning of this sentence is "China encourages foreign merchants to invest in agriculture".

In this paper, we focus on analyzing the relationship between the syntactic dependency information and the SRL performance. In particular, we investigate the following four aspects: 1) *Quality* of the syntactic information: whether the performance of the syntactic parser output affects the SRL performance; 2) *Representation* of the syntactic information: how to represent the syntactic dependencies to better preserve the original structural information; 3) *Incorporation* of the syntactic information: at which layer of the SRL model and how to incorporate the syntactic information; and 4) the *Relationship* with other external resources: when we append other external resources into the SRL model, whether their contributions are orthogonal to the syntactic dependencies.

For the main architecture of the SRL model, many neural-network-based models use BiLSTM

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 616–626, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

as the encoder (e.g., Cai et al. (2018); Li et al. (2018); He et al. (2018)), while recently self-attention-based encoder becomes popular due to both the effectiveness and the efficiency (Vaswani et al., 2017; Tan et al., 2017; Strubell et al., 2018). By its nature, the self-attention-based model directly captures the relation between words in the sentence, which is convenient to incorporate syntactic dependency information. Strubell et al. (2018) replace one attention head with pre-trained syntactic dependency information, which can be viewed as a *hard* way to inject syntax into the neural model. Enlightened by the machine translation model proposed by Shaw et al. (2018), we introduce the *Relation-Aware* method to incorporate syntactic dependencies, which is a *softer* way to encode richer structural information.

Various experiments for the Chinese SRL on the CoNLL-2009 dataset are conducted to evaluate our hypotheses. From the empirical results, we observe that: 1) The quality of the syntactic information is essential when we incorporate structural information into the SRL model; 2) Deeper integration of the syntactic information achieves better results than the simple concatenation to the inputs; 3) External pre-trained contextualized word representations help to boost the SRL performance further, which is not entirely overlapping with the syntactic information.

In summary, the contributions of our work are:

- We present detailed experiments on different aspects of incorporating syntactic information into the SRL model, in what quality, in which representation and how to integrate.
- We introduce the relation-aware approach to employ syntactic dependencies into the self-attention-based SRL model.
- We compare our approach with previous studies, and achieve state-of-the-art results with and without external resources, i.e., in the so-called *closed* and *open* settings.

2 Related work

Traditional semantic role labeling task (Gildea and Jurafsky, 2002) presumes that the syntactic structure of the sentence is given, either being a constituent tree or a dependency tree, like in the CoNLL shared tasks (Carreras and Màrquez, 2005; Surdeanu et al., 2008; Hajič et al., 2009). Recent neural-network-based approaches can be roughly categorized into two classes: 1) making use of the syntactic information (FitzGerald et al., 2015; Roth and Lapata, 2016; Qian et al., 2017; Marcheggiani and Titov, 2017), and 2) pure end-to-end learning from tokens to semantic labels, e.g., Zhou and Xu (2015); Marcheggiani et al. (2017).

Roth and Lapata (2016) utilize an LSTM model to obtain embeddings from the syntactic dependency paths; while Marcheggiani and Titov (2017) construct Graph Convolutional Networks to encode the dependency structure. Although He et al. (2017)'s approach is a pure end-to-end learning, they have included an analysis of adding syntactic dependency information into English SRL in the discussion section. Cai et al. (2018) have compared syntax-agnostic and syntax-aware approaches and Xia et al. (2019) have compared different ways to represent and encode the syntactic knowledge.

In another line of research, Tan et al. (2017) utilize the Transformer network for the encoder instead of the BiLSTM. Strubell et al. (2018) present a novel and effective multi-head self-attention model to incorporate syntax, which is called LISA (Linguistically-Informed Self-Attention). We follow their approach of replacing one attention head with the dependency head information, but use a softer way to capture the pairwise relationship between input elements (Shaw et al., 2018).

For the datasets and annotations of the SRL task, most of the previous research focuses on 1) PropBank (Palmer et al., 2005) and NomBank (Meyers et al., 2004) annotations, i.e., the CoNLL 2005 (Carreras and Màrquez, 2005) and CoNLL 2009 (Hajič et al., 2009) shared tasks; 2) OntoNotes annotations (Weischedel et al., 2011), i.e., the CoNLL 2005 and CoNLL 2012 datasets and more; 3) and FrameNet (Baker et al., 1998) annotations. For the non-English languages, not all of them are widely available. Apart from these, in the broad range of semantic processing, other formalisms non-exhaustively include abstract meaning representation (Banarescu et al., 2013), universal decompositional semantics (White et al., 2016), and semantic dependency parsing (Oepen et al., 2015). Abend and Rappoport (2017) give a better overview of various semantic representations. In this paper, we primarily work on the Chinese and English datasets from the

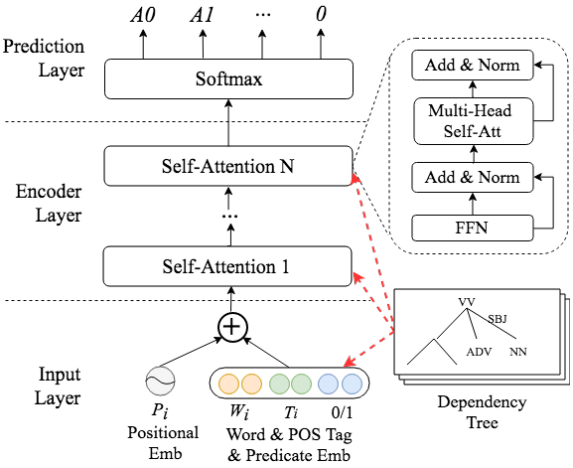

Figure 2: Architecture of our syntax-enhanced self-attention-based SRL model. Red dotted arrows indicate different locations where we incorporate linguistic knowledge in different forms. The dotted box on the upper right is the detailed composition of the self-attention block.

CoNLL-2009 shared task and focus on the effectiveness of incorporating syntax into the Chinese SRL task.

3 Approaches

In this section, we first introduce the basic architecture of our self-attention-based SRL model, and then present two different ways to encode the syntactic dependency information. Afterwards, we compare three approaches to incorporate the syntax into the base model, concatenation to the input embedding, LISA, and our proposed relation-aware method.

3.1 The Basic Architecture

Our basic model is a multi-head self-attention-based model, which is effective in SRL task as previous work proves (Tan et al., 2018). The model consists of three layers: the input layer, the encoder layer and the prediction layer as shown in Figure 2.

3.1.1 Input Layer

The input layer contains three types of embeddings: token embedding, predicate embedding, and positional embedding.

Token Embedding includes word embedding, part-of-speech (POS) tag embedding.

Predicate Embedding has been proposed by He et al. (2017), and its binary embedding is used to indicate the predicates indices in each sentence.

Positional Embedding encodes the order of the input word sequence. We follow Vaswani et al. (2017) to use time positional embedding, which is formulated as follows:

$$\begin{aligned} PE(t, 2i) &= sin(t/10000^{2i/d}) \\ PE(t, 2i+1) &= cos(t/10000^{2i/d}) \end{aligned} \quad (1)$$

where t is the position, i means the dimension, and d is the dimension of the model input embedding.

3.1.2 Encoder Layer

The self-attention block is almost the same as Transformer encoder proposed by Vaswani et al. (2017). Specifically the Transformer encoder contains a feed-forward network (**FFN**) and a multi-head attention network. The former is followed by the latter. In this work, we exchange their order, so that the multi-head attention module is moved behind the FFN module[1] as Figure 2 shows.

FFN The FFN module consists of two affine layers with a ReLU activation in the middle. Formally, we have the following equation:

$$FFN(x) = max(0, xW_1 + b_1)W_2 + b_2 \quad (2)$$

Multi-Head Attention The basic attention mechanism used in the multi-head attention function is called "Scaled Dot-Product Attention", which is formulated as follows:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V \quad (3)$$

where Q is queries, K is keys, and V is values.

In the multi-head attention setting, it first maps the input matrix X into queries, keys and values matrices by using h different learned linear projections. Taking queries Q as an example:

$$Linear_i^Q(X) = XW_i^Q + b_i^Q \quad (4)$$

where $0 \leq i < h$. Keys and values use similar projections.

On each of these projections, we perform the scaled dot-product attention in parallel. These parallel output values are concatenated and once again projected into the final values. Equation 5 depicts the above operations.

$$MultiHead(X) = Concat(head_1, \ldots, head_h)W^O \quad (5)$$

[1]Changing the order delivers better empirical results (Tan et al., 2018) and our experiments show the same trend. The details of the experiments are not listed in this paper.

where

$$head_i = Attention(Linear_i^Q(X), Linear_i^K(X), Linear_i^V(X)) \quad (6)$$

More details about multi-head attention can be found in Vaswani et al. (2017).

Add & Norm We employ a residual connection to each module, followed by a layer normalization (Ba et al., 2016) operation. The output of each module is formulated as

$$x = LayerNorm(x + f(x)) \quad (7)$$

where $f(x)$ is implemented by each above module.

3.2 Representation of the Syntactic Dependencies

3.2.1 Dependency Head & Relation

The most intuitive way to represent syntactic information is to use individual dependency relations directly, like dependency head and dependency relation label, denoted as DEP and REL for short.

Except for LISA, where DEP is a one-hot matrix of dependency head word index described in 3.3.2, in other cases, we use the corresponding head word. REL is the dependency relation between the word and its syntactic head. We take both DEP and REL as common strings and map them into dense vectors in the similar way of word embedding.

3.2.2 Dependency Path & Relation Path

In order to preserve the structural information of dependency trees as much as possible, we take the syntactic path between candidate arguments and predicates in dependency trees as linguistic knowledge. Referring to Xia et al. (2019), we use the Tree-based Position Feature (TPF) as Dependency Path (DEPPATH) and use the Shortest Dependency Path (SDP) as Relation Path (RELPATH).

To generate DEPPATH & RELPATH between candidate argument and predicate, we firstly find their lowest common ancestor. Then we get two sub-paths, one is from the ancestor to the predicate and the other is from the ancestor to the argument. For DEPPATH, we compute distance from ancestor to predicate and argument respectively and then concatenate two distances with the separator ‘,’.

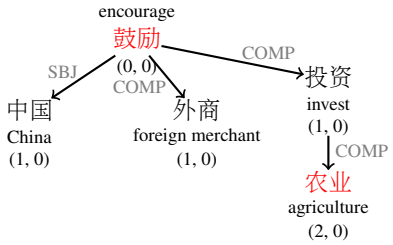

Figure 3: The syntactic dependency tree of the sentence “中国鼓励外商投资农业” (China encourages foreign merchants to invest in agriculture). Numbers in brackets are the DEPPATH for each candidate argument with the predicate “鼓励 (encourage)”. Light grey labels on the arcs are the syntactic dependency labels.

For RELPATH, we concatenate the labels appearing in each sub-path with the separator “_” respectively to get two label paths, and then concatenate the two label paths with the separator ‘,’.

As shown in Figure 3, the lowest common ancestor of the predicate “鼓励 (encourage)” and the candidate argument “农业 (agriculture)” is “鼓励 (encourage)”, so their DEPPATH is “2,0” and its RELPATH is “COMP_COMP,”[2].

We take both DEPPATH and RELPATH as common strings and map them into dense vectors in the similar way of DEP and REL.

3.3 Incorporation Methods

3.3.1 Input Embedding Concatenation

To incorporate syntactic knowledge, one simple method is to take it as part of the neural network input, denoted as INPUT. We represent the syntactic information with dense vectors, and concatenate it with other information like word embedding:

$$input = E_W \oplus E_S. \quad (8)$$

where $\oplus$ means concatenation; E_W means the original inputs of the neural model and E_S means the embedding of syntax information, such as DEP/REL or DEPPATH/RELPATH.

3.3.2 LISA

Strubell et al. (2018) propose the linguistically-informed self-attention model (LISA for short) to combine SRL and dependency parsing as multi-task learning in a subtle way. Based on the multi-head self-attention model, LISA uses one attention head to predict the dependency results and it

[2] When predicate is the ancestor of argument, sub-path from ancestor to predicate is none. We use ‘0’ to represent distance and use empty string to represent the label path, and vice versa.

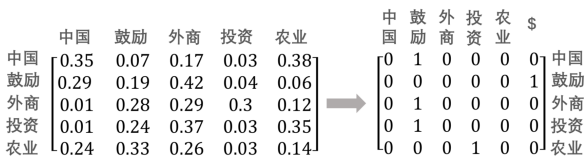

Figure 4: Attention matrix of the replaced attention head in the LISA model. The left matrix is the original $softmax$ attention, and the right is a one-hot matrix copied from the syntactic dependency head results.

can also directly use pre-trained dependency head results to replace the attention matrix during testing.

Being different from their multi-task learning, we make the replacement of one attention head during both training and testing. Instead of the original $softmax$ attention matrix, we use a one-hot matrix, generated by mapping the dependency head index of each word into a 0-1 vector of the sentence length as Figure 4 shows.

We add the dependency relation information with V in the replaced head so that we can make full use of the syntactic knowledge. The replaced attention head is formulated as follows:

$$Attention(Q, K, V) = M_D\ (V \oplus E_R) \quad (9)$$

where M_D is the one-hot dependency head matrix and E_R means the embedding of dependency relation information, such as REL or RELPATH.

3.3.3 Relation-Aware Self-Attention

Relation-aware self-attention model (RELAWE for brevity) incorporates external information into the attention. By this way, the model considers the pairwise relationships between input elements, which highly agrees with the task of SRL, i.e., aiming to find the semantic relations between the candidate argument and predicate in one sentence.

Compared to the standard attention, in this paper, we add the dependency information into Q and V in each attention head, like equation (10) shows:

$$Attention(Q, K, V) = softmax(\frac{(Q + E_D + E_R)K^T}{\sqrt{d_k}})(V + E_D + E_R) \quad (10)$$

where E_D and E_R mean the syntactic dependency head and relation information respectively. For our multi-layer multi-head self-attention model, we make this change to each head of the first N self-attention layers.

	dev		test	
	UAS	**LAS**	**UAS**	**LAS**
AUTO	80.50	78.34	80.70	78.46
BIAFFINE	89.00	85.86	89.05	85.60
BIAFFINEBERT	91.76	89.08	92.14	89.23

Table 1: Syntactic dependency performance for different parsers. AUTO indicates the automatic dependency trees provided by the CoNLL-09 Chinese dataset. BIAFFINE means the trees are generated by BiaffineParser with pre-trained word embedding on the Gigaword corpus while BIAFFINEBERT is the same parser with BERT. We use the labeled accuracy score (LAS) and unlabeled accuracy score (UAS) to measure the quality of syntactic dependency trees.

4 Experiment

4.1 Settings

Datasets & Evaluation Metrics Our experiments are conducted on the CoNLL-2009 shared task dataset (Hajič et al., 2009). We use the official evaluation script to compare the output of different system configurations, and report the labeled precision (P), labeled recall (R) and labeled f-score (F1) for the semantic dependencies.

Word Representations Most of our experiments are conducted in the *closed* setting without any external word embeddings or data resources than those provided by the CoNLL-2009 datasets. In the *closed* setting, word embedding is initialized by a Gaussian distribution with mean 0 and variance $\frac{1}{\sqrt{d}}$, where d is the dimension of embedding size of each layer.

For the experiments with external resources in the *open* setting, we utilize 1) word embeddings pre-trained with GloVe (Pennington et al., 2014) on the Gigaword corpus for Chinese and the published embeddings with 100 dimensions pre-trained on Wikipedia and Gigaword for English; and 2) ELMo[3] (Peters et al., 2018) and BERT[4] (Devlin et al., 2018), two recently proposed effective deep contextualized word representations[5].

[3]We use the released model on their website: https://github.com/allenai/allennlp/blob/master/tutorials/how_to/elmo.md

[4]We generate our pre-trained BERT embedding with the released model in https://github.com/google-research/bert. The model uses character-based tokenization for Chinese, which require us to maintain alignment between our input text and output text of Bert. So we take take embedding of the first word piece as the whole word representation.

[5]In *open* setting, we use pre-trained word embedding instead of random initialized embedding. If using BERT and Elmo additionally, we project them into representation vectors of same dimension as word embedding and concatenate

Other embeddings, i.e., POS embedding, linguistic knowledge embedding, and so on are initialized in same way as random word embedding no matter in *closed* or *open* setting.

Syntactic Parsers In Table 1, both AUTO and GOLD syntactic dependencies are provided by the dataset. Since the performance of the AUTO is far behind the state-of-the-art BiaffineParser (Dozat and Manning, 2016), we generate more dependency results by training BiaffineParser[6] with different external knowledge, including pre-trained word embedding and BERT. Performance for different parsers is listed in Table 1.

Parameters In this work, we set word embedding size $d_w = 100$, POS embedding size $d_t = 50$. The predicate embedding size is set as $d_p = 100$. The syntax-related embedding size varies along with different configurations, so as the feature embedding size d_f.

To facilitate residual connections, all sublayers in the model produce outputs of dimension $d_{model} = d_f + d_p$. The hidden dimension $d_{ff} = 800$ is applied for all the experiments. We set the number of shared self-attention blocks $N = 10$. The number of heads varies with d_{model}, but dimension of each head is 25. Besides, LISA incorporates syntax knowledge in the 5-th self-attention layer while RELAWE incorporates in the first 5 layers.

We apply the similar dropout strategy as Vaswani et al. (2017), i.e., the attention and residual dropout values are 0.2 and 0.3 respectively. The dropout is also applied in the middle layer of FFN with value 0.2. We also employ label smoothing (Szegedy et al., 2015) of value 0.1 during training.

We use softmax-cross-entropy as our loss function, and use the Adadelta optimizer (Zeiler, 2012) with $\epsilon = 10^{-6}$ and $\rho = 0.95$. For all experiments, we train the model $200,000$ steps with learning rate $lr = 1.0$, and each batch has 4096 words.

All the hyper-parameters are tuned on the development set.

Configurations We use different abbreviations to represent the parsing results, syntactic dependency representations, and incorporation methods. All the system configurations in our experiments are listed in Table 2.

them with other input.

[6]We split train data into 5-fold, and train model with 4-fold to generate automatic trees of the left 1-fold train data.

Abbreviation	Description
NONE	No syntactic knowledge
Syn. Parser	
AUTO	Parsing result from CoNLL09
AUTODEL	Remove syntax errors of AUTO
BIAFFINE	BiaffineParser result
BIAFFINEBERT	BiaffineParser with BERT
GOLD	Gold syntax from CoNLL09
Syn. Representation	
DEP	Dependency head
REL	Dependency relation label
DEPPATH	Tree-based position feature
RELPATH	Shortest relation label path
Incorporation	
INPUT	Add to the input embedding
LISA	From Strubell et al. (2018)
RELAWE	Relation-aware self-attention

GOLD	91.00	91.43	91.22

Table 3: SRL results with dependency trees of different quality on the Chinese dev set. These experiments are conducted on the RELAWE model with DEP&REL representations.

4.2 Quality of the Syntactic Dependencies

We use the above-mentioned dependency trees of different quality for comparison, with DEP&REL representation on our RELAWE model. In addition, we generate one more data AUTODEL by deleting all the erroneous dependency heads and relations from the provided AUTO data according to the gold heads and relations, and we do not replace them with any alternative heads and relations[7]. We take this setting as another reference (along with GOLD) to indicate that erroneous syntax information may hurt the performance of the SRL model. We take the GOLD as the upperbound reference of our task setting. Experiment results in Table 3 demonstrate that, incorporating syntactic knowledge into the SRL model can achieve better performance and overall, the better the quality is, the better the SRL model performs. This is consistent with the previous study by He et al. (2017) on the English dataset.

[7]For the AUTODEL data, we cannot guarantee that there exists a syntactic path between the two words. Therefore, we do not conduct experiments under the DepPath&RelPath setting.

GOLD			
DEPPATH&RELPATH	92.20	92.53	92.37

Table 4: SRL results with different syntactic representations on the Chinese dev set. Experiments are conducted on the RELAWE method.

Closer observation reveals two additional interesting phenomena. Firstly, SRL performance improvement is not proportionate to the improvement of dependency quality. When switching syntactic dependency trees from AUTO to BIAFFINE, SRL performance improves 0.5%, although syntactic dependency improves about 8%. In contrast, the difference between BIAFFINE and BIAFFINEBERT shows more significant improvement of 1.5%. The possible reason is that BIAFFINEBERT provides key dependency information which is missing in other configurations. Secondly, the SRL performance gap between AUTODEL and AUTO is large though they provide the same correct syntactic information. This may indicate that incorporating erroneous syntactic knowledge hurts the SRL model, and even providing more correct dependencies cannot make up for the harm (cf. BIAFFINEBERT).

4.3 Representation of the Syntactic Dependencies

Apart from DEP and REL, we also use DEPPATH and RELPATH to encode the syntactic knowledge. In this subsection, we conduct experiments to compare different syntactic encoding in our SRL model. We base the experiments on our RELAWE model, since it is easier to incorporate different representations for comparison. When generating the RELPATH, we filter the paths 1) when the dependency distance between the predicate and the candidate argument is more than 4, and 2) when the RELPATH's frequency is less than 10[8].

No matter in which representation, dependency label information is more important than the head and the combination of the two achieves better performance as our experiment results in Table 4 show. Furthermore, using BIAFFINE dependency trees, DEPPATH and RELPATH perform better than DEP and REL. This is because of the capability of DEPPATH and RELPATH to capture more structural information of the dependency trees.

Comparing Table 3 and 4, when using gold dependencies, DEPPATH&RELPATH can achieve much better result than DEP&REL. But with the AUTO trees, DEPPATH&RELPATH is much worse. Therefore, structural information is much more sensitive to the quality of dependency trees due to error propagation.

[8]As we know, dependency parsers cannot deal with long distance dependency well and it is unlikely to deliver a reliable result. And our experiments show that filtration achieves empirically better results.

Table 7: SRL results on the Chinese test set. We choose the best settings for each configuration of our model.

pendency information for the comparison.

Firstly, results in Table 5 show that with little dependency information (DEP), LISA performs better, while incorporating richer syntactic knowledge (DEP&REL or DEP&RELPATH), three methods achieve similar performance. Overall, RELAWE achieves best results given enough syntactic knowledge.

Secondly, INPUT and LISA achieve much better performance when we combine the dependency head information and the relation, while Strubell et al. (2018) have not introduced relation information to the LISA model and Xia et al. (2019) have not combined the head and relation information either. Our proposed RELAWE method with DEPPATH&RELPATH representation performs the best, which encodes the richest syntactic knowledge.

Lastly, under the same settings, LISA and RELAWE perform better than INPUT, which indicates the importance of the location where the model incorporates the syntax, the input layer vs. the encoder layer.

4.5 External Resources

Apart from the experiments with syntactic knowledge itself, we also compare different external resources to discover their relationship with the syntax, including pre-trained word embeddings, ELMo, and BERT. We conduct experiments with our best setting, the RELAWE model with DEPPATH & RELPATH and the results are listed in Table 6.

The plain word embedding improves a little in such settings with syntactic information, while for the newly proposed ELMO and BERT, both of them can boost the models further.

4.6 Final Results on the Chinese Test Data

Based on the above experiments and analyses, we present the overall results of our model in this subsection. We train the three models (INPUT, LISA, and RELAWE) with their best settings without any external knowledge as CLOSED, and we take the same models with BERT as OPEN. The DEPPATH&RELPATH from GOLD without external knowledge serves as the GOLD for reference. Since we have been focusing on the task of argument identification and labeling, for both CLOSED and OPEN, we follow Roth and Lapata (2016) to use existing systems' predicate senses (Johansson and Nugues, 2008) to exclude them from comparison.

Table 7 shows that our OPEN model achieves more than 3 points of f1-score than the state-of-the-art result, and RELAWE with DEPPATH&RELPATH achieves the best in both CLOSED and OPEN settings. Notice that our best CLOSED model can almost perform as well as the state-of-the-art model while the latter utilizes pre-trained word embeddings. Besides, performance gap between three models under OPEN setting is very small. It indicates that the representation ability of BERT is so powerful and may contains rich syntactic information. At last, the GOLD result is much higher than the other models, indicating that there is still large space for improvement for this task.

English	P	R	F1
LISA(DEP)[10]	89.26	85.46	87.32
LISA(DEP&RELPATH)	89.74	85.38	87.51
INPUT(DEPPATH)	89.33	85.60	87.42
INPUT(DEPPATH&RELPATH)	89.70	85.48	87.54
RELAWE(DEPPATH&RELPATH)	89.55	85.92	**87.70**

Table 8: SRL results on the English test set. We use syntactic dependency results generated by BiaffineParser (On test set, syntactic performance is: UAS = 94.35%, and LAS = 92.54%, which improves about 6% compared to automatic trees in CoNLL-2009.).

4.7 Results on the English Data

We also conduct several experiments on the English dataset to validate the effectiveness of our approaches on other languages than Chinese and the results are in Table 8. Although both configurations are not exactly the same as their original papers, we tried our best to reproduce their methods on the CoNLL2009 dataset for our comparison. Overall, the results are consistent with the Chinese experiments, while the improvement is not as large as the Chinese counterparts. The RELAWE model with DEPPATH&RELPATH still achieves the best performance. Applying our syntax-enhanced model to more languages will be an interesting research direction to work on in the future.

5 Conclusion and Future Work

This paper investigates how to incorporate syntactic dependency information into semantic role labeling in depth. Firstly, we confirm that dependency trees of better quality are more helpful for the SRL task. Secondly, we present different ways to encode the trees and the experiments show that keeping more (correct) structural information during encoding improves the SRL performance. Thirdly, we compare three incorporation methods and discover that our proposed relation-aware self-attention-based model is the most effective one.

Although our experiments are primarily on the Chinese dataset, the approach is largely language independent. Apart from our tentative experiments on the English dataset, applying the approach to other languages will be an interesting research direction to work on in the future.

[10]We reimplement LISA in Strubell et al. (2018) as LISA(DEP), and Xia et al. (2019)'s best DEPPATH approach as INPUT(DEPPATH). Therefore, we can compare with their work as fairly as possible. Other settings are the best configurations for their corresponding methods.

Abstract

We present VerbAtlas, a new, hand-crafted lexical-semantic resource whose goal is to bring together all verbal synsets from WordNet into semantically-coherent frames. The frames define a common, prototypical argument structure while at the same time providing new concept-specific information. In contrast to PropBank, which defines enumerative semantic roles, VerbAtlas comes with an explicit, cross-frame set of semantic roles linked to selectional preferences expressed in terms of WordNet synsets, and is the first resource enriched with semantic information about implicit, shadow, and default arguments. We demonstrate the effectiveness of VerbAtlas in the task of dependency-based Semantic Role Labeling and show how its integration into a high-performance system leads to improvements on both the in-domain and out-of-domain test sets of CoNLL-2009. VerbAtlas is available at http://verbatlas.org.

1 Introduction

During the last two decades, we have witnessed increased attention to Natural Language Understanding, a core goal of Natural Language Processing (NLP). Several challenges, however, are yet to be overcome when it comes to performing sentence-level semantic tasks (Navigli, 2018). In order to understand the meaning of sentences, the semantics of verbs plays a crucial role, since verbs define the argument structure roughly in terms of "who" did "what" to "whom", with the arguments being the constituents that bear a semantic relation (called semantic role) with the verb. In the following example, "Joe" and "lunch" are arguments of "eat", whose argument structure identifies them, respectively, as the Agent and the Patient of the scenario evoked by the verb:

[Joe]$_{\texttt{Agent}}$ is [eating]$_{\texttt{Verb}}$ his [lunch]$_{\texttt{Patient}}$

The automatic identification and labeling of argument structures is a task pioneered by Gildea and Jurafsky (2002) called Semantic Role Labeling (SRL). SRL has become very popular thanks to its integration into other related NLP tasks such as machine translation (Liu and Gildea, 2010), visual semantic role labeling (Silberer and Pinkal, 2018) and information extraction (Bastianelli et al., 2013).

In order to be performed, SRL requires the following core elements: 1) a verb inventory, and 2) a semantic role inventory. However, the current verb inventories used for this task, such as PropBank (Palmer et al., 2005) and FrameNet (Baker et al., 1998), are language-specific and lack high-quality interoperability with existing knowledge bases. Furthermore, such resources provide low to medium coverage of the verbal lexicon (cf. Table 1), with PropBank showing the best figures, but still lower than other lexical inventories like WordNet (Fellbaum et al., 1998). Finally, the informativeness of the semantic roles defined in the various resources ranges from underspecified, as in PropBank's roles, to overspecified, as in FrameNet's frame elements. This poses multiple issues in terms of interpretability or cross-domain applicability.

To overcome the above limitations, in this paper we present VerbAtlas, a manually-crafted inventory of verbs and argument structures which provides several contributions: 1) full coverage of the English verbal lexicon, 2) prototypical argument structures for each cluster of synsets that define a semantically-coherent frame, 3) cross-domain explicit semantic roles, 4) the specification of refined semantic information and selectional preferences for the argument structure of frames, 5) linkage to WordNet and, as a result, to BabelNet (Navigli and Ponzetto, 2010) and Open Multilingual Wordnet (Bond and Foster, 2013), which in turn enable scalability across languages. Furthermore, to

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 627–637, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

	Cluster types	#	Argument roles	#	Meaning units	#
FrameNet	Frames	1,224	Frame elements	10,542	Lexical units	5,200
VerbNet	Levin's classes	329	Thematic roles	39	Senses	6,791
PropBank	Verbs	5,649	Proto-roles	6	Framesets	10,687
WordNet	–	–	–	–	Synsets	13,767
VerbAtlas	Frames	466	Semantic roles	25	Synsets	13,767

Table 1: Quantitative analysis of popular verbal resources. Since each of these resources is based on different linguistic assumptions, in the top row we use general labels to encompass resource-specific terms that can be viewed as homologous: cluster type, argument roles and meaning units. WordNet does not provide argument structures except for sentence frames which, however, are syntactic and do not specify any roleset.

make VerbAtlas suitable for NLP tasks that rely on PropBank, we also provide a mapping to its framesets. Finally, we prove through an SRL experiment that VerbAtlas is robust and enables state-of-the-art performances on the CoNLL-2009 dataset.

2 Related work

The most popular English verbal resources are FrameNet (Baker et al., 1998), PropBank (Palmer et al., 2005), and VerbNet (Kipper-Schuler, 2005). Each resource is based on a different linguistic theory, which leads to different information being provided for each verb (cf. Table 1). FrameNet, in particular, was the first resource to be used for SRL (Gildea and Jurafsky, 2002): it is based on frame semantics, theorized by Fillmore (1976), which assumes different roles, i.e., frame elements, for different frames[1]. This led to a proliferation of thousands of roles for only 5200 verbs. Such domain specificity makes it difficult to scale to open-text SRL (Hartmann et al., 2017).

PropBank challenges the issue of FrameNet's roles with a repository of only 6 different core roles plus 19 modifiers for 10,687 framesets[2]. This resource is the most widely adopted for SRL, as also attested by the popularity of datasets such as CoNLL-2005 (Carreras and Màrquez, 2005) and CoNLL-2009 (Hajič et al., 2009). PropBank's methodology was also used for other languages, such as Arabic (Palmer et al., 2008), Chinese (Xue and Palmer, 2003), Spanish and Catalan (Taulé et al., 2008), Hindi-Urdu (Bhatt et al., 2009), Brazilian Portuguese (Duran and Aluísio, 2011), Finnish (Haverinen et al., 2015), Turkish (Şahin and Adalı, 2018), Basque (Aldezabal et al., 2010), among others. Its application goes well beyond the annotation of corpora: in fact, it was also adopted for the Abstract Meaning Representation (Banarescu et al., 2013), a semantic language that aims at abstracting away from cross-lingual syntactic idiosyncrasies, and NomBank (Meyers et al., 2004), a resource which provides argument structures for nouns. However, PropBank's major drawback is that its roles do not explicitly mark the type of semantic relation with the verb, instead they just enumerate the arguments (i.e., `Arg0`, `Arg1`, etc.). Due to this, role labels do not preserve the same type of semantic relation across verbs, e.g., the first arguments of "eat" and "feel" are both labeled with `Arg0` even if they express different relations (`Agent` and `Experiencer`, respectively).

VerbNet addresses this limit by providing explicit, human-readable roles such as `Agent`, `Patient`, `Experiencer`, etc. Yet, VerbNet suffers from low coverage, in that it includes only 6791 verbs, which makes it a suboptimal resource for wide-coverage SRL. Another drawback of VerbNet is its organization into Levin's classes (Levin, 1993), namely, 329 groups of verbs sharing the same syntactic behavior, independently of their meaning. As a consequence, its classes cannot be used straightforwardly in a semantic task.

On top of their individual limitations, the above resources also have some common drawbacks. One of these is language specificity, which implies a considerable amount of work will be needed for the creation of a corresponding resource for each new language of interest. Another common problem is the lack of coverage, as shown in Table 1. The highest-coverage inventory is PropBank, with its 10,687 framesets and 5,649 verbs. However, PropBank's coverage is still limited when compared to computational lexicons like WordNet, which contains 13,767 verbal concepts and 11,529 distinct verbs.

[1] "By the term 'frame' I have in mind any system of concepts related in such a way that to understand any one of them you have to understand the whole structure in which it fits." (Fillmore, 1982).

[2] "A frameset corresponds to a coarse-grained sense of the verb which has a specific set of semantic arguments." (Babko-Malaya, 2005).

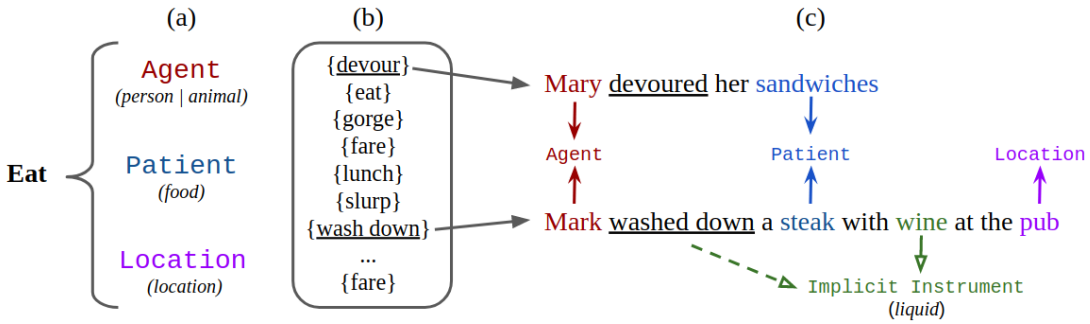

Figure 1: Structure of the EAT frame. The colored roles on the left (a) constitute the Predicate Argument Structure of the frame and their respective selectional preferences within round brackets. Box (b) shows a sample of the frame's synsets (a synonym per synset is shown). In the example sentences (c), we show the head words colored according to their semantic roles. While in the first sentence the synset {devour} does not project the `Location`, the synset {wash down} projects an implicit `Instrument` with its synset-level selectional preference *(liquid)*.

To get the best of the three worlds, there have been attempts to map the aforementioned resources to each other. To our knowledge the most popular endeavors are SemLink (Palmer, 2009; Bonial et al., 2013) and Predicate Matrix (De Lacalle et al., 2014), the latter being an extension of the former via automatic methods. However, while the main drawback of SemLink is coverage, the Predicate Matrix suffers from quality issues.

Both the foregoing limitations are addressed in VerbAtlas, the manually-curated resource that we present in this paper. With VerbAtlas we provide the community with a resource that improves the main features of the existing inventories of verbs, while also adding new semantic information. Compared to FrameNet, VerbAtlas has fewer frames and roles while at the same time presenting full coverage in terms of concepts (cf. Table 1). VerbNet's roles, instead, provided inspiration for our role repository, but we reduced the number of roles from 39 to 25 in order to alleviate data sparsity issues. PropBank was mapped to VerbAtlas synsets and roles in order to enable SRL systems to exploit its additional semantic information and improve verb coverage. Moreover, in contrast to the other resources, the use of WordNet synsets makes VerbAtlas able to scale multilingually through resources such as BabelNet.

In Section 3 we introduce VerbAtlas and its features; in Section 4 we explain how this resource was built and organized. Finally, Section 5 validates VerbAtlas experimentally in the SRL task.

3 VerbAtlas

We now introduce VerbAtlas, a new verbal semantic resource structured into frames which group semantically-coherent synsets from WordNet (v3.0). A VerbAtlas frame is a cluster of verb meanings expressing similar semantics, which expands upon the frame notion of FrameNet. Each frame is provided with an argument structure that generalizes over all the synsets in the frame plus preferential selections for each semantic role. Furthermore, synsets are enriched with novel semantic information. In Figure 1 we show the structure of the EAT frame in VerbAtlas, which we use as a running example to illustrate the new features in our work and compare them with current verbal resources.

3.1 Frame organization

We define a frame in VerbAtlas as a cluster of WordNet synsets that, with different shades of meaning, express a certain scenario. For instance, the EAT frame, an excerpt of which is shown in Figure 1(b), comprises all the synsets specializing the general scenario of "eating", including synsets such as {eat}, {devour, guttle, raven, pig}, etc.

This organization of frames is intended to overcome the limitations affecting VerbNet and FrameNet. In fact, while the former organizes verbs by syntactic rather than semantic behavior, the latter is affected by the sparsity of 5,200 verbal senses (i.e., lexical units) distributed across frames. Instead, PropBank's framesets correspond to a coarse-grained sense of a verb, but each frameset expresses its own separate argument structure.

Differently from the other resources, VerbAtlas frames are organized into 466 wide-coverage and semantically-coherent clusters (cf. Table 1) which provide cross-frame argument structures.

3.2 Semantic roles

A limit in PropBank is its inventory of so-called proto-roles (`Arg0`, `Arg1`, etc., with the first two roughly corresponding, respectively, to a proto-agent and a proto-patient (Dowty, 1991)), which does not provide human-readable labels and is predicate-specific (i.e., the same label does not necessarily depict the same semantic relation across predicates).

While PropBank roles do not provide clear explicit semantics, FrameNet roles are explicit but frame-specific (e.g., `Ingestor` and `Ingestibles` for the "Ingestion" frame, or `Impactor` and `Impactee` for the "Impact" frame). This produces a fine-grained role inventory that makes it difficult for SRL systems to generalize across frames. In VerbAtlas we follow VerbNet and take a middle-ground approach: our inventory of 25 semantic roles is inspired by VerbNet, whose 39 labels (like `Agent`, `Patient`, `Time`, etc.) are explicit, cross-frame and domain-general. The rationale is that these features enable neural networks employed in the SRL task to generalize across frames in a consistent way, as we show in Section 5.2. For example, we can tag the arguments of different VerbAtlas frames – such as EAT, HIT and CONQUER – with just two roles, namely: `Agent` and `Patient`.

3.3 Prototypical Argument Structure

Each VerbAtlas frame expresses a Prototypical Argument Structure (PAS) that generalizes over all the synsets in a particular frame. The PAS specifies a roleset that defines the frame's overall meaning (e.g., in Figure 1(a) `Agent`, `Patient` and `Location`). In Figure 1(c) we show two sentences annotated with argument roles.

Since we do not distinguish between core roles and adjuncts, we decided to also include in the various PAS roles which might be projected optionally by argument structures that are nonetheless present in the scenario evoked by the frame. For instance, the inclusion of the `Location` role in the PAS of the EAT example ensures a robust descriptiveness of the PAS across synsets in the same frame.

3.4 Selectional preferences

To narrow down the number of candidates for a particular argument slot and provide further semantic structure, the semantic role of the PAS has been manually labeled with selectional preferences from a set of 116 macro-concepts. Our selectional preferences are defined by WordNet synsets whose hyponyms are expected to be likely candidates to the corresponding argument slot, a strategy similar to that of Agirre and Martinez (2002) which, instead, was algorithm-based.

Consider again the EAT frame and its PAS: `Agent`, `Patient`, `Location` (Figure 1 (a)). In this frame, most of the example sentences from the WordNet synsets express a `Patient` like "cake", "meat" or "banana", thus, since their common hypernym is "food", we provided the PAS with the information that the `Patient` prototypically expects hyponyms of the {food, solid food} synset. The `Location` role is labeled with its homonymous {location} synset given its generality.

3.5 Synset-level semantic information

To enrich the semantic representation of synsets, VerbAtlas provides semantic and pragmatic (English-specific) information regarding implicit (1,028 labels), shadow and default arguments (2,979 labels) inspired by Pustejovsky (1995) and inferred from synset's glosses and examples. To our knowledge, the following information is new in a large-scale verbal resource such as ours:

- **implicit arguments**, i.e., implicit in the argument structure of the verb but not always syntactically expressed. Consider the synset {overleap, vault} in our JUMP frame: since its gloss is "Jump across or leap over (an obstacle)", we know that the `Patient` of this verb can be a hyponym of {obstacle}, therefore implying a selectional preference on the role with the {obstacle} synset.

- **shadow and default arguments**: the former is incorporated in the meaning of the verb but not syntactically expressed. An example from the EAT frame is {eat in, dine in} ("Eat at home"). This synset is tagged with the shadow argument `Location` = {home}, since the latter is not expressed syntactically. On the other hand, default arguments are logically implied but not syntactically expressed. These are also tagged as shadow arguments. For instance, the synset {deliver} (as in "Our local supermarket delivers") has the label `Patient` = {grocery} to provide the commonsense information that what a supermarket usually delivers is groceries.

We are aware of the problems raised about Pustejovsky's framework of analysis (Fodor and Lepore, 1998), but we believe that this new information, if properly exploited, would be fruitful for better meaning representations.

3.6 Linkage to PropBank and multilingual resources

To allow a straightforward applicability to and evaluation of VerbAtlas on semantic tasks based on PropBank, such as SRL, each frameset and roleset in the CoNLL-2009 dataset was mapped to the corresponding VerbAtlas frame and roleset. This mapping was done starting from the Predicate Matrix (De Lacalle et al., 2014) and then manually corrected and augmented. Finally, we aligned PropBank's roles with the corresponding roles in VerbAtlas PAS (e.g., `Arg0` and `Arg1` of PropBank's eat.01 frameset were mapped, respectively, to the VerbAtlas PAS roles `Agent` and `Patient` of the frame EAT).

Moreover, thanks to the use of WordNet and its semantic nature, VerbAtlas can easily scale to arbitrary languages. This can be achieved by leveraging BabelNet (Navigli and Ponzetto, 2010), a lexical-semantic resource that provides multilingual synsets in 284 different languages linked to WordNet itself. As a result, VerbAtlas can be used in virtually any language, in contrast to PropBank and other resources which are inherently language-specific and require considerable human intervention in each new language.

Finally, the above implies that if there is a verbal repository for one of the languages linked to the aforementioned resources, its argument structures can be seamlessly aligned with the PAS of VerbAtlas, as well as with VerbAtlas frames.

4 Methodology

4.1 Bottom-up approach

The manual construction of VerbAtlas was performed in a bottom-up fashion. Rather than forcing synsets into a predetermined set of frames, we started the clustering process from the full inventory of 13,767 WordNet synsets, which represent the building blocks of VerbAtlas frames. This allowed us to induce the semantics of 466 frames (with an average of 29.5 synsets per frame) and make VerbAtlas consistent both in terms of lexical semantics and the frame's argument structures.

EAT	CLASSIFY	SWITCH
KILL	CLEAN	MOVE SOMETHING
DRINK	AMELIORATE	JUDGE
POUR	TRANSPORT	PERFORM
OBTAIN	BEHAVE	STOP
GIVE	HIT	COMBINE

Table 2: Frames with the highest number of synsets.

4.2 Creation of frames

VerbAtlas frames were induced via semantic similarity between synsets. During multiple iterations over the verb inventory, if two or more synsets were perceived as similar, namely, if they shared features like the purpose of the action and the participants in the action (Hill et al., 2015) (e.g., "dine" and "lunch"), they were clustered together to form a new semantically-coherent frame. A one-synset-one-frame strategy was used to avoid any future mapping problem with other resources. The process is based on synset-by-synset human inspection. Two synsets are clustered together in the same frame if they express semantically-similar scenarios. For example, the verbs "kill" and "slaughter" share similar participants in the action (an `Agent` who kills/slaughters; a `Patient` who is killed/slaughtered) and purpose (`Agent` makes `Patient` die), so they are clustered into the KILL frame.

At the end of the first iteration, we checked the resulting frames and named them according to the common action implied by the synsets contained therein. For example, the EAT frame (Figure 1(b)) is composed of synsets that depict different kinds of action implying eating, like {devour, ..., pig} and {gorge, ..., glut}. In Table 2 we report the frames with the highest number of verb synsets.

To validate the resulting frames we adopted a strategy similar to Hovy et al. (2006): we provided 3 linguists not involved in the clustering with a random sample of 1000 frame-synset pairs and asked them if the action expressed by the synset was implied by that expressed by the frame. We iterated over the inventory various times and moved the synsets from one frame to another until the Cohen's Kappa coefficient (Eugenio and Glass, 2004) of their (yes or no) agreement was $\kappa \geq 0.80$. Once this value was attained, we finalized the overall clustering and the resulting frames.

4.3 Establishing explicit semantic roles

Inspired by existing research on semantic roles (Bonial et al., 2011; Allen and Teng, 2018),

Agent	Material
Attribute	Patient
Beneficiary	Product
Cause	Purpose
Co-Agent	Recipient
Co-Patient	Result
Co-Theme	Source
Destination	Stimulus
Experiencer	Theme
Extent	Time
Goal	Topic
Instrument	Value
Location	

Table 3: List of VerbNet roles which make up the VerbAtlas role inventory.

Affector	Manner
Axis	Path
Context	Pivot
Duration	Precondition
Final_Time	Predicate
Initial_Location	Reflexive
Initial_State	Trajectory

Table 4: List of VerbNet roles unused in VerbAtlas.

VerbAtlas implements VerbNet's human-readable role labels across its frames and merges together some VerbNet roles which can be seen as complementary. For example, Initial_Location and Initial_State are subsumed by Source. The hunch is that we can consider them as playing the same role but in different scenarios: the former is the Source for verbs of change of location, while the latter is the Source for verbs of change of state. Furthermore, in VerbAtlas we did not want to use poorly instantiated roles (e.g., Affector), therefore 14 of the roles (Table 4) were subsumed by coarser and more common roles (e.g., Agent in place of Affector, see Table 3).

4.4 Rationale of a Prototypical Argument Structure

We defined as "prototypical" an argument structure capable of being applied to all the synsets in a frame. To achieve this, each PAS was defined at the end of the first iteration over the inventory of synsets and constantly adjusted until the last iteration. The initial PAS was inspired by the argument structure of the common verbal concept implied by the synsets constituting the frame. For instance, in the case of BETRAY, Agent and Patient. The PAS was later expanded due to synsets inside the frame that projected additional arguments (e.g., the Goal role of {defect, desert} as in the sentence "The reporter defected to another *network*").

4.5 Rationale of selectional preferences

Each semantic role of a PAS was provided with selectional preferences from a set of 116 synsets. The set was created by generalizing across the arguments in the example sentences of each synset in a given frame. The result for each PAS argument was one or more hypernyms in the WordNet taxonomy which were common across the frame synsets.

In contrast to VerbNet selectional restrictions, the selectional preferences in VerbAtlas do not restrict the occurrence of words with a particular feature (e.g., solid, liquid, etc.), rather, they suggest the most prototypical hypernym(s) for a given argument. We opted for preferences instead of restrictions to not exclude the potential metaphorical use of a verb.

5 Experiments

In previous sections we discussed the qualitative and structural advantages of VerbAtlas compared to existing resources. Because, in principle, a new linguistic resource might seem to provide an arbitrary contribution, we also provide here an experimental validation of its usefulness in an SRL task. First, we present our experimental setup (Section 5.1) and then discuss our results (Section 5.2).

5.1 Experimental setup

Goal We argue that the quality and wealth of information in VerbAtlas can effectively improve the performance of an existing, high-performance SRL system like Cai et al. (2018).

Datasets We performed our experiments on the English part of CoNLL-2009 in-domain and out-of-domain datasets (Hajič et al., 2009) designed for the dependency-based SRL task and whose annotations concern predicate argument structures from PropBank and nominal argument structures from NomBank (Meyers et al., 2004). The dataset consists of 39,279 sentences and 958,167 tokens (18.7% of which are argument bearers).

Through this experiment we aim to show that the additional information provided by VerbAtlas frames and semantic roles improves the performance of a neural network on the in-domain test set. We also aim to demonstrate a better ability to generalize on the out-of-domain dataset.

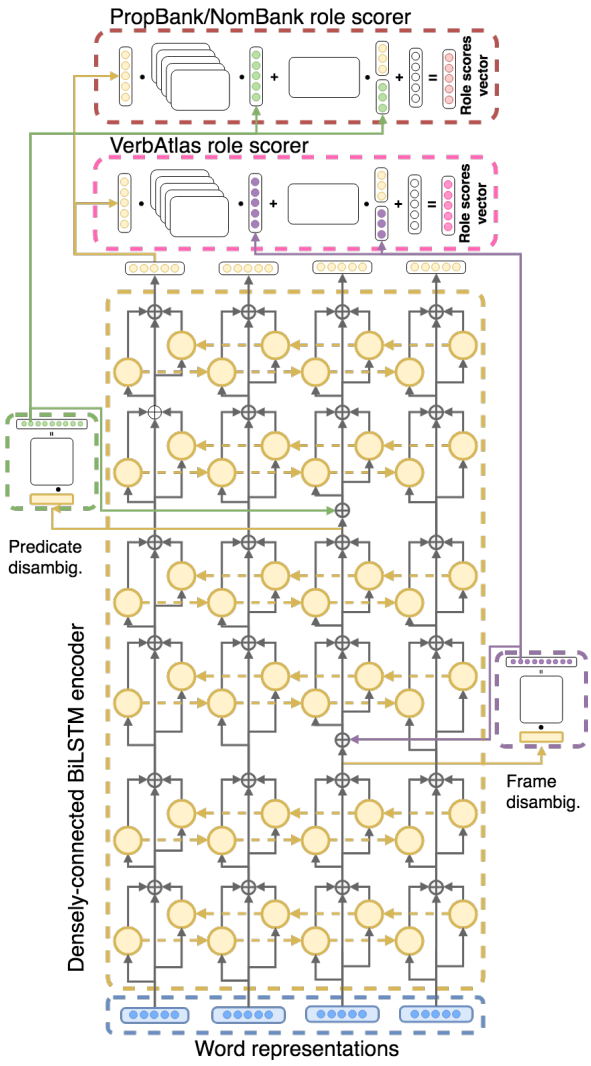

Figure 2: Overview of the model architecture. From bottom to top, a sequence of word embeddings is fed to a densely-connected BiLSTM encoder where the output of each encoding layer is concatenated with its input. The predicate hidden representation from the second BiLSTM layer is used for VerbAtlas frame disambiguation (right), whereas the predicate hidden representation from the fourth BiLSTM layer is used for PropBank predicate disambiguation (left). The topmost output of the BiLSTM encoder is used together with the output of the PropBank predicate disambiguation layer to obtain a PropBank-style SRL output, and together with the output of the VerbAtlas frame disambiguation layer to obtain a VerbAtlas-style SRL output.

Baseline model Our baseline model in Figure 2 is built on top of the syntax-agnostic model proposed by Cai et al. (2018) in that it is mainly composed of a word representation layer, a sequence encoder and a biaffine attentional role scorer. A key difference is that our model features a multi-output layer that returns PropBank (PB) and NomBank (NB) labels (i.e., framesets and their roles) and, if the predicate is a verb, also VerbAtlas labels (i.e., frames and their roles). With this design choice, the output of our model can be directly compared to the output of previous SRL models. At the same time, our model achieves a deeper and more general understanding of the relations between a PB or NB predicate and its arguments by learning from the corresponding VerbAtlas frame and its semantically-coherent roles.

Formally, our model is built on top of the following components:

- A **word representation layer** that, given a sentence $\mathbf{s} = \langle w_1, w_2, \ldots, w_n \rangle$, builds a sequence of word representations $\mathbf{x} = \langle \mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n \rangle$ where $\mathbf{x}_i$ is an embedding representing w_i. Each $\mathbf{x}_i$ is the result of the concatenation of a pre-trained word embedding $\mathbf{e}^{pt}$, and the following trainable vectors: a word embedding $\mathbf{e}^{w}$, a lemma embedding $\mathbf{e}^{l}$, a POS embedding $\mathbf{e}^{pos}$, and a predicate lemma embedding $\mathbf{e}^{pred}$ (active only if w_i is a predicate). Formally: $\mathbf{x}_i = \mathbf{e}^{pt} \oplus \mathbf{e}^{w} \oplus \mathbf{e}^{l} \oplus \mathbf{e}^{pos} \oplus \mathbf{e}^{pred}$. We use GloVe embeddings (Pennington et al., 2014) as our underlying pre-trained word embeddings.

- A **densely-connected BiLSTM encoder** that, given a sequence $\mathbf{x}$ of word representations, returns a sequence of encodings $\mathbf{y} = \langle \mathbf{y}_i = \text{BiLSTM}(\mathbf{x}_i; \mathbf{x}) : \forall i \in \{1, \ldots, n\} \rangle$, where $\mathbf{y}_i$ is a dynamic representation of $\mathbf{x}_i$ with respect to the context defined by the whole sequence $\mathbf{x}$. In a densely-connected BiLSTM encoder, the output of each layer is concatenated with the input of the same layer to mitigate the vanishing gradient problem. If $\mathbf{h}_i^k$ is the encoding of the k-th layer for $\mathbf{x}_i$, then $\mathbf{h}_i^{k+1} = \mathbf{h}_i^k \oplus \text{LSTM}^f(\mathbf{h}_i^k; \mathbf{h}_{1:i-1}^k) \oplus \text{LSTM}^b(\mathbf{h}_i^k; \mathbf{h}_{i+1:n}^k)$, and $\mathbf{y}_i = \mathbf{h}_i^m$ where $m = 6$ is the final BiLSTM layer, while LSTM^f and LSTM^b are the forward and backward LSTM transformations.

- A **frame disambiguation layer** that, given the BiLSTM encoding $\mathbf{y}_{pred}^i$ of a predicate w_{pred} at the i-th encoder layer (with $i = 2$), disambiguates w_{pred} with a VerbAtlas frame f, returning a trainable frame embedding $\mathbf{e}^f$:

$$\mathbf{h}_{pred}^i = \text{ReLU}(\mathbf{W}' \cdot \mathbf{y}_{pred}^i + \mathbf{b}')$$

$$f = \text{argmax}(\mathbf{W}^f \cdot \mathbf{h}_{pred}^i + \mathbf{b}^f)$$

- A **predicate disambiguation layer** that, given the BiLSTM encoding $\mathbf{y}^j_{pred}$ of a predicate w_{pred} at the j-th encoder layer (with $j = 4$) and the frame embedding $\mathbf{e}^f$, disambiguates w_{pred} with a PB or NB frameset p, returning a trainable predicate embedding $\mathbf{e}^p$:

$$\mathbf{h}^j_{pred} = \text{ReLU}(\mathbf{W}'' \cdot (\mathbf{y}^j_{pred} \oplus \mathbf{e}^f) + \mathbf{b}'')$$

$$p = \text{argmax}(\mathbf{W}^p \cdot \mathbf{h}^j_{pred} + \mathbf{b}^p)$$

- A **biaffine attentional PB and NB role scorer** that, given a BiLSTM encoding $\mathbf{y}_i$ for a word w_i and a predicate embedding $\mathbf{e}^p$, returns a vector $\mathbf{s}^p_i$ of PB/NB role scores for w_i with respect to p in a similar fashion to Cai et al. (2018). Formally:

$$\mathbf{s}^p_i = \mathbf{y}_i^\top \cdot \mathbf{W}^{role}_{\text{PB}} \cdot \mathbf{e}^p + \mathbf{U}^{role}_{\text{PB}}(\mathbf{y}_i \oplus \mathbf{e}^p) + \mathbf{b}^{role}_{\text{PB}}$$

- A **biaffine attentional VerbAtlas role scorer** that, given a BiLSTM encoding $\mathbf{y}_i$ for a word w_i and a frame embedding $\mathbf{e}^f$, returns a vector $\mathbf{s}^f_i$ of VerbAtlas role scores for w_i with respect to f. Formally:

$$\mathbf{s}^f_i = \mathbf{y}_i^\top \cdot \mathbf{W}^{role}_{\text{VA}} \cdot \mathbf{e}^f + \mathbf{U}^{role}_{\text{VA}}(\mathbf{y}_i \oplus \mathbf{e}^f) + \mathbf{b}^{role}_{\text{VA}}$$

We found it beneficial to interleave the frame disambiguation layer and the predicate disambiguation layer within the BiLSTM encoder layers, enhancing the input of the upper encoder layers with the corresponding frame and predicate embeddings. Finally, our model loss is defined as:

$$l_{\text{total}} = l_{\text{PropBank/NomBank roles}} + l_{\text{VerbAtlas roles}} + l_{\text{predicate disambiguation}} + l_{\text{frame disambiguation}}$$

Since the choice of hyperparameters for an LSTM-based model can significantly affect results (Reimers and Gurevych, 2017), we trained our baseline using the same values as in Cai et al. (2018) unless otherwise stated.

5.2 Results

In-domain SRL Table 5 reports the results of our syntax-agnostic baseline model on the CoNLL-2009 in-domain test set. Not only does our model outperform the syntax-agnostic model of Cai et al. (2018) by a significant margin (according to a χ^2 test, $p < 0.05$, on precision and recall) with a 0.4% F_1 improvement, but it also slightly outperforms the syntax-aware model of Li et al. (2018) with a 0.2% F_1 improvement. We recall that the main difference between our baseline model and that of Cai et al. (2018) lies in the additional VerbAtlas frame disambiguation layer and role scorer. This demonstrates the boost provided by VerbAtlas in PropBank/NomBank-based SRL.

Syntax-aware system	P	R	F_1
Roth and Lapata (2016)	88.1	85.3	86.7

This work	81.1	**78.4**	**79.7**

Table 7: Results on the English out-of-domain test.

In-domain predicate disambiguation Remarkably, as shown in Table 6, our model outperforms the previously reported best scores in the predicate disambiguation subtask, scoring 96.0% in precision for the in-domain test set and reporting a 1.0% improvement over Cai et al. (2018) and a 0.5% improvement over He et al. (2018).

Out-of-domain SRL The results of our baseline model on the out-of-domain SRL CoNLL-2009 dataset are shown in Table 7. Our system improves the results reported by Cai et al. (2018) by 0.7% F_1, proving that using VerbAtlas improves the model's ability to generalize across domains.

F_1 evaluated on	verbs + nouns	only verbs
This work	90.0	91.1
without VerbAtlas	89.5	90.5
without PB *nor* NB	–	90.9

Table 8: The model shows a significant F_1 decrease when it is trained without exploiting VerbAtlas frames and roles (second row) falling in line with Cai et al. (2018) (89.5% vs 89.6%, respectively). On the contrary, removing the PropBank role scorer leads to a negligible performance drop (last row).

5.3 Analysis

Our main experiment proved that a semantics-focused resource for verbal predicates such as VerbAtlas can be successfully employed for CoNLL-like SRL datasets that include a mix of nominal and verbal predicates. But what is the contribution of VerbAtlas (i.e., of its semantically-clustered frames and semantically-coherent roles) to the overall performance? How does a VerbAtlas-only model fare when evaluated solely on verbal predicates against a PropBank-only model? To answer these questions, we evaluated the model in two further settings.

A first study aimed at quantifying the boost in performance the model gets from the use of VerbAtlas. Removing the VerbAtlas frame disambiguation layer and role scorer from our model significantly decreases (according to a χ^2 test, $p < 0.05$, on precision and recall) the overall performance in F_1 score by 0.5%, as reported in Table 8 (left column), with results that are comparable to those of Cai et al. (2018) (89.5% vs 89.6% F_1, Tables 8 and 5, respectively). This proves that the model with VerbAtlas achieves a better understanding of semantic roles, thanks to using the VerbAtlas frame disambiguation layer and role scorer.

A second study aimed at comparing PropBank and VerbAtlas on their common ground, i.e., their coverage and organization of verb meanings into framesets and frames, respectively. Table 8 (right column) shows that removing the PropBank bi-affine role scorer leads to a negligible performance drop (0.2% F_1) in how it performs on argument labeling of verb predicates using only the semantic roles of VerbAtlas mapped at the output layer to PropBank roles (see Section 3.6); we note that the higher number of roles in VerbAtlas makes the argument labeling problem potentially harder. In contrast, when VerbAtlas is removed, the drop in performance is noteworthy, with a 0.6% decrease in F_1 on SRL of verbal predicates.

6 Conclusions and Future Work

In this paper we presented VerbAtlas, a new large-scale verbal semantic resource which provides generalizing argument structures with cross-frame semantic roles. The resource is available at `http://verbatlas.org`.

In contrast to other verb repositories, VerbAtlas offers full coverage of the English verbs and addresses the issues of current predicate resources, while at the same time providing linkage to WordNet and PropBank. This makes the resource fully compatible with previous datasets and scalable to arbitrary languages thanks to BabelNet.

While the frame creation process resulted in a strong agreement between annotators, we further validated the quality of VerbAtlas experimentally by showing that the integration of its frame information together with its explicit semantic roles enables a neural architecture to improve its performance on the Semantic Role Labeling task. This improvement translates across domains, demonstrating the robustness and variety of the knowledge provided in our resource.

As future work, we plan to take full advantage of the novel semantic features available in VerbAtlas, such as wide-coverage selectional preferences and synset-level information, by exploiting them in multilingual SRL and Word Sense Disambiguation tasks. Our plans include integrating the selectional preferences from SyntagNet (Maru et al., 2019), a new, large-scale lexical-semantic combination resource. We also plan to extend our methodology to nouns and adjectives, in a similar fashion to (O'Gorman et al., 2018) and connect the resulting frames to those in VerbAtlas.

Abstract

We propose a simple and robust non-parameterized approach for building sentence representations. Inspired by the Gram-Schmidt Process in geometric theory, we build an orthogonal basis of the subspace spanned by a word and its surrounding context in a sentence. We model the semantic meaning of a word in a sentence based on two aspects. One is its relatedness to the word vector subspace already spanned by its contextual words. The other is the word's novel semantic meaning which shall be introduced as a new basis vector perpendicular to this existing subspace. Following this motivation, we develop an innovative method based on orthogonal basis to combine pre-trained word embeddings into sentence representations. This approach requires zero parameters, along with efficient inference performance. We evaluate our approach on 11 downstream NLP tasks. Our model shows superior performance compared with non-parameterized alternatives and it is competitive to other approaches relying on either large amounts of labelled data or prolonged training time.

1 Introduction

The concept of word embeddings has been prevalent in NLP community in recent years, as they can characterize semantic similarity between any pair of words, achieving promising results in a large number of NLP tasks (Mikolov et al., 2013; Pennington et al., 2014; Salle et al., 2016). However, due to the hierarchical nature of human language, it is not sufficient to comprehend text solely based on isolated understanding of each word. This has prompted a recent rise in search for semantically robust embeddings for longer pieces of text, such as sentences and paragraphs.

Based on learning paradigms, the existing approaches to sentence embeddings can be categorized into two categories: i) parameterized methods and ii) non-parameterized methods.

Parameterized sentence embeddings. These models are parameterized and require training to optimize their parameters. SkipThought (Kiros et al., 2015) is an encoder-decoder model that predicts adjacent sentences. Pagliardini et al. (2018) proposes an unsupervised model, Sent2Vec, to learn an n-gram feature in a sentence to predict the center word from the surrounding context. Quick thoughts (QT) (Logeswaran and Lee, 2018) replaces the encoder with a classifier to predict context sentences from candidate sequences. Khodak et al. (2018) proposes *à la carte* to learn a linear mapping to reconstruct the center word from its context. Conneau et al. (2017) generates the sentence encoder InferSent using Natural Language Inference (NLI) dataset. Universal Sentence Encoder (Yang et al., 2018; Cer et al., 2018) utilizes the emerging transformer structure (Vaswani et al., 2017; Devlin et al., 2018) that has been proved powerful in various NLP tasks. The model is first trained on large scale of unsupervised data from Wikipedia and forums, and then trained on the Stanford Natural Language Inference (SNLI) dataset. Wieting and Gimpel (2017b) propose the gated recurrent averaging network (GRAN), which is trained on Paraphrase Database (PPDB) and English Wikipedia. Subramanian et al. (2018) leverages a multi-task learning framework to generate sentence embeddings. Wieting et al. (2015a) learns the paraphrastic sentence representations as the simple average of updated word embeddings.

Non-parameterized sentence embedding. Recent work (Arora et al., 2017) shows that, surprisingly, a weighted sum or transformation of word representations can outperform many sophisticated neural network structures in sen-

tence embedding tasks. These methods are parameter-free and require no further training upon pre-trained word vectors. Arora et al. (2017) constructs a sentence embedding called SIF as a sum of pre-trained word embeddings, weighted by reverse document frequency. Ethayarajh (2018) builds upon the random walk model proposed in SIF by setting the probability of word generation inversely related to the angular distance between the word and sentence embeddings. Rücklé et al. (2018) concatenates different power mean word embeddings as a sentence vector in p-mean. As these methods do not have a parameterized model, they can be easily adapted to novel text domains with both fast inference speed and high-quality sentence embeddings. In view of this trend, our work aims to further advance the frontier of this group and make its new state-of-the-art.

In this paper, we propose a novel sentence embedding algorithm, Geometric Embedding (GEM), based entirely on the geometric structure of word embedding space. Given a d-dim word embedding matrix $\boldsymbol{A} \in \mathbb{R}^{d \times n}$ for a sentence with n words, any linear combination of the sentence's word embeddings lies in the subspace spanned by the n word vectors. We analyze the geometric structure of this subspace in $\mathbb{R}^d$. When we consider the words in a sentence one-by-one in order, each word may bring in a novel orthogonal basis to the existing subspace. This new basis can be considered as the new semantic meaning brought in by this word, while the length of projection in this direction can indicate the intensity of this new meaning. It follows that a word with a strong intensity should have a larger influence in the sentence's meaning. Thus, these intensities can be converted into weights to linearly combine all word embeddings to obtain the sentence embedding. In this paper, we theoretically frame the above approach in a QR factorization of the word embedding matrix $\boldsymbol{A}$. Furthermore, since the meaning and importance of a word largely depends on its close neighborhood, we propose the sliding-window QR factorization method to capture the context of a word and characterize its significance within the context.

In the last step, we adapt a similar approach as Arora et al. (2017) to remove top principal vectors before generating the final sentence embedding. This step is to ensure commonly shared background components, e.g. stop words, do not bias sentence similarity comparison. As we build a new orthogonal basis for each sentence, we propose to have disparate background components for each sentence. This motivates us to put forward a sentence-specific principal vector removal method, leading to better empirical results.

We evaluate our algorithm on 11 NLP tasks. Our algorithm outperforms all non-parameterized methods and many parameterized approaches in 10 tasks. Compared to SIF (Arora et al., 2017), the performance is boosted by 5.5% on STS benchmark dataset, and by 2.5% on SST dataset. Plus, the running time of our model compares favorably with existing models.

The rest of this paper is organized as following. In Section 2, we describe our sentence embedding algorithm GEM. We evaluate our model on various tasks in Section 3 and Section 4. Finally, we summarize our work in Section 5. Our implementation is available online[1].

2 Approach

We introduce three scores to quantify the importance of a word, as will be explained in this section. First, **novelty score** α_n measures the portion of the new semantic meaning in a word. Second, **significance score** α_s describes the alignment between the new semantic meaning and the sentence-level meaning. Finally, **uniqueness score** α_u examines the uniqueness of the new semantic meaning in the corpus level.

2.1 Quantify New Semantic Meaning

Let us consider the idea of word embeddings (Mikolov et al., 2013), where a word w_i is projected as a vector $\boldsymbol{v}_{w_i} \in \mathbb{R}^d$. Any sequence of words can be viewed as a subspace in $\mathbb{R}^d$ spanned by its word vectors. Before the appearance of the ith word, $\boldsymbol{S}$ is a subspace in $\mathbb{R}^d$ spanned by $\{\boldsymbol{v}_{w_1}, \boldsymbol{v}_{w_2}, ..., \boldsymbol{v}_{w_{i-1}}\}$. Its orthonormal basis is $\{\boldsymbol{q}_1, \boldsymbol{q}_2, ..., \boldsymbol{q}_{i-1}\}$. The embedding $\boldsymbol{v}_{w_i}$ of the ith word w_i can be decomposed into

$$\begin{aligned} \boldsymbol{v}_{w_i} &= \sum_{j=1}^{i-1} r_j \boldsymbol{q}_j + r_i \boldsymbol{q}_i \\ r_j &= \boldsymbol{q}_j^T \boldsymbol{v}_{w_i} \\ r_i &= \|\boldsymbol{v}_{w_i} - \sum_{j=1}^{i-1} r_j \boldsymbol{q}_j\|_2 \end{aligned} \tag{1}$$

[1] https://github.com/ziyi-yang/GEM

where $\sum_{j=1}^{i-1} r_j \boldsymbol{q}_j$ is the part in $\boldsymbol{v}_{w_i}$ that resides in subspace $\boldsymbol{S}$, and $\boldsymbol{q}_i$ is orthogonal to $\boldsymbol{S}$ and is to be added to $\boldsymbol{S}$. The above algorithm is also known as **Gram-Schmidt Process**. In the case of rank deficiency, i.e., $\boldsymbol{v}_{w_i}$ is already a linear combination of $\{\boldsymbol{q}_1, \boldsymbol{q}_2, ...\boldsymbol{q}_{i-1}\}$, $\boldsymbol{q}_i$ is a zero vector and $r_i = 0$. In matrix form, this process is also known as *QR factorization*, defined as follows.

QR factorization. Define an embedding matrix of n words as $\boldsymbol{A} = [\boldsymbol{A}_{:,1}, \boldsymbol{A}_{:,2}, ..., \boldsymbol{A}_{:,n}] \in \mathbb{R}^{d\times n}$, where $\boldsymbol{A}_{:,i}$ is the embedding of the ith word w_i in a word sequence $(w_1, \ldots, w_i, \ldots, w_n)$. $\boldsymbol{A} \in \mathbb{R}^{d\times n}$ can be factorized into $\boldsymbol{A} = \boldsymbol{QR}$, where the non-zero columns in $\boldsymbol{Q} \in \mathbb{R}^{d\times n}$ are the orthonormal basis, and $\boldsymbol{R} \in \mathbb{R}^{n\times n}$ is an upper triangular matrix.

The process above computes the novel semantic meaning of a word w.r.t all preceding words. As the meaning of a word influences and is influenced by its close neighbors, we now calculate the novel orthogonal basis vector $\boldsymbol{q}_i$ of each word w_i in its neighborhood, rather than only w.r.t the preceding words.

Definition 1 (Contextual Window Matrix) *Given a word w_i, and its m-neighborhood window inside the sentence $(w_{i-m}, \ldots, w_{i-1}, w_i, w_{i+1}, \ldots, w_{i+m})$, define the contextual window matrix of word w_i as:*

$$\boldsymbol{S}^i = [\boldsymbol{v}_{w_{i-m}} ... \boldsymbol{v}_{w_{i-1}}, \boldsymbol{v}_{w_{i+1}} ... \boldsymbol{v}_{w_{i+m}}, \boldsymbol{v}_{w_i}] \quad (2)$$

Here we shuffle $\boldsymbol{v}_{w_i}$ to the end of $\boldsymbol{S}^i$ to compute its novel semantic information compared with its context. Now the QR factorization of $\boldsymbol{S}^i$ is

$$\boldsymbol{S}^i = \boldsymbol{Q}^i \boldsymbol{R}^i \quad (3)$$

Note that $\boldsymbol{q}_i$ is the last column of $\boldsymbol{Q}^i$, which is also the new orthogonal basis vector to this contextual window matrix.

Next, in order to generate the embedding for a sentence, we will assign a weight to each of its words. This weight should characterize how much new and important information a word brings to the sentence. The previous process yields the orthogonal basis vector $\boldsymbol{q}_i$. We propose that $\boldsymbol{q}_i$ represents the novel semantic meaning brought by word w_i. We will now discuss how to quantify i) the novelty of $\boldsymbol{q}_i$ to other meanings in w_i, ii) the significance of $\boldsymbol{q}_i$ to its context, and iii) the corpus-wise uniqueness of $\boldsymbol{q}_i$ w.r.t the whole corpus.

2.2 Novelty

We propose that a word w_i is more important to a sentence if its novel orthogonal basis vector $\boldsymbol{q}_i$ is a large component in $\boldsymbol{v}_{w_i}$, quantified by the proposed novelty score α_n. Let $\boldsymbol{r}$ denote the last column of $\boldsymbol{R}^i$, and $\boldsymbol{r}_{-1}$ denote the last element of $\boldsymbol{r}$, α_n is defined as:

$$\alpha_n = \exp(\frac{\|\boldsymbol{q}_i\|_2}{\|\boldsymbol{v}_{w_i}\|_2}) = \exp(\frac{\boldsymbol{r}_{-1}}{\|\boldsymbol{r}\|_2}) \quad (4)$$

Note that $\|\boldsymbol{q}_i\|_2 = \boldsymbol{r}_{-1}$ and $\|\boldsymbol{v}_{w_i}\|_2 = \|\boldsymbol{r}\|_2$. One can show that α_n is the exponential of the normalized distance between $\boldsymbol{v}_{w_i}$ and the subspace spanned by its context.

2.3 Significance

The significance of a word is related to how semantically aligned it is to the meaning of its context. To identify principal directions, i.e. meanings, in the contextual window matrix $\boldsymbol{S}^i$, we employ *Singular Value Decomposition*.

Singular Value Decomposition. Given a matrix $\boldsymbol{A} \in \mathbb{R}^{d\times n}$, there exists $\boldsymbol{U} \in \mathbb{R}^{d\times n}$ with orthogonal columns, diagonal matrix $\boldsymbol{\Sigma} = \text{diag}(\sigma_1, ..., \sigma_n)$, $\sigma_1 \geq \sigma_2 \geq ... \geq \sigma_n \geq 0$, and orthogonal matrix $\boldsymbol{V} \in \mathbb{R}^{n\times n}$, such that $\boldsymbol{A} = \boldsymbol{U\Sigma V}^T$.

The columns of $\boldsymbol{U}$, $\{\boldsymbol{U}_{:,j}\}_{j=1}^n$, are an orthonormal basis of $\boldsymbol{A}$'s columns subspace and we propose that they represent a set of semantic meanings from the context. Their corresponding singular values $\{\sigma_j\}_{j=1}^n$, denoted by $\sigma(\boldsymbol{A})$, represent the importance associated with $\{\boldsymbol{U}_{:,j}\}_{j=1}^n$. The SVD of w_i's contextual window matrix is $\boldsymbol{S}^i = \boldsymbol{U}^i\boldsymbol{\Sigma}^i\boldsymbol{V}^{iT} \in \mathbb{R}^{d\times(2m+1)}$. It follows that $\boldsymbol{q}_i^T\boldsymbol{U}^i$ is the coordinate of $\boldsymbol{q}_i$ in the basis of $\{\boldsymbol{U}^i_{:,j}\}_{j=1}^{2m+1}$.

Intuitively, a word is more important if its novel semantic meaning has a better alignment with more principal meanings in its contextual window. This can be quantified as $\|\sigma(\boldsymbol{S}^i) \odot (\boldsymbol{q}_i^T\boldsymbol{U}^i)\|_2$, where $\odot$ denotes element-wise product. Therefore, we define the significance of w_i in its context to be:

$$\alpha_s = \frac{\|\sigma(\boldsymbol{S}^i) \odot (\boldsymbol{q}_i^T\boldsymbol{U}^i)\|_2}{2m+1} \quad (5)$$

It turns out α_s can be rewritten as

$$\begin{aligned}\alpha_s &= \frac{\|\boldsymbol{q}_i^T\boldsymbol{U}^i\boldsymbol{\Sigma}^i\|_2}{2m+1} = \frac{\|\boldsymbol{q}_i^T\boldsymbol{U}^i\boldsymbol{\Sigma}^i\boldsymbol{V}^i\|_2}{2m+1} \\ &= \frac{\|\boldsymbol{q}_i^T\boldsymbol{S}^i\|_2}{2m+1} = \frac{\boldsymbol{q}_i^T\boldsymbol{v}_{w_i}}{2m+1} = \frac{\boldsymbol{r}_{-1}}{2m+1}\end{aligned} \quad (6)$$

and we use the fact that $\boldsymbol{V}^i$ is an orthogonal matrix and $\boldsymbol{q}_i$ is orthogonal to all but the last column of $\boldsymbol{S}^i$, $\boldsymbol{v}_{w_i}$. Therefore, α_s is essentially the distance between $\boldsymbol{w}_i$ and the context hyper-plane, normalized by the context size.

Although α_s and α_n look alike in mathematics form, they model distinct quantities in word w_i against its contextual window. α_n is a function of $\|\boldsymbol{q}_i\|_2$ divided by $\|\boldsymbol{w}_i\|_2$, i.e., the portion of the new semantic meaning in word w_i. In contrast, eq. (6) shows that α_s equals $\|\boldsymbol{q}_i\|_2$ divided by a constant, namely α_s quantifies the absolute magnitude of the new semantic meaning $\boldsymbol{q}_i$.

2.4 Corpus-wise Uniqueness

Similar to the idea of inverse document frequency (IDF) (Sparck Jones, 1972), a word that is commonly present in the corpus is likely to be a stop word, thus its corpus-wise uniqueness is small. In our solution, we compute the principal directions of the corpus and then measure their alignment with the novel orthogonal basis vector $\boldsymbol{q}_i$. If there is a high alignment, w_i will be assigned a relatively low corpus-wise uniqueness score, and vice versa.

2.4.1 Compute Principal Directions of Corpus

In Arora et al. (2017), given a corpus containing a set of N sentences, an embedding matrix $\boldsymbol{X} = [\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N] \in \mathbb{R}^{d \times N}$ is generated, where $\boldsymbol{x}_i$ is the sentence embedding for the i-th sentence in the corpus, computed by SIF algorithm. Then principal vectors of $\boldsymbol{X}$ are computed and projections onto the principal vectors are removed from each sentence embedding $\boldsymbol{x}_i$.

In contrast to Arora et al. (2017), we do not form the embedding matrix after we obtain the final sentence representation. Instead, we obtain an intermediate coarse-grained embedding matrix $\boldsymbol{X}^c = [\boldsymbol{g}_1, \ldots, \boldsymbol{g}_N]$ as follows. Suppose the SVD of the sentence matrix of the ith sentence is $\boldsymbol{S} = [\boldsymbol{v}_{w_1}, \ldots, \boldsymbol{v}_{w_n}] = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$. Then the coarse-grained embedding for the ith sentence is defined as:

$$\boldsymbol{g}_i = \sum_{j=1}^{n} f(\sigma_j)\boldsymbol{U}_{:,j} \tag{7}$$

where $f(\sigma_j)$ is a monotonically increasing function. We then compute the top K principal vectors $\{\boldsymbol{d}_1, ..., \boldsymbol{d}_K\}$ of $\boldsymbol{X}^c$, with singular values $\sigma_1 \geq \sigma_2 \geq ... \geq \sigma_K$.

2.4.2 Uniqueness Score

In contrast to Arora et al. (2017), we select different principal vectors of $\boldsymbol{X}^c$ for each sentence, as different sentences may have disparate alignments with the corpus. For each sentence, $\{\boldsymbol{d}_1, ..., \boldsymbol{d}_K\}$ are re-ranked in descending order of their correlation with sentence matrix $\boldsymbol{S}$. The correlation is defined as:

$$o_i = \sigma_i \|\boldsymbol{S}^T \boldsymbol{d}_i\|_2, 1 \leq i \leq K \tag{8}$$

Next, the top h principal vectors after re-ranking based on o_i are selected: $\boldsymbol{D} = \{\boldsymbol{d}_{t_1}, ..., \boldsymbol{d}_{t_h}\}$, with $o_{t_1} \geq o_{t_2} \geq ... \geq o_{t_h}$ and their singular values in $\boldsymbol{X}^c$ are $\boldsymbol{\sigma}_d = [\sigma_{t_1}, ..., \sigma_{t_h}] \in \mathbb{R}^h$.

Finally, a word w_i with new semantic meaning vector $\boldsymbol{q}_i$ in this sentence will be assigned a corpus-wise uniqueness score:

$$\alpha_u = \exp\left(-\|\boldsymbol{\sigma}_d \odot (\boldsymbol{q}_i^T \boldsymbol{D})\|_2 / h\right) \tag{9}$$

This ensures that common stop words will have their effect diminished since their embeddings are closely aligned with the corpus' principal directions.

2.5 Sentence Vector

A sentence vector $\boldsymbol{c}_s$ is computed as a weighted sum of its word embeddings, where the weights come from three scores: a novelty score (α_n), a significance score (α_s) and a corpus-wise uniqueness score (α_u).

$$\begin{aligned} \alpha_i &= \alpha_n + \alpha_s + \alpha_u \\ \boldsymbol{c}_s &= \sum_i \alpha_i \boldsymbol{v}_{w_i} \end{aligned} \tag{10}$$

We provide a theoretical explanation of Equation (10) in Appendix.

Sentence-Dependent Removal of Principal Components. Arora et al. (2017) shows that given a set of sentence vectors, removing projections onto the principal components of the spanned subspace can significantly enhance the performance on semantic similarity task. However, as each sentence may have a different semantic meaning, it could be sub-optimal to remove the same set of principal components from all sentences.

Therefore, we propose the *sentence-dependent principal component removal* (SDR), where we re-rank top principal vectors based on correlation

with each sentence. Using the method from Section 2.4.2, we obtain $\boldsymbol{D} = \{\boldsymbol{d}_{t_1}, ..., \boldsymbol{d}_{t_r}\}$ for a sentence s. The final embedding of this sentence is then computed as:

$$\boldsymbol{c}_s \leftarrow \boldsymbol{c}_s - \sum_{j=1}^{r} (\boldsymbol{d}_{t_j}^T \boldsymbol{c}_s) \boldsymbol{d}_{t_j} \quad (11)$$

Ablation experiments show that sentence-dependent principal component removal can achieve better result. The complete algorithm is summarized in Algorithm 1 with an illustration in Figure 1.

2.6 Handling of out-of-vocabulary Words

In many NLP algorithms, the out-of-vocabulary (OOV) words are projected to a special "UNK" token. However, in this way, different OOV words with drastically different meanings will share the same embedding. To fix this problem, we change this projection method by mapping OOVs to pre-trained in-vocabulary words, based on a hash function SHA-256 of its characters. In this way, two different OOV words will almost certainly have different embeddings. In the experiments, we apply this OOV projection technique in both STS-B and CQA tasks.

3 Experiments

3.1 Semantic Similarity Tasks: STS Benchmark

We evaluate our model on the STS Benchmark (Cer et al., 2017), a sentence-level semantic similarity dataset. The goal for a model is to predict a similarity score of two sentences given a sentence pair. The evaluation is by the Pearson's coefficient r between human-labeled similarity (0 - 5 points) and predictions.

Experimental settings. We report two versions of our model, one only using GloVe word vectors (GEM + GloVe), and the other using word vectors concatenated from LexVec, fastText and PSL (Wieting et al., 2015b) (GEM + L.F.P). The final similarity score is computed as an inner product of normalized sentence vectors. Since our model is non-parameterized, it does not utilize any information from the dev set when evaluating on the test set and vice versa. Hyper-parameters are chosen at $m = 7$, $h = 17$, $K = 45$, and $t = 3$ by conducing hyper-parameters search on dev set. Results on the dev and test set are reported in Table 1. As shown,

Non-parameterized models	dev	test
GEM + L.F.P (ours)	83.5	78.4
GEM + LexVec (ours)	81.9	76.5
SIF (Arora et al., 2017)	80.1	72.0
uSIF (Ethayarajh, 2018)	**84.2**	79.5
LexVec	58.78	50.43
L.F.P	62.4	52.0
word2vec skipgram	70.0	56.5
Glove	52.4	40.6
ELMo	64.6	55.9
Parameterized models		
PARANMT-50M (Wieting and Gimpel, 2017a)	-	**79.9**
Reddit + SNLI (Yang et al., 2018)	81.4	78.2
GRAN (Wieting and Gimpel, 2017b)	81.8	76.4
InferSent (Conneau et al., 2017)	80.1	75.8
Sent2Vec (Pagliardini et al., 2018)	78.7	75.5
Paragram-Phrase (Wieting et al., 2015a)	73.9	73.2

Table 1: Pearson's $r \times 100$ on STSB. Best results are in bold.

GEM + L.F.P (ours)	**49.11**
Reddit + SNLI tuned	47.44
KeLP-contrastive1	49.00
SimBow-contrastive2	47.87
SimBow-primary	47.22

Table 2: MAP on CQA subtask B.

on the test set, our model has a 6.4% higher score compared with another non-parameterized model SIF, and 26.4% higher than the baseline of averaging L.F.P word vectors. It also outperforms all parameterized models including GRAN, InferSent, Sent2Vec and Reddit+SNLI.

3.2 Semantic Similarity Tasks: CQA

We evaluate our model on subtask B of the SemEval Community Question Answering (CQA) task, another semantic similarity dataset. Given an original question Q_o and a set of the first ten related questions $(Q_1, ..., Q_{10})$ retrieved by a search engine, the model is expected to re-rank the related questions according to their similarity with respect to the original question. Each retrieved question Q_i is labelled "PerfectMatch", "Relevant" or "Irrelevant", with respect to Q_o. Mean average precision (MAP) is used as the evaluation measure.

We encode each question text into a unit vector $\boldsymbol{u}$. Retrieved questions $\{Q_i\}_{i=1}^{10}$ are ranked according to their cosine similarity with Q_o. Results are shown in Table 2. For comparison, we include results from the best models in 2017 competition: SimBow (Charlet and Damnati, 2017),

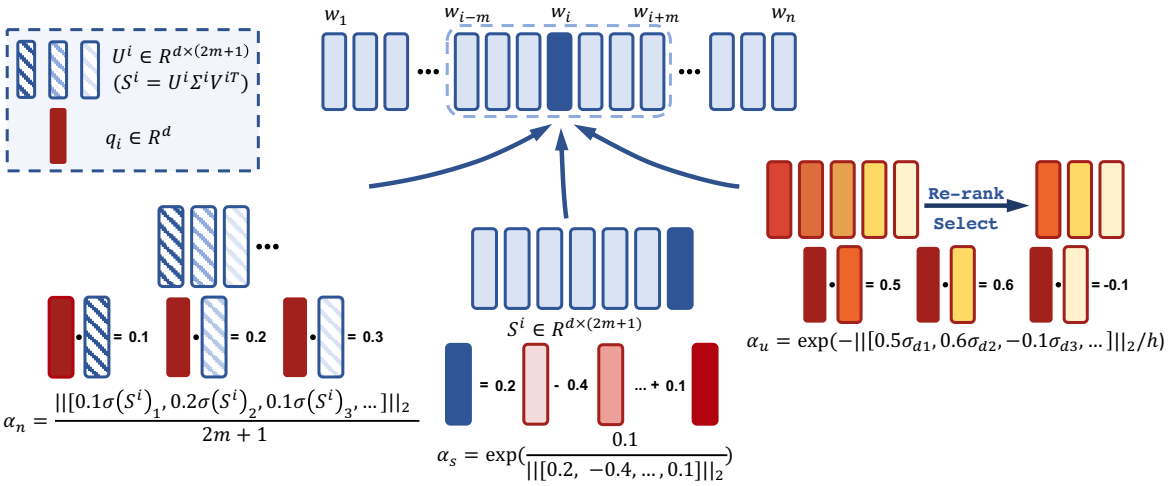

Figure 1: An illustration of GEM algorithm. Top middle: The sentence to encode, with words w_1 to w_n. The contextual window of word w_i is inside the dashed line. Bottom middle: Form contextual window matrix $\boldsymbol{S}^i$ for w^i, compute $\boldsymbol{q}_i$ and novelty score α_n (Section 2.1 and Section 2.2). Bottom left: SVD of $\boldsymbol{S}^i$ and compute the significance score α_s (Section 2.3). Bottom right: Re-rank and select from principal components (orange blocks) and compute uniqueness score α_u (Section 2.4).

Algorithm 1 Geometric Embedding (GEM)

Inputs:

A set of sentences $\mathcal{S}$, vocabulary $\mathcal{V}$, word embeddings $\{\boldsymbol{v}_w \in \mathbb{R}^d \,|\, w \in \mathcal{V}\}$

Outputs:

Sentence embeddings $\{\boldsymbol{c}_s \in \mathbb{R}^d \,|\, s \in \mathcal{S}\}$

for ith sentence s in $\mathcal{S}$ **do**

Form matrix $\boldsymbol{S} \in \mathbb{R}^{d\times n}$, $\boldsymbol{S}_{:,j} = \boldsymbol{v}_{w_j}$ and w_j is the jth word in s

The SVD is $\boldsymbol{S} = \boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T$

The ith column of the coarse-grained sentence embedding matrix $\boldsymbol{X}^c_{:,i}$ is $\boldsymbol{U}(\sigma(\boldsymbol{S}))^3$

end for

Take first K singular vectors $\{\boldsymbol{d}_1, ..., \boldsymbol{d}_K\}$ and singular values $\sigma_1 \geq \sigma_2 \geq ... \geq \sigma_K$ of $\boldsymbol{X}^c$

for sentence s in $\mathcal{S}$ **do**

Re-rank $\{\boldsymbol{d}_1, ..., \boldsymbol{d}_K\}$ in descending order by $o_i = \sigma_i \|\boldsymbol{S}^T\boldsymbol{d}_i\|_2, 1 \leq i \leq K$.

Select top h principal vectors as $\boldsymbol{D} = [\boldsymbol{d}_{t_1}, ..., \boldsymbol{d}_{t_h}]$, with singular values $\boldsymbol{\sigma}_d = [\sigma_{t_1}, ..., \sigma_{t_h}]$.

for word w_i in s **do**

$\boldsymbol{S}^i = [\boldsymbol{v}_{w_{i-m}}, ..., \boldsymbol{v}_{w_{i-1}}, \boldsymbol{v}_{w_{i+1}}, ..., \boldsymbol{v}_{w_{i+m}}, \boldsymbol{v}_{w_i}]$ is the contextual window matrix of w_i.

Do QR decomposition $\boldsymbol{S}^i = \boldsymbol{Q}^i\boldsymbol{R}^i$, let $\boldsymbol{q}_i$ and $\boldsymbol{r}$ denote the last column of $\boldsymbol{Q}^i$ and $\boldsymbol{R}^i$

$\alpha_n = \exp(\boldsymbol{r}_{-1}/\|\boldsymbol{r}\|_2), \alpha_s = \boldsymbol{r}_{-1}/(2m+1), \alpha_u = \exp\left(-\|\boldsymbol{\sigma}_d \odot (\boldsymbol{q}_i^T\boldsymbol{D})\|_2/h\right)$

$\alpha_i = \alpha_n + \alpha_s + \alpha_u$

end for

$\boldsymbol{c}_s = \sum_{\boldsymbol{v}_i \in \boldsymbol{s}} \alpha_i \boldsymbol{v}_{w_i}$

Principal vectors removal: $\boldsymbol{c}_s \leftarrow \boldsymbol{c}_s - \boldsymbol{D}\boldsymbol{D}^T\boldsymbol{c}_s$

end for

KeLP (Filice et al., 2017), and Reddit + SNLI tuned. Note that all three benchmark models require learning on CQA training set, and SimBow and KeLP leverage optional features including usage of comments and user profiles. In comparison, our model only uses the question text without any training. Our model clearly outperforms Reddit + SNLI tuned, SimBow-primary and KeLP model.

3.3 Supervised tasks

We further test our model on nine supervised tasks, including seven classification tasks: movie review (MR) (Pang and Lee, 2005), Stanford Sentiment Treebank (SST) (Socher et al., 2013),

question-type classification (TREC) (Voorhees and Dang, 2003), opinion polarity (MPQA) (Wiebe et al., 2005), product reviews (CR) (Hu and Liu, 2004), subjectivity/objectivity classification (SUBJ) (Pang and Lee, 2004) and paraphrase identification (MRPC) (Dolan et al., 2004). We also evaluate on two entailment and semantic relatedness tasks: SICK similarity (SICK-R) and the SICK entailment (SICK-E) (Marelli et al., 2014). The sentence embeddings generated are fixed and only the downstream task-specific neural structure is learned. For classification tasks, a linear classifier is trained on top, following Kiros et al. (2015), and classification accuracy are reported. For relatedness tasks, we follow Tai et al. (2015) to train a logistic regression to learn the probability distribution of relatedness scores, and we report Pearson's correlation. The four hyper-parameters are chosen the same as those in STS benchmark experiment. For fair comparison, embeddings models are divided into two categories: non-parameterized and parameterized ones, as described in section 1. Results are shown in Table 3.

GEM outperforms all other non-parameterized sentence embedding models, including SIF, p-mean (Rücklé et al., 2018), and BOW on GloVe. The consistent superior performance again demonstrates GEM's advantage on weighting scheme. It also compares favorably with most of parameterized models, including *à la carte* (Khodak et al., 2018), FastSent (Hill et al., 2016), InferSent, QT, Sent2Vec, SkipThought-LN (with layer normalization) (Kiros et al., 2015), SDAE (Hill et al., 2016), STN (Subramanian et al., 2018) and USE (Yang et al., 2018). Note that sentence representations generated by GEM have much smaller dimension compared to most of benchmark models, and the subsequent neural structure has fewer trainable parameters. This observation suggests that local multi-word level information in sentences has already provided revealing information for sophisticated downstream tasks. The fact that GEM does well on several classification tasks (e.g. TREC and SUBJ) indicates that the proposed weight scheme is able to recognize important words sentences. Also, GEM's competitive performance on sentiment tasks shows that exploiting the geometric structures of two sentence subspaces is semantically informative.

4 Discussion

Comparison with Arora et al. (2017). We would like to point out that although sharing the idea of modelling the sentence as the weighted sum of its word vectors, GEM is substantially different from Arora et al. (2017). First, we adopt well-established numerical linear algebra to quantify the semantic meaning and importance of words in the sentences context. And this new approach proves to be effective. Second, the weights in SIF (and uSIF) are calculated from the statistic of vocabularies on very large corpus (wikipedia). In contrast, the weights in GEM are directly computed from the sentences themselves along with the dataset, independent with prior statistical knowledge of language or vocabularies. Furthermore, the components in GEM's weights are derived from numerical linear algebra eq. (4) to (9), while SIF directly includes a hyper-parameter term in its weight scheme, i.e. its smooth term.

Robustness and Effectiveness. Besides experiments mentioned above, we also test the robustness and effectiveness GEM on several simple but non-trivial examples. These experiments demonstrate that GEM is quite insensitive against the removal of non-important stop words. Also GEM can correctly assign higher weights for words with more significant semantic meanings in the sentence.

We first test the robustness of GEM by removing one non-important stop word in a sentence and computed the similarity between the original sentence and the one after removal. For example:

- original sentence: "the first tropical system to slam the US this year is expected to make landfall as a hurricane"
- remove 7 stop words: "first tropical system slam US this year expected make landfall hurricane"

The cosine similarity between these two sentences given by GEM is 0.954. Even though aggressively removing 7 stop words, GEM still assigns pretty similar embeddings for these two sentences.

We further demonstrate that GEM does assign higher weights to words with more significant semantic meanings. Consider the following sentence: "there are two ducks swimming in the river". Weights assigned by GEM are (sorted from high to low): [ducks: 4.93, river:4.72 , swimming: 4.70, two: 3.87, are: 3.54, there:

Model	Dim	Training time (h)	MR	CR	SUBJ	MPQA	SST	TREC	MRPC	SICK-R	SICK-E

Table 3: Results on supervised tasks. Sentence embeddings are fixed for downstream supervised tasks. Best results for each task are underlined, best results from models in the same category are in bold. SIF results are extracted from Arora et al. (2017) and Rücklé et al. (2018), and training time is collected from Logeswaran and Lee (2018).

3.23, in:3.04, the:2.93]. GEM successfully assigns higher weight to informative words like ducks and river, and downplay stop words like the and there. More examples can be found in the Appendix.

Ablation Study. As shown in in Table 4, every GEM weight $(\alpha_n, \alpha_s, \alpha_u)$ and proposed principal components removal methods contribute to the performance. As listed on the left, adding GEM weights improves the score by 8.6% on STS dataset compared with averaging three concatenated word vectors. The sentence-dependent principal component removal (SDR) proposed in GEM improves 1.7% compared to directly removing the top h corpus principal components (SIR). Using GEM weights and SDR together yields an overall improvement of 21.1%. As shown on the right in Table 4, every weight contributes to the performance of our model. For example, three weights altogether improve the score in SUBJ task by 0.38% compared with only using α_n.

Sensitivity Study. We evaluate the effect of all four hyper-parameters in our model: the window size m in the contextual window matrix, the number of candidate principal components K, the number of principal components to remove h, and the power of the singular value in coarse sentence embedding, i.e. the power t in $f(\sigma_j) = \sigma_j^t$ in Equation (7). We sweep the hyper-parameters and test on STSB dev set, SUBJ, and MPQA. Unspecified parameters are fixed at $m = 7$, $K = 45$, $h = 17$ and $t = 3$. As shown in Figure 2, our model is quite robust with respect to hyper-parameters.

Configurations	STSB dev	SUBJ
Mean of L.F.P	62.4	-
GEM weights	71.0	-
GEM weights + SIR	81.8	-
GEM weights + SDR	83.5	-
α_n + SDR	81.6	93.42
α_n, α_s + SDR	81.9	93.6
$\alpha_n, \alpha_s, \alpha_u$ + SDR	83.5	93.8

Table 4: Comparison of different configurations demonstrates the effectiveness of our model on STSB dev set and SUBJ. SDR stands for sentence-dependent principal component removal in Section 2.4.2. SIR stands for sentence-independent principal component removal, i.e. directly removing top h corpus principal components from the sentence embedding.

Inference speed. We also compare the inference speed of our algorithm on the STSB test set with the benchmark models SkipThought and InferSent. SkipThought and InferSent are run on a NVIDIA Tesla P100 GPU, and our model is run on a CPU (Intel Xeon CPU E5-2690 v4 @2.60GHz). For fair comparison, batch size in InferSent and SkipThought is set to be 1. The results are shown in Table 5. It shows that without acceleration from GPU, our model is still faster than InferSent and is 54% faster than SkipThought.

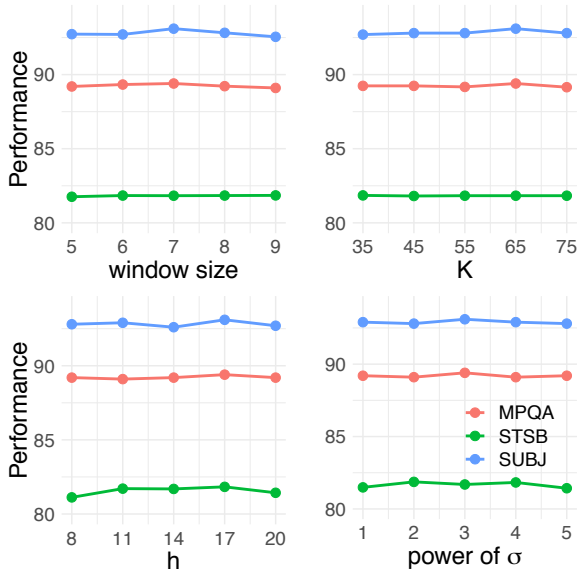

Figure 2: Sensitivity tests on four hyper-parameters, the window size m in contextual window matrix, the number of candidate principal components K, the number of principal components to remove h, and the exponential power of singular value in coarse sentence embedding.

	Average run time (s)	Variance
GEM (CPU)	**20.08**	0.23
InferSent(GPU)	21.24	0.15
SkipThought (GPU)	43.36	0.10

Table 5: Run time of GEM, InferSent and SkipThought on encoding sentences in STSB test set. GEM is run on CPU, InferSent and SkipThought is run on GPU. Data are collected from 5 trials.

5 Conclusions

We proposed a simple non-parameterized method to generate sentence embeddings, based entirely on the geometric structure of the subspace spanned by word embeddings. Our sentence embedding evolves from the new orthogonal basis vector brought in by each word, which represents novel semantic meaning. The evaluation shows that our method not only sets up the new state-of-the-art of non-parameterized models but also performs competitively when compared with models requiring either large amount of training data or prolonged training time. In future work, we plan to consider subwords into the model and explore more geometric structures in sentences.

Abstract

Prior work on pretrained sentence embeddings and benchmarks focuses on the capabilities of representations for stand-alone sentences. We propose DiscoEval, a test suite of tasks to evaluate whether sentence representations include information about the role of a sentence in its discourse context. We also propose a variety of training objectives that make use of natural annotations from Wikipedia to build sentence encoders capable of modeling discourse information. We benchmark sentence encoders trained with our proposed objectives, as well as other popular pretrained sentence encoders, on DiscoEval and other sentence evaluation tasks. Empirically, we show that these training objectives help to encode different aspects of information from the surrounding document structure. Moreover, BERT (Devlin et al., 2019) and ELMo (Peters et al., 2018a) demonstrate strong performance across DiscoEval tasks with individual hidden layers showing different characteristics.[1]

1 Introduction

Pretrained sentence representations have been found useful in various downstream tasks such as visual question answering (Tapaswi et al., 2016), script inference (Pichotta and Mooney, 2016), and information retrieval (Le and Mikolov, 2014; Palangi et al., 2016). Benchmark datasets (Adi et al., 2017; Conneau and Kiela, 2018; Wang et al., 2018a, 2019) have been proposed to evaluate the encoded knowledge, where the focus has been primarily on natural language understanding capabilities of the representation of a stand-alone sentence, such as its semantic roles, rather than the broader context in which it is situated.

[The European Community's consumer price index rose a provisional 0.6% in September from August]$_1$ [and was up 5.3% from September 1988,]$_2$ [according to Eurostat, the EC's statistical agency.]$_3$

Figure 1: An RST discourse tree from the RST Discourse Treebank. "N" represents "nucleus", containing basic information for the relation. "S" represents "satellite", containing additional information about the nucleus.

In this paper, we seek to incorporate and evaluate discourse knowledge in general purpose sentence representations. A discourse is a coherent, structured group of sentences that acts as a fundamental type of structure in natural language (Jurafsky and Martin, 2009). A discourse structure is often characterized by the arrangement of semantic elements across multiple sentences, such as entities and pronouns. The simplest such arrangement (i.e., linearly-structured) can be understood as sentence ordering, where the structure is manifested in the timing of introducing entities. Deeper discourse structures use more complex relations among sentences (e.g., tree-structured; see Figure 1).

Theoretically, discourse structures have been approached through Centering Theory (Grosz et al., 1995) for studying distributions of entities across text and Rhetorical Structure Theory (RST; Mann and Thompson, 1988) for modelling the logical structure of natural language via discourse trees. Researchers have found modelling discourse useful in a range of tasks (Guzmán et al., 2014; Narasimhan and Barzilay, 2015; Liu and Lapata, 2018; Pan et al., 2018), including summarization (Gerani et al., 2014), text classification (Ji

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 649–662, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

and Smith, 2017), and text generation (Bosselut et al., 2018).

In this paper, we propose DiscoEval, a task suite designed to evaluate discourse-related knowledge in pretrained sentence representations. DiscoEval comprises 7 task groups covering multiple domains, including Wikipedia, stories, dialogues, and scientific literature. The tasks are probing tasks (Shi et al., 2016; Adi et al., 2017; Belinkov et al., 2017; Peters et al., 2018b; Conneau et al., 2018; Poliak et al., 2018; Tenney et al., 2019; Liu et al., 2019a; Ettinger, 2019; Chen et al., 2019, *inter alia*) based on sentence ordering, annotated discourse relations, and discourse coherence. The data is either generated semi-automatically or based on human annotations (Carlson et al., 2001; Prasad et al., 2008; Lin et al., 2009; Kummerfeld et al., 2019).

We also propose a set of novel multi-task learning objectives building upon standard pretrained sentence encoders, which rely on the assumption of distributional semantics of text. These objectives depend only on the natural structure in structured document collections like Wikipedia.

Empirically, we benchmark our models and several popular sentence encoders on DiscoEval and SentEval (Conneau and Kiela, 2018). We find that our proposed training objectives help the models capture different characteristics in the sentence representations. Additionally, we find that ELMo shows strong performance on SentEval, whereas BERT performs the best among the pretrained embeddings on DiscoEval. Both BERT and Skip-thought vectors (Kiros et al., 2015), which have training losses explicitly related to surrounding sentences, perform much stronger compared to their respective prior work, demonstrating the effectiveness of incorporating losses that make use of broader context. Through per-layer analysis, we also find that for both BERT and ELMo, deep layers consistently outperform shallower ones on DiscoEval, showing different trends from SentEval where the shallow layers have the best performance.

2 Related Work

Discourse modelling and discourse parsing have a rich history (Marcu, 2000; Barzilay and Lapata, 2008; Zhou et al., 2010; Kalchbrenner and Blunsom, 2013; Ji and Eisenstein, 2015; Li and Jurafsky, 2017; Wang et al., 2018c; Liu et al., 2018; Lin et al., 2019, *inter alia*), much of it based on recovering linguistic annotations of discourse structure.

Several researchers have defined tasks related to discourse structure, including sentence ordering (Chen et al., 2016; Logeswaran et al., 2016; Cui et al., 2018), sentence clustering (Wang et al., 2018b), and disentangling textual threads (Elsner and Charniak, 2008, 2010; Lowe et al., 2015; Mehri and Carenini, 2017; Jiang et al., 2018; Kummerfeld et al., 2019).

There is a great deal of prior work on pretrained representations (Le and Mikolov, 2014; Kiros et al., 2015; Hill et al., 2016; Wieting et al., 2016; McCann et al., 2017; Gan et al., 2017; Peters et al., 2018a; Logeswaran and Lee, 2018; Devlin et al., 2019; Tang and de Sa, 2019; Yang et al., 2019; Liu et al., 2019b, *inter alia*). Skip-thought vectors form an effective architecture for general-purpose sentence embeddings. The model encodes a sentence to a vector representation, and then predicts the previous and next sentences in the discourse context. Since Skip-thought performs well in downstream evaluation tasks, we use this neighboring-sentence objective as a starting point for our models.

There is also work on incorporating discourse related objectives into the training of sentence representations. Jernite et al. (2017) propose binary sentence ordering, conjunction prediction (requiring manually-defined conjunction groups), and next sentence prediction. Similarly, Sileo et al. (2019) and Nie et al. (2019) create training datasets automatically based on discourse relations provided in the Penn Discourse Treebank (PDTB; Lin et al., 2009).

Our work differs from prior work in that we propose a general-purpose pretrained sentence embedding evaluation suite that covers multiple aspects of discourse knowledge and we propose novel training signals based on document structure, including sentence position and section titles, without requiring additional human annotation.

3 Discourse Evaluation

We propose DiscoEval, a test suite of 7 tasks to evaluate whether sentence representations include semantic information relevant to discourse processing. Below we describe the tasks and datasets, as well as the evaluation framework. We closely follow the SentEval sentence embedding evaluation suite, in particular its supervised sentence and

sentence pair classification tasks, which use predefined neural architectures with slots for fixed-dimensional sentence embeddings. All DiscoEval tasks are modelled by logistic regression unless otherwise stated in later sections.

We also experimented with adding hidden layers to the DiscoEval classification models. However, we find simpler linear classifiers to provide a clearer comparison among sentence embedding methods. More complex classification models lead to noisier results, as more of the modelling burden is shifted to the optimization of the classifiers. Hence we decide to evaluate the sentence embeddings with simple classification models.

In the rest of this section, we will use $[\cdot, \cdot, \cdots]$ to denote concatenation of vectors, $\odot$ for element-wise multiplication, and $|\cdot|$ for element-wise absolute value.

3.1 Discourse Relations

As the most direct way to probe discourse knowledge, we consider the task of predicting annotated discourse relations among sentences. We use two human-annotated datasets: the RST Discourse Treebank (RST-DT; Carlson et al., 2001) and the Penn Discourse Treebank (PDTB; Prasad et al., 2008). They have different labeling schemes. PDTB provides discourse markers for adjacent sentences, whereas RST-DT offers document-level discourse trees, which recently was used to evaluate discourse knowledge encoded in document-level models (Ferracane et al., 2019). The difference allows us to see if the pretrained representations capture local or global information about discourse structure.

More specifically, as shown in Figure 1, in RST-DT, text is segmented into basic units, elementary discourse units (EDUs), upon which a discourse tree is built recursively. Although a relation can take multiple units, we follow prior work (Ji and Eisenstein, 2014) to use right-branching trees for non-binary relations to binarize the tree structure and use the 18 coarse-grained relations defined by Carlson et al. (2001).

When evaluating pretrained sentence encoders on RST-DT, we first encode EDUs into vectors, then use averaged vectors of EDUs of subtrees as the representation of the subtrees. The target prediction is the label of nodes in discourse trees and the input to the classifier is $[x_{\text{left}}, x_{\text{right}}, x_{\text{left}} \odot x_{\text{right}}, |x_{\text{left}} - x_{\text{right}}|]$, where x_{left} and x_{right} are vector representations of the left and right subtrees respectively. For example, the input for target "NN-Attribution" in Figure 1 would be $x_{\text{left}} = \frac{x_1+x_2}{2}$, $x_{\text{right}} = x_3$, where x_i is the encoded representation for the ith EDU in the text. We use the standard data splits, where there are 347 documents for training and 38 documents for testing. We choose 35 documents from the training set to serve as a validation set.

1. In any case, the brokerage firms are clearly moving faster to create new ads than they did in the fall of 1987.
2. [But] it remains to be seen whether their ads will be any more effective.
label: Comparison.Contrast

Figure 2: Example in the PDTB explicit relation task. The words in [] are taken out from input sentence 2.

1. "A lot of investor confidence comes from the fact that they can speak to us," he says.
2. [so] "To maintain that dialogue is absolutely crucial."
label: Contingency.Cause

Figure 3: Example in the PDTB implicit relation task.

For PDTB, we use a pair of sentences to predict discourse relations. Following Lin et al. (2009), we focus on two kinds of relations from PDTB: explicit (PDTB-E) and implicit (PDTB-I). The sentence pairs with explicit relations are two consecutive sentences with a particular connective word in between. Figure 2 is an example of an explicit relation.

In the PDTB, annotators insert an implicit connective between adjacent sentences to reflect their relations, if such an implicit relation exists. Figure 3 shows an example of an implicit relation. The PDTB provides a three-level hierarchy of relation tags. In DiscoEval, we use the second level of types (Lin et al., 2009), as they provide finer semantic distinctions compared to the first level. To ensure there is a reasonable amount of evaluation data, we use sections 2-14 as training set, 15-18 as development set, and 19-23 as test set. In addition, we filter out categories that have less than 10 instances. This leaves us 12 categories for explicit relations and 11 for implicit ones. Category names are listed in the supplementary material.

We use the sentence embeddings to infer sentence relations with supervised training. As input to the classifier, we encode both sentences to vector representations x_1 and x_2, concatenated with their element-wise product and absolute difference: $[x_1, x_2, x_1 \odot x_2, |x_1 - x_2|]$.

- She was excited thinking she must have lost weight.
- Bonnie hated trying on clothes.
- Then she realized they actually size 14s, and 12s.
- She picked up a pair of size 12 jeans from the display.
- When she tried them on they were too big!

Figure 4: Example from the ROC Stories domain of the Sentence Position task. The first sentence should be in the fourth position.

3.2 Sentence Position (SP)

We create a task that we call Sentence Position. It can be seen as way to probe the knowledge of linearly-structured discourse, where the ordering corresponds to the timings of events. When constructing this dataset, we take five consecutive sentences from a corpus, randomly move one of these five sentences to the first position, and ask models to predict the true position of the first sentence in the modified sequence.

We create three versions of this task, one for each of the following three domains: the first five sentences of the introduction section of a Wikipedia article (Wiki), the ROC Stories corpus (ROC; Mostafazadeh et al., 2016), and the first 5 sentences in the abstracts of arXiv papers (arXiv; Chen et al., 2016). Figure 4 shows an example of this task for the ROC Stories domain. The first sentence should be in the fourth position among these sentences. To make correct predictions, the model needs to be aware of both typical orderings of events as well as how events are described in language. In the example shown, Bonnie's excitement comes from her imagination so it must happen after she picked up the jeans and tried them on but right before she realized the actual size.

To train classifiers for these tasks, we do the following. We first encode the five sentences to vector representations x_i. As input to the classifier, we include x_1 and the concatenation of $x_1 - x_i$ for all i: $[x_1, x_1 - x_2, x_1 - x_3, x_1 - x_4, x_1 - x_5]$.

3.3 Binary Sentence Ordering (BSO)

Similar to sentence position prediction, Binary Sentence Ordering (BSO) is a binary classification task to determine the order of two sentences. The fact that BSO only has a pair of sentences as input makes it different from Sentence Position, where there is more context, and we hope that BSO can evaluate the ability of capturing local discourse coherence in the given sentence representations. The data comes from the same three domains as Sentence Position, and each instance is a pair of consecutive sentences.

1. These functions include fast and synchronized response to environmental change, or long-term memory about the transcriptional status.
2. Focusing on the collective behaviors on a population level, we explore potential regulatory functions this model can offer.

Figure 5: Example from the arXiv domain of the Binary Sentence Ordering task (incorrect ordering shown).

Figure 5 shows an example from the arXiv domain of the Binary Sentence Ordering task. The order of the sentences in this instance is incorrect, as the "functions" are referenced before they are introduced. To detect the incorrect ordering in this example, the encoded representations need to be able to provide information about new and old information in each sentence.

To form the input when training classifiers, we concatenate the embeddings of both sentences with their element-wise difference: $[x_1, x_2, x_1 - x_2]$.

3.4 Discourse Coherence (DC)

Inspired by prior work on chat disentanglement (Elsner and Charniak, 2008, 2010) and sentence clustering (Wang et al., 2018b), we propose a sentence disentanglement task. The task is to determine whether a sequence of six sentences forms a coherent paragraph. We start with a coherent sequence of six sentences, then randomly replace one of the sentences (chosen uniformly among positions 2-5) with a sentence from another discourse. This task, which we call Discourse Coherence (DC), is a binary classification task and the datasets are balanced between positive and negative instances.

We use data from two domains for this task: Wikipedia and the Ubuntu IRC channel.[2] For Wikipedia, we begin by choosing a sequence of six sentences from a Wikipedia article. For purposes of choosing difficult distractor sentences, we use the Wikipedia categories of each document as an indication of its topic. To create a negative instance, we randomly sample a sentence from another document with a similar set of categories (measured by the percentage of overlapping categories). This sampled sentence replaces one of the six consecutive sentences in the original sequence. When splitting the train, development,

[2] irclogs.ubuntu.com/

1. It is possible he was the youngest of the family as the name "Sextus" translates to sixth in English implying he was the sixth of two living and three stillborn brothers.
2. According to Roman tradition, his rape of Lucretia was the precipitating event in the overthrow of the monarchy and the establishment of the Roman Republic.
3. Tarquinius Superbus was besieging Ardea, a city of the Rutulians.
4. The place could not be taken by force, and the Roman army lay encamped beneath the walls.
5. **He was soon elected to the Academy's membership (although he had to wait until 1903 to be elected to the Society of American Artists), and in 1883 he opened a New York studio, dividing his time for several years between Manhattan and Boston.**
6. As nothing was happening in the field, they mounted their horses to pay a surprise visit to their homes.

Figure 6: An example from the Wikipedia domain of the Discourse Coherence task. This sequence is not coherent; the boldface sentence was substituted in for the true fifth sentence from another article.

and test sets, we ensure there are no overlapping documents among them.

Our proposed dataset differs from the sentence clustering task of Wang et al. (2018b) in that it preserves sentence order and does not anonymize or lemmatize words, because they play an important role in conveying information about discourse coherence.

For the Ubuntu domain, we use the human annotations of conversation thread structure from Kummerfeld et al. (2019) to provide us with a coherent sequence of utterances. We filter out sentences by heuristic rules to avoid overly technical and unsolvable cases. The negative sentence is randomly picked from other conversations. Similarly, when splitting the train, development, and test sets, we ensure there are no overlapping conversations among them.

Figure 6 is an instance of the Wikipedia domain of the Discourse Coherence task. This instance is not coherent and the boldfaced text is from a different document. The incoherence can be found either by comparing characteristics of the entity being discussed or by the topic of the sentence group. Solving this task is non-trivial as it may require the ability to perform inference across multiple sentences.

In this task, we encode all sentences to vector representations and concatenate all of them ($[x_1, x_2, x_3, x_4, x_5, x_6]$) as input to the classification model. Note that in this task, we use a hidden layer of 2000 dimensions with sigmoid activation in the classification model, as this is necessary for the classifier to use features based on multiple inputs simultaneously given the simple concatenation as input. We could have developed richer ways to encode the input so that a linear classifier would be feasible (e.g., use the element-wise products of all pairs of sentence embeddings), but we wish to keep the input dimensionality of the classifier small enough that the classifier will be learnable given fixed sentence embeddings and limited training data.

1. The theory behind the SVM and the naive Bayes classifier is explored.
2. This relocation of the active target may be repeated an arbitrary number of times.

Figure 7: Examples from Sentence Section Prediction. The first is from an Abstract while the second is not.

Task	PDTB-E	PDTB-I	Ubuntu	RST-DT	Others
Train	9383	8693	5816	17051	10000
Dev.	3613	2972	1834	2045	4000
Test	3758	3024	2418	2308	4000

Table 1: Size of datasets in DiscoEval.

3.5 Sentence Section Prediction (SSP)

The Sentence Section Prediction (SSP) task is defined as determining the section of a given sentence. The motivation behind this task is that sentences within certain sections typically exhibit similar patterns because of the way people write coherent text. The pattern can be found based on connectives or specificity of a sentence. For example, "Empirically" is usually used in the abstract or introduction sections in scientific writing.

We construct the dataset from PeerRead (Kang et al., 2018), which consists of scientific papers from a variety of fields. The goal is to predict whether or not a sentence belongs to the Abstract section. After eliminating sentences that are too easy for the task (e.g., equations), we randomly sample sentences from the Abstract or from a section in the middle of a paper.[3] Figure 7 shows two sentences from this task, where the first sentence is more general and from an Abstract whereas the second is more specific and is from another section. In this task, the input to the classifier is simply the sentence embedding.

Table 1 shows the number of instances in each DiscoEval task introduced above.

[3]We avoid sentences from the Introduction or Conclusion sections to make the task more solvable.

4 Models and Learning Criteria

Having described DiscoEval, we now discuss methods for incorporating discourse information into sentence embedding training. All models in our experiments are composed of a single encoder and multiple decoders. The encoder, parameterized by a bidirectional Gated Recurrent Unit (Bi-GRU; Chung et al., 2014), encodes the sentence, either in training or in evaluation of the downstream tasks, to a fixed-length vector representation (i.e., the average of the hidden states across positions).

The decoders take the aforementioned encoded sentence representation, and predict the targets we define in the sections below. We first introduce Neighboring Sentence Prediction, the loss for our baseline model. We then propose additional training losses to encourage our sentence embeddings to capture other context information.

4.1 Neighboring Sentence Prediction (NSP)

Similar to prior work on sentence embeddings (Kiros et al., 2015; Hill et al., 2016), we use an encoded sentence representation to predict its surrounding sentences. In particular, we predict the immediately preceding and succeeding sentences. All of our sentence embedding models use this loss. Formally, the loss is defined as

$$\text{NSP} = -\log p_\theta(s_{t-1}|s_t) - \log p_\phi(s_{t+1}|s_t)$$

where we parameterize p_θ and p_ϕ as separate feedforward neural networks and compute the log-probability of a target sentence using its bag-of-words representation.

4.2 Nesting Level (NL)

A table of contents serves as a high level description of an article, outlining its organizational structure. Wikipedia articles, for example, contain rich tables of contents with many levels of hierarchical structure. The "nesting level" of a sentence (i.e., how many levels deep it resides) provides information about its role in the overall discourse. To encode this information into our sentence representations, we introduce a discriminative loss to predict a sentence's nesting level in the table of contents:

$$\text{NL} = -\log p_\theta(l_t|s_t)$$

where l_t represents the nesting level of the sentence s_t and p_θ is parameterized by a feedforward neural network. Note that sentences within the same paragraph share the same nesting level. In Wikipedia, there are up to 7 nesting levels.

4.3 Sentence and Paragraph Position (SPP)

Similar to nesting level, we add a loss based on using the sentence representation to predict its position in the paragraph and in the article. The position of the sentence can be a strong indication of the relations between the topics of the current sentence and the topics in the entire article. For example, the first several sentences often cover the general topics to be discussed more thoroughly in the following sentences. To encourage our sentence embeddings to capture such information, we define a position prediction loss

$$\text{SPP} = -\log p_\theta(sp_t|s_t) - \log p_\phi(pp_t|s_t)$$

where sp_t is the sentence position of s_t within the current paragraph and pp_t is the position of the current paragraph in the whole document.

4.4 Section and Document Title (SDT)

Unlike the previous position-based losses, this loss makes use of section and document titles, which gives the model more direct access to the topical information at different positions in the document. The loss is defined as

$$\text{SDT} = -\log p_\theta(st_t|s_t) - \log p_\phi(dt_t|s_t)$$

Where st_t is the section title of sentence s_t, dt_t is the document title of sentence s_t, and p_θ and p_ϕ are two different bag-of-words decoders.

5 Experiments

5.1 Setup

We train our models on Wikipedia as it is a knowledge rich textual resource and has consistent structures over all documents. Details on hyperparameters are in the supplementary material. When evaluating on DiscoEval, we encode sentences with pretrained sentence encoders. Following SentEval, we freeze the sentence encoders and only learn the parameters of the downstream classifier. The "Baseline" row in Table 2 are embeddings trained with only the NSP loss. The subsequent rows are trained with extra losses defined in Section 4 in addition to the NSP loss.

	SentEval				DiscoEval							
	USS	SSS	SC	Probing	SP	BSO	DC	SSP	PDTB-E	PDTB-I	RST-DT	avg.

ALL	58.8	76.3	77.0	70.2	43.9	63.3	60.3	78.7	36.5	38.2	55.8	54.1

Table 2: Results for SentEval and DiscoEval. The highest number in each column is boldfaced. The highest number for our models in each column is underlined. "All" uses all four losses. "avg." is the averaged accuracy for all tasks in DiscoEval.

Additionally, we benchmark several popular pretrained sentence encoders on DiscoEval, including Skip-thought,[4] InferSent (Conneau et al., 2017),[5] DisSent (Nie et al., 2019),[6] ELMo,[7] and BERT.[8] For ELMo, we use the averaged vector of all three layers and time steps as the sentence representations. For BERT, we use the averaged vector at the position of the "[CLS]" token across all layers. We also evaluate per-layer performance for both models in Section 6.

When reporting results for SentEval, we compute the averaged Pearson correlations for Semantic Textual Similarity tasks from 2012 to 2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016). We refer to the average as unsupervised semantic similarity (USS) since those tasks do not require training data. We compute the averaged results for the STS Benchmark (Cer et al., 2017), textual entailment, and semantic relatedness (Marelli et al., 2014) and refer to the average as supervised semantic similarity (SSS). We compute the average accuracy for movie review (Pang and Lee, 2005); customer review (Hu and Liu, 2004); opinion polarity (Wiebe et al., 2005); subjectivity classification (Pang and Lee, 2004); Stanford sentiment treebank (Socher et al., 2013); question classification (Li and Roth, 2002); and paraphrase detection (Dolan et al., 2004), and refer to it as sentence classification (SC). For the rest of the linguistic probing tasks (Conneau et al., 2018), we report the average accuracy and report it as "Probing".

5.2 Results

Table 2 shows the experiment results over all SentEval and DiscoEval tasks. Different models and training signals have complex effects when performing various downstream tasks. We summarize our findings below:

- On DiscoEval, Skip-thought performs best on RST-DT. DisSent performs strongly for PDTB tasks but it requires discourse markers from PDTB for generating training data. BERT has the highest average by a large margin, but ELMo has competitive performance on multiple tasks.
- The NL or SPP loss alone has complex effects across tasks in DiscoEval, but when they are combined, the model achieves the best performance, outperforming our baseline by 0.6% on average. In particular, it yields 39.3% accuracy on PDTB-I, outperforming Skip-thought by 0.6%. This is presumably caused by the differing, yet complementary, effects of these two losses (NL and SPP).
- The SDT loss generally hurts performance on DiscoEval, especially on the position-related tasks (SP, BSO). This can be explained by the notion that consecutive sentences in the same section are encouraged to have the same sentence representations when using the SDT loss. However, the SP and BSO tasks involve differentiating neighboring sentences in terms of their position and ordering information.

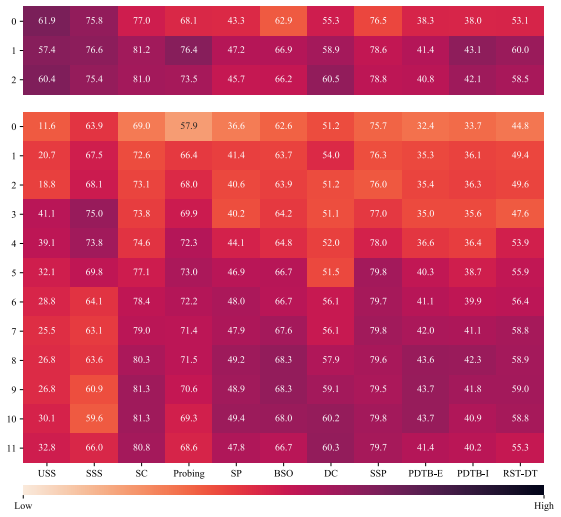

Figure 8: Heatmap for individual hidden layers of BERT-Base (lower part) and ELMo (upper part).

	ELMo	BERT-Base
SentEval	0.8	5.0
DiscoEval	1.3	8.9

Table 3: Average of the layer number for the best layers in SentEval and DiscoEval.

- On SentEval, SDT is most helpful for the USS tasks, presumably because it provides the most direct information about the topic of each sentence, which is a component of semantic similarity. SDT helps slightly on the SSS tasks. NL gives the biggest improvement in SSS.
- In comparing BERT to ELMo and Skip-thought to InferSent on DiscoEval, we can see the benefit of adding information about neighboring sentences. Our proposed training objectives show complementary improvements over NSP, which suggests that they can potentially benefit these pretrained representations.

6 Analysis

Per-Layer analysis. To investigate the performance of individual hidden layers, we evaluate ELMo and BERT on both SentEval and DiscoEval using each hidden layer. For ELMo, we use the averaged vector from the targeted layer. For BERT-Base, we use the vector from the position of the "[CLS]" token. Figure 8 shows the heatmap of performance for individual hidden layers. We note that for better visualization, colors in each column are standardized. On SentEval, BERT-Base performs better with shallow layers on USS, SSS, and Probing (though not on SC), but on DiscoEval, the results using BERT-Base gradually increase with deeper layers. To evaluate this phenomenon quantitatively, we compute the average of the layer number for the best layers for both ELMo and BERT-Base and show it in Table 3. From the table, we can see that DiscoEval requires deeper layers to achieve better performance. We assume this is because deeper layers can capture higher-level structure, which aligns with the information needed to solve the discourse tasks.

Baseline w/o hidden layer	52.0
Baseline w/ hidden layer	61.2

Table 4: Accuracies with baseline encoder on Discourse Coherence task, with or without a hidden layer in the classifier.

DiscoEval architectures. In all DiscoEval tasks except DC, we use no hidden layer in the neural architectures, following the example of SentEval. However, some tasks are unsolvable with this simple architecture. In particular, the DC tasks have low accuracies with all models unless a hidden layer is used. As shown in Table 4, when adding a hidden layer of 2000 to this task, the performance on DC improves dramatically. This shows that DC requires more complex comparison and inference among input sentences. Our human evaluation below on DC also shows that human accuracies exceed those of the classifier based on sentence embeddings by a large margin.

Human Evaluation. We conduct a human evaluation on the Sentence Position, Binary Sentence Ordering, and Discourse Coherence datasets. A native English speaker was provided with 50 examples per domain for these tasks. While the results in Table 5 show that the overall human accuracies exceed those of the classifier based on BERT-Large by a large margin, we observe that within some specific domains, for example Wiki in BSO, BERT-Large demonstrates very strong performance.

Does context matter in Sentence Position? In the SP task, the inputs are the target sentence together with 4 surrounding sentences. We study the effect of removing the surrounding 4 sentences, i.e., only using the target sentence to predict its position from the start of the paragraph.

	Sentence Position			Binary Sentence Ordering			Discourse Coherence	
Human	77.3			84.7			87.0	
BERT-Large	49.9			69.3			60.5	
	Wiki	arXiv	ROC	Wiki	arXiv	ROC	Wiki	Ubuntu
Human	84.0	76.0	94.0	64.0	72.0	96.0	98.0	74.0
BERT-Large	43.0	56.0	50.9	70.3	66.8	70.9	64.9	56.1

Table 5: Accuracies (%) for a human annotator and BERT-Large on Sentence Position, Binary Sentence Ordering, and Discourse Coherence tasks.

Random	20
Baseline w/o context	43.2
Baseline w/ context	46.0

Table 6: Accuracies (%) for baseline encoder on Sentence Position task when using downstream classifier with or without context.

Table 6 shows the comparison of the baseline model performance on Sentence Position with or without the surrounding sentences and a random baseline. Since our baseline model is already trained with NSP, it is expected to see improvements over a random baseline. The further improvement from using surrounding sentences demonstrates that the context information is helpful in determining the sentence position.

7 Conclusion

We proposed DiscoEval, a test suite of tasks to evaluate discourse-related knowledge encoded in pretrained sentence representations. We also proposed a variety of training objectives to strengthen encoders' ability to incorporate discourse information. We benchmarked several pretrained sentence encoders and demonstrated the effects of the proposed training objectives on different tasks. While our learning criteria showed benefit on certain classes of tasks, our hope is that the DiscoEval evaluation suite can inspire additional research in capturing broad discourse context in fixed-dimensional sentence embeddings.

Acknowledgments

We thank Jonathan Kummerfeld for helpful discussions about the IRC Disentanglement dataset, Davis Yoshida for discussions about BERT, and the anonymous reviewers for their feedback that improved this paper. This research was supported in part by a Bloomberg data science research grant to K. Gimpel.

Extracting Possessions from Social Media: Images Complement Language

Abstract

This paper describes a new dataset and experiments to determine whether authors of tweets possess the objects they tweet about. We work with 5,000 tweets and show that both humans and neural networks benefit from images in addition to text. We also introduce a simple yet effective strategy to incorporate visual information into any neural network beyond weights from pretrained networks. Specifically, we consider the tags identified in an image as an additional textual input, and leverage pretrained word embeddings as usually done with regular text. Experimental results show this novel strategy is beneficial.

1 Introduction

Social media are platforms for sharing information online. Social media posts and online behavior in general (e.g., Facebook likes, following other users in Twitter) have been shown to predict human traits (Burke et al., 2010; Schwartz et al., 2013). Many social media posts include an image alongside text, and the percentage keeps growing as doing so boosts user engagement (Patel, 2016).

Pictures and text in social media usually complement each other. Thus, even if the information of interest can be understood from either communication modality, considering both is beneficial. Consider the tweet in Figure 1. The text indicates that *Arnold* (the author of the tweet) goes on *bike* rides when he travels. The image shows him riding a bike, indicating that he was riding a *bike* when he tweeted thus he was in possession of a *bike*. On the other hand, if the picture were a screenshot of his Twitter posting statistics, *Arnold* most likely would not be in possession of a *bike* when tweeting, but rather sharing a log of his previous trips with his followers. In this paper, we extract possession relations from social media

Figure 1: Sample tweet with text and an image. We can infer that *Arnold* possessed a *bike* when he tweeted.

posts containing both text and images. Possession is an asymmetric semantic relation between two entities, where one entity (the possessee) *belongs* to the other entity (the possessor) (Stassen, 2009). Following the literature, we consider not only ownership, but also control possessions. In control possessions, the possessor has temporary control of the possessee but not necessarily ownership (Tham, 2004), e.g., *Bill borrowed the ozone generator from John*.

While we do not explore any, extracting possessions has many potential applications. For example, possessions could help to reveal hobbies and to find people with similar interests. Possessions could also improve recommender systems. For example, people without cars are unlikely to be interested in oil changes and auto mechanics. Similarly, people who recently purchased a home may be interested in moving and remodeling services. Extracting possessions could also be useful to identify skills. For example, peo-

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 663–672,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

ple who possess a bike are likely to be able to ride bikes, and those who have control possession of an 18-wheeler are typically able to drive large trucks. The main contributions of this paper are: (a) a corpus of 5,000 tweets (text and images) annotated with possession relations including type (alienable or control), temporal anchors with respect to the tweet timestamp, and interest in something,[1] (b) detailed corpus analysis showing, among others, that humans understand more possession relations when they have access to both the text and images, (c) experimental results showing that the task can be automated and features extracted from the images improve results. Regarding visual features, we show that incorporating weights from pretrained networks—a common practice in previous work—is beneficial, but we obtain more substantial improvements incorporating the objects and events identified in an image as an additional textual input and leveraging word embeddings.

2 Previous Work

Possession relations have primarily been studied in efforts targeting large relation repositories between arguments connected with some lexico-syntactic pattern. Tratz and Hovy (2013) work with 17 semantic relations realized by possessive constructions, Badulescu and Moldovan (2009) with 36 relations realized by genitives, and Nakov and Hearst (2013) and Tratz and Hovy (2010) target noun compounds. Blodgett and Schneider (2018) annotate 50 supersenses (including roles and relations between entities) for possessives. These efforts extract possessions from text, and target possessors and possessees connected by specific patterns. Unlike them, we extract possessions using both text and images. In addition to possession existence, we also extract types, temporal anchors, and interest in the possessee.

Two recent efforts target possession relation extraction from text without strict syntactic constraints. In our previous work, we extract intra-sentential possessions from OntoNotes (Chinnappa and Blanco, 2018). In the work described here, we use the list of synsets from our previous work to select possessees (Section 3). Banea and Mihalcea (2018) work with blogs and annotate possession existence at the time of utterance. Unlike these previous works, we (a) leverage both text and images, (b) work with informal tweets (instead of standard English), (c) temporally anchor possessions before, during and after the tweet timestamp, and (d) also extract whether somebody has an interest in a concrete object regardless of possession existence.

Using multiple modalities (e.g., text and images) to better solve some task is not new. Among many others, Specia et al. (2016) propose multimodal machine translation and Moon et al. (2018) show that named entity recognition benefits from taking into account both text and images. Our innovation is twofold. First, we show that humans understand more possession information when they have access to the image accompanying a text, as opposed to only reporting improvements on (automatically) solving some task. Second, our neural image component includes two subcomponents. The first one—weights from InceptionNet—is common in previous work, but the second one is novel. Specifically, the second component considers the objects and events identified in an image as an additional textual input. This allows us to leverage pretrained word embeddings and recurrent neural networks, a strategy that we prove beneficial.

3 A Corpus of Possession Relations

We start with a collection of English tweets consisting of text and images (Hu et al., 2018). First, we discard tweets that do not contain *I*, *me*, *my*, or *mine* in order to maximize the amount of tweets published by individuals and avoid tweets by organizations as well as advertisements. Second, we select as potential possessors the authors of tweets, and as potential possesses the nouns subsumed by the WordNet synsets (Miller, 1995) proposed in previous work (Section 2) except the following nouns: *fan*, *filter*, *launch*, *mini*, *release* and *safe*. We eliminate them because they almost never yield possession relations in social media. For example, *fan* almost always refers to a person (e.g., *This Bucks fan put on a show*) instead of to an "apparatus with rotating blades," and *filter* almost always refers to a photo effect (e.g., *Bare face plus a snap filter*) instead of to a "porous device for removing impurities." Finally, we randomly select 5,000 possessor-possessee pairs.

3.1 Annotation Tasks And Guidelines

In addition to possession existence (i.e., whether the potential possessor possesses the potential pos-

Table 1: Inter-annotator agreements (observed and Cohen's κ) having access to (a) the text and (b) the text and image. κ values between 0.60 and 0.80 are considered *substantial*, and above 0.80 *nearly perfect*.

sessee), we also annotate possession type (alienable or control), temporal anchors with respect to the tweet timestamp (before, during and after), and whether the potential possessor has an interest in the potential possessee regardless of possession existence and possession type.

Possession Existence. The first annotation task is to determine whether the potential possessor (x) possesses the potential possessee (y). Annotators choose between the following labels:

- `yes` if a possession exists (i.e., x possesses y) at some point of time;
- `never` if a possession does not exist (i.e., x does not possess y) at any point of time; or
- `unk` (unknown) if it is sound to ask whether x possesses y, but there is not enough information to choose `yes` or `never`.

Possession Type. If a possession relation exists (existence: `yes`), annotators also indicate the type:

- `alienable`: if x can be separated from y and x is the owner of y, regardless of spatial proximity or other variables; or
- `control`: if x can be separated from y and x has control over y, regardless of ownership, spatial proximity or other variables.

Note that according to these definitions, control possessions, unlike alienable possessions, do not require ownership. For example, people driving a rental car have control possession of the car but not alienable possession. Control possession and alienable possession are mutually exclusive labels. We study possession types (`alienable` and `control`) to understand the strength of the possession relation between the possessor and the possessee. We do not consider inalienable possessions because they are uncommon in social media.

Temporal Anchors. If a possession relation exists (existence: `yes`), annotators also indicate when it is true with respect to the tweet timestamp:

- `before yes` or `no`: whether x possesses y the day before tweeting or earlier;
- `during yes` or `no`: whether x possesses y the day he tweeted; and
- `after yes` or `no`: whether x possesses y the day after tweeting or later.

Interest in the Possessee. Finally, annotators also indicate whether x has an interest in y (`interest_yes` or `interest_no`), regardless of the labels for possession existence and type. Interest does not entail past, current or future possession existence. It indicates that x shows curiosity or excitement about y. Let us consider John Doe and a tweet about eating more vegetables (with a fork) because of a doctor's recommendation. In this context, John would have possession of the *fork* but no interest in it.

3.2 Annotation Set-Up and Quality

Annotations were done in-house by two graduate students. We developed a simple interface that showed one tweet at a time, and annotators were instructed to use world knowledge and common sense. In order to minimize biases, the interface did not show the twitter handle, profile picture or any other user information. In addition, we sampled 200 tweets and only in 7% of them the image possibly provided information about the tweet author (e.g., gender, age, race, ethnicity).

In a first round of annotations, annotators had access only to the text in the tweet. In a second round, they had access to both the text and the image. Our rationale is that we are interested in comparing human judgments depending on whether the image is available or not (Section 4.1).

Inter-Annotator Agreement. Table 1 shows inter-annotator agreements (observed and Cohen's κ) when annotators have access to (a) only the text and (b) the text and image. Agreements are very similar regardless of whether the image is available, and as we shall see (Section 4.1), doing so results in more possession information. Cohen's

Possession existence and type	yes, alienable	38.4%
	yes, control	7.5%
	never	38.6%
	unk	15.5%
Interest	interest_yes	40.2%
	interest_no	59.8%

Table 2: Label distributions. We divide the percentage of yes into alienable and control.

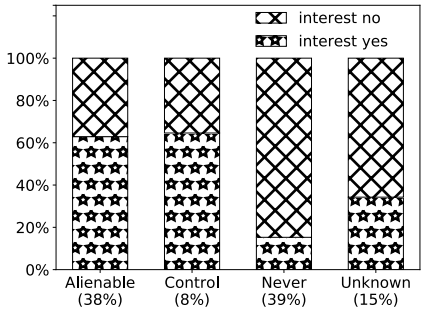

Figure 2: Distribution of *interest in the possessee* labels depending on possession existence and type. People often have an interest in objects they do not possess and when possessions cannot be determined (never, unk).

κ for possession existence and type (first row) is 0.82 with text and images, it ranges from 0.78 to 0.81 for temporal anchors (rows 2–4), and it is 0.78 for interest in the possessee (row 5). κ values between 0.60 and 0.80 are *substantial*, and above 0.80 *nearly perfect* (Artstein and Poesio, 2008).

4 Corpus Analysis

We start describing the final corpus, which was annotated with both text and images. Then, we compare the corpus obtained when annotators have access to (a) only the text and (b) the text and image.

Label Distributions. Table 2 shows the label distributions for the three annotation tasks: possession existence, possession type (yes: alienable or control) and interest in the possessee.

Overall, the percentage of unknown label (unk) is low (15.5%), indicating that possession existence can almost always be determined. More importantly, the procedure described in Section 3 allows us to reveal useful knowledge in 84.5% of all generated possessor-possessee pairs (alienable, control and never). Most possessions are alienable (83.6%, 38.4% of all possessor-possesee pairs) and the percentage of control possession is low. The never label is somewhat common (38.6), indicating that people often tweet about objects that they have never possessed.

		alienable	control
before	yes	79.5%	45.8%
	never	20.5%	54.2%
during	yes	95.9%	76.3%
	no	4.1%	23.7%
after	yes	90.5%	29.5%
	no	9.5%	70.5%

Table 3: Distribution of temporal anchor labels depending on the possession type (alienable or control).

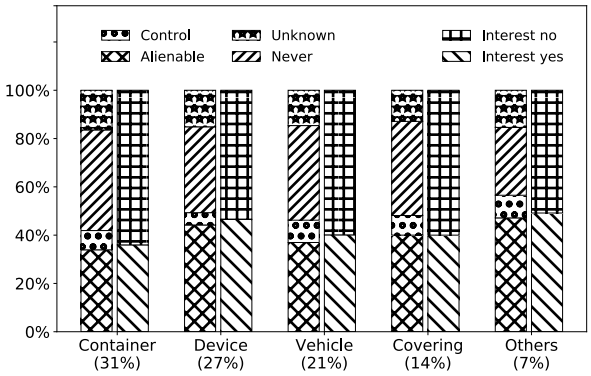

Figure 3: Label distribution (left column: possession existence and type, right column: interest) depending on the WordNet synset of the possessee.

Regarding interest, the possessor has an interest in the possessee in 40.2% of the 5,000 generated pairs. Figure 2 provides insights regarding possession existence and interest for the generated pairs. First, the possessor has an interest in the possessee in (a) 35% of pairs for which possession could not be determined (unk) and (b) 15% of pairs for which no possession exists (never). Second, regardless of possession type, the percentage of interest_yes remains at approximately 60%.

The distributions of temporal anchor labels (before, during and after) per possession type (Table 3) show that possession type substantially influences *when* the possession is true with respect to the tweet timestamp. Regarding alienable possessions, people tweet more about what they own or will own in the future than what they owned in the past (95.9% and 90.5% vs. 79.5%). Control possessions show mostly uniform distribution with anchor before, and are unlikely to be true the day after tweeting (29.5%).

Finally, Figure 3 presents the distribution of possession existence, possession type and interest in the possessee depending on the WordNet synset of the possessee. Regarding possession existence and possession type labels (left columns), we observe similar distributions across synsets, although

Table 4: Annotation examples when annotators have access to the text and image. We indicate possession existence and type (alienable, control, never, unk), temporal anchors (B: before, D: during, A: after) and interest.

devices (e.g., watch, guitar, cell phone) yield more possessions (`alienable` and `control` labels) and most of the possessions are `alienable`. In other words, people tend to tweet about *devices* they own, and rarely about *devices* they only have control over. Regarding interest in the possessee (right columns), people are slightly more likely to have an interest if the possessee is a *device*.

Annotation Examples. We present annotation examples in Table 4. Note that unlike in these examples, the annotation interface did not show the Twitter handle and profile picture in an effort to minimize potential biases (Section 3.2).

In Example (a), annotators understood that the author of the tweet was a competitive biker (bike stunt, racing flag), and world knowledge tells us that competitive bikers own their bikes. Thus, the author had an alienable possession with the bike. The text clearly indicates that the possession was true in the past (*2 years ago*), and hints that the author has an interest in bikes (*miss being on X*).

Example (b) is a straightforward example of control possession: the author does not own the *jacket*. While weekends last for two days, it is unknown when the author tweeted, so annotators chose only *during* temporal anchor. Additionally, neither the text or image indicate that the author has any interest in the *jacket*.

Example (c) illustrates an alienable possession in which the author possesses the possessee (i.e., the *bag*) before, during and after tweeting. While there is no specific cue indicating that the author will own the *bag* for an extended period of time, common sense indicates so. Additionally, the text (*my cutest bag ever*) indicates that the author is excited and has an interest in the *bag*.

Example (d) illustrates `never` label. In this case, the author is talking about the baby's *sun-*

		Only Text			
		alienable	control	never	unk
Text and Image	alienable	80.5%	7.8%	10.0%	38.7%
	control	9.4%	82.8%	3.0%	12.2%
	never	8.3%	6.3%	83.3%	23.4%
	unk	1.8%	3.1%	4.7%	25.7%
Total		100.0%	100.0%	100.0%	100.0%

Table 5: Changes in labels depending on whether annotators have access to the image. Note that 74.3% of instances annotated unk with only text become alienable (38.7%), control (12.2%) or never (23.4%).

	(a)			(b)			(c)		
									
	Possessee: *denim*			Possessee: *candle*			Possessee: *hat*		
	Ex., Type	Temporal	Interest	Ex., Type	Temporal	Interest	Ex., Type	Temporal	Interest
T	unk	n/a	no	unk	n/a	no	alienable	B, D, A	no
T+I	alienable	B, D, A	yes	alienable	B, D, A	no	never	n/a	no

Table 6: Examples of tweets which are annotated different depending on whether annotators have access to only the text (first row of labels, T) or the text and image (second row of labels, T+I). Note that the image allows to annotate more possessions (Examples (a) and (b)) as well as fix mistakes (Example (c)).

glasses. Additionally, there is no indication of the author having an interest about the *sunglasses*.

Examples (e, f) illustrate unk and never labels. The author of tweet (d) is sharing his favorite *boots*, and there is not enough information to determine whether she owns any. The author is, however, interested in *boots*, as she went through the task of choosing her favorite *boot* picks. Finally, in Example (f), *pants* cannot be a possessee as it is part of the name of a movie character.

4.1 Text vs. Text and Image

Annotators chose different labels depending on whether they had access to (a) only the text or (b) the text and image. Table 5 summarizes the changes in annotations. Most labels remain the same (alienable: 80.5%, control: 82.8%, never: 83.3%), however, most instances labeled unk when annotators have access only to text (74.3%) become alienable (38.7%), control (12.2%), or never (23.4%) when they also have access to the image (last column).

Table 6 shows examples of changes in annotation. Given only the text in Tweet (a), it appears that the author dislikes *denim*. Looking at the image, however, it becomes clear that the author is being sarcastic and not only owns *denim* clothes but actually has a strong interest in *denim*. The text in Tweet (b) is basically two quotes, and looking only at the text one cannot determine whether the author owns any candles. Taking into account the picture, however, one can conclude that the author does own a *candle* (the picture illustrates the advice from the quote) although she does not have an interest in it. The last example, Tweet (c), illustrates how images also help discarding possessions that appear obvious from the text. The *hat* is not an actual object (it is a drawing on top of the picture) thus no alienable possession exists.

5 Experiments and Results

We experiment primarily with neural networks. Regarding libraries, we use Keras (Chollet et al., 2015) with TensorFlow as a backend (Abadi et al.,

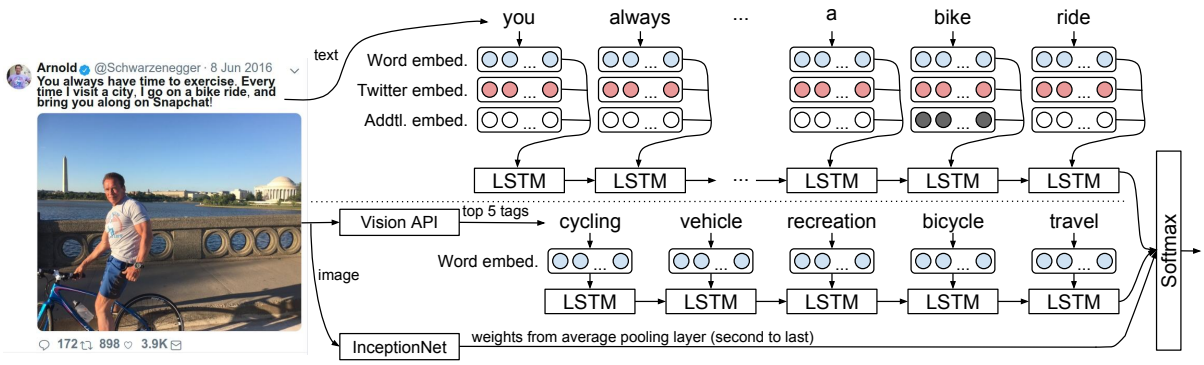

Figure 4: Neural network architecture to predict possession existence, type, temporal anchors and interest. We include a text component (above dotted line) and two image components (below dotted line). Note that the top 5 tags from the Vision API become a textual input, and we use pretrained word embeddings and an LSTM for them.

2015). Each possessor-possessee pair (and corresponding tweet) becomes an instance, and we create stratified training (80%) and test (20%) sets. We train the neural network for up to 200 epochs using the Adam optimizer (Kingma and Ba, 2014), categorical cross entropy, and batch size 32. We stop the training process before 200 epochs if no improvement occurs in the validation set (15% of the training set) for 10 epochs. More specifically, we train six classifiers. The first classifier predicts possession existence (`yes`, `never` or `unk`). The second classifier predicts possession types, i.e., classifies pairs between which a possession exists (`yes`) into `alienable` or `control`. The third, fourth and fifth classifiers predict temporal anchors, i.e., classify pairs between which a possession holds—either alienable or control—into `before yes` or `before no`, `during yes` or `during no`, and `after yes` or `after no`. Finally, the sixth classifier predicts interest in the possessee (`interest_yes` or `interest_no`).[2]

5.1 Neural Network Architecture

Figure 4 shows the neural network architecture, which includes components for the text and image (above and below dotted line respectively).

Text Component. The text component is an LSTM (Hochreiter and Schmidhuber, 1997). Each token is represented with the concatenation of three embeddings. The first two are Glove word embeddings pretrained with Common Crawl and Twitter (Pennington et al., 2014). The third embedding only takes two possible values (dark grey: possessee, white: non-possessee) and it is used to indicate the potential possessee. Only the additional embeddings are tuned along with other network parameters. Intuitively, the additional embedding allows the LSTM to focus on the context surrounding the potential possessee.

Image Component. The image component leverages two pretrained neural networks: InceptionNet (Szegedy et al., 2015) and Cloud Vision API.[3] Generally speaking, InceptionNet is pretrained to identify objects, and the Vision API outputs tags describing images including not only objects but also events (e.g., *cycling*, *recreation*, *travel* from the image in the tweet in Figure 4). Regarding InceptionNet, we follow previous work (Section 2) and include the weights of the average pooling layer (second to last layer). This incorporates features (real numbers) capturing characteristics of the image to the output Softmax layer, where the features are useful for object prediction.

More interestingly, we also incorporate the top 5 tags identified in the image by the Cloud Vision API. The main novelty of our architecture is the strategy to incorporate them. Rather than using one-hot encodings or training special-purpose embeddings, we consider the top 5 tags as an additional textual input and leverage pretrained GloVe word embeddings and an LSTM. Word embeddings allow us to bring meaning to the tags. Intuitively, this is more beneficial than incorporating weights from InceptionNet because the embeddings are a distributed representation of word meaning, and they are useful to, among others, determining word similarity and solving analogies (Pennington et al., 2014). The LSTM is useful because tags may be more than one token (e.g., *whipped cream*, *electronic device*) thus the top 5

Table 8: Results for predicting temporal anchors with the neural network (only text, and text and image).

tags are a sequence of at least five tokens—not necessarily five tokens. To the best of our knowledge, this strategy to incorporate information extracted from an image is novel. While simple, we show that it is effective at determining possession existence despite our dataset is relatively small.

5.2 Experimental Results

Tables 7 and 8 present the experimental results (Precision, Recall and F1-score). We present results per label and the macro average.

Baselines. We use the majority baseline and logistic regression using bag-of-words features (not shown, F1-scores are 0.48 (existence), 0.56 (types) and 0.58 (interest)). The full LSTM (NN text + img) outperforms the baselines predicting possession existence and types (existence F1: 0.66 vs. 0.21–0.64; types F1: 0.83 vs. 0.46–0.52)), but all models except the majority baseline perform roughly the same predicting interest in the possessee (F1: 0.58–0.59).

5.2.1 Neural Network

Table 7 presents the results obtained with four versions of the neural network: using (a) only the text component, (b) the text component and the weights from InceptionNet (text + IN), (c) the text component and the tags from the Vision API as an additional textual input (text + Itags), and (d) the full network (text + img). We also obtained results with only the image components, but do not report the results because they were much worse.

Possession Existence. All variations of the neural network outperform the baselines (logistic regression obtains 0.48 F1, not shown). Weights from InceptionNet do not bring any improvement by themselves, but the tags from the Vision API used as an additional textual input do (F1: 0.64 vs. 0.60). More importantly, combining both of them yields 10% improvement (F1: 0.66 vs. 0.60). Further examination revealed that this is due to leveraging pretrained word embeddings with the tags from the Vision API—using one-hot encodings does not bring improvements (not shown).

Possession Type and Interest in the Possessee. Regarding possession type, we observe a similar trend than with possession existence. This time, however, the differences in results are larger (F1: 0.50 vs. 0.83) and the network with both image components (NN text + img) is the only model predicting control reliably (0.77 vs. 0.10–0.14).

Regarding interest in the possessee, all models but the majority baseline (including logistic re-

gression) obtain similar F1s (0.58–0.59). While there is certainly room for improvement, the current results lead to the conclusion that a few keywords are sufficient to obtain 0.58 F1: neither images nor word embeddings bring improvements.

Temporal Anchors. Table 8 presents results obtained with the neural network when predicting temporal anchors. The image components are beneficial with all anchors, especially `before` (F1: 0.47 vs. 0.59, +25%) and `after` (0.55 vs. 0.67, +22%), and to a lesser degree `during` (0.48 vs. 0.52; 8%). F1 scores are higher for `yes` label than `no` label across all temporal anchors.

6 Conclusions

We have presented a corpus of 5,000 tweets and experimental results to extract possession relations. Specifically, we work with text and images in order to reveal the possesees of the author of a tweet. Beyond possession existence, we also consider possession type, temporal anchors with respect to the tweet timestamp, and whether the author has an interest in the potential possessor regardless of possession existence.

The corpus analysis shows that humans understand more possessions when they have access to both the text and images. Authors of tweets often have an interest in potential possessees when there is no possession relation or there is not enough information to determine whether a possession exists (`never` and `unk` labels). Finally, experimental results show that incorporating pretrained networks for object identification and image understanding complement neural components that consider text. Crucially, we show that considering the top 5 tags identified in images (objects and events) as an additional textual input and leveraging word embeddings and recurrent neural networks yields better results than incorporating only weights from intermediate layers, as previous work does.

Abstract

We introduce a large-scale crowdsourced text adventure game as a research platform for studying grounded dialogue. In it, agents can perceive, emote, and act whilst conducting dialogue with other agents. Models and humans can both act as characters within the game. We describe the results of training state-of-the-art generative and retrieval models in this setting. We show that in addition to using past dialogue, these models are able to effectively use the state of the underlying world to condition their predictions. In particular, we show that grounding on the details of the local environment, including location descriptions, and the objects (and their affordances) and characters (and their previous actions) present within it allows better predictions of agent behavior and dialogue. We analyze the ingredients necessary for successful grounding in this setting, and how each of these factors relate to agents that can talk and act successfully.

1 Introduction

There has been remarkable progress in language modeling (Jozefowicz et al., 2016; Devlin et al., 2018; Radford et al., 2019) and building dialogue agents (Dinan et al., 2019a). Nevertheless, the current state of the art uses only the statistical regularities of language data, without explicit understanding of the world that the language describes. This work is built on the hypothesis that dialogue agents embodied in a rich and cohesive (but tractable) world can more easily be trained to use language effectively than those only exposed to standard large-scale text-only corpora.

To that end, we introduce the LIGHT[1] research platform. LIGHT is a multi-player fantasy text adventure world designed for studying situated dialogue, and allows interactions between humans, models as situated agents, and the world itself. It consists of a large crowdsourced game world (663 locations, 3462 objects and 1755 characters) described entirely in natural language. Within that game world, we collect a large set (11k episodes) of character-driven human-human crowdworker interactions involving actions, emotes, and dialogue, with the aim of training models to engage humans in a similar fashion. Our complete framework is made publicly available in ParlAI (http://parl.ai/projects/light).

We use the collected dataset to investigate how a model can both speak *and* act grounded in perception of its environment and dialogue from other speakers. This is done by evaluating state-of-the-art models on our task and evaluating the effects of providing additional grounding. In particular, we adapt the BERT contextual language model (Devlin et al., 2018) to the task of dialogue in two ways: as a bi-ranker, which is fast and practical as a retrieval model, and as a cross-ranker which is slower at inference time but allows more feature cross-correlation between context and response. Both models outperform existing methods. Our ablation analysis shows the importance of each part of the grounding (location, objects, characters, other's actions, self-actions) in terms of the ability to both understand and use language. While models that use grounding show clear improvements, our best performing models are still unable to perform at human level, making our setup a suitable challenge for future research.

2 Related Work

Most recent work in dialogue exploring generative or retrieval models for goal-directed (Henderson et al., 2014; Bordes et al., 2017) or chit-chat tasks (Vinyals and Le, 2015; Sordoni et al., 2015; Zhang et al., 2018) is not situated, or even

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 673–683,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

grounded in perception. Models typically take the last few utterances from the dialogue history as input, and output a new utterance. While some goal-directed setups may use external knowledge bases (e.g. flight data for airline booking), dialogues tend to implicitly refer to an external world during the conversations without explicit grounding to objects or actions.

Several position papers have proposed virtual embodiment as a strategy for language research (Brooks, 1991; Kiela et al., 2016; Gauthier and Mordatch, 2016; Mikolov et al., 2016; Lake et al., 2017). Single-player text adventure game frameworks for training reinforcement learning agents exist, i.e., Narasimhan et al. (2015) and TextWorld (Côté et al., 2018), but these do not have human dialogue within the game. Similar single player text adventure games have also been used to study referring expressions (Gabsdil et al., 2001, 2002) and parsing (Koller et al., 2004). Yang et al. (2017) and Bordes et al. (2010) also proposed small world setups for instruction following or labeling, but these are much more restricted than the large multi-player text adventure game environment with rich dialogue that we propose here.

A number of visual, rather than text, platforms have been proposed such as House3D (Wu et al., 2018b), HoME (Brodeur et al., 2017), MINOS (Savva et al., 2017), Matterport3D (Chang et al., 2017) and AI2-THOR (Kolve et al., 2017), and the Minecraft MALMO project (Johnson et al., 2016), but they typically are suited to reinforcement learning of actions, and involve templated language for navigation or question answering tasks, if at all (Oh et al., 2017; Yi et al., 2018).

Other examples are instruction-following in the Neverwinter Nights game (Fleischman and Roy, 2005), studies of emotional response in adventure games (Fraser et al., 2018), dialogue about soccer videogames (Pasunuru and Bansal, 2018), placing blocks appropriately given a final plan (Wang et al., 2016) and a more open ended building task using a grid of voxels (Wang et al., 2017). In the latter two cases the communication is one-sided with only the human issuing instructions, rather than dialogue, with the agent only able to act.

There are also setups that consider static language and perception, for example image captioning (Lin et al., 2014), video captioning (Yu et al., 2016), visual QA (Antol et al., 2015) and visual dialogue (Das et al., 2017; Shuster et al., 2018; Mostafazadeh et al., 2017). While grounded, the agent has no ability to act in these tasks. Talk the Walk (de Vries et al., 2018) introduces a navigation game that involves action, perception and two-way dialogue, but is limited to small grids.

In summary, compared to many setups, our framework allows learning from both actions and (two-way) dialogue, while many existing simulations typically address one or the other but not both. In addition, being based on a gaming setup, our hope is that LIGHT can be fun for humans to interact with, enabling future engagement with our models. All utterances in LIGHT are produced by human annotators, thus inheriting properties of natural language such as ambiguity and coreference, making it a challenging platform for grounded learning of language and actions.

3 LIGHT Environment and Task Setup

LIGHT is a large-scale, configurable text adventure environment for research on learning grounded language and actions. It features both humans and models as agents situated (symbolically) within a multi-player fantasy MUD (multi-user dungeon)-like (Dieterle, 2009) environment. The environment is moderated by a simple game engine which passes dialogue and emote turns between characters and allows actions to cause transitions of the world state. It is in this unimodal (text-only), environment that we consider the agents to be situated.

To facilitate natural human-sourced (fantasy) situations described by natural language, almost the entire environment is crowdsourced, including locations, objects and their affordances, characters and their personalities, and most importantly character interactions: dialogues and actions. These components are collected through a series of annotation tasks that we will now describe. These tasks are designed so that they can be combinatorially recombined. Data quality was maintained by requiring annotators to take a test (see Appendix D). Overall statistics of the collected elements are given in Table 1. This environment can then be used to both train agents, and to evaluate them *in situ* via their online interactions.

Locations We first crowdsourced a set of 663 game location settings from a base set of 37 categories (*countryside*, *forest*, *inside/outside castle*, *shore*, *graveyard*, *bazaar*, ...– full list in Appendix H) which were selected by us to pro-

Split	Train	Valid	Test Seen	Test Unseen

Actions	20256	1518	3227	1880
Vocabulary Size	32182	11327	11984	9984
Utterance Length	18.3	19.2	19.4	16.2

Table 1: LIGHT dataset statistics.

vide both inspiration and cohesion to annotators. Workers were provided a category and asked to create a description, backstory, names of connected locations, and contained objects and characters. See Table 2a for an example. Many descriptions are quite detailed, and there are clear semantics between entities (e.g. alligators being in swamps, cacti in a desert).

As all remaining tasks build upon the locations created in this first step, we selected 6 location categories (*underwater aquapolis*, *frozen tundra*, *supernatural*, *magical realm*, *city in the clouds*, and *netherworld*) designed to be distinct from the others to provide an isolated set of locations, characters, and objects for testing. These will be used to build what we refer to as an *unseen* test set.

Each location is collected independently, with the eventual aim that they can be glued together as desired to randomize world generation. In this work, we consider actions and dialogues within a single location, so building a world map is not necessary. However, we will show that the environment has considerable influence on the dialogue, actions and grounded learning of models.

Objects We crowdsourced 3462 objects, each with a textual description, and a set of affordances (whether it is a container, can be picked up, has a surface, is a weapon, is wearable, is food, is a drink). See Table 2c for examples. As before, we sourced this list of objects to annotate from the ones annotated for the locations and characters.

Characters We crowdsourced 1755 game characters from animals to trolls and orcs to humans of various types (wizards, knights, village clerk). See Table 2b for detailed examples. Each character has a textual description, a persona (defined as a set of 3-5 profile sentences describing their traits, modeled after the Persona-Chat dataset (Zhang et al., 2018)), and a set of objects that are currently being carried, wielded, or worn. We sourced this list of characters to annotate from the ones provided in the location creation task.

Actions and Emotes There are a set of actions in the game consisting of physical manipulations, and a set of emotes that display feelings to other characters, in line with existing MUDs.

Physical actions include *get*, *drop*, *put*, *give*, *steal*, *wear*, *remove*, *eat*, *drink*, *hug* and *hit*, each taking either one or two arguments, e.g. *put robes in closet*. Every action has an explicit unambiguous effect on the underlying game state, and can only be executed if constraints are met, e.g. if the agent is holding the robes in the latter example. These constraints are what indirectly provide an agent with object affordances, as the list of possible actions provides all ways the agent can interact with their environment (Gibson, 1977).

Emotes include *applaud, blush, cringe, cry, dance, frown ..., sulk, wave, wink* (22 in total) and have no effect on the game state other than to notify nearby characters of the emote, which can have effects on their behavior. See Appendix E for further detailed descriptions.

Interaction Now that we have a fully realized underlying environment, we can attempt to learn and evaluate agents that can act and speak within it. For this, we collect a human-human dataset of episodic interactions within the environment.

For each dialogue, we place two characters in a random location (either two characters that were already assigned to it, or else randomly assigned characters), complete with the objects assigned to the location and to those characters. Each character has access to their persona, the location description, and the objects present, and the interaction episode begins. The two characters take turns within the episode, and can execute one action (physical action or emote) and produce one dialogue utterance on each turn. We crowdsourced 10,777 dialogues. Examples are given in Figure 1 and Appendix Figures 10-16.

Seen and Unseen Test Sets We provide two distinct test sets. The *seen* test set consists of dialogues set in the same world (set of locations) as the training set, thus also consists of characters, objects, and personas that can appear in the training data. In contrast, the *unseen* test set is com-

Category:	Graveyard
Description:	Two-and-a-half walls of the finest, whitest stone stand here, weathered by the passing of countless seasons. There is no roof, nor sign that there ever was one. All indications are that the work was abruptly abandoned. There is no door, nor markings on the walls. Nor is there any indication that any coffin has lain here... yet.
Backstory:	Bright white stone was all the fad for funerary architecture, once upon a time. It's difficult to understand why someone would abandon such a large and expensive undertaking. If they didn't have the money to finish it, they could have sold the stone, surely - or the mausoleum itself. Maybe they just haven't needed it yet? A bit odd, though, given how old it is. Maybe the gravedigger remembers... if he's sober.
Neighbors:	Dead Tree, south, following a dirt trail behind the mausoleum Fresh Grave, west, walking carefully between fallen headstones
Characters:	gravedigger, *thief, peasant, mouse, bat*
Objects:	wall, *carving, leaf, dirt*

(a) Example room created from the room collection and labelling tasks.

Character:	Thief	Gravedigger
Persona:	I live alone in a tent in the woods. I steal food from the townspeople and coal from the blacksmith. The village police can not find me to put me in jail.	I am low paid labor in this town. I do a job that many people shun because of my contact with death. I am very lonely and wish I had someone to talk to who isn't dead.
Description:	The thief is a sneaky fellow who takes from the people and does so in a way that disturbs the livelihood of the others.	You might want to talk to the gravedigger, specially if your looking for a friend, he might be odd but you will find a friend in him.
Carrying:	meat, potatoes, coal	shovel
Wearing:	dark tunic, cloak	*nothing annotated*
Wielding:	knife	*nothing annotated*

(b) Example characters annotated via character collection tasks.

Object	**Description**	**Tags**
shovel	The shovel is made of metal and silver. It is quite sturdy and appears new.	gettable, wieldable
wall	The wall is pure white, the richest of which you have ever seen.	*none*

(c) Example objects annotated via object collection tasks

Table 2: Example entities from the LIGHT environment. Each was collected via tasks described in Section 3.

prised of dialogues collected on the unseen set of locations (described in 3). The unseen test set allows for evaluation of generalization capability to unseen topics in a similar domain and as we shall see, provides a more challenging test for current techniques.

4 Learning Methods

We consider a variety of models that can predict actions, emotes and dialogue, and explore the importance of grounding upon the location, objects, and other characters within the setting. For all models, we represent context as a large text sequence with a special token preceding each input type (persona, setting, self emote, partner emote, etc.). We work with two model classes: *ranking* models that output the maximal scoring response from a set of potential candidate responses and *generative* models that decode word by word.

Ranking Candidates Each of the three tasks has a different method for determining candidates. Dialogue candidates are the ground truth and 19 randomly chosen candidates. Action candidates are usually the list of all possible actions, however in a no-affordance ablation we provide all well-formed actions over the current environment (which may include things that can't be executed like "wear paint can"). Emote candidates are the 22 possible emotes.

Baseline Ranking Methods We report a Random baseline (selecting a random candidate from the candidates) and an Information Retrieval (IR) baseline that uses word overlap with TF/IDF weighting. We use *Starspace* (Wu et al., 2018a) which learns a bag-of-words embedding for context and candidates to maximize the inner product of the true label using a ranking loss. Lastly, we use *fastText* (Joulin et al., 2016) to classify which emote should be predicted next as there are only

Persona 1: Servant	**Persona 2: King**
I come from the lower class. I do what I am told without question. I can not read. I have not seen my family in a long time.	I am a king of the whole empire. I give rules and pursuit them. I am brave and fearless.
Carrying: a duster, a small bucket, a rag Wearing: a shirt	Carrying: a crown, a scepter

Setting: The main foyer is massive. A grand staircase sits to the back of the foyer leading to the upstairs. At the front of the foyer stand two servants ready to help anyone who comes to visit. To the left of the room there is a doorway leading into a corridor. To the right there is a door leading to another corridor for the King's servants. At the foot of the stairs there is a bearskin rug that is staring at you almost as if still hungry. The walls are lined with portraits of the king and his family.

Servant: my humble king. What am I to do to serve you?
King: Ahhh. My loyal servant. Polish my scepter.
Action: give scepter to servant
Servant: Yes my lord. I will polish it immediately. Am I to return it to you personally?
Action: put scepter in small bucket
King: Yes. Yes. Of course. Also check the jewels in my crown. They seem loose.
Action: give crown to servant
Servant: But sire I am not qualified to do that. Would you prefer I take it to someone?
King: Oh fine then.
Emote: gesture sigh
Servant: I am sorry sir the rug startled me
Action: drop crown
King: Haha! That's bear I slain on my latest hunting trip. He's a mighty beast!
Emote: gesture laugh
Servant: and if I may ask where did you go hunting sire?
King: The great woods of course. This bear was stealing children in the kingdom. Surely you heard about it.
Servant: sire. I have not been outside of these walls in quiet some time. I have not seen my family in ages.
King: Such is the life of a servant I suppose. How's that scepter looking?
Servant: it is almost ready sire. and the crown who would you like me to take it to?
Action: get scepter from small bucket
King: Here just give it back. I'll have the queen find someone.

Figure 1: Example dialogue from the LIGHT dataset.

22 classes. Finally, we compare the performance of our best models to human performance on each of the prediction tasks.

Transformer Memory Network We use the transformer memory-based ranking model from Dinan et al. (2019b). It uses a transformer (Vaswani et al., 2017) to produce separate representations (memory slots) for each sentence from the grounding information (setting, persona, objects). It then performs attention given the dialogue context over the memories to produce a context embedding, which is used to score candidates via the dot product with the transformer-based representation of the candidate. At training time, other samples in the batch are used as negative candidates. For emote prediction, we train by ranking against the full set of possible emotes as there are only 22 distinct classes.

BERT Bi-Ranker and Cross-Ranker We adapt the BERT pretrained language model (Devlin et al., 2018) to the tasks of dialogue and action prediction. We explore two architectures for leveraging BERT. First, we use the *BERT-based Bi-Ranker* to produce a vector representation for the context and a separate representation for each candidate utterance. This representation is obtained by passing the first output of BERT's 12 layers through an additional linear layer, resulting in an embedding of dimension 768. It then scores candidates via the dot product between these embeddings and is trained using a ranking loss.

Second, the *BERT-based Cross-Ranker* instead concatenates the context with each candidate utterance, similar to Wolf et al. (2019). Then, each candidate is scored by computing a softmax over all candidates. Unlike the BERT-based Bi-Ranker, the concatenation of the context with each individual candidate allows the model to attend to the context when encoding each candidate, building a *context-dependent* representation of each candidate. In contrast, the Bi-Ranker can use self-attention to build the candidate and context representations, but cannot modify their representation based upon the context. However, the Cross-Encoder is far more computationally expensive (~11,000 slower than the Bi-Ranker for dialogue retrieval) as each concatenated representation must be recomputed, while the Bi-Ranker can cache the candidates for reuse (see Appendix B).

Table 3: Neighboring Starspace phrase embeddings (no pretraining from other data) for different types of entities and actions. The first row are arbitrarily chosen queries (chicken, pirate, coffin, rake, tavern, meadow), and the subsequent rows are their nearest objects, agents, locations, actions and vocabulary in embedding space.

Generative Models Similarly to the ranking setting, we use the Transformer Memory Network from Dinan et al. (2019b) to encode the context features (such as dialogue, persona, and setting). However, to predict an action, emote, or dialogue sequence, we use a Transformer architecture to decode while attending to the encoder output.

For the task of action generation, the set of candidates for ranking models to rank the true action sequence against is constrained by the set of valid actions. For example, the character cannot *pick up book* if there is no book. In the generative model, we compute the log likelihood for the set of possible candidates and normalize to constrain the output space to valid actions to improve the results.

4.1 Implementation

We implement models using PyTorch in ParlAI (Miller et al., 2017). Ranking Transformer models are pretrained on Reddit data (Mazaré et al., 2018) and fine-tuned. We use the BERT (Devlin et al., 2018) implementation provided by Hugging Face[2] with pre-trained weights, then adapted to our Bi-Ranker and Cross-Ranker setups. Generative models are pretrained on the Toronto Books Corpus and fine-tuned except for emote prediction which does not leverage pretraining. We apply byte-pair encoding (Sennrich et al., 2016) to reduce the vocabulary size for generative models. We decode using beam search with beam size 5.

[2]https://github.com/huggingface/pytorch-pretrained-BERT

4.2 Evaluation

Automatic To evaluate our models, we calculate percentage accuracy for action and emote prediction. For dialogue, we report Recall@1/20 for ranking the ground truth among 19 other randomly chosen candidates for ranking models and perplexity and unigram F1 for generative models.

Human We present humans with the same ranking task and report R@1/20 to estimate their performance on this task. We report the human accuracy and one standard deviation of error.

Quality control was particularly difficult for human evaluations, as the task of ranking one of 20 candidates is fairly tedious and easy to fake. In order to mitigate these problems, during the evaluation we provide annotated examples on the training in addition to examples on the test set. We only keep the annotations of evaluators who had high accuracy on the training examples to filter low-accuracy evaluators. The training accuracy bar was selected due to the difficulty of the separate tasks as evaluated by our own success rates. Our methods for human evaluation are described in more detail in Appendix F along with how many turns were evaluated.

5 Results

The ranking models are compared in Table 4 on the seen and unseen test sets, and ablations are shown for both the BERT-based Bi-Ranker and

Method	Test Seen Dialogue R@1/20	Test Seen Action Acc	Test Seen Emote Acc	Test Unseen Dialogue R@1/20	Test Unseen Action Acc	Test Unseen Emote Acc

Table 6: Generative Transformer ablations (valid set).

Generative Transformer in Tables 5 and 6.

5.1 Comparison of Models and Baselines

The IR baseline shows non-random performance, but is outperformed by Starspace which is a stronger baseline. We also tried *FastText* on the emote tasks as classification is appropriate over the 22 possible emotes, and it did better than Starspace. Transformer architectures prove significantly stronger at all tasks, with BERT pretraining proving important for best results as used in the Bi-Ranker and Cross-Ranker architectures. The latter, which can create a context dependent representation of each label candidate, is better at actions and emotes. Human performance is still above all these models, leaving space for future improvements in these tasks. We conducted Wilcoxon signed-rank tests and found comparisons between Starspace and the differing transformers for dialogue on test seen in Table 4 are all significantly different at the $p<0.01$ level. The generative Transformer model did not work as well as the retrieval models using these metrics.

5.2 Generalization Capability on Unseen Test

The six new unseen test settings are a slightly easier task in absolute numbers (Table 4, right), with improved scores for humans and some models. We observe that BERT-based models exhibit good transfer ability relative to other models, but the gap between their performance and human performance increases from the seen test set to the unseen one. Specifically, there is a 21 point gap on the unseen dialogue test set compared to an 11 point gap on the seen test set, making this a significant challenge for future methods.

5.3 Data Inter-connectedness and Coverage

To illustrate the coverage of entities and actions in the LIGHT world, and the inter-connectedness between them learnable from our data, we trained a simple Starspace embedding model with no prebuilt embeddings (so, on our data alone, thus precluding BERT) on all three tasks and show embeddings in Table 3. There is clearly a vast variety of learnable concepts and rich structure between characters, locations, objects, actions and the language describing them. We also show additional t-SNE plots and heatmaps showcasing these relationships in Appendix G.

Persona: I am a part of a group of travelers. I go from town to town selling food to the locals. I grew up poor, but my travels have paid off well.	
Setting 1: Fishmonger's stall, Port A small booth near the edge of the port, it's protected by a piece of old, sun-bleached sailcloth. Baskets of freshly-caught fish, bivalves, and eels sit in the shade in stained wooden troughs of water. A small, aggressive-looking dog is chained to one table, presumably to keep cats away. The stall is redolent with the aroma of fish.	**Setting 2: Dunes, Desert** A massive hilly landscape that is nothing but sand and a few rocks. As you walk this area, you can find some human and animal remains along with broken down wood wagons.
Friend: I wonder what I could eat around here... *Emote:* ponder **Traveler:** Customer, are you here shopping for fish too? **Friend:** What brings you to this place? **Traveler:** I like to come around here for food. Sometimes people who travel through drop the most delicious things. Once in a while it's roasted meet or fish.	**Friend:** I wonder what I could eat around here... *Emote:* ponder **Traveler:** Well, the desert is certainly the wrong place for you my friend. **Friend:** What brings you to this place? **Traveler:** I am travelling to the castle market to sell my goods. I have a terrible sense of direction and have been wondering in the sweltering heat for hours until I found your Oasis.

Table 7: Predicted dialogue by the BERT-based Bi-Ranker (as the *traveler* character) given different settings.

Self name: Sea Witch. Self Previous Dialogue: What do you know about that knight standing over there?		
Input Dialogue + Emote	**Partner**	**Prediction**
His armor is garrish. You know I don't fraternize with land dwellers, *pout*	Mermaid Thief	laugh frown
He is a terrible knight and I hate him, *cry*	Mermaid Troll	scream laugh
I will battle him until the end of my days, *scream*	Mermaid Orc	stare nod

Table 8: Predicted emotes by the Generative Transformer given example inputs from dialogue partner.

5.4 Importance of Grounding

Effect of Various Environment Features We provide a large quantity of information about the environment to each of our models — not only dialogue, but the description of the setting, the character's persona, present objects with descriptions, and more. We analyze the usefulness of the additional grounding information in Tables 5 and 6.

For the dialogue task, having access to all of the environmental information provides the best performance for both retrieval and generative models. Training on dialogue alone substantially decreases performance, while each experiment that adds additional grounding information such as the past actions, persona or the setting description, improves the score. Providing object descriptions as a feature leads to the least improvement. As there are both a large quantity of objects that can be present and objects tend to have long descriptions, it can be challenging for the model to associate such information to a dialogue, action, or emote prediction task. The persona features were found to be impactful, which makes sense as they shape the things the character says (and does).

Action sequence and emote prediction are much improved when using the dialogue history compared to using only past action history. Other features generally have lesser impact in this case, but still give some improvements. Including all features appears challenging for the model, perhaps because of the large input to attend over, resulting in improved results for some ablations.

For the action prediction task, we found that affordance information provides comparable impact to model performance as the rest of the features. A model given only actions and emotes as features and the set of possible actions as candidates has similar perfomance to a model given the best features for the task (dialogue, action, emote, persona, and setting) with a candidate set including actions that would be normally filtered by affordances (such as "wield paint"). This suggests the context or quantity we provided the models in these experiments is not sufficient to be able to implicitly predict affordances at a high enough accuracy to not be distracted by impossible choices.

Most importantly, for all tasks training on the available dialogue data is necessary for good performance. Providing only the action and emote as context results in the worst performance, even on action and emote prediction tasks. Moreover, using dialogue and actions simultaneously improves results almost everywhere. The integrated environment in which agents can both act and speak to other agents provides relevant information that can be used across all tasks.

Context affects predicted utterances We investigate the effect of the environmental context on the predictions by modifying the context and examining the changes in predicted dialogue, ac-

Input from Partner: Wizard	**Prediction** (Self name: Servant)
I'm feeling sad	hug wizard
You must die!	hit master wizard
Try putting on something else	remove patterned outfit
I'd like you to feed me	give food to master wizard
Can you grab me a paper	give book to wizard's assistant
Can you grab me a beer	get beer
Clean up	get duster
Hide the gold	put gold in satchel
Input from different agents	**Prediction**
Wizard: Can I have some drink?	drop potion
Servant: Can I have some drink?	give wine to servant
Bear: Can I have some drink?	give water to bear

Table 9: Predicted actions by the BERT-based Bi-Ranker given example inputs from the dialogue partner.

tion, and emotes using the BERT-based Bi-Ranker.

The input dialogue and speaker has a strong effect on the predicted action, as shown in Table 9, ranking over all training set actions. For example, a partner asking for an item results in a predicted action dependent on the asker to retrieve it, despite our dataset not being explicitly instructional.

A similar effect is observed for emote prediction. Modifying the dialogue and emote input produces a variety of different predicted emotes in Table 8. Further, keeping the context otherwise fixed but modifying the partner name from *mermaid* to *orc* results in a different predicted emote — the mermaid stating *I will battle him* leads to a *stare* while the orc receives a *nod*.

Finally, for dialogue prediction we find the model produces different outputs that are more appropriate for a given setting, even if the dialogue and characters are the same, see Table 7. With the same text about food, the model retrieved dialogue that was setting appropriate. In the fishmonger's stall, it asked if the human agent was a customer shopping for fish, but in the desert dunes it suggested we might be looking in the wrong place.

6 Conclusion

We introduced a large-scale crowdsourced fantasy text adventure game research platform where agents—both models and humans—can act and speak in a rich and diverse environment of locations, objects, and other characters. We analyzed a variety of models and their ability to leverage the grounding information present in the environment. We hope that this work can enable future research in grounded language learning and further the ability of agents to model a holistic world, complete with other agents within it.

Help, Anna! Visual Navigation with Natural Multimodal Assistance via Retrospective Curiosity-Encouraging Imitation Learning

Khanh Nguyen[⊙] and **Hal Daumé III**[⊙♡]
University of Maryland, College Park[⊙], Microsoft Research, New York[♡]
{kxnguyen,hal}@umiacs.umd.edu

Abstract

Mobile agents that can leverage help from humans can potentially accomplish more complex tasks than they could entirely on their own. We develop "Help, Anna!" (HANNA), an interactive photo-realistic simulator in which an agent fulfills object-finding tasks by requesting and interpreting natural language-and-vision assistance. An agent solving tasks in a HANNA environment can leverage simulated human assistants, called ANNA (Automatic Natural Navigation Assistants), which, upon request, provide natural language and visual instructions to direct the agent towards the goals. To address the HANNA problem, we develop a memory-augmented neural agent that hierarchically models multiple levels of decision-making, and an imitation learning algorithm that teaches the agent to avoid repeating past mistakes while simultaneously predicting its own chances of making future progress. Empirically, our approach is able to ask for help more effectively than competitive baselines and, thus, attains higher task success rate on both previously seen and previously unseen environments. We publicly release code and data at https://github.com/khanhptnk/hanna .

1 Introduction

The richness and generalizability of natural language makes it an effective medium for directing mobile agents in navigation tasks, even in environments they have never encountered before (Anderson et al., 2018b; Chen et al., 2019; Misra et al., 2018; de Vries et al., 2018; Qi et al., 2019). Nevertheless, even with language-based instructions, such tasks can be overly difficult for agents on their own, especially in unknown environments. To accomplish tasks that surpass their knowledge and skill levels, agents must be able to actively seek for and leverage assistance in the environment. Humans are rich external knowledge sources but, unfortunately, they may not be available all the time to provide guidance, or may be unwilling to help too frequently. To reduce the needed effort from human assistants, it is essential to design research platforms for teaching agents to request help mindfully.

In natural settings, human assistance is often:

- ◇ derived from *interpersonal* interaction (a lost tourist asks a local for directions);
- ◇ *reactive* to the situation of the receiver, based on the assistant's knowledge (the local may guide the tourist to the goal, or may redirect them to a different source of assistance);
- ◇ delivered via a *multimodal* communication channel (the local uses a combination of language, images, maps, gestures, etc.).

We introduce the "Help, Anna!" (HANNA) problem (§ 3), in which a mobile agent has to navigate (without a map) to an object by interpreting its first-person visual perception and requesting help from *Automatic Natural Navigation Assistants* (ANNA). HANNA models a setting in which a human is not always available to help, but rather that human assistants are scattered throughout the environment and provide help upon request (modeling the *interpersonal* aspect). The assistants are *not* omniscient: they are only familiar with certain regions of the environment and, upon request, provide *subtasks*, expressed in language and images (modeling the *multimodal* aspect), for getting *closer* to the goal, not necessarily for fully completing the task (modeling the *reactive* aspect).

In HANNA, when the agent gets lost and becomes unable to make progress, it has the option of requesting assistance from ANNA. At test time, the agent must decide where to go and whether to request help from ANNA without additional supervision. At training time, we leverage imitation learning to learn an effective agent, both in terms of navigation, and in terms of being able to decide

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 684–695, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

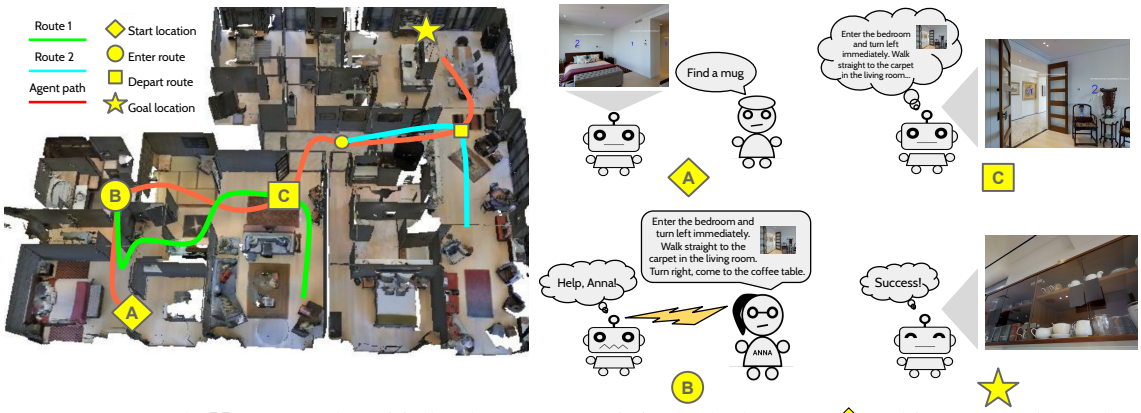

Figure 1: An example HANNA task. Initially, the agent stands in the bedroom at A and is requested by a human requester to "find a mug." The agent begins, but gets lost somewhere in the bathroom. It gets to the start location of route (B) to request help from ANNA. Upon request, ANNA assigns the agent a navigation subtask described by a natural language instruction that guides the agent to a target location, and an image of the view at that location. The agents follows the language instruction and arrives at C, where it observes a match between the target image and the current view, thus decides to depart route. After that, it resumes the main task of finding a mug. From this point, the agent gets lost one more time and has to query ANNA for another subtask that helps it follow route and enter the kitchen. The agent successfully fulfills the task it finally stops within ϵ meters of an instance of the requested object (☆). Here, the ANNA feedback is simulated using two pre-collected language-assisted routes (and).

when it is most worthwhile to request assistance.

This paper has two primary contributions:

1. Constructing the HANNA simulator by augmenting an indoor photo-realistic simulator with simulated human assistance, mimicking a scenario where a mobile agent finds objects by asking for directions along the way (§3).
2. An effective model and training algorithm for the HANNA problem, which includes a hierarchical memory-augmented recurrent architecture that models human assistance as *sub-goals* (§ 5), and introduces an imitation learning objective that enhances exploration of the environment and interpretability of the agent's help-request decisions. (§4).

We embed the HANNA problem in the photo-realistic Matterport3D environments (Chang et al., 2017) with *no* extra annotation cost by reusing the pre-existing Room-to-Room dataset (Anderson et al., 2018b). Empirical results (§ 7) show that our agent can effectively learn to request and interpret language and vision instructions, given a training set of 51 environments and less than 9,000 language instructions. Even in new environments, where the scenes and the language instructions are previously unseen, the agent successfully accomplishes 47% of its tasks. Our methods for training the navigation and help-request policies outperform competitive baselines by large margins.

2 Related work

Simulated environments provide an inexpensive platform for fast prototyping and evaluating new ideas before deploying them into the real world. Video-game and physics simulators are standard benchmarks in reinforcement learning (Todorov et al., 2012; Mnih et al., 2013; Kempka et al., 2016; Brockman et al., 2016; Vinyals et al., 2017). Nevertheless, these environments under-represent the complexity of the world. Realistic simulators play an important role in sim-to-real approaches, in which an agent is trained with arbitrarily many samples provided by the simulators, then transferred to real settings using sample-efficient transfer learning techniques (Kalashnikov et al., 2018; Andrychowicz et al., 2018; Karttunen et al., 2019). While modern techniques are capable of simulating images that can convince human perception (Karras et al., 2017, 2018), simulating language interaction remains challenging. There are efforts in building complex interactive text-based worlds (Côté et al., 2018; Urbanek et al., 2019) but the lack of a graphical component makes them not suitable for visually grounded learning. On the other hand, experimentation on real humans and robots, despite expensive and time-consuming, are important for understanding the true complexity of real-world scenarios (Chai et al., 2018, 2016; Rybski et al., 2007; Mohan and Laird, 2014; Liu et al., 2016; She et al., 2014).

Recent navigation tasks in photo-realistic simulators have accelerated research on teaching agents to execute human instructions. Nevertheless, modeling human assistance in these problems remains simplistic (Table 1): they either do not incorporate the ability to request additional help while executing tasks (Misra et al., 2014, 2017; Anderson et al., 2018b; Chen et al., 2019; Das et al., 2018; Misra et al., 2018; Wijmans et al., 2019; Qi et al., 2019), or mimic human verbal assistance with primitive, highly scripted language (Nguyen et al., 2019; Chevalier-Boisvert et al., 2019). HANNA improves the realisticity of the VNLA setup (Nguyen et al., 2019) by using fully natural language instructions.

Imitation learning algorithms are a great fit for training agents in simulated environments: access to ground-truth information about the environments allows optimal actions to be computed in many situations. The "teacher" in standard imitation learning algorithms (Daumé III et al., 2009; Ross et al., 2011; Ross and Bagnell, 2014; Chang et al., 2015; Sun et al., 2017; Sharaf and Daumé III, 2017) does not take into consideration the agent's capability and behavior. He et al. (2012) present a coaching method where the teacher gradually increases the complexity of its demonstrations over time. Welleck et al. (2019) propose an "unlikelihood" objective, which, similar to our curiosity-encouraging objective, penalizes likelihoods of candidate negative actions to avoid mistake repetition. Our approach takes into account the agent's past and future behavior to determine actions that are most and least beneficial to them, combining the advantages of both model-based and progress-estimating methods (Wang et al., 2018; Ma et al., 2019a,b).

Problem	Request assistance	Multimodal instructions	Simulated humans
VLN	✗	✗	✗
VNLA	✓	✗	✓
CVDN	✓	✗	✗
HANNA (this work)	✓	✓	✓

Table 1: Comparing HANNA with other photo-realistic navigation problems. VLN (Anderson et al., 2018b) does not allow agent to request help. VNLA (Nguyen et al., 2019) models an advisor who is always present to help but speaks simple, templated language. CVDN (Thomason et al., 2019b) contains natural conversations in which a human assistant aids another human in navigation tasks but offers limited language interaction simulation, as language assistance is not available when the agent deviates from the collected trajectories and tasks. HANNA simulates human assistants that provide language-and-vision instructions that adapt to the agent's current position and goal.

3 The HANNA Simulator

Problem. HANNA simulates a scenario where a *human requester* asks a mobile *agent* via language to find an object in an indoor environment. The task request is only a high-level command ("find [object(s)]"), modeling the general case when the requester does not need know how to accomplish a task when requesting it. We assume the task is always feasible: there is at least an instance of the requested object in the environment.

Figure 1, to which references in this section will be made, illustrates an example where the agent is asked to "find a mug." The agent starts at a random location (A), is given a task request, and is allotted a budget of T time steps to complete the task. The agent succeeds the if its final location is within $\epsilon_{\text{success}}$ meters of the location of any instance of the requested object (☆). The agent is not given any sensors that help determine its location or the object's location and must navigate only with a monocular camera that captures its first-person view as an RGB image (e.g., image in the upper right of Figure 1).

The only source of help the agent can leverage in the environment is *assistants*, who are present at both training and evaluation time. The assistants are not aware of the agent unless it enters their *zones of attention*, which include all locations within ϵ_{attn} meters of their locations. When the agent is in one of these zones, it has an option to request help from the corresponding assistant. The assistant helps the agent by giving a *subtask*, described by a natural language instruction that guides the agent to a specific location, and an image of the view at that location.

In our example, at (B), the assistant says *"Enter the bedroom and turn left immediately. Walk straight to the carpet in the living room. Turn right, come to the coffee table."* and provides an image of the destination in the living room. Executing the subtask may not fulfill the main task, but is guaranteed to get the agent to a location closer to a goal than where it was before (e.g., C).

Photo-realistic Navigation Simulator. HANNA uses the Matterport3D simulator (Chang

et al., 2017; Anderson et al., 2018b) to photo-realistically emulate a first-person view while navigating in indoor environments. HANNA features 68 Matterport3D environments, each of which is a residential building consisting of multiple rooms and floors. Navigation is modeled as traversing an undirected graph $G = (V, E)$, where each location corresponds to a node $v \in V$ with 3D-coordinates $\mathbf{x}_v$, and edges are weighted by their lengths (in meters). The state of the agent is fully determined by its pose $\tau = (v, \psi, \omega)$, where v is its location, $\psi \in (0, 2\pi]$ is its heading (horizontal camera angle), and $\omega \in \left[-\frac{\pi}{6}, \frac{\pi}{6}\right]$ is its elevation (vertical camera angle). The agent does not know v, and the angles are constrained to multiples of $\frac{\pi}{6}$. In each step, the agent can either stay at its current location, or it can rotate toward and go to a location adjacent to it in the graph[1]. Every time the agent moves (and thus changes pose), the simulator recalculates the image to reflect the new view.

Automatic Natural Navigation Assistants (ANNA). ANNA is a simulation of human assistants who do not necessarily know themselves how to optimally accomplish the agent's goal: they are only familiar with scenes along certain paths in the environment, and thus give advice to help the agent make partial progress. Specifically, the assistance from ANNA is modeled by a set of *language-assisted routes* $R = \{r_1, r_2, \ldots, r_{|R|}\}$. Each route $r = (\psi^r, \omega^r, p^r, l^r)$ is defined by initial camera angles (ψ^r, ω^r), a path p^r in the environment graph, and a natural language instruction l^r. A route becomes *enterable* when its start location is adjacent to and within ϵ_{attn} meters of the agent's location. When the agent enters a route, it first adjusts its camera angles to (ψ^r, ω^r), then attempts to interpret the language instructions l^r to traverse along p^r. At any time, the agent can *depart* the route by stopping following l^r. An example of a route in Figure 1 is the combination of the initial camera angles at B, the path, and the language instruction *"Enter the bedroom and turn left immediately..."*

The set of all routes starting from a location simulates a *human assistant* who can recall scenes along these routes' paths. The *zone of attention* of the simulated human is the set of all locations from which the agent can enter one of the routes; when the agent is in this zone, it may ask the human for help. Upon receiving a help request, the human selects a route $r^\star$ for the agent to enter (e.g.,), and a location v_d on the route where it wants the agent to depart (e.g., C). It then replies the agent with a *multimedia message* $(l^{r^\star}, \mathcal{I}^{v_d})$, where $l^{r^\star}$ is the selected route's language instruction, and $\mathcal{I}^{v_d}$ is an image of the panoramic view at the departure location. The message describes a *subtask* which requires the agent to follow the direction described by $l^{r^\star}$ and to stop if it reaches the location referenced by $\mathcal{I}^{v_d}$. The route $r^\star$ and the departure node v_d are selected to get the agent as close to a goal location as possible. Concretely, let R_{curr} be the set of all routes associated with the requested human. The selected route minimizes the distance to the goal locations among all routes in R_{curr}:

$$r^\star = \underset{r \in R_{\text{curr}}}{\operatorname{argmin}} \; \bar{d}\left(r, V_{\text{goal}}\right) \tag{1}$$

$$\text{where } \bar{d}\left(r, V_{\text{goal}}\right) \overset{\text{def}}{=} \min_{g \in V_{\text{goal}}, v \in p^r} d\left(g, v\right) \tag{2}$$

$d(.,.)$ returns the (shortest-path) distance between two locations, and V_{goal} is the set of all goal locations. The departure location minimizes the distance to the goal locations among all locations on the selected route:

$$v_d = \underset{g \in V_{\text{goal}}, v \in p_{r^\star}}{\operatorname{argmin}} \; d\left(g, v\right) \overset{\text{def}}{=} \bar{d}\left(r^\star, V_{\text{goal}}\right) \tag{3}$$

When the agent chooses to depart the route (not necessarily at the departure node), the human further assists it by providing $\mathcal{I}^{g^\star}$, an image of the panoramic view at the goal location closest to the departure node:

$$g^\star = \underset{g \in V_{\text{goal}}}{\operatorname{argmin}} \; d\left(g, v_d\right) \tag{4}$$

The way the agent leverages ANNA to accomplish tasks is analogous to how humans travel using public transportation systems (e.g., bus, subway). For example, passengers of a subway system utilize fractions of pre-constructed routes to make progress toward a destination. They execute travel plans consisting of multiple subtasks, each of which requires entering a start stop, following a route (typically described by its name and last stop), and exiting at a departure stop (e.g., *"Enter the Penn Station, hop on the Red line in the direction toward the South Ferry, get off at the World Trade Center"*). Occasionally, users walk short distances (at a lower speed) to switch routes. Our setup follows the same principle, but instead of having physical vehicles and railways, we employ

[1] We use the "panoramic action space" (Fried et al., 2018).

low-level language-and-vision instructions as the "high-speed means" to accelerate travel.

Constructing ANNA route system. Given a photo-realistic simulator, the primary cost for constructing the HANNA problem comes from crowdsourcing the natural language instructions. Ideally, we want to collect sufficient instructions to simulate humans in any location in the environment. Let $N = |V|$ be the number of locations in the environment. Since each simulated human is familiar with at most N locations, in the worst case, we need to collect $O(N^2)$ instructions to connect all location pairs. However, we theoretically prove that, assuming the agent executes instructions perfectly, it is possible to guide the agent between any location pair by collecting only $\Theta(N \log N)$ instructions. The key idea is using $O(\log N)$ instead of a single instruction to connect each pair, and reusing an instruction for multiple routes.

Lemma 1. *(proof in Appendix A) To guide the agent between any two locations using $O(\log N)$ instructions, we need to collect instructions for $\Theta(N \log N)$ location pairs.*

In our experiments, we leverage the pre-existing Room-to-room dataset (Anderson et al., 2018b) to construct the route system. This dataset contains 21,567 natural language instructions crowdsourced from humans and is originally intended to be used for the Vision-Language Navigation task (such as those in Figure 1), where an agent executes a language instruction to go to a location. We exclude instructions of the test split and their corresponding environments because ground-truth paths are not given. We use (on average) 211 routes to connect (on overage) 125 locations per environment. Even though the routes are selected randomly in the original dataset, our experiments show that they are sufficient for completing the tasks (assuming perfect assistance interpretation).

4 Retrospective Curiosity-Encouraging Imitation Learning

Agent Policies. Let s be a fully-observed state that contains ground-truth information about the environment and the agent (e.g., object locations, environment graph, agent parameters, etc.). Let o_s be the corresponding observation given to the agent, which only encodes the current view, the current task, and extra information that the agent keeps track of (e.g., time, action history, etc.). The agent maintains two stochastic policies: a navigation policy $\hat{\pi}_{\text{nav}}$ and a help-request policy $\hat{\pi}_{\text{ask}}$. Each policy maps an observation to a probability distribution over its action space. Navigation actions are tuples $(v, \Delta\psi, \Delta\omega)$, where v is a next location that is adjacent to the current location and $(\Delta\psi, \Delta\omega)$ is the camera angle change. A special `stop` action is added to the set of navigation actions to signal that the agent wants to terminate the main task or a subtask (by departing a route). The action space of the help-request policy contains two actions: `request_help` and `do_nothing`. The `request_help` action is only available when the agent is in a zone of attention. Alg 1 describes the effects of these actions during a task episode.

Algorithm 1 Task episode, given agent help-request policy $\hat{\pi}_{\text{ask}}$ and navigation policy $\hat{\pi}_{\text{nav}}$

agent receives task request e

        set the target image: $I_t^{\text{tgt}} \leftarrow I^{\text{goal}}$
        set navigation action: $\hat{a}_t^{\text{nav}} \leftarrow (v_t, 0, 0)$
      end if
    end if
  end if
  agent executes $\hat{a}_t^{\text{nav}}$ to go to the next location
end for

Imitation Learning Objective. The agent is trained with imitation learning to mimic behaviors suggested by a navigation teacher $\pi^\star_{\text{nav}}$ and a help-request teacher $\pi^\star_{\text{ask}}$, who have access to the fully-observed states. In general, imitation learning (Daumé III et al., 2009; Ross et al., 2011; Ross

and Bagnell, 2014; Chang et al., 2015; Sun et al., 2017) finds a policy $\hat{\pi}$ that minimizes the expected imitation loss $\mathcal{L}$ with respect to a teacher policy $\pi^\star$ under the agent-induced state distribution $\mathcal{D}_{\hat{\pi}}$:

$$\min_{\hat{\pi}} \mathbb{E}_{s\sim\mathcal{D}_{\hat{\pi}}}\left[\mathcal{L}(s,\hat{\pi},\pi^\star)\right] \tag{5}$$

We frame the HANNA problem as an instance of *Imitation Learning with Indirect Intervention* (I3L) (Nguyen et al., 2019). Under this framework, assistance is viewed as augmenting the current environment with new information. Interpreting the assistance is cast as finding the optimal acting policy in the augmented environment. Formally, I3L searches for policies that optimize:

$$\min_{\hat{\pi}_{\text{ask}},\hat{\pi}_{\text{nav}}} \mathbb{E}_{s\sim\mathcal{D}^{\text{state}}_{\hat{\pi}_{\text{nav}},\mathcal{E}},\mathcal{E}\sim\mathcal{D}^{\text{env}}_{\hat{\pi}_{\text{ask}}}}\left[L(s)\right] \tag{6}$$

$$L(s) = \mathcal{L}_{\text{nav}}(s,\hat{\pi}_{\text{nav}},\pi^\star_{\text{nav}}) + \mathcal{L}_{\text{ask}}(s,\hat{\pi}_{\text{ask}},\pi^\star_{\text{ask}})$$

where $\mathcal{L}_{\text{nav}}$ and $\mathcal{L}_{\text{ask}}$ are the navigation and help-request loss functions, respectively, $\mathcal{D}^{\text{env}}_{\hat{\pi}_{\text{ask}}}$ is the environment distribution induced by $\hat{\pi}_{\text{ask}}$, and $\mathcal{D}^{\text{state}}_{\hat{\pi}_{\text{nav}},\mathcal{E}}$ is the state distribution induced by $\hat{\pi}_{\text{nav}}$ in environment $\mathcal{E}$. A common choice for the loss functions is the agent-estimated negative log likelihood of the reference action:

$$\mathcal{L}_{\text{NL}}(s,\hat{\pi},\pi^\star) = -\log\hat{\pi}(a^\star \mid o_s) \tag{7}$$

where $a^\star$ is the reference action suggested by $\pi^\star$. We introduce novel loss functions that enforce more complex behaviors than simply mimicking reference actions.

Reference Actions. The navigation teacher suggests a reference action $a^{\text{nav}\star}$ that takes the agent to the next location on the shortest path from its location to the target location. Here, the target location refers to the nearest goal location (if no target image is available), or the location referenced by the target image (provided by ANNA). If the agent is already at the target location, $a^{\text{nav}\star} = \texttt{stop}$. To decide whether the agent should request help, the help-request teacher verifies the following conditions:

1. `lost`: the agent will not get (strictly) closer to the target location in the future;
2. `uncertain_wong`: the entropy[2] of the navigation action distribution is greater than or equal to a threshold γ, and the highest-probability predicted navigation action is *not* suggested by the navigation teacher;
3. `never_asked`: the agent previously never requested help at the current location;

If condition (1) or (2), and condition (3) are satisfied, we set $a^{\text{ask}\star} = \texttt{request_help}$; otherwise, $a^{\text{ask}\star} = \texttt{do_nothing}$.

Curiosity-Encouraging Navigation Teacher. In addition to a reference action, the navigation teacher returns $A^{\text{nav}\otimes}$, the set of all non-reference actions that the agent took at the current location while executing the same language instruction:

$$A^{\text{nav}\otimes}_t = \{a \in A^{\text{nav}} : \exists t' < t,\ v_t = v_{t'},\ l_t = l_{t'},\ a = a^{\text{nav}}_{t'} \neq a^{\text{nav}\star}_{t'}\} \tag{8}$$

where A^{nav} is the navigation action space.

We devise a *curiosity-encouraging* loss $\mathcal{L}_{\text{curious}}$, which minimizes the log likelihoods of actions in $A^{\text{nav}\otimes}$. This loss prevents the agent from repeating past mistakes and motivates it to explore untried actions. The navigation loss is:

$$\mathcal{L}_{\text{nav}}(s,\hat{\pi}_{\text{nav}},\pi^\star_{\text{nav}}) = \overbrace{-\log\hat{\pi}_{\text{nav}}(a^{\text{nav}\star} \mid o_s)}^{\mathcal{L}_{\text{NL}}(s,\hat{\pi}_{\text{nav}},\pi^\star_{\text{nav}})} + \underbrace{\alpha\frac{1}{|A^{\text{nav}\otimes}|}\sum_{a\in A^{\text{nav}\otimes}}\log\hat{\pi}_{\text{nav}}(a \mid o_s)}_{\mathcal{L}_{\text{curious}}(s,\hat{\pi}_{\text{nav}},\pi^\star_{\text{nav}})} \tag{9}$$

where $\alpha \in [0,\infty)$ is a weight hyperparameter.

Retrospective Interpretable Help-Request Teacher. In deciding whether the agent should ask for help, the help-request teacher must consider the agent's future situations. Standard imitation learning algorithms (e.g., DAgger) employ an *online* mode of interaction which queries the teacher at every time step. This mode of interaction is not suitable for our problem: the teacher must be able to predict the agent's future actions if it is queried when the episode is not finished. To overcome this challenge, we introduce a more efficient *retrospective* mode of interaction, which waits until the agent completes an episode and queries the teacher for reference actions for *all* time steps at once. With this approach, because the future actions at each time step are now fully observed, they can be taken into consideration when computing the reference action. In fact, we prove that the retrospective teacher is optimal for teaching the agent to determine the `lost` condition, which is the only condition that requires knowing the agent's future.

Lemma 2. *(proof in Appendix B) At any time step, the retrospective help-request teacher suggests the*

[2]Precisely, we use *efficiency*, or entropy of base $|A^{\text{nav}}| = 37$, where A^{nav} is the navigation action space.

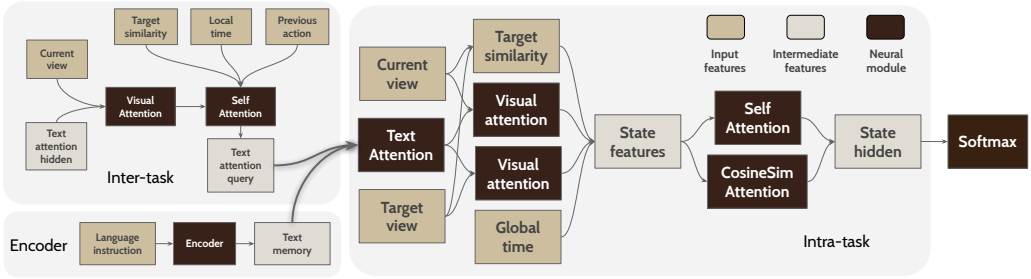

Figure 2: Our hierarchical recurrent model architecture (the navigation network). The help-request network is mostly similar except that the navigation action distribution is fed as an input to compute the "state features".

action that results in the agent getting closer to the target location in the future under its current navigation policy (if such an action exists).

To help the agent better justify its help-request decisions, we train a *reason classifier* Φ to predict which conditions are satisfied. To train this classifier, the teacher provides a reason vector $\rho^\star \in \{0,1\}^3$, where $\rho^\star_i = 1$ indicates that the i-th condition is met. We formulate this prediction problem as multi-label binary classification and employ a binary logistic loss for each condition. Learning to predict the conditions helps the agent make more accurate and interpretable decisions. The help-request loss is:

$$\mathcal{L}_{\text{ask}}(s, \hat{\pi}_{\text{ask}}, \pi^\star_{\text{ask}}) = \overbrace{-\log \hat{\pi}_{\text{ask}}(a^{\text{ask}\star} \mid o_s)}^{\mathcal{L}^{\text{NL}}(s,\hat{\pi}_{\text{ask}},\pi^\star_{\text{ask}})} \quad (10)$$
$$\underbrace{-\frac{1}{3}\sum_{i=1}^{3}[\rho^\star_i \log \hat{\rho}_i + (1-\rho^\star_i)\log(1-\hat{\rho}_i)]}_{\mathcal{L}_{\text{reason}}(s,\hat{\pi}_{\text{ask}},\pi^\star_{\text{ask}})}$$

where $(a^{\text{ask}\star}, \rho^\star) = \pi^\star_{\text{ask}}(s)$, and $\hat{\rho} = \Phi(o_s)$ is the agent-estimated likelihoods of the conditions.

5 Hierarchical Recurrent Architecture

We model the navigation policy and the help-request policy as two separate neural networks. The two networks have similar architectures, which consists of three main components: the *text-encoding* component, the *inter-task* component, and the *intra-task* component (Figure 2). We use self-attention instead of recurrent neural networks to better capture long-term dependency, and develop novel cosine-similarity attention and ResNet-based time-encoding. Detail on the computations in each module is in the Appendix.

The text-encoding component computes a text memory M^{text}, which stores the hidden representation of the current language instruction. The inter-task module computes a vector h^{inter}_t representing the state of the current task's execution. During the episode, every time the current task is altered (due to the agent requesting help or departing a route), the agent re-encodes the new language instruction to generate a new text memory and resets the inter-task state to a zero vector. The intra-task module computes a vector h^{intra}_t representing the state of the entire episode. To compute this state, we first calculate $\bar{h}^{\text{intra}}_t$, a tentative current state, and $\tilde{h}^{\text{intra}}_t$, a weighted combination of the past states at nearly identical situations. h^{intra}_t is computed as:

$$h^{\text{intra}}_t = \bar{h}^{\text{intra}}_t - \beta \cdot \tilde{h}^{\text{intra}}_t \quad (11)$$
$$\beta = \sigma(W_{\text{gate}} \cdot [\bar{h}^{\text{intra}}_t; \tilde{h}^{\text{intra}}_t]) \quad (12)$$

Eq 11 creates an context-sensitive dissimilarity between the current state and the past states at nearly identical situations. The scale vector β determines how large the dissimilarity is based on the inputs. This formulation incorporates past related information into the current state, thus enables the agent to optimize the curiosity-encouraging loss effectively. Finally, h^{intra}_t is passed through a softmax layer to produce an action distribution.

Split	Environments	Tasks	ANNA Instructions

Table 3: Results on test splits. The agent with "perfect assistance interpretation" uses the teacher navigation policy ($\pi^{\star}_{\text{nav}}$) to make decisions when executing a subtask from ANNA. Results of our final system are in bold.

language instruction vocabulary contains 2,332 words. The numbers of locations on the shortest paths to the requested objects are restricted to be between 5 and 15. With an average edge length of 2.25 meters, the agent has to travel about 9 to 32 meters to reach its goals. We evaluate the agent in environments that are seen during training (SEENENV), and in environments that are not seen (UNSEENALL). Even in the case of SEENENV, the tasks and the ANNA language instructions given during evaluation were never given in the same environments during training.

Hyperparameters. See Appendix.

Baselines and Skylines. We compare our agent against the following *non-learning* agents: 1. SHORTEST: uses the navigation teacher policy to make decisions (this is a skyline); 2. RANDOMWALK: randomly chooses a navigation action at every time step; 3. FORWARD10: navigates to the next location closest to the center of the current view to advance for 10 time steps. We compare our learned help-request policy with the following *heuristics*: 1. NOASK: does not request help; 2. RANDOMASK: randomly chooses to request help with a probabilty of 0.2, which is the average help-request ratio of our learned agent; 3. ASKEVERY5: requests help as soon as walking at least 5 time steps.

Evaluation metrics. Our main metrics are: *success rate* (SR), the fraction of examples on which the agent successfully solves the task; *navigation error*, the average (shortest-path) distance between the agent's final location and the nearest goal from that location; and *SPL* (Anderson et al., 2018a), which weights task success rate by travel distance as follows:

$$\text{SPL} = \frac{1}{N}\sum_{i=1}^{N} S_i \frac{L_i}{\max(P_i, L_i)} \qquad (13)$$

where N is the number of tasks, S_i indicates whether task i is successful, P_i is the agent's travel distance, and L_i is the shortest-path distance to the goal nearest to the agent's final location.

7 Results

Main results. From Table 3, we see that our problem is challenging: simple heuristic-based baselines such as RANDOMWALK and FORWARD10 attain success rates less than 7%. An agent that learns to accomplish tasks without additional assistance from ANNA succeeds only 17.21% of the time on TEST SEENENV, and 8.10% on TEST UNSEENALL. Leveraging help from ANNA dramatically boosts the success rate by 71.16% on TEST SEENENV and by 39.35% on TEST UNSEENALL over not requesting help. Given the small size of our dataset (e.g., the agent has fewer than 9,000 subtask instructions to learn from), it is encouraging that our agent is successful in nearly half of its tasks. On average, the agent takes paths that are 1.38 and 1.86 times longer than the optimal paths on TEST SEENENV and TEST UNSEENALL, respectively. In unseen environments, it issues on average twice as many requests to as it does in seen environments. To understand how well the agent interprets the ANNA instructions, we also provide results where our agent uses the optimal navigation policy to make decisions while executing subtasks. The large gaps on TEST SEENENV indicate there is still much room for improvement in the future, purely in learning to exe-

Table 5: Success rates (%) of different help-request policies on test splits.

cute language instructions.

Does understanding language improve generalizability? Our agent is assisted with both language and visual instructions; similar to Thomason et al. (2019a), we disentangle the usefulness two these two modes of assistance. As seen in Table 4, the improvement from language on TEST UNSEENALL (+15.17%) is substantially more than that on TEST SEENENV (+3.42%), largely the agent can simply memorize the seen environments. This confirms that understanding language-based assistance effectively enhances the agent's capability of accomplishing tasks in novel environments.

Is learning to request help effective? Table 5 compares our learned help-request policies with baselines. We find that ASKEVERY5 provides a surprisingly strong baseline for this problem, leading to an improvement of +26.32% over not requesting help on TEST UNSEENALL. Nevertheless, our learned policy, with the ability to predict the future and access to the agent's uncertainty, outperforms all baselines by at least 10.40% in success rate on TEST UNSEENALL, while making less help requests. The small gap between the learned policy and ASKEVERY5 on TEST UNSEENALL is expected because, on this split, the performance is mostly determined by the model's memorizing capability and is mostly insensitive to the help-request strategy.

Is proposed model architecture effective? We implement an LSTM-based encoder-decoder model that is based on the architecture proposed by (Wang et al., 2019). To incorporate the target image, we add an attention layer that uses the image's vector set as the attention memory. We train this model with imitation learning using the standard negative log likelihood loss (Eq 7), without the curiosity-encouraging and reason-prediction losses. As seen in Table 6, our hierarchical recurrent model outperforms this model by a large margin on TEST UNSEENALL (+28.2%).

Model	SR ↑ (%)	Nav. mistake ↓ repeat (%)	Help-request ↓ repeat (%)
LSTM-ENCDEC	19.25	31.09	49.37
Our model ($\alpha = 0$)	43.12	25.00	40.17
Our model ($\alpha = 1$)	**47.45**	**17.85**	**21.10**

Table 6: Results on TEST UNSEENALL of our model, trained with and without curiosity-encouraging loss, and an LSTM-based encoder-decoder model (both models have about 15M parameters). "Navigation mistake repeat" is the fraction of time steps on which the agent repeats a non-optimal navigation action at a previously visited location while executing the same task. "Help-request repeat" is the fraction of help requests made at a previously visited location while executing the same task.

Does the proposed imitation learning algorithm achieve its goals? The curiosity-encouraging training objective is proposed to prevent the agent from making the same mistakes at previously encountered situations. Table 6 shows that training with the curiosity-encouraging objective reduces the chance of the agent looping and making the same decisions repeatedly. As a result, its success rate is greatly boosted (+4.33% on TEST UNSEENALL) over no curiosity-encouraging.

8 Conclusion

In this work, we present a photo-realistic simulator that mimics primary characteristics of real-life human assistance. We develop effective imitation learning techniques for learning to request and interpret the simulated assistance, coupled with a hierarchical neural network model for representing subtasks. Future work aims to provide more natural, linguistically realistic interaction between the agent and humans (e.g., providing the agent the ability ask a natural *question* rather than just signal for help), and to establish a theoretical framework for modeling human assistance. We are also exploring ways to deploy and evaluate our methods on real-world platforms.

Abstract

Language grounding is an active field aiming at enriching textual representations with visual information. Generally, textual and visual elements are embedded in the same representation space, which implicitly assumes a one-to-one correspondence between modalities. This hypothesis does not hold when representing words, and becomes problematic when used to learn sentence representations — the focus of this paper — as a visual scene can be described by a wide variety of sentences. To overcome this limitation, we propose to transfer visual information to textual representations by learning an intermediate representation space: the grounded space. We further propose two new complementary objectives ensuring that (1) sentences associated with the same visual content are close in the grounded space and (2) similarities between related elements are preserved across modalities. We show that this model outperforms the previous state-of-the-art on classification and semantic relatedness tasks.

1 Introduction

Representing text by vectors that capture meaningful semantics is a long-standing issue in Artificial Intelligence. Distributional Semantic Models (Mikolov et al., 2013; Peters et al., 2018) are well-known recent efforts in this direction, based on the *distributional hypothesis* (Harris, 1954). They rely on large text corpora to learn word embeddings. At another granularity level, having high-quality and general-purpose sentence representations is crucial for all models that encode sentences into semantic vectors, such as the ones used in machine translation (Bahdanau et al., 2014) or relation extraction (Wang et al., 2019). Moreover, encoding semantics of sentences is paramount because sentences describe relationships between objects, and thus convey complex and high-level knowledge better than individual words (Norman, 1972).

Relying only on text can lead to biased representations and unrealistic predictions such as "*the sky is green*" (Baroni, 2016). Besides, it has been shown that human understanding of language is *grounded* in physical reality and perceptual experience (Fincher-Kiefer, 2001). To overcome this limitation, an emerging approach is to *ground* language in the visual world: this consists in leveraging visual information, usually from images, to enrich textual representations.[*]

Leveraging images resulted in improved linguistic representations on intrinsic and downstream tasks (Bruni et al., 2014; Silberer and Lapata, 2014). In most of these approaches, cross-modal projections are learned to incorporate visual semantics in the final representations (Lazaridou et al., 2015b; Collell et al., 2017; Kiela et al., 2018). These works rely on paired textual and visual data and the hypothesis of a one-to-one correspondence between modalities is implicitly assumed: an image of an object univocally represents a word. However, there is no obvious reason implying that the structure of the two spaces should match. Indeed, Collell and Moens (2018) empirically show that cross-modal projection of a source modality does not resemble the target modality in terms of its neighborhood structure. This is especially the case for sentences, where many different sentences can describe a similar image. Therefore, we argue that learning grounded representations with projections to a visual space is particularly inadequate in the case of sentences.

To overcome this issue, we propose an alter-

[*] Equal contribution.

[*] In the Computer Vision community, *grounding* can also refer to the task of linking phrases with image regions (Xiao et al., 2017), but this is not the focus of the present paper.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 696–707, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

native approach where the structure of the visual space is *partially transferred* to the textual space. This is done by distinguishing two types of complementary information sources. First, the *cluster information*: the implicit knowledge that sentences associated with the same image refer to the same underlying reality. Second, the *perceptual information*, which is contained within high-level representations of images. These two sources of information aim at transferring the structure of the visual space to the textual space. Besides, to preserve textual semantics and to avoid an over-constrained textual space, we propose to incorporate the visual information to textual representations using an intermediate representation space that we call *grounded space*, on which cluster and perceptual objectives are trained.

Our contributions are the following: (1) we define two complementary objectives to ground the textual space, based on implicit and explicit visual information; (2) we propose to incorporate visual semantics through the means of an intermediate space, within which the objectives are learned. Moreover (3) we perform quantitative and qualitative evaluations on several transfer tasks, showing the advantages of our approach with respect to previous grounding methods.

2 Related work

Over the last years, several approaches have been proposed to learn semantic representations for sentences. This includes supervised and task-specific techniques with recursive networks (Socher et al., 2013), convolutional networks (Kalchbrenner et al., 2014) or self-attentive networks (Lin et al., 2017; Conneau et al., 2017), but also unsupervised methods producing universal representations given large text corpora. Examples of the latter include models such as FastSent (Hill et al., 2016), QuickThought (Logeswaran and Lee, 2018), Word Information Series (Arroyo-Fernández et al., 2019), Universal Sentence Encoder (Cer et al., 2018), or SkipThought (Kiros et al., 2015), where a sentence is encoded with a Gated Recurrent Unit (GRU), and two GRU decoders are trained to reconstruct the adjacent sentences in a dataset of ordered sentences.

To model the way language conveys meaning, traditional approaches consider language as a purely symbolic system based on words and syntactic rules (Chomsky, 1980; Burgess and Lund, 1997). However, W. Barsalou (1999); Fincher-Kiefer (2001) insist on the intuition that language has to be grounded in physical reality and perceptual experience. The importance of language grounding is underlined in Gordon and Van Durme (2013), where an important bias is reported: the frequency at which objects, relations, or events occur in natural language is significantly different from their real-world frequency (e.g., in texts, people are *murdered* four times more than they *breathe*). Thus, leveraging visual resources, in addition to textual resources, is a promising way to acquire commonsense knowledge (Lin and Parikh, 2015; Yatskar et al., 2016) and to cope with the bias between text and reality.

This intuition has motivated several works for learning visually grounded representations for words, using images — or abstract scenes (Kottur et al., 2016). Two lines of work can be distinguished. First, *sequential* techniques combine textual and visual representations that were learned separately (Bruni et al., 2014; Silberer and Lapata, 2014; Collell et al., 2017). Second, *joint* methods learn a multimodal representation from multiple sources simultaneously. The advantage is that visual information associated with concrete words can be transferred to more abstract ones, which usually have no associated visual data (Hill et al., 2014; Lazaridou et al., 2015b). Closer to our contribution, some approaches learn grounded word embeddings by building upon the skip-gram objective (Mikolov et al., 2013) and enforcing word vectors to be close to their corresponding visual features (Lazaridou et al., 2015b) or their visual context (Zablocki et al., 2018) in a multimodal representation space. These approaches learn word representations while we specifically target sentences. This task is more challenging since sentences are inherently different than words due to their sequential and compositional nature. Moreover, a great number of different sentences can be generated for the same image.

Finally, some works learn sentence representations by aligning visual data to sentences within captioning datasets. Chrupala et al. (2015) propose the `IMAGINET` model where two sentence encoders share word embeddings: a first GRU encoder learns a language model objective and the other one is trained to predict the visual features associated to a sentence. The model of Kiela et al. (2018) is close to `IMAGINET` and additionally

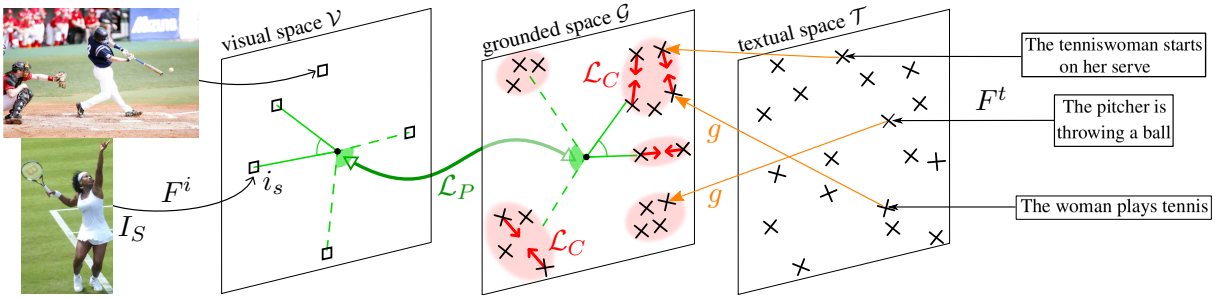

Figure 1: Model overview. Red circles indicate visual clusters. Red arrows represent the gradient of the cluster loss, which gathers visually equivalent sentences — the contrastive term in loss $\mathcal{L}_C$ is not represented. The green arrow and angles illustrate the perceptual loss, ensuring that cosine similarities correlate across modalities. The origin is at the center of each space.

hypothesizes that associated captions ground the meaning of a sentence. Both of these works learn a projection of the sentence representation to the corresponding image, which we argue is problematic as it over-constrains the textual space and can degrade textual representations. Indeed, Collell and Moens (2018) empirically demonstrated that when a cross-modal mapping is learned, the projection of the source modality does not resemble the target modality, in the sense of nearest neighbor comparison. This suggests that cross-modal projections are not appropriate to incorporate visual semantics in text representations.

3 Incorporating visual semantics within an intermediate grounded space

3.1 Model overview

In this work, we aim at learning grounded representations by jointly leveraging the textual and visual contexts of a sentence. We note S a sentence and $s = F^t(S; \theta^t)$ its representation computed with a sentence encoder F^t parametrized by θ^t. We follow the classical approach developed in the language grounding literature at the word level (Lazaridou et al., 2015b; Zablocki et al., 2018), which balances a textual objective $\mathcal{L}_\mathcal{T}$ with an additional grounding objective $\mathcal{L}_\mathcal{G}$:

$$\mathcal{L}(\theta^t, \theta^i) = \mathcal{L}_\mathcal{T}(\theta^t) + \mathcal{L}_\mathcal{G}(\theta^t, \theta^i) \qquad (1)$$

The parameters θ^t of the sentence encoder F^t are shared in $\mathcal{L}_\mathcal{T}$ and $\mathcal{L}_\mathcal{G}$, and therefore benefit from both textual and grounding objectives. θ^i denotes extra grounding parameters, including the weights of the image encoder F^i. Note that any textual objective $\mathcal{L}_\mathcal{T}$ and sentence encoder F^t can be used. In our experiments, we choose the well-known SkipThought model (Kiros et al., 2015), trained on a corpus of ordered sentences.

In what follows, we focus on the modeling of the grounding objective $\mathcal{L}_\mathcal{G}$, learned on a captioning corpus, where each image is associated with several captions. Grounding approaches generally leverage visual information by embedding textual and visual elements within the same multimodal space (Silberer and Lapata, 2014; Kiela et al., 2018). However, it is not satisfying since texts and images are forced to be in one-to-one correspondence. Moreover, a caption can (1) have a wide variety of paraphrases and related sentences describing the same scene (e.g., *the kitten is devouring a mouse* versus *a cat eating a mouse*), (2) be visually ambiguous (e.g., *a cat is eating* can be associated with many different images, depending on the visual scene/context), or (3) carry non-visual information (e.g., *cats often think about their meals*). Usual grounding objectives, that embed sentences in the visual space, can discard non-visual information (3) through the projection function. They can handle (1) by projecting related sentences to the same location in the visual space. However, they are over-sensitive to visual ambiguity (2), because ambiguous sentences should be projected to different locations of the visual space, which is not possible with current grounding models.

To overcome this lack of flexibility, we propose the following approach, illustrated in Figure 1. To cope with (1), sentences associated with the same image should be close — we call this *cluster information*. To cope with (2), we want to avoid projecting sentences to a particular point of the visual space: instead, we require that the similarity between two images in the visual space (which is linked to the context discrepancy) should be close to the similarity between their associated sentences in the textual space. We call this *perceptual information*. Finally, as we want to preserve non-visual information in sentence representations (3), we make use of an intermediate space,

called *grounded space*, that allows textual representations to benefit from visual properties without degrading the semantics brought by the textual objective $\mathcal{L}_\mathcal{T}$.

3.2 Grounding space and objectives

In this section, we introduce more formally the grounded space and the different information (cluster and perceptual) captured in the grounding loss $\mathcal{L}_\mathcal{G}$.

Grounded space The grounded space relaxes the assumption that textual and visual representations should be guided by one-to-one correspondences. It rather assumes that the structure of the textual space might be partially modeled on the structure of the visual space. Thus, instead of directly applying the grounding objectives on a sentence s embedding, we propose to train the grounding objective $\mathcal{L}_\mathcal{G}$ on an intermediate space called *grounded space*. Practically, we use a projection $g(s;\theta^i_g)$ of a sentence s from the textual space to the grounded space. We denote it $g(s)$ for simplicity, where g is a multi-layer perceptron with input $s = F^t(S;\theta^t)$ and parameters θ^i_g ($\theta^i_g \subset \theta^i$).

Cluster information ($\mathbf{C}_g$) The cluster information leverages the fact that two sentences describe, or not, the same underlying reality. In other words, the goal is to measure if two sentences are *visually equivalent* (assumption (1) in Section 3.1) without considering the content of related images. For convenience, two sentences are said to be *visually equivalent* (resp. *visually different*) if they are associated with the same image (resp. different images), i.e. if they describe the same (resp. different) underlying reality. We call *cluster* a set of visually equivalent sentences. For instance, in Figure 1, sentences *The tenniswoman starts on her serve* and *The woman plays tennis* are visually equivalent and belong to the same cluster.

Our hypothesis is that *the similarity between visually equivalent sentences* (s, s^+) *should be higher than visually different sentences* (s, s^-). We translate this hypothesis into the constraint in the grounded space: $\cos(g(s), g(s^+)) \leq \cos(g(s), g(s^-))$. Following (Karpathy and Li, 2015; Carvalho et al., 2018), we use a max-margin ranking loss to ensure the gap between both terms is higher than a fixed margin γ (cf. red elements in Figure 1) resulting in the cluster loss $\mathcal{L}_\mathcal{C}$:

$$\mathcal{L}_C = \sum_{(s,s^+,s^-)} \left[\gamma - \cos(g(s), g(s^+)) + \cos(g(s), g(s^-))\right]_+ \quad (2)$$

where s^+ (resp. s^-) is a randomly sampled visually equivalent (resp. different) sentence to s. This loss function is also used in the cross-modal retrieval literature to enforce structure-preserving constraints between sentences describing a same image (Wang et al., 2016).

Perceptual information ($\mathbf{P}_g$) The cluster hypothesis alone ignores the structure of the visual space and only uses the visual modality as a proxy to assess if two sentences are visually equivalent or different. Moreover, the ranking loss $\mathcal{L}_\mathcal{C}$ simply drives apart visually different sentences in the representation space, which can be a problem when two images have a closely related content. For instance, the baseball and tennis images in Figure 1 may be different, but they are both sports images, and thus their corresponding sentences should be somehow close in the grounded space. Finally, it supposes that we have a dataset of images associated with several captions.

To cope with these limitations, we consider the structure of the visual space and use the content of images. The intuition is that the structure of the textual space should be modeled on the structure of the visual one to extract visual semantics. We choose to preserve *similarities* between related elements across spaces (cf. green elements in Figure 1). We thus assume that *the similarity between two sentences in the grounded space should be correlated with the similarity between their corresponding images in the visual space.* We translate this hypothesis into the perceptual loss $\mathcal{L}_\mathcal{P}$:

$$\mathcal{L}_\mathcal{P} = -\rho(\{sim^{\text{text}}_{k_1,k_2}\}, \{sim^{\text{im}}_{k_1,k_2}\}) \quad (3)$$

where ρ is the Pearson correlation, $sim^{\text{text}}_{k_1,k_2} = \cos(g(s_{k_1}), g(s_{k_2}))$ and $sim^{\text{im}}_{k_1,k_2} = \cos(i_{k_1}, i_{k_2})$ are respectively textual and visual similarities computed over several randomly sampled pairs of matching sentences and images.

Grounded loss Taking altogether, the grounded space and cluster/perceptual information leads to the grounding objective $\mathcal{L}_\mathcal{G}(\theta^t, \theta^i)$ as a linear combination of the aforementioned objectives:

$$\mathcal{L}_\mathcal{G}(\theta^t, \theta^i) = \alpha_C \mathcal{L}_C(\theta^t, \theta^i) + \alpha_P \mathcal{L}_P(\theta^t, \theta^i) \quad (4)$$

where α_C and α_P are hyper-parameters weighting contributions of $\mathcal{L}_C$ and $\mathcal{L}_P$. θ^i corresponds to all the grounding-related parameters, i.e. those of the image encoder F^i and of the projection function g (i.e., θ^i_g).

4 Evaluation protocol

4.1 Datasets

Textual dataset. Following (Kiros et al., 2015; Hill et al., 2016), we use the Toronto BookCorpus dataset as the textual corpus. This corpus consists of 11K books, and 74M ordered sentences, with an average of 13 words per sentence.

Visual dataset. We use the MS COCO (Lin et al., 2014) dataset as the visual corpus. This image captioning dataset consists of 118K/5K/41K (train/val/test) images, each with five English descriptions. Note that the number of sentences in the training set of COCO (590K sentences) only represents 0.8% of the sentence data in BookCorpus, which is negligible, and the additional textual training data cannot account for performance discrepancies between textual and grounded models.

4.2 Baselines and Scenarios

In the experiments, we focus on one of the most established sentence models: SkipThought (noted **T**) as the textual baseline: the parameters of the sentence embedding model are obtained by minimizing $\mathcal{L}_\mathcal{T}$. Then, we derive several baselines and scenarios based on **T**, each representing a different approach of grounding. Since our focus is to study the impact of grounding on sentence representations, all baselines and scenarios share the same representation dimension $d_t = 2048$ and are trained on the same datasets (cf. sect. 4.1). We also report a textual model of dimension $\frac{d_t}{2}$ that we call $\mathbf{T}_{1024}$, to compare with the GroundSent model of (Kiela et al., 2018).

Model Scenarios. We test variants of our grounding model presented in sect. 3, all based on **T**: $\mathbf{T} + \mathbf{C}_g$, $\mathbf{T} + \mathbf{P}_g$, $\mathbf{T} + \mathbf{C}_g + \mathbf{P}_g$, where $\mathbf{C}_g$ (resp. $\mathbf{P}_g$) represents the loss $\mathcal{L}_C$ (resp. $\mathcal{L}_P$). We also consider scenarios where g equals the identity function (no grounded space), which we note $\mathbf{C}_{id}$, $\mathbf{P}_{id}$, $\mathbf{C}_{id} + \mathbf{P}_{id}$, etc. Finally, we also performed preliminary analysis learning only from the visual modality: $\mathbf{C}_{g/id}$, $\mathbf{P}_{g/id}$, $\mathbf{C}_{g/id} + \mathbf{P}_{g/id}$.

Baselines. We adapt two classical multimodal word embedding models for sentences. Accordingly, models from the two existing model families are considered:

Cross-modal Projection (**CM**): Inspired by Lazaridou et al. (2015b), this baseline learns to project sentences in the visual space using a max-margin loss:

$$\sum_{(s,i_s,i^-)} \left\lfloor \gamma' + \cos(f(s), i^-) - \cos(f(s), i_s) \right\rfloor_+$$

where f is a MLP, γ' a fixed margin and i^- a non-matching image. Similarly to our scenarios, the sentence encoder is initialized with **T**.

Sequential (**SEQ**): Inspired by Collell et al. (2017), we learn a linear regression model (W, b) to predict the visual representation of an image, from the representation of a matching caption. The grounded word embedding is the concatenation of the original SkipThought vector **T** and its predicted ("*imagined*") representation $W\mathbf{T} + b$, which is projected using a PCA into dimension d_t.

In both cases, the parameters to be learned, in addition to the sentence encoder, are the cross-modal projections – and the sentence representation is obtained by averaging word vectors.

GroundSent Model We re-implement the GroundSent models of Kiela et al. (2018), obtaining comparable results. The authors propose two objectives to learn a grounded vector: (a) Cap2Img: the cross-modal projections of sentences are pushed towards their respective images via a max-margin ranking loss, and (b) Cap2Cap: a visually equivalent sentence is predicted via a LSTM sentence decoder. The Cap2Both objective is a combination of these two objectives. Once the grounded vectors are learned, they are concatenated with a textual vector (learned via a SkipThought objective) to form the GS-Img, GS-Cap and GS-Both vectors.

4.3 Evaluation tasks and metrics

In line with previous works (Kiros et al., 2015; Hill et al., 2016), we consider several benchmarks to evaluate the quality of our grounded embeddings:

Semantic relatedness. We use two semantic similarity benchmarks: STS (Cer et al., 2017) and SICK (Marelli et al., 2014a), which consist of

Model	Structural measures				Semantic relatedness				
	mNNO	ρ_{vis}	C_{inter}	C_{intra}	STS/All	STS/Cap	STS/News	STS/Forum	SICK
T	10.0	4.1	54.2	70.1	30	41	36	21	51

Table 1: Intrinsic evaluations carried out on the grounded space for models with g = MLP; the textual space for **T**, **CM** (text) and models with $g = id$; and the visual space for **CM** (vis).

pairs of sentences that are associated with human-labeled similarity scores. STS is subdivided into three textual sources: *Captions* contain concrete sentences describing daily-life actions, whereas the others contain more abstract sentences: news headlines in *News* and posts from user forums in *Forum*. The Spearman correlations are measured between the cosine similarity of our learned sentence embeddings and human-labeled scores.

Classification benchmarks. All extrinsic evaluations are carried out using the SentEval pipeline (Conneau and Kiela, 2018). The tasks are the following: opinion polarity (MPQA) (Wiebe and Cardie, 2005), movie review sentiment (MR) (Pang and Lee, 2005), subjectivity/objectivity classification (SUBJ) (Pang and Lee, 2004), customer reviews (CR) (Hu and Liu, 2004), binary sentiment analysis on SST (Socher et al., 2013), paraphrase identification (MSRP) (Dolan et al., 2004) as well as two entailment classification benchmarks: SNLI (Bowman et al., 2015) and SICK (Marelli et al., 2014b). For each dataset, a logistic regression classifier is learned from the extracted sentence embeddings, and we report the classification accuracy.

Structural measures. To probe the learned grounded space, we define structural measures, and report their values on the validation set of MS COCO (5K images, 25K captions). First, we report the *mean Nearest Neighbor Overlap* (mNNO) metric, as defined in Collell and Moens (2018), that indicates the proportion of shared nearest neighbors between image representations and their corresponding captions in their respective spaces. To study *perceptual information*, we define ρ_{vis}, the Pearson correlation $\rho(\cos(s, s'), \cos(v_s, v_{s'}))$ between images and their corresponding sentences' similarities. For *cluster information*, we introduce $C_{intra} = \mathbb{E}_{v_s = v_{s'}}[cos(s, s')]$, which measures the homogeneity of each cluster, and $C_{inter} = \mathbb{E}_{v_s \neq v_{s'}}[cos(s, s')]$, which measures how well clusters are separated from each other.

4.4 Implementation details

Images are processed using a pretrained Inception-v3 network (Szegedy et al., 2016) ($d_i = 2048$). The model is trained with ADAM (Kingma and Ba, 2014) and a learning rate $l_r = 8.10^{-4}$. As done in Kiros et al. (2015), our sentence encoder is a GRU with a vocabulary of 20K words, represented in dimension 620; we perform vocabulary expansion at inference. All hyperparameters are tuned using the Pearson correlation measure on the validation set of the SICK benchmark: $\gamma = \gamma' = 0.5$, $\alpha_C = \alpha_P = 0.01$, $d_g = 512$; functions f and g are 2-layer MLP. As done in (Kiela et al., 2018), we set $d_t = 2048$. Our code is available at https://github.com/pbordes/multimodal_sentence_rep.

5 Experiments and Results

Our main objective is to study the contribution brought by the visual modality to the grounded sentence representations, and we do not attempt to outperform purely textual sentence encoders from the literature. We show that textual models can benefit from grounding approaches without requiring any changes to the original textual objectives $\mathcal{L}_T$. We report quantitative and qualitative insights (sect. 5.1), and quantitative results on the SentEval benchmark (sect. 5.2).

5.1 Study of the grounded space

We study the impact of the various grounding hypotheses on the structure of the grounded space, using intrinsic measures. In Table 1, we report the structural measures and the semantic relatedness scores of the baselines, namely **T** and **CM**, and on the various scenarios of our model. The textual loss is discarded to isolate the effect of the different grounding hypotheses.

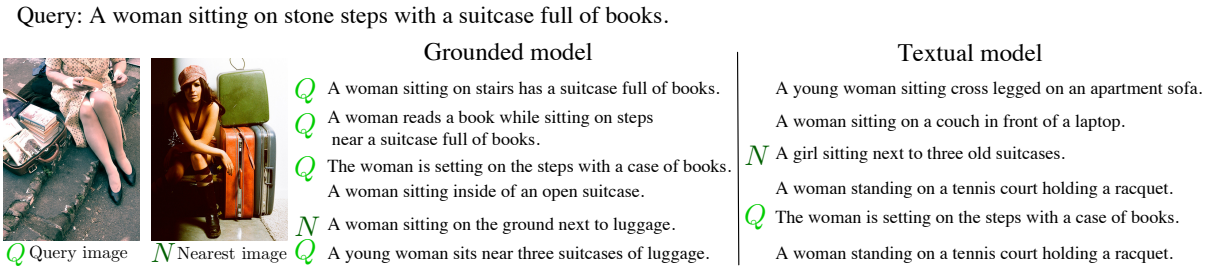

Figure 2: Nearest neighbors of a selected sentence in the validation set of MS COCO, for both grounded and purely textual models. Q is the query image, N is the nearest neighbor of Q in the visual space. Sentences that are caption of Q or N are prefixed with Q or N.

Query	Textual model	Grounded model
Two people are in **love**	Two people are fencing indoors	A couple just got married and are taking a picture with family
A man is **horrified**	A man and a woman are smiling	A teenage boy wearing a cap looks irritated
This is a **tragedy**	A group of people are at a party	Men doing a war reenactment

Table 2: Qualitative analysis: nearest neighbor of a given query (containing an abstract word) among Flickr30K sentences.

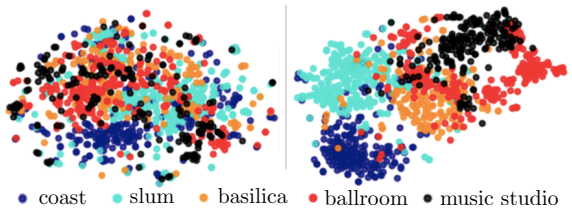

Figure 3: t-SNE visualization on CMPlaces sentences for a set of randomly sampled visual scenes. Left: textual model $\mathbf{T}$. Right: grounded model $\mathbf{C}_g + \mathbf{P}_g$.

The impact of grounding We investigate the effect of grounding on sentence representations. Results highlight that all grounded models improve over the baseline $\mathbf{T}$. Moreover, our model $\mathbf{C}_g + \mathbf{P}_g$ is generally the most effective regarding the mNNO measure and semantic relatedness tasks.

Influence of concreteness To understand in which cases grounding is useful, we compute the average visual concreteness $\bar{c}$ of the STS benchmark, which is divided in three categories (*Captions*, *News*, *Forum*). This is done by using a concreteness dataset built by Brysbaert et al. (2013) consisting of human ratings of concreteness (between 0 and 5) for 40,000 English words; for a given benchmark, we compute the sum of these scores and average over all words that are in the concreteness dataset. The performance gain Δ between $\mathbf{C}_g + \mathbf{P}_g$ and $\mathbf{T}$ are observed when the visual concreteness $\bar{c}$ is high: for *Captions* ($\bar{c} = 3.10$), the improvement is substantial: ($\Delta = +43$); for benchmarks with a lower concreteness (*News* with $\bar{c} = 2.61$ and *Forum* with $\bar{c} = 2.39$), the improvement is smaller ($\Delta = +12$). Thus, grounding brings useful complementary information, especially for concrete sentences.

t-SNE visualization This finding is also supported by a qualitative experiment showing that grounding groups together similar visual situations. Using sentences from CMPlaces (Castrejon et al., 2016), which describe visual scenes (e.g., *coast*, *shoe-shop*, *plaza*, etc.) and are classified in 205 scene categories, we randomly sample 5 visual scenes and plot in Figure 3 the corresponding sentences using t-SNE (Maaten and Hinton, 2008). We notice that our grounded model is better able to cluster sentences that have a close visual meaning than the text-only model. This is reinforced by the structural measures computed on the five clusters of Figure 3: $C_{inter} = 19, C_{intra} = 22$ for $\mathbf{T}$, $C_{inter} = 11, C_{intra} = 27$ for $\mathbf{C}_g + \mathbf{P}_g$. Indeed, C_{inter} (resp. C_{intra}), is lower (resp. higher) for the grounded model $\mathbf{C}_g + \mathbf{P}_g$ compared to $\mathbf{T}$, which shows that clusters corresponding to different scenes are more clearly separated (resp. sentences corresponding to a given scene are more packed).

Nearest neighbors search Furthermore, we show in Table 2 that concrete knowledge acquired via our grounded model can also be transferred to abstract sentences. To do so, we manually build sentences using words with low concreteness (between 2.5 and 3.5) from the USF dataset (Nelson et al., 2004). Then, nearest neighbors are retrieved from the set of sentences of Flickr30K (Plummer et al., 2015). In this sample, we see that our grounded model is more accurate than the purely textual model to capture visual meaning. The observation that visual information propagates from

Table 3: Extrinsic evaluations with SentEval. All models give sentences in dimension $d_t = 2048$ (except $\mathbf{T}_{1024}$). 'AVG' stands for the average accuracies reported in the other columns. '†': the model has been re-implemented (we obtained higher scores than the one given in the original papers). '‡': the baseline is an adaptation of the model to the case of sentences. '$*$': significantly differs from the best scenario among our models.

concrete sentences to abstract ones is analogous to findings made in previous research on word embeddings (Hill and Korhonen, 2014).

Neighboring structure To illustrate the discrepancy on the mNNO metric observed between $\mathbf{C}_g + \mathbf{P}_g$ and $\mathbf{T}$, we select a query image Q in the validation set of MS COCO, along with its corresponding caption S; we display, in Figure 2, the nearest neighbor of Q in the visual space, noted N, and the nearest neighbors of S in the grounded space. With our grounded model, the neighborhood S is mostly made of sentences corresponding to Q or N.

Hypotheses validation We now validate our hypotheses (cf. sect. 3.1) on the grounded space, using the Cross-Modal Projection baseline (**CM**) and our model scenarios as outlined in Table 1. For fair comparison, metrics for the baseline **CM** are estimated either on the visual or the textual space depending on whether our models rely on the grounded space (g) or not (id). These results correspond to the rows **CM** (text) and **CM** (vis.) in Table 1.

Results highlight that: (1) Using a grounded space is beneficial; indeed, semantic relatedness and mNNO scores are higher in the lower half of Table 1, e.g., $\mathbf{C}_g > \mathbf{C}_{id}$, $\mathbf{P}_g > \mathbf{P}_{id}$ and $\mathbf{C}_g + \mathbf{P}_g > \mathbf{C}_{id} + \mathbf{P}_{id}$; (2) Solely using cluster information leads to the highest C_{intra} and lowest C_{inter}, which suggests that $\mathbf{C}_\bullet$ is the most efficient model at separating visually different sentences; (3) Using only perceptual information in $\mathbf{P}_\bullet$ logically leads to highly correlated textual and visual spaces (highest ρ_{vis}), but the local neighborhood structure is not well preserved (lowest C_{intra}); (4) Our model $\mathbf{C}_\bullet + \mathbf{P}_\bullet$ is better than **CM** at capturing cluster information (higher C_{intra}, lower C_{inter}) and perceptual information (higher ρ_{vis}). This also translates in a higher mNNO measure for $\mathbf{C}_\bullet + \mathbf{P}_\bullet$, leading us to think that the conjunction of both perceptual and cluster information leads to high correlation of modalities, in terms of neighborhood structure. Moreover, this high mNNO score results in better performances for our model $\mathbf{C}_\bullet + \mathbf{P}_\bullet$ in terms of semantic relatedness.

5.2 Evaluation on transfer tasks

We now focus on extrinsic evaluation of the embeddings. Table 3 reports evaluations of our baselines and scenarios on SentEval (Conneau and Kiela, 2018), a classical benchmark used for evaluating sentence embeddings. Before further analysis, we find that our grounded models systematically outperform the textual baseline **T**, on all benchmarks, which shows the first substantial improvement brought by grounding and visual information in a sentence representation model. Indeed, models GS-Cap, GS-Img and GS-Both from (Kiela et al., 2018), despite improving over $\mathbf{T}_{1024}$, perform worse than the textual model of the same dimension **T** — this is consistent with what they report in their paper.

Our results interpretation is the following: (1) our joint approach shows superior performances over the sequential one, confirming results reported at the word level (Zablocki et al., 2018). Indeed, both sequential models, GS models (Kiela et al., 2018) and **SEQ** (inspired from (Collell et al., 2017)) are systematically worse than our grounded

models for all benchmarks. (2) Preserving the structure of the visual space is more effective than learning cross-modal projections; indeed, all our models outperform $\mathbf{T} + \mathbf{CM}$ on average ('AVG' column). (3) Making use of a grounded space yields slightly improved sentence representations. Indeed, our models that use the grounded space (g = MLP) can take advantage of more expression power provided by the trainable g than models which integrate grounded information directly in the textual space ($g = id$). (4) Among our model scenarios, $\mathbf{T} + \mathbf{P}_g$ has maximal scores on the most tasks; however, it shows lower scores on SNLI and SICK, which are entailment tasks. Models using cluster information $\mathbf{C}_g$ are naturally more suited for these tasks and hence obtain higher results. Finally, the combined model $\mathbf{T} + \mathbf{C}_g + \mathbf{P}_g$ shows a good balance between classification and entailment tasks.

6 Conclusion

We proposed a multimodal model aiming at preserving the structure of visual and textual spaces to learn grounded sentence representations. Our contributions include (1) leveraging both perceptual and cluster information and (2) using an intermediate grounded space enabling to relax the constraints on the textual space. Our approach is the first to report consistent positive results against purely textual baselines on a variety of natural language tasks. As future work, we plan to use visual information to specifically target complex downstream tasks requiring commonsense and reasoning such as question answering or visual dialogue.

Abstract

We introduce the new *Birds-to-Words* dataset of 41k sentences describing fine-grained differences between photographs of birds. The language collected is highly detailed, while remaining understandable to the everyday observer (e.g., "heart-shaped face," "squat body"). Paragraph-length descriptions naturally adapt to varying levels of taxonomic and visual distance—drawn from a novel stratified sampling approach—with the appropriate level of detail. We propose a new model called *Neural Naturalist* that uses a joint image encoding and comparative module to generate comparative language, and evaluate the results with humans who must use the descriptions to distinguish real images.

Our results indicate promising potential for neural models to explain differences in visual embedding space using natural language, as well as a concrete path for machine learning to aid citizen scientists in their effort to preserve biodiversity.

1 Introduction

Humans are adept at making fine-grained comparisons, but sometimes require aid in distinguishing visually similar classes. Take, for example, a citizen science effort like iNaturalist,[1] where everyday people photograph wildlife, and the community reaches a consensus on the taxonomic label for each instance. Many species are visually similar (e.g., Figure 1, top), making them difficult for a casual observer to label correctly. This puts an undue strain on lieutenants of the citizen science community to curate and justify labels for a large number of instances. While everyone may be capable of making such distinctions visually, non-experts require training to know what to look for.

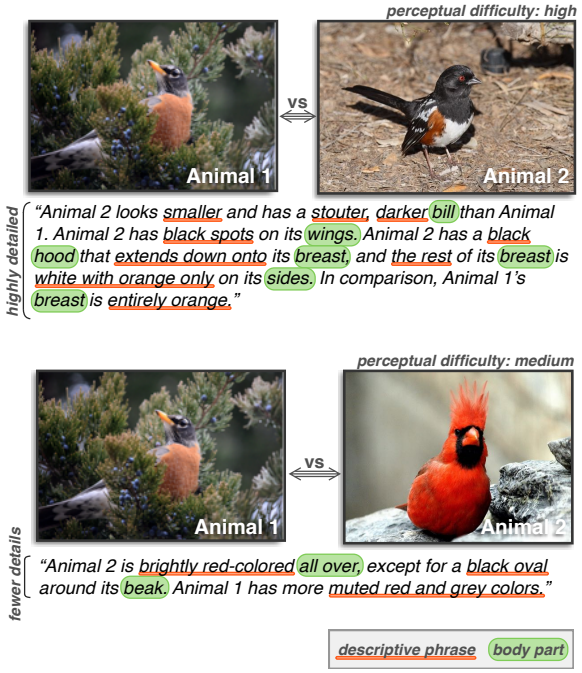

Figure 1: The Birds-to-Words dataset: comparative descriptions adapt naturally to the appropriate level of detail (orange underlines). A difficult distinction (TOP) is given a longer and more fined-grained comparison than an easier one (BOTTOM). Annotators organically use everyday language to refer to parts (green highlights).

Field guides exist for the purpose helping people learn how to distinguish between species. Unfortunately, field guides are costly to create because writing such a guide requires expert knowledge of class-level distinctions.

In this paper, we study the problem of explaining the differences between two images using natural language. We introduce a new dataset called *Birds-to-Words* of paragraph-length descriptions of the differences between pairs of bird photographs. We find several benefits from eliciting comparisons: (a) without a guide, annotators naturally break down the subject of the image (e.g.,

Work done during an internship at Google.

a bird) into pieces understood by the everyday observer (e.g., head, wings, legs); (b) by sampling comparisons from varying visual and taxonomic distances, the language exhibits naturally adaptive granularity of detail based on the distinctions required (e.g., "red body" vs "tiny stripe above its eye"); (c) in contrast to requiring comparisons between categories (e.g., comparing one species vs. another), non-experts can provide high-quality annotations without needing domain expertise.

We also propose the *Neural Naturalist* model architecture for generating comparisons given two images as input. After embedding images into a latent space with a CNN, the model combines the two image representations with a joint encoding and comparative module before passing them to a Transformer decoder. We find that introducing a comparative module—an additional Transformer encoder—over the combined latent image representations yields better generations.

Our results suggest that these classes of neural models can assist in fine-grained visual domains when humans require aid to distinguish closely related instances. Non-experts—such as amateur naturalists trying to tell apart two species—stand to benefit from comparative explanations. Our work approaches this sweet-spot of visual expertise, where any two in-domain images can be compared, and the language is detailed, adaptive to the types of differences observed, and still understandable by laypeople.

Recent work has made impressive progress on context sensitive image captioning. One direction of work uses class labels as context, with the objective of generating captions that distinguish why the image belongs to one class over others (Hendricks et al., 2016; Vedantam et al., 2017). Another choice is to use a second image as context, and generate a caption that distinguishes one image from another. Previous work has studied ways to generalize single-image captions into comparative language (Vedantam et al., 2017), as well as comparing two images with high pixel overlap (e.g., surveillance footage) (Jhamtani and Berg-Kirkpatrick, 2018). Our work complements these efforts by studying directly comparative, everyday language on image pairs with no pixel overlap.

Our approach outlines a new way for models to aid humans in making visual distinctions. The Neural Naturalist model requires two instances as input; these could be, for example, a query image

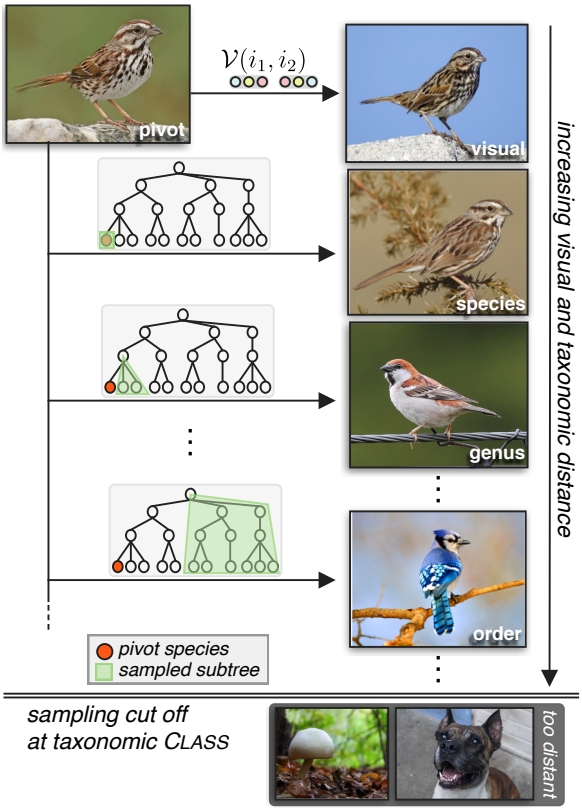

Figure 2: Illustration of pivot-branch stratified sampling algorithm used to construct the Birds-to-Words dataset. The algorithm harnesses visual and taxonomic distances (increasing vertically) to create a challenging task with board coverage.

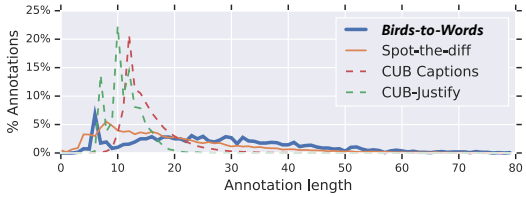
and an image from a candidate class. By differentiating between these two inputs, a model may help point out subtle distinctions (e.g., one animal has spots on its side), or features that indicate a good match (e.g., only a slight difference in size). These explanations can aid in understanding both differences between species, as well as variance within instances of a single species.

2 Birds-to-Words Dataset

Our goal is to collect a dataset of tuples (i_1, i_2, t), where i_1 and i_2 are images, and t is a natural language comparison between the two. Given a domain $\mathcal{D}$, this collection depends critically on the criteria we use to select image pairs.



If we sample image pairs uniformly at random, we will end up with comparisons encompassing a broad range of phenomena. For example, two images that are quite different will yield categorical comparisons (*"One is a bird, one is a mushroom."*). Alternatively, if the two images are very similar, such as two angles of the same creature,

Dataset	Domain	Lang	Images Ctx	Images Cap	Example
CUB Captions *(R, 2016)*	Birds	M	1	1	*"An all black bird with a very long rectrices and relatively dull bill."*
CUB-Justify *(V, 2017)*	Birds	S	7	1	*"The bird has white orbital feathers, a black crown, and yellow tertials."*
Spot-the-Diff *(J&B, 2018)*	Surveilance	E	2	1–2	*"Silver car is gone. Person in a white t shirt appears. 3rd person in the group is gone."*
Birds-to-Words *(this work)*	Birds	E	2	2	*"Animal1 is gray, while animal2 is white. Animal2 has a long, yellow beak, while animal1's beak is shorter and gray. Animal2 appears to be larger than animal1."*

Table 1: Comparison with recent fine-grained language-and-vision datasets. *Lang* values: S = scientific, E = everyday, M = mixed. *Images Ctx* = number of images shown, *Images Cap* = number of images described in caption. Dataset citations: *R* = *Reed et al.*, *V* = *Vedantam et al.*, *J&B* = *Jhamtani and Berg-Kirkpatrick*.

comparisons between them will focus on highly detailed nuances, such as variations in pose. These phenomena support rich lines of research, such as object classification (Deng et al., 2009) and pose estimation (Murphy-Chutorian and Trivedi, 2009).

We aim to land somewhere in the middle. We wish to consider sets of distinguishable but intimately related pairs. This sweet spot of visual similarity is akin to the genre of differences studied in fine-grained visual classification (Wah et al., 2011; Krause et al., 2013). We approach this collection with a two-phase data sampling procedure. We first select *pivot* images by sampling from our full domain uniformly at random. We then *branch* from these images into a set of secondary images that emphases fine-grained comparisons, but yields broad coverage over the set of sensible relations. Figure 2 provides an illustration of our sampling procedure.

Birds-to-Words Dataset	
Image pairs	3,347
Paragraphs / pair	4.8
Paragraphs	16,067
Tokens / paragraph	32.1 MEAN
Sentences	40,969
Sentences / paragraph	2.6 MEAN
Clarity rating	$\geq 4/5$
Train / dev / test	80% / 10% / 10%

Figure 3: Annotation lengths for compared datasets (TOP), and statistics for the proposed Birds-to-Words dataset (BOTTOM). The Birds-to-Words dataset has a large mass of long descriptions in comparison to related datasets.

2.1 Domain

We sample images from iNaturalist, a citizen science effort to collect research-grade[2] observations of plants and animals in the wild. We restrict our domain $\mathcal{D}$ to instances labeled under the taxonomic CLASS[3] *Aves* (i.e., birds). While a broader domain would yield some comparable instances (e.g., *bird* and *dragonfly* share some common body parts), choosing only *Aves* ensures that all instances will be similar enough structurally to be comparable, and avoids the gut reaction comparison pointing out the differences in animal type. This choice yields 1.7M research-grade images and corresponding taxonomic labels from iNaturalist. We then perform pivot-branch sampling on this set to choose pairs for annotation.

2.2 Pivot Images

The *Aves* domain in iNaturalist contains instances of 9k distinct species, with heavy observation bias to more common species (such as the mallard duck). We uniformly sample species from the set of 9k to help overcome this bias. In total, we select 405 species and corresponding photographs to use as i_1 images.

[2]Research-grade observations have met or exceeded iNaturalist's guidelines for community consensus of the taxonomic label for a photograph.

[3]To disambiguate *class*, we use CLASS to denote the taxonomic rank in scientific classification, and simply "class" to refer to the machine learning usage of the term as a label in classification.

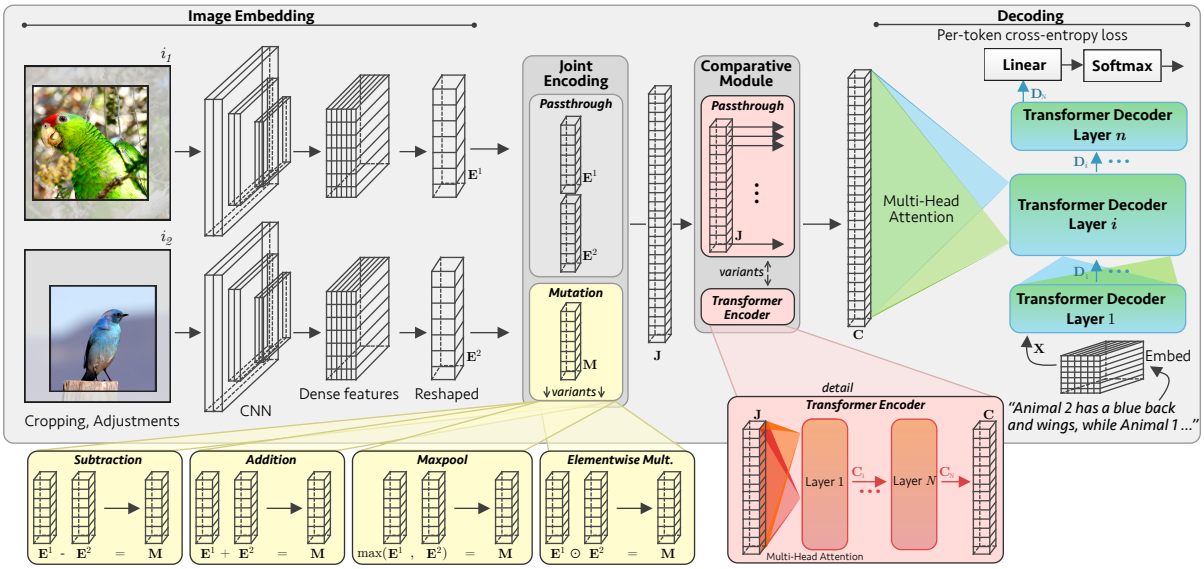


Figure 4: The proposed Neural Naturalist model architecture. The multiplicative joint encoding and Transformer-based comparative module yield the best comparisons between images.

2.3 Branching Images

We use both a visual similarity measure and taxonomy to sample a set of comparison images i_2 branching off from each pivot image i_1. We use a branching factor of $k = 12$ from each pivot image.

To capture visually similar images to i_1, we employ a similarity function $\mathcal{V}(i_1, i_2)$. We use an Inception-v4 (Szegedy et al., 2017) network pretrained on ImageNet (Deng et al., 2009) and then fine-tuned to perform species classification on all research-grade observations in iNaturalist. We take the embedding for each image from the last layer of the network before the final softmax. We perform a k-nearest neighbor search by quantizing each embedding and using L2 distance (Wu et al., 2017; Guo et al., 2016), selecting the $k_v = 2$ closest images in embedding space.

We also use the iNaturalist scientific taxonomy $\mathcal{T}(\mathcal{D})$ to sample images at varying levels of taxonomic distance from i_1. We select $k_t = 10$ taxonomically branched images by sampling two images each from the same SPECIES ($\ell = 1$), GENUS, FAMILY, ORDER, and CLASS ($\ell = 5$) as c. This yields 4,860 raw image pairs (i_1, i_2).

2.4 Language Collection

For each image pair (i_1, i_2), we elicit five natural language paragraphs describing the differences between them.

An annotator is instructed to write a paragraph (usually 2–5 sentences) comparing and contrasting the animal appearing in each image. We instruct annotators not to explicitly mention the species (e.g., *"Animal 1 is a penguin"*), and to instead focus on visual details (e.g., *"Animal 1 has a black body and a white belly"*). They are additionally instructed to avoid mentioning aspects of the background, scenery, or pose captured in the photograph (e.g., *"Animal 2 is perched on a coconut"*).

We discard all annotations for an image pair where either image did not have at least $\frac{4}{5}$ positive ratings of image clarity. This yields a total of 3,347 image pairs, annotated with 16,067 paragraphs. Detailed statistics of the Birds-to-Words dataset are shown in Figure 3, and examples are provided in Figure 5. Further details of our both our algorithmic approach and dataset construction are given in Appendices A and B.

3 Neural Naturalist Model

Task Given two images (i_1, i_2) as input, our task is to generate a natural language paragraph $t = x_1 \dots x_n$ that compares the two images.

Architecture Recent image captioning approaches (Xu et al., 2015; Sharma et al., 2018) extract image features using a convolutional neural network (CNN) which serve as input to a language decoder, typically a recurrent neural network (RNN) (Mikolov et al., 2010) or Transformer (Vaswani et al., 2017). We extend this paradigm with a joint encoding step and comparative module to study how best to encode and transform

Figure 5: Samples from the dev split of the proposed Birds-to-Words dataset, along with Neural Naturalist model output (M) and one of five ground truth paragraphs (G). The second row highlights failure cases in red. The model produces *coherent* descriptions of *variable granularity*, though *emphasis* and *assignment* can be improved.

multiple latent image embeddings. A schematic of the model is outlined in Figure 4, and its key components are described in the upcoming sections.

$$\mathbf{E}^1 = \langle \mathbf{e}^1_{1,1}, \ldots, \mathbf{e}^1_{d,d} \rangle = \text{CNN}(i_1)$$
$$\mathbf{E}^2 = \langle \mathbf{e}^2_{1,1}, \ldots, \mathbf{e}^2_{d,d} \rangle = \text{CNN}(i_2)$$

3.1 Image Embedding

Both input images are first processed using CNNs with shared weights. In this work, we consider ResNet (He et al., 2016) and Inception (Szegedy et al., 2017) architectures. In both cases, we extract the representation from the deepest layer immediately before the classification layer. This yields a dense 2D grid of local image feature vectors, shaped (d, d, f). We then flatten each feature grid into a (d^2, f) shaped matrix:

3.2 Joint Encoding

We define a joint encoding $\mathbf{J}$ of the images which contains both embedded images $(\mathbf{E}^1, \mathbf{E}^2)$, a mutated combination $(\mathbf{M})$, or both. We consider as possible mutations $\mathbf{M} \in \{\mathbf{E}^1 + \mathbf{E}^2, \mathbf{E}^1 - \mathbf{E}^2, \max(\mathbf{E}^1, \mathbf{E}^2), \mathbf{E}^1 \odot \mathbf{E}^2\}$. We try these encoding variants to explore whether simple mutations can effectively combine the image representations.

3.3 Comparative Module

Given the joint encoding of the images ($\mathbf{J}$), we would like to represent the differences in feature space ($\mathbf{C}$) in order to generate comparative descriptions. We explore two variants at this stage. The first is a direct passthrough of the joint encoding ($\mathbf{C} = \mathbf{J}$). This is analogous to "standard" CNN+LSTM architectures, which embed images and pass them directly to an LSTM for decoding. Because we try different joint encodings, a passthrough here also allows us to study their effects in isolation.

Our second variant is an N-layer Transformer encoder. This provides an additional self-attentive mutations over the latent representations $\mathbf{J}$. Each layer contains a multi-headed attention mechanism (ATTN_{MH}). The intent is that self-attention in Transformer encoder layers will guide comparisons across the joint image encoding.

Denoting LN as *Layer Norm* and FF as *Feed Forward*, with $\mathbf{C}_i$ as the output of the ith layer of the Transformer encoder, $\mathbf{C}_0 = \mathbf{J}$, and $\mathbf{C} = \mathbf{C}_N$:

$$\mathbf{C}_i^H = \text{LN}(\mathbf{C}_{i-1} + \text{ATTN}_{\text{MH}}(\mathbf{C}_{i-1}))$$
$$\mathbf{C}_i = \text{LN}(\mathbf{C}_i^H + \text{FF}(\mathbf{C}_i^H))$$

3.4 Decoder

We use an N-layer Transformer decoder architecture to produce distributions over output tokens. The Transformer decoder is similar to an encoder, but it contains an intermediary multi-headed attention which has access to the encoder's output $\mathbf{C}$ at every time step.

$$\mathbf{D}_i^{H_1} = \text{LN}(\mathbf{X} + \text{ATTN}_{\text{MASK,MH}}(\mathbf{X}))$$
$$\mathbf{D}_i^{H_2} = \text{LN}(\mathbf{D}_i^{H_1} + \text{ATTN}_{\text{MH}}(\mathbf{D}_i^{H_1}, \mathbf{C}))$$
$$\mathbf{D}_i = \text{LN}(\mathbf{D}_i^{H_2} + \text{FF}(\mathbf{D}_i^{H_2}))$$

Here we denote the text observed during training as $\mathbf{X}$, which is modulated with a position-based encoding and masked in the first multi-headed attention.

4 Experiments

We train the Neural Naturalist model to produce descriptions of the differences between images in the Birds-to-Words dataset. We partition the dataset into train (80%), val (10%), and test (10%) sections by splitting based on the pivot images i_1. This ensures i_1 species are unique across the different splits.

We provide model hyperparameters and optimization details in Appendix C.

4.1 Baselines and Variants

The *most frequent* paragraph baseline produces only the most observed description in the training data, which is that the two animals appear to be exactly the same. *Text-Only* samples captions from the training data according to their empirical distribution. *Nearest Neighbor* embeds both images and computes the lowest total L_2 distance to a training set pair, sampling a caption from it. We include two standard neural baselines, CNN (+ Attention) + LSTM, which concatenate the images embeddings, optionally perform attention, and decode with an LSTM. The main model variants we consider are a simple joint encoding ($\mathbf{J} = \langle \mathbf{E}^1, \mathbf{E}^2 \rangle$), no comparative module ($\mathbf{C} = \mathbf{J}$), a small (1-layer) decoder, and our full Neural Naturalist model. We also try several other ablations and model variants, which we describe later.

4.2 Quantitative Results

Automatic Metrics We evaluate our model using three machine-graded text metrics: BLEU-4 (Papineni et al., 2002), ROUGE-L (Lin, 2004), and CIDEr-D (Vedantam et al., 2015). Each generated paragraph is compared to all five reference paragraphs.

For human performance, we use a one-vs-rest scheme to hold one reference paragraph out and compute its metric using the other four. We average this score across twenty-five runs over the entire split in question.

Results using these metrics are given in Table 2 for the main baselines and model variants. We observe improvement across BLEU-4 and ROUGE-L scores compared to baselines. Curiously, we observe that the CIDEr-D metric is susceptible to common patterns in the data; our model, when stopped at its highest CIDEr-D score, outputs a variant of, *"these animals appear exactly the same"* for 95% of paragraphs, nearly mimicking the behavior of the most frequent paragraph (*Freq.*) baseline. The corpus-level behavior of CIDEr-D gives these outputs a higher score. We observed anecdotally higher quality outputs correlated with ROUGE-L score, which we verify using a human evaluation (paragraph after next).

	Dev			Test		
	BLEU-4	ROUGE-L	CIDEr-D	BLEU-4	ROUGE-L	CIDEr-D
Most Frequent	0.20	0.31	**0.42**	0.20	0.30	**0.43**
Text-Only	0.14	0.36	0.05	0.14	0.36	0.07
Nearest Neighbor	0.18	0.40	0.15	0.14	0.36	0.06
CNN + LSTM (Vinyals et al., 2015)	0.22	0.40	0.13	0.20	0.37	0.07
CNN + Attn. + LSTM (Xu et al., 2015)	0.21	0.40	0.14	0.19	0.38	0.11
Neural Naturalist – Simple Joint Encoding	0.23	0.44	0.23	-	-	-
Neural Naturalist – No Comparative Module	0.09	0.27	0.09	-	-	-
Neural Naturalist – Small Decoder	0.22	0.42	0.25	-	-	-
Neural Naturalist – Full	**0.24**	**0.46**	0.28	**0.22**	**0.43**	0.25
Human	0.26 +/- 0.02	0.47 +/- 0.01	0.39 +/- 0.04	0.27 +/- 0.01	0.47 +/- 0.01	0.42 +/- 0.03

Table 2: Experimental results for comparative paragraph generation on the proposed dataset. For human captions, mean and standard deviation are given for a one-vs-rest scheme across twenty-five runs. We observed that CIDEr-D scores had little correlation with description quality. The Neural Naturalist model benefits from a strong joint encoding and Transformer-based comparative module, achieving the highest BLEU-4 and ROUGE-L scores.

Ablations and Model Variants We ablate and vary each of the main model components, running the automatic metrics to study coarse changes in the model's behavior. Results for these experiments are given in Table 3. For the *joint encoding*, we try combinations of four element-wise operations with and without both encoded images. To study the *comparative module* in greater detail, we examine its effect on the top three joint encodings: $(i_1, i_2, -)$, $-$, and $\odot$. After fixing the best joint encoding and comparative module, we also try variations of the *decoder* (Transformer depth), as well as *decoding algorithms* (greedy decoding, multinomial sampling, and beamsearch).

Overall, we we see that the choice of joint encoding requires a balance with the choice of comparative module. More disruptive joint encodings (like element-wise multiplication $\odot$) appear too destructive when passed directly to a decoder, but yield the best performance when paired with a deep comparative module. Others (like subtraction) function moderately well on their own, and are further improved when a comparative module is introduced.

Human Evaluation To verify our observations about model quality and automatic metrics, we also perform a human evaluation of the generated paragraphs. We sample 120 instances from the test set, taking twenty each from the six categories for choosing comparative images (visual similarity in embedding space, plus five taxonomic distances). We provide annotators with the two images in a random order, along with the output from the model at hand. Annotators must decide which image contains *Animal 1*, and which contains *Animal 2*, or they may say that there is no way to tell (e.g., for a description like *"both look exactly the same"*).

We collect three annotations per datum, and score a decision only if $\geq 2/3$ annotators made that choice. A model receives +1 point if annotators decide correctly, 0 if they cannot decide or agree there is no way to tell, and -1 point if they decide incorrectly (label the images backwards). This scheme penalizes a model for confidently writing incorrect descriptions. The total score is then normalized to the range $[-1, 1]$. Note that *Human* uses one of the five gold paragraphs sampled at random.

Results for this experiment are shown in Table 4. In this measure, we see the frequency and text-only baselines now fall flat, as expected. The frequency baseline never receives any points, and the text-only baseline is often penalized for incorrectly guessing. Our model is successful at making distinctions between visually distinct species (GENUS column and ones further right), which is near the challenge level of current fine-grained visual classification tasks. However, it struggles on the two data subsets with highest visual similarity (VISUAL, SPECIES). The significant gap between all methods and human performance in these columns indicates ultra fine-grained distinctions are still possible for humans to describe, but pose a challenge for current models to capture.

4.3 Qualitative Analysis

In Figure 5, we present several examples of the model output for pairs of images in the dev set, along with one of the five reference paragraphs. In

Table 3: Variants and ablations for the Neural Naturalist model. We find the best performing combination is an elementwise multiplication ($\odot$) for the joint encoding, a 6-layer Transformer comparative module, a 6-layer Transformer decoder, and using beamsearch to perform inference.

the following section, we split an analysis of the model into two parts: largely positive findings, as well as common error cases.

Positive Findings

We find that the model exhibits **dynamic granularity**, by which we mean that it adjusts the magnitude of the descriptions based on the scale of differences between the two animals. If two animals are quite similar, it generates fine-grained descriptions such as, *"Animal 2 has a slightly more curved beak than Animal 1,"* or *"Animal 1 is more iridescent than Animal 2."* If instead the two animals are very different, it will generate text describing larger-scale differences, like, *"Animal 1 has a much longer neck than Animal 2,"* or *"Animal 1 is mostly white with a black head. Animal 2 is almost completely yellow."*

We also observe that the model is able to produce coherent paragraphs of **varying linguistic structure.** These include a range of comparisons set up across both single and multiple sentences. For example, one it generates straightforward comparisons of the form, *Animal 1 has X, while Animal 2 has Y.* But it also generates contrastive expressions with longer dependencies, such as *Animal 1 is X, Y, and Z. Animal 2 is very similar, except W.* Furthermore, the model will mix and match different comparative structures within a single paragraph.

Finally, in addition to varying linguistic structure, we find the model is able to produce **coherent semantics** through a series of statements. For example, consider the following full output: *"Animal 1 has a very long neck compared to Animal 2. Animal 1 has shorter legs than Animal 2. Animal 1 has a black beak, Animal 2 has a brown beak. Animal 1 has a yellow belly. Animal 2 has*

	VISUAL	SPECIES	GENUS	FAMILY	ORDER	CLASS

Human	0.55	0.55	0.85	1.00	1.00	1.00

Table 4: Human evaluation results on 120 test set samples, twenty per column. Scale: -1 (perfectly wrong) to 1 (perfectly correct). Columns are ordered left-to-right by increasing distance. Our model outperforms baselines for several distances, though highly similar comparisons still prove difficult.

darker wings than Animal 1." The range of concepts in the output covers *neck, legs, beak, belly, wings* without repeating any topic or getting sidetracked.

Error Analysis

We also observe several patterns in the model's shortcomings. The most prominent error case is that the model will sometimes **hallucinate differences** (Figure 5, bottom row). These range from pointing out significant changes that are missing (e.g., *"a black head"* where there is none (Fig. 5, bottom left)), to clawing at subtle distinctions where there are none (e.g., *"[its] colors are brighter . . . and [it] is a bit bigger"* (Fig. 5, bottom right)). We suspect that the model has learned some associations between common features in animals, and will sometimes favor these associations over visual evidence.

The second common error case is **missing obvious distinctions**. This is observed in Fig. 5 (bottom middle), where the prominent beak of Animal 1 is ignored by the model in favor of mundane details. While outlying features make for lively descriptions, we hypothesize that the model may sometimes avoid taking them into account given its per-token cross entropy learning objective.

Finally, we also observe the model sometimes **swaps which features are attributed to which animal**. This is partially observed in Fig. 5 (bottom left), where the *"black head"* actually belongs to Animal 1, not Animal 2. We suspect that mixing up references may be a trade-off for the representational power of attending over both images; there is no explicit bookkeeping mechanism to enforce which phrases refer to which feature comparisons in each image.

5 Related Work

Employing visual comparisons to elicit focused natural language observations was proposed by (Maji, 2012), and later investigated in the context of crowdsourcing by (Zou et al., 2015). We take inspiration from these works.

Previous work has collected natural language captions of bird photographs: CUB Captions (Reed et al., 2016) and CUB-Justify (Vedantam et al., 2017) are both language annotations on top of the CUB-2011 dataset of bird photographs (Wah et al., 2011). In addition to describing two photos instead of one, the language in our dataset is more complex by comparison, containing a diversity of comparative structures and implied semantics. We also collect our data without an anatomical guide for annotators, yielding everyday language in place of scientific terminology.

Conceptually, our paper offers a complementary approach to works that generate single-image class-discriminative or image-discriminative captions (Hendricks et al., 2016; Vedantam et al., 2017). Rather than discriminative captioning, we focus on comparative language as a means for bridging the gap between varying granularities of visual diversity.

Methodologically, our work is most closely related to the Spot-the-diff dataset (Jhamtani and Berg-Kirkpatrick, 2018). While dataset captions two images with only a small section of pixels that change (surveillance footage), we consider image pairs with no pixel overlap, which motivates our stratified sampling approach for drawing good comparisons.

Finally, the recently released NLVR^2 dataset (Suhr et al., 2018) introduces a challenging natural language reasoning task using two images as context. Our work instead focuses on generating comparative language rather than reasoning.

6 Conclusion

We present the new Birds-to-Words dataset and Neural Naturalist model for generating comparative explanations of fine-grained visual differences. This dataset features paragraph-length, adaptively detailed descriptions written in everyday language. We hope that continued study of this area will produce models that can aid humans in critical domains like citizen science.

Fine-Grained Evaluation for Entity Linking

Henry Rosales-Méndez, Aidan Hogan, Barbara Poblete
IMFD Chile & Department of Computer Science, University of Chile
{hrosales,ahogan,bpoblete}@dcc.uchile.cl

Abstract

The Entity Linking (EL) task identifies entity mentions in a text corpus and associates them with an unambiguous identifier in a Knowledge Base. While much work has been done on the topic, we first present the results of a survey that reveal a lack of consensus in the community regarding what forms of mentions in a text and what forms of links the EL task should consider. We argue that no one definition of the Entity Linking task fits all, and rather propose a fine-grained categorization of different types of entity mentions and links. We then re-annotate three EL benchmark datasets – ACE2004, KORE50, and VoxEL – with respect to these categories. We propose a fuzzy recall metric to address the lack of consensus and conclude with fine-grained evaluation results comparing a selection of online EL systems.

1 Introduction

Entity Linking (EL) is an Information Extraction task whose goal is to identify mentions of entities in a text and to link each mention to an unambiguous identifier in a Knowledge Base (KB) such as Wikipedia, BabelNet (Moro et al., 2014), DBpedia (Lehmann et al., 2015), Freebase (Bollacker et al., 2008), Wikidata (Vrandečić and Krötzsch, 2014) or YAGO (Rebele et al., 2016) (among others). The results of this task offer a practical bridge between unstructured text and structured KBs, where EL has applications for semantic search, document classification, relation extraction, and more besides (Wu et al., 2018).

While a broad number of EL techniques and systems have been proposed in recent years (Wu et al., 2018), a number of authors have noted that there is a lack of consensus on the fundamental question of what kinds of mentions in a text an EL system should link to which identifiers in the KB (Ling et al., 2015; Waitelonis et al., 2016; Jha et al., 2017; Rosales-Méndez et al., 2018b).

A closely related task to EL is that of Named Entity Recognition (NER), which identifies mentions of (named) entities in a task, but without linking the mention with a KB identifier. The types of entities that the NER task should target were defined at the Message Understanding Conference 6 (MUC-6) (Grishman and Sundheim, 1996), specifically entities corresponding to types such as Person, Organization, Place and other Numerical/Temporal expressions. While this provided a consensus for evaluating NER systems, some authors noted that such a categorization is coarse-grained and proposed finer-grained classification mechanisms (Fleischman and Hovy, 2002).

In the context of EL, target Knowledge Bases will often contain entities from a wide variety of classes, including Movies, Products, Events, Laws, etc., not considered by the traditional NER definitions; a dataset such as Wikidata has around 50,000 entity classes, for example. As a result, class-based definitions of entities are restrictive. Hence some authors have proposed more general definitions for the EL task: as Ling et al. (2015) note, while some authors follow traditional NER definitions, others propose a looser definition that any KB identifier (e.g., Wikipedia article URL) can be the target for a link; they further note that within these definitions there is a lack of guidelines with respect to how EL datasets should be labeled and what sorts of mentions and links EL systems should (ideally) offer.

This ambiguity complicates research and applications relating to EL, as highlighted previously by various authors (Ling et al., 2015; Jha et al., 2017; Rosales-Méndez et al., 2018b). Figure 1 shows the results of a selection of popular online EL systems: Babelfy (Moro et al., 2014), DBpedia Spotlight (Mendes et al., 2011),

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 718–727, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

FRED (Gangemi et al., 2017) and TagME (Ferragina and Scaiella, 2010). We see significant differences in the annotations provided, which we argue are due not only to differing precision/recall of the systems, but also to differing policies on issues such as overlapping entities (should "Michael Jackson" be annotated within the documentary title), common/named entities (should "interview" be linked to the corresponding Wikipedia article `wiki:Interview`), and more besides. With such varying perspectives on the EL task, it is not clear how we should define gold standards that offer a fair comparison of tools (Ling et al., 2015).

The standard approach to tackle this issue has been to make certain design choices explicit, such as to enforce a particular policy with respect to overlapping mentions, or common entities, etc., when labeling an EL dataset or performing evaluation. However, the appropriate policy may depend on the particular application, setting, etc. In this paper we pursue an alternative approach, which is to embrace different perspectives of the EL task, proposing a fine-grained categorization of different types of EL mentions and links, and then re-annotating three existing datasets with respect to these categories, allowing us to compare the performance of EL tools within the different categories. Specifically, our contributions are as follows (indicating also the relevant section):

§ 2 We design and present the results of a questionnaire addressed to authors of EL papers intended to understand the consensus (or lack thereof) regarding the goals of the EL task.

§ 3 We argue that no one definition of an entity mention/link fits all, and hence propose a fine-grained categorization scheme for the EL task covering details regarding base form, part of speech, overlap, and reference type.

§ 4 We relabel three existing EL datasets – ACE2004 (subset), KORE50 and VoxEL – per our novel categorization scheme, extending the set of annotations as appropriate.

§ 5 We conduct a fine-grained evaluation of the performance of five EL systems with respect to individual categories of EL annotations.

§ 6 Addressing the lack of consensus, we propose a fuzzy recall and F_1 measure based on a configurable membership function, presenting results for the five EL systems.

In an [interview]^{td} with [Martin Bashir]^{btf} for the 2003 [documentary]^{td} [Living with {Michael Jackson}^{bd}]^{btf}, the King of [Pop]^{d} recalled that [Joe]^{t} often sat with a white belt at hand as he and his four [siblings]^{td} rehearsed.

Figure 1: Output annotations made by four different systems – Babelfy (b), TagME (t), DBpedia Spotlight (d) and FRED (f) – on the same input text.

§ 7 We present conclusions about the performance of the EL systems surveyed for different types of entity mentions/links and highlight open challenges for the EL task.

2 Questionnaire: Lack of Consensus

To understand what consensus (or lack thereof) exists within the EL community regarding the EL task, we designed a concise questionnaire with two sentences for which we proposed a variety of EL annotations, providing the text, the annotated text mentions, and proposed links to the respective Wikipedia articles. The two sentences – shown in Figure 2 (with a summary of results that will be described presently) – were designed to exemplify the types of design choices that vary from author to author (Ling et al., 2015); specifically, we target the following questions:

1. *Entity types*: should types not typically considered under MUC-6 definitions (other than as MISC) be linked (e.g., linking Living with Michael Jackson to the corresponding Wikipedia article)?

2. *Overlapping mentions*: should mentions inside other mentions be annotated (e.g., Michael Jackson)?

3. *Common entities*: should common nouns be annotated (e.g., documentary)?

4. *Parts of speech*: should only nouns be annotated or should other parts of speech also be linked (e.g., reports or white)?

5. *Mention types*: should complex types of mentions, such as pronouns (e.g., he) or descriptive noun phrases indicating named entities, be annotated (e.g., linking he and his four siblings to `wiki:The_Jackson_5`)?

In an [interview]$^{.19}$ with [Martin Bashir]^{1} for the [2003]$^{.28}$ [documentary]$^{.28}$ [Living with {Michael Jackson}$^{.75}$]$^{.97}$, the [{King}$^{.08}$ of {Pop}$^{.33}$]$^{.94}$ [recalled]$^{.06}$ that [Joe]^{1} often [sat]$^{.08}$ with a [white]$^{.11}$ [belt]$^{.14}$ at [hand]$^{.14}$ as [{he}$^{.56}$ and {his}$^{.39}$ {four}$^{.08}$ {siblings}$^{.14}$]$^{.50}$ [rehearsed]$^{.08}$.

[Russian]$^{.61}$ [daily]$^{.14}$ [Kommersant]$^{.97}$ [reports]$^{.06}$ that [Moscow]$^{.94}$ will [supply]$^{.06}$ the [Greeks]$^{.94}$ with [gas]$^{.36}$ at [{rock}^{0} bottom {prices}$^{.19}$]$^{.28}$ as [Tsipras]$^{.92}$ [prepares]$^{.03}$ to [meet]$^{.06}$ the [{Russian}$^{.53}$ {President}$^{.12}$]$^{.97}$.

Figure 2: The sentences included in the questionnaire and the ratio of respondents who suggested to annotate the mentions. Multiple links were proposed for the mentions underlined (see Table 1).

6. *Link types*: should mentions link to the explicitly named entity (e.g., linking Moscow to `wiki:Moscow`), or should complex forms of reference such as *meronymy* (e.g., linking Moscow to `wiki:Government_of_Russia`), *hypernymy* (e.g., linking daily to `wiki:Newspaper` as the closest entity present in the KB, or linking Russian President to `wiki:Vladimir_Putin`), or *metaphor* (e.g., linking King to `wiki:King`) be considered?

For each sentence, respondents were asked to select the mentions and links that they consider an EL system should *ideally* provide; specifically, they were presented an optional multiple choice question for each mention: the option to select one (or more, in underlined cases) suggested links, and the option to not annotate the mention. In order to address this survey to the EL research community, we extracted the emails of all papers referenced in the recent survey by Wu et al. (2018) that are directly related to EL. We sent the questionnaire to 321 researchers, of which 232 requests were delivered successfully. We received a total of 36 responses. Aggregated responses are available online[1], where in Figure 2 we provide a summary of results, indicating in superscript the ratio of respondents who agreed to some link being provided for the given mention.

First we see that the only mentions that all 36 respondents agreed should be linked are Martin Bashir and Joe, which are traditional MUC types, non-overlapping, named entities, with direct mentions and links; on the other hand, there was also consensus that `rock` should not be linked. Otherwise, all other mentions showed some level of disagreement. Regarding our questions:

1. *Entity types*: per Living with Michael Jackson (0.97), the vast majority of respondents do not restrict to non-MISC MUC types.

2. *Overlapping mentions*: per Michael Jackson (0.75), most respondents also allow mentions contained in other mentions.

3. *Common entities*: most respondents do not consider common entities, with the highest response appearing for documentary (0.28).

4. *Parts of speech*: the consensus was mostly that EL should focus on nouns, with his (0.39) and white (0.11) being the most popularly selected non-nouns.

5. *Mention types*: here there was a notable split, with he (0.56) and he and his four siblings (0.5)[2] being selected for annotation by roughly half of the respondents.

6. *Link types*: for this we introduce Table 1, where we see how respondents preferred different types of reference (respondents could select multiple options); from this we conclude that although respondents preferred to use a country directly to represent nationality, they also preferred to resolve complex types of reference, such as the meronymic use of Moscow to refer to the government rather than the city, and the use of Putin's title to refer to him rather than the title itself.

So who is correct? We argue that there is no "correct" answer here. Common entities may, for example, rather be considered the target of a separate Word Sense Disambiguation task (Navigli, 2009), while pro-forms may be considered the target of a separate Coreference/Anaphora Resolution task (Sukthanker et al., 2018); these are matters of convention. In more practical terms, the

[1] `https://users.dcc.uchile.cl/~hrosales/questionnaire`

[2] One respondent noted that it was not certain that this referred to The Jackson 5.

importance of each individual EL annotation may vary from application to application; for example, for relation extraction, it may be important to identify all repeated mentions of an entity (as each such mention may lie within a distinct relation), while for semantic search having repeated mentions may be less critical (a subset of mentions may suffice to know the document is relevant for a given entity). We propose that no one definition of the EL task fits all, and rather propose a categorization that covers different perspectives.

3 Categorization Scheme

Inspired by the results of the questionnaire and related discussion by Ling et al. (2015), among other authors, in Figure 3 we propose a categorization scheme aiming to capture and organize these diverse perspectives on the EL task. This scheme makes explicit the types of *annotations* – mention–link pairs – that can be considered when annotating EL datasets, or when developing, evaluating and applying EL systems. The categorization scheme has four dimensions: *Base Form*, *Part of Speech*, *Overlap* and *Reference*. We propose that each EL annotation be labeled with precisely one leaf-node from each dimension. Our objective with this categorization is not to imply that all types of annotations *should* be considered as part of the EL task, but rather to map out the types of annotations that *could* be considered for EL.

3.1 Base Form

The *Base Form* considers the type of mention: is it a name, a common noun, a number, a date, etc.

We separate *Proper Noun* into more specific categories that deal with the difference between mentions and KB labels: *Full Name*, *Short Name*, *Extended Name* and *Alias*. The first three should be tagged when the mentions are equal (Michael Jackson), shorter (Jackson) or longer (Michael Joseph Jackson), respectively, than the primary label of their corresponding KB-entity (wiki:Michael_Jackson). On the other hand, *Alias* is used for mentions that vary from the primary label of the KB (King of Pop).

Numeric/Temporal are mentions that refer to a number or a given temporal concept (e.g., 1, 1900, first, October, July 07, Tuesday, 2018/01/32, etc.). Such mentions were included in the MUC-6 definition and some such expressions have corresponding Wikipedia articles. The next category is *Pro-form*, which includes any pronoun (*he*, *his*, etc.) referring to a named entity elsewhere. The final category is *Common Form*, which refers to a common word, such as documentary, sat, etc., or a noun-phrase referring to a named entity with a common head term, e.g., he and his four siblings.

3.2 Part of Speech

Part of Speech denotes the grammatical function of a word in a sentence, where we include four high-level classes for which we have found instances that could be linked to the Wikipedia KB (without referring to their own syntactic form). As we have already discussed, the most common target for EL is *Noun Phrases*; we divide these into *Singular* and *Plural* for additional granularity. However, we also include *Verb*s (e.g., divorcing, metastasized), *Adjective*s (e.g., anaerobic, French) and *Adverb*s (e.g., polynomially, Socratically) for linking to the Knowledge Base.

3.3 Overlap

The *Overlap* dimension, as its name suggests, captures the nature of overlap between mentions. As an example, for the mention New York City Police Museum, the mention New York would have *Minimal* overlap (assuming York is not incorrectly identified), New York City Police would have *Intermediate* overlap, and New York City Police Museum would have *Maximal* overlap.

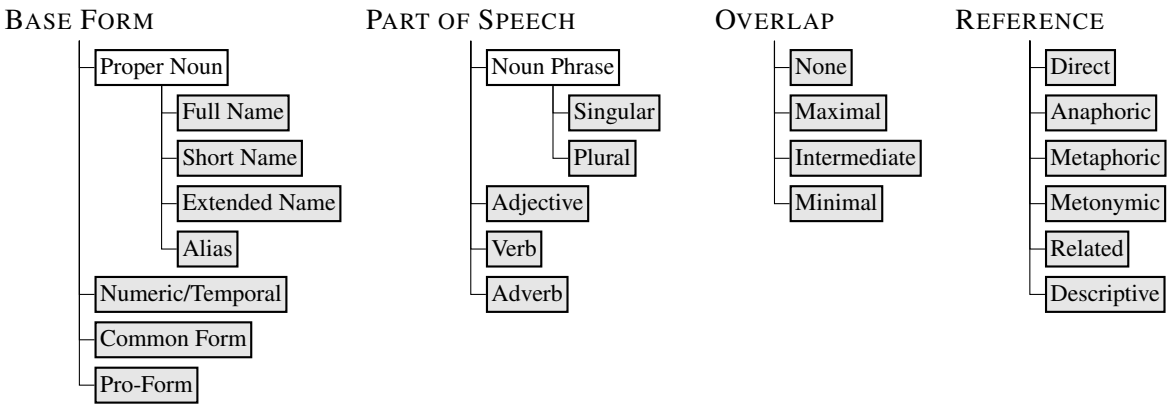

Figure 3: EL categorization scheme with concrete alternatives (leaf-nodes) shaded for each dimension

3.4 Reference

The *Reference* dimension considers the relation between the mention and the linked entity. The topic of *reference* is a complex one that has been the subject of much attention over many decades (Strawson, 1950); here we propose a pragmatic but comprehensive set of options.

The *Direct* category considers a direct explicit mention of an entity based on a known KB label/alias, such as M. Jackson or the King of Pop for `wiki:Michael_Jackson` or divorcing for `wiki:Divorce`. *Anaphoric* denotes a reference to an antecedent (or postcedent) for pro-forms such as he or her that are coreferent with a named entity. *Metaphoric* captures figurative references to entities whose characteristics are referred to, such as He is a pool [shark] linking to `wiki:Shark`. *Metonymic* indicates reference by common association, such as using Moscow to refer to `wiki:Government_of_Russia` or using Peru to refer to `wiki:Peru_national_football_team`. *Related* is used when only a near-synonym, hypernym or hyponym is available for a mention in the KB, such as the Russian [daily] being linked to `wiki:Newspaper`.[3] Finally, *Descriptive* is used for (non-pro, non-proper) referring noun-phrases, such as his father referring to `wiki:Joe_Jackson`; unlike similar *Anaphoric* references, *Descriptive* references do not necessarily rely on an antecedent to be disambiguated, as per the case of Hendix's band referring to `wiki:The_Jimi_Hendrix_Experience` or Fiji's capital referring to `wiki:Suva` without requiring further context to disambiguate.

[3] Wikipedia will often redirect from a term to a related article; for example, `wiki:Daily_newspaper` currently redirects to `wiki:Newspaper`.

4 Fine-Grained Datasets

A wide variety of EL datasets have been proposed (e.g., ACE2004 (Ratinov et al., 2011), KORE50 (Hoffart et al., 2012), MEANTIME (Minard et al., 2016), DBpedia Spotlight (Mendes et al., 2011), VoxEL (Rosales-Méndez et al., 2018a)) to support EL quality measurement. However, often the guidelines followed in the annotation process are left implicit, such as the inclusion/exclusion of overlapping mentions, common entities, etc. Furthermore, different types of entities are not distinguished.

To put our categorization into practice, we select three existing datasets – KORE50, ACE2004, and VoxEL – and categorize each annotation. We further add novel annotations not considered in the original labeling process with the goal of capturing as many potential (categorized) links to Wikipedia articles as possible. The process of annotation was done manually by three authors (with the help of the NIFify tool (Rosales-Méndez et al., 2019) for labeling overlaps, parts of speech, as well as validation). The annotation process was iterative. The first author began an initial annotation based on a strict and relaxed notion of "entity", with strict referring to classical definitions of entities, and relaxed referring to any entity mention linkable with Wikipedia (following the literature). This process raised ambiguities regarding metonymic references, descriptive noun phrases, etc. Hence the authors defined fine-grained categories to address ambiguous cases and designed the questionnaire to better understand the community consensus. The first author relabeled the data per the fine-grained categorization, with semi-automated verification. The other authors then revised these annotations in detail; there were significant dif-

ferences, leading to further discussion and refinements in the categorization. Ambiguities and disagreements were iteratively resolved by the authors through discussion and modification of the categories. The resulting datasets reflect the consensus of the authors. The categorization scheme shown in Figure 3 is also a result of this process, where we iteratively extended and refined these categories as we encountered specific cases in these datasets; as a result, these categories suffice to cover all cases of possible mentions of Wikipedia entities in the datasets.

The labeling process was extremely time consuming (taking place over six months) due to the large number of annotations generated, particularly for common-form mentions; for this reason, in the case of ACE2004, we only annotate 20 documents (from a total of 57) wherein, for example, the number of annotations increases from 108 in the original data to 3,351 in our fine-grained version[4]. Per MUC-6, we also include emerging/not-in-lexicon entities and entity types in our annotations. Additionally, we label some mentions with multiple alternatives (per Table 1).

In Table 2 we summarize details of the reconstructed version of these three datasets, including the number of documents, sentences and annotations. Except for the case of ACE2004, our re-annotated datasets maintain the same text collection as in the original version. For each category, we also show the number of annotations tagged with it. The most frequent annotations are those that belong to *Common Form*, *Singular Noun*, *Non-Overlapping* and *Direct* categories.

In the final iteration, we perform validation checking for erroneous links avoiding invalid, redirect and disambiguation pages; erroneous categorizations, e.g., multiple tags in the same category; erroneous mentions, such as trailing spaces; etc. During this process, we also encountered and resolved numerous issues with the original datasets; of note, in ACE2004 we found various spelling errors of entity names, e.g., Stewart Talbot as a misspelling of Strobe Talbott, Coral Islands as a misspelling of Kuril Islands, etc.

5 Fine-Grained Evaluation

Our fine-grained datasets allow us to understand the performance of EL systems in more detail regarding different types of EL annotations. In Table 3, we present the Precision (**P**), Recall (**R**) and F_1 score ($\mathbf{F}_1$) for five popular EL systems with online APIs: Babelfy (**B**), TagME (**T**), DBpedia Spotlight (**D**), AIDA (**A**) and FREME (**F**). In the case of Babelfy, we consider both settings: *strict*, which excludes common entities ($\mathbf{B}_s$); and *relaxed*, which includes common entities ($\mathbf{B}_r$). Results are shown for subsets of annotations corresponding to a particular category (A), where we also present the number of unique mentions for annotations of that category ($|A|$). Recall that our gold standard may have multiple annotations for a single mention in the gold standard, listing different possible links for an individual mention (see, e.g., Table 1); on the other hand, evaluated systems predict a single link for each mention. We thus evaluate annotations on a mention-by-mention basis.[5] We consider a predicted mention to be a *true positive* if it is included in A and the predicted link

corresponds to any of the possible links given by A for that mention. We consider a predicted mention to be a *false positive* if the mention is given by A, but the predicted link is not given by A for that mention; in other words, when restricting A by category, system annotations on mentions outside of A are ignored.[6] Finally we consider a mention to be a *false negative* if it is given by A but either the mention is not predicted by the system or the system predicts a link not given by A for tht mention. We also show the overall result in the final row considering the full gold standard. The results consider a unified dataset that concatenates all three datasets. Better results (closer to 1) are shaded darker to aid with visual comparison.

Comparing the different types of annotations, on a high-level, we can see that recall, in particular, varies widely across categories; unsurprisingly perhaps, systems, in general, exhibit higher recall for proper nouns (particularly full and extended names) with direct references. Looking at categories with poor results, we see that none of the evaluated systems consider anaphoric references, perhaps considered as a task distinct from EL. Interestingly, no system captures metonymic references, though as previously seen the results of our questionnaire (see Table 1) indicate that respondents prefer such types of links over their literal counterparts (e.g., linking Moscow in the given context with `wiki:Government_of_Russia` rather than `wiki:Moscow`). Comparing systems, Babelfy (relaxed) and TagME achieve much higher recall for common forms than the other systems: we attribute this to these systems making the design choice to additionally support common entities.

While the previous results consider dimensions independently, there are $7 \times 5 \times 4 \times 6 = 840$ possible combinations across the four dimensions; not all of these can occur (for example, a *Pro-form* mention requires *Anaphoric* reference). In the unified dataset, we found 123 combinations to have at least one annotation. In order to understand in more detail how the systems perform for annotations in combined categories, for the six system configurations, Figure 4 presents a best-first accumulative progression of Precision, Recall and F_1: we start with the combined category in which each system performs best ($x = 1$), adding tags in the next-best combined category until all annotations in the gold standard are considered. We see that although precision remains relatively high throughout the gold standard, recall drops considerably as combined categories on which there is less consensus are added. The recall and F_1 measures, in particular, present a clear division in the systems: Babelfy (relaxed) and TagME maintain a higher recall as more combined categories are considered due to their inclusion of common entities (but suffer from reduced precision as a result).

[6] If a system predicts a link present in the gold standard for the mention but with a different category than tested, it will thus be considered a false positive for the tested category.

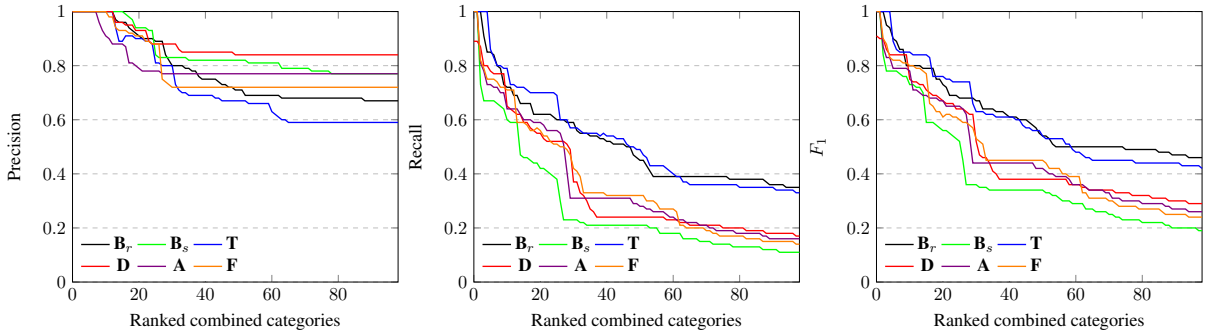

Figure 4: Cumulative results for Babelfy (relaxed/strict), TagME, DBpedia Spotlight, AIDA and FREME for the unified dataset over ranked combinations of categories

6 Fuzzy Recall and F_1 Measures

While the previous results provide insights into different design choices taken by different systems with respect to different types of EL annotations, still, per Table 1, the results are perhaps *too* fine-grained. For the purposes of comparing the performance of systems, we may rather prefer a measure that aggregates performance across different categories. However, this presents a conceptual problem: for some applications or definitions of the EL task, certain categories may be considered more important than others. For instance, should we penalize a system equally for missing the annotations gas and Tspiras in the second sentence of Figure 2? In most EL settings, the former is arguably less important than the latter, but nonetheless it may depend on the setting.

Reflecting the lack of consensus for the EL task, we rather propose a measure inspired by Fuzzy Set Theory (Zadeh, 1965): given a universe of elements U and a particular element $x \in U$, rather than considering traditional *crisp* sets A with binary membership (where $x \in A$ or $x \notin A$), a fuzzy set A^* is associated with a membership function $\mu_{A^*} : U \rightarrow [0, 1]$, which denotes the degree to which an element x is a member of A^* (given by $\mu_{A^*}(x)$). Given that a crisp set A can be defined as a fuzzy set with membership function $\mu_A : U \rightarrow \{0, 1\}$, fuzzy sets are a generalization of crisp sets. Intuitively, we can then consider a gold standard with a fuzzy set of annotations A^*, where (e.g.) annotations forming part of the core consensus of EL have a higher membership degree than those for which consensus does not exist; different membership degrees can also be applied for evaluation in different application settings.

Formally, an annotation is a triple $a = (o, o', l)$, where o and o' denotes the start and end offset of a mention in a text ($o < o'$), and l denotes a link (a KB identifier or a not-in-lexicon string). For a given text, a gold standard G is a set of annotations, as is the result of a system S. The set of *true positives* is defined as $TP = G \cap S$, *false positives* as $FP = S - G$, and *false negatives* as $FN = G - S$. In this case, however, while we still consider S to be a crisp set, we allow a fuzzy version of the gold standard G^* with $\mu_{G^*} : G \rightarrow [0, 1]$.[7] In practice, for a given annotation $a \in G$, we propose that $\mu_{G^*}(a)$ is a function of the categorization for a; for example, with reference to Figure 2, we may consider that common forms have a lower degree of membership than proper forms. We are left to define Precision, Recall and F_1 measures for S with respect to G^*.

For a given system result S, gold standard G and its fuzzy version G^*, we propose that precision be computed in the traditional way for the crisp version of the gold standard – $P = \frac{|TP|}{|S|}$ – with the intuition that false positives proposed by the system (type I error) be weighted equally: if the system proposes an annotation, it should be correct, independently of the type of annotation. On the other hand, a gold standard annotation *not* proposed by the system may be due to different design choices; we hence propose to use a fuzzy recall measure with respect to G^*, namely $R^* = \frac{\sum_{a \in S} \mu_{G^*}(a)}{\sum_{a \in G} \mu_{G^*}(a)}$, thus applying different costs for missing annotations (type II errors) depending on the annotation in question. We then define the fuzzy F_1 measure in the natural way: $F_1^* = \frac{2 \cdot P \cdot R^*}{P + R^*}$. The following properties can be verified for R^* and F_1^*:

- PROP1: the values for R^* and F_1^* both range between 0 and 1, inclusive.

[7] For annotations $a \notin G$, we assume $\mu_{G^*}(a) = 0$.

- PROP2: when $\mu_{G^*} : G \rightarrow \{1\}$ (i.e., when memberships are binary), R^* and F_1^* correspond to R and F_1.

- PROP3: missing annotations with higher membership degree are penalized more in R^* and F_1^* than those with lower degree.

The definition of the membership function μ_{G^*} is then dependent on the setting. Here we define an instance of μ_{G^*} based on the questionnaire results shown in Figure 2. Specifically, we consider annotations with *Proper Forms*, *Noun Phrases*, *No Overlap* and *Direct Reference* – which consistently score greater than 0.9 in Figure 2 – to have a membership degree of 1; we consider these to be *strict* annotations. We assign all other annotations – which we call *relaxed* annotations – a constant membership degree of α, where higher values of α place more importance on achieving relaxed annotations; when $\alpha = 0$, relaxed false negatives are not punished; when $\alpha = 1$, both strict and relaxed false negatives are weighted equally.

Finally, the gold standard may offer multiple alternative links for a mention while the evaluated systems predict one link per mention. We apply the same procedure outlined previously: checking for each mention that the predicted link matches one of the alternatives in the gold standard. In the case of R^*, the membership score for a mention in G^* is given as the maximum membership score over all annotations/links for that mention in G^*; e.g., if a system predicts a link for a mention with weight α in G^* but there exists another link for that mention with weight 1 in G^*, the system will score $\frac{\alpha}{\max\{1,\alpha\}} = \alpha$ for that mention in R^*.

The F_1^* results are shown in Figure 5, where we again can distinguish the systems that link common entities – Babelfy (relaxed) and TagME – from those that do not; the former group of systems performs worse for stricter definitions of EL annotations, but outperform other systems as the definition is relaxed.[8] The raw data for these experiments can be found online.[9]

7 Conclusions

We have (i) presented the results of a questionnaire that assesses consensus on the goals of the EL task, (ii) proposed a fine-grained categorization scheme for EL annotations, (iii) comprehensively (re-)labeled three datasets accordingly to this scheme, (iv) presented results for five EL systems with respect to annotations in different categories, and (v) proposed fuzzy recall/F_1 measures to address the lack of consensus, presenting results for the five systems on a strict/relaxed spectrum.

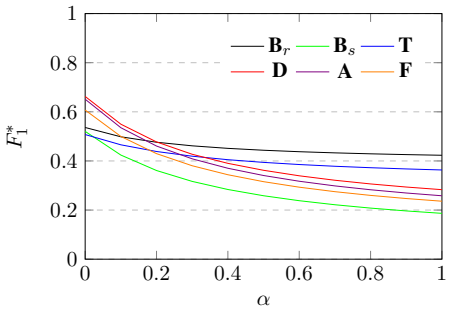

Figure 5: α-based fuzzy F_1 scores

Our main conclusions are as follows:

- Though there is consensus on some EL annotations, opinions differ for common entities, pro-forms, descriptive references, etc.

- The EL systems tested offer little or no support for pro-forms, meronymic references, referencing noun phrases, etc., despite there being considerable support for such EL annotations in the questionnaire.

- Our fine-grained evaluation distinguishes two groups of EL systems: one group targeting common entities and named entities, the other group focused on named entities.

The results of our questionnaire and system evaluation suggest the need for future work on supporting complex forms of reference within EL systems; the datasets we provide can be used to evaluate such approaches. Another important direction is to either reach a consensus on the EL task (perhaps in a similar style to MUC-6 for NER), or define protocols for evaluation in the absence of such a consensus; our fuzzy recall/F_1 metrics are concrete steps in this direction.

Acknowledgements The work of Henry Rosales-Méndez was supported by CONICYT-PCHA/Doctorado Nacional/2016-21160017. The work was also supported by the Millennium Institute for Foundational Research on Data (IMFD) and by Fondecyt Grant No. 1181896.

[8] We remark that P is agnostic to α and would result in a straight line; R^* thus follows the same trend as F_1^*.

Abstract

We propose a novel supervised open information extraction (Open IE) framework that leverages an ensemble of unsupervised Open IE systems and a small amount of labeled data to improve system performance. It uses the outputs of multiple unsupervised Open IE systems plus a diverse set of lexical and syntactic information such as word embedding, part-of-speech embedding, syntactic role embedding and dependency structure as its input features and produces a sequence of word labels indicating whether the word belongs to a relation, the arguments of the relation or irrelevant.

Comparing with existing supervised Open IE systems, our approach leverages the knowledge in existing unsupervised Open IE systems to overcome the problem of insufficient training data. By employing multiple unsupervised Open IE systems, our system learns to combine the strength and avoid the weakness in each individual Open IE system. We have conducted experiments on multiple labeled benchmark data sets. Our evaluation results have demonstrated the superiority of the proposed method over existing supervised and unsupervised models by a significant margin.

1 Introduction

Open Information Extraction (Open IE) extracts textual tuples consisting of a relation phrase and argument phrases from a sentence (Banko et al., 2007). Open IE was introduced as an alternative to traditional supervised information extraction (IE) method to address two major limitations of supervised approaches. First, supervised IE relies heavily on labeled training data. Since manual relation annotation is very expensive, this method does not scale to a large number of relations and is very difficult to adapt to new domains. Second, supervised IE systems require the target relations to be predetermined and learn to extract only the predefined relations. Therefore, they miss new and potentially meaningful domain relations that are prominent in a given dataset.

In contrast, Open IE operates in a completely domain-independent manner and is suitable when the target relations are not known in advance. Recently, Open IE has gained much attention, and various Open IE tools have been developed (Fader et al., 2011; Mausam et al., 2012; Akbik and Löser, 2012; Corro and Gemulla, 2013; Pal and Mausam, 2016; Yu et al., 2017; Kadry and Dietz, 2017; Roth et al., 2018; Stanovsky et al., 2018). Many Open IE systems demonstrated that they can scale to massive open-domain corpora such as the Web and Wikipedia (Banko et al., 2007), and the extracted tuples can be used as intermediate representation for various downstream NLP tasks such as knowledge base population (Soderland et al., 2010), question answering (Fader et al., 2014; Khot et al., 2017) and event schema induction (Mausam, 2016a).

Typically, these systems read in one sentence at a time and extract tuples with a relation phrase and one or more arguments. Most Open IE systems extract binary relations using domain-independent syntactic and lexical constraints. However, systems specialized in other syntactic constructions were also developed, such as noun-mediated relations (Pal and Mausam, 2016), n-ary relations (Akbik and Löser, 2012), nested propositions (Bhutani et al., 2016) and numerical Open IE (Saha et al., 2017a). Further, in recent years, there have been efforts to create a supervised Open IE system. (Stanovsky and Dagan, 2016) constructed an annotated corpus for Open IE, and (Stanovsky et al., 2018) and (Cui et al., 2018) used the annotated data to build a supervised Open IE system by formulating Open IE as sequence tagging and generation problems respectively.

However, while most existing Open IE systems

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 728–737, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

extract verbal relations, each of the systems focuses on different relational structures and extraction rules, resulting in heterogeneous results. Table 1 shows the different extraction results from the same sentence by three different Open IE systems. These variations makes it hard to compare different Open IE systems and select one for a new task, given their different strengths and weaknesses. This observation motivates us to explore an ensemble model which can learn from multiple existing Open IE systems which performs better than the underlying systems. This is especially attractive as no retraining or customization is needed to apply multiple existing Open IE systems.

In this paper, we propose a new Open IE method employing an ensemble of multiple unsupervised Open IE methods and a manually annotated data set. Similarly to (Stanovsky et al., 2018), we define Open IE as a sequence tagging problem and classify each word if it is a part of a relation, arguments or none. We first run several existing IE systems on the labeled data and use their extraction results as input features along with other rich features including word embedding, part-of-speech embedding, syntactic role embedding and syntactic dependency information. The model is then trained using the labeled data.

In this paradigm, our model can enjoy the advantages of both unsupervised Open IE approach and labeled data, since our model can learn the combined knowledge of the Open IE systems as well as optimized according to the labeled data. Evaluations with several benchmark datasets and Open IE systems show that our method outperforms the baseline systems by a large margin validating our hypothesis.

2 Supervised Ensemble of Open IE

In this work, we propose a new Open IE paradigm, a supervised ensemble of Open IE (*SenseOIE*). While there are many existing Open IE systems, each of the systems provides unique extraction rules and supports different relation constructs. This results in no single clear winner of the existing methods, when one tries to apply Open IE to a new data set. Rather, it would be more beneficial to apply multiple OpenIE systems and combine the wisdoms of all the systems. In this work we propose supervised ensemble of three different IE systems. These systems are Stanford Open IE(Angeli et al., 2015), OpenIE 5[1] and UKG (a private Open IE tool). Stanford Open IE is a dependency parser based system that uses handcrafted patterns to extract a predicate-argument triple from a sentence. On the other hand OpenIE 5 can extract verbal relation, nominal relation, relation with numeric argument and relation from consecutive sentences. UKG extracts verbal binary relations based on noun phrase detection, named entity recognition and dependency parsing. All three of these Open IE systems have different extraction rules and patterns focusing on extracting different relation tuples. Stanford Open IE, OpenIE 5 and UKG can complement each other when combined together. As a result, by ensembling these IE systems, our proposed system SenseOIE achieves better and larger coverage of all possible relation extractions. We utilize a small amount of labeled data to further optimize the model that can produce higher quality tuples.

2.1 System Overview

In this work, we consider extraction of binary relations from sentences. Let us consider an input sentence S. The goal of our system is to extract a set of relation tuples T from S, where $T = \{T_1, T_2, \ldots, T_n\}$ and the i-th tuple T_i consists of $< e_{i1}, r_i, e_{i2} >$, where r_i is the relation phrase of T_i and e_{i1} and e_{i2} are the first and second arguments of r_i. We frame this task as a sequence tagging, and the model annotates each word in the sentence to $E1$, $E2$, R or O (EOR tags). $E1$ and $E2$ denote the first and the second arguments, R is the relation, and O represents all other words. Figure 1 shows a system overview of *SenseOIE*.

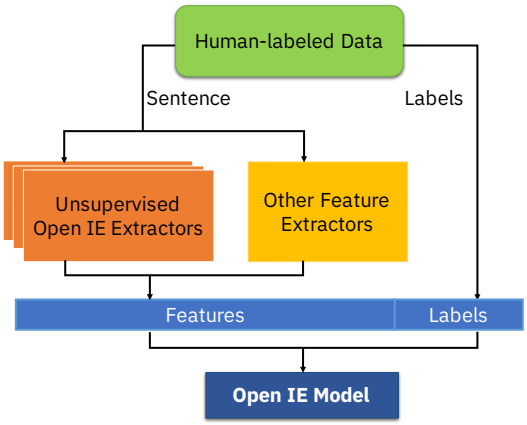

Figure 1: System Overview of *SenseOIE*

Table 1: Extracted tuples by different OpenIE systems for an input sentence

2.2 Features

For an input to our system, we extract features for each word in the corpus. We first collect the Open IE system outputs by 1) running the existing Open IE systems as a black-box on the labeled corpus, 2) mapping the extracted tuples back to the original input sentence, and 3) assigning the EOR tags to each word based on the outputs of each Open IE system. This gives us k EOR tags for each word from k Open IE tools (*e.g.*, 'E, E, O' by three Open IE systems). In addition to the Open IE results, we extract part-of-speech (pos) tags, syntactic role and dependency parse tree.

In particular, we consider dependency parse tree based on the one-hop neighbors (*i.e.*, parent and children) of a word in the dependency tree. We use $\text{parent}(w_i)$, the parent of word w_i, and $\text{left-child}(w_i)$ and $\text{right-child}(w_i)$, the closest left and right children of w_i.

Formally, given an input sentence S, we extract a feature vector $\mathcal{F}(w_i)$ for each word $w_i \in S$ defined as follows:

$$\begin{aligned}\mathcal{F}(w_i) =& emb(w_i) \oplus \mathcal{F}_B(w_i) \\ &\oplus \mathcal{F}_B(\text{parent}(w_i)) \\ &\oplus \mathcal{F}_B(\text{left-child}(w_i)) \\ &\oplus \mathcal{F}_B(\text{right-child}(w_i))\end{aligned}$$

where $\oplus$ denotes concatenation, $\mathcal{F}_B(w_i) = emb(pos(w_i)) \oplus emb(role(w_i)) \oplus EOR_{1,\ldots,k}(w_i)$; $pos(w_i)$ is the part-of-speech of w_i; $role(w_i)$ is the syntactic role of w_i; $emb(\cdot)$ is the respective embedding for the categorical input that can be trained as part of the model, or pre-trained; and $EOR_{1,\ldots,k}(w_i)$ represent the k EOR tags for w_i assigned by the k Open IE tools.

2.3 Model Architecture

Our system uses bidirectional long short term memory (Bi-LSTM) (Schuster and Paliwal, 1997) to aggregate features and classify the labels of a sequence of words. The advantage of using Bi-LSTM is that we can leverage the information from neighboring words from both sides. The outputs are used in softmax for each word, producing independent probability distributions over possible EOR tags

2.4 Implementation Details

We implement *SenseOIE* using the Keras framework (Chollet et al., 2015) with TensorFlow backend [2]. We use 2 layers of stacked bidirectional LSTM, each with 100 neurons with tanh activation. We use the RMSprop optimizer which is often recommended for recurrent neural network. The model is trained using early stopping to prevent over fitting. We use the batch size of 32 samples, with 10% word-level dropout. The word embeddings are initialized using the word2vec (Mikolov et al., 2013) Google News 300-dimensions pre-trained embeddings. The part of speech and syntactic role embeddings are 25 dimensional and randomly initialized and updated during training.

3 Experiments

We validate *SenseOIE* with several benchmark data sets and compare it with the state-of-the-art Open IE systems including (1) a supervised Open IE system by (Stanovsky et al., 2018); (2) three unsupervised Open IE systems, OpenIE5 [3], Stanford OpenIE [4] (Angeli et al., 2015) and UKG which is a proprietary Open IE tool.

3.1 Baseline Systems

RnnOIE is the first supervised model built for Open IE (Stanovsky et al., 2018). The model is based on a Bi-LSTM transducer and is trained using the annotated corpus built by the same research

[2] https://www.tensorflow.org/
[3] http://openie.allenai.org
[4] https://stanfordnlp.github.io/CoreNLP/openie.html

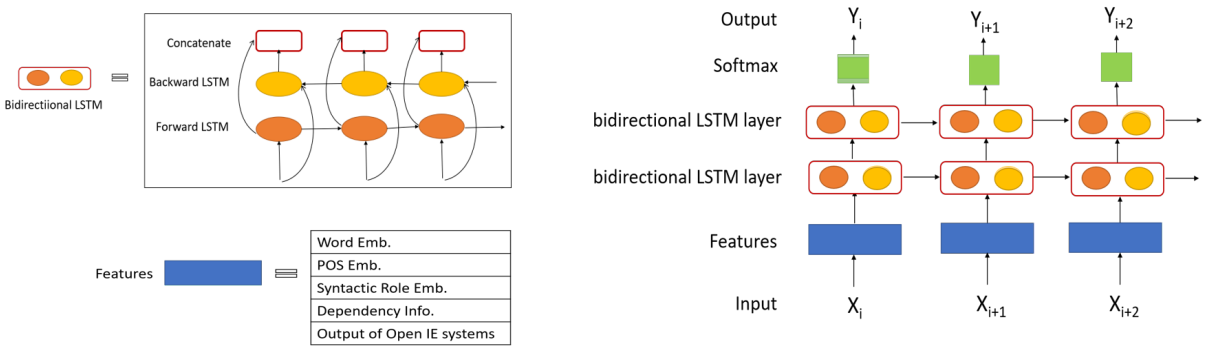

Figure 2: Model Architecture of *SenseOIE*

team (Stanovsky and Dagan, 2016). It takes a sentence and the word index of the predicate's syntactic head as input, and generates a feature vector for each word in the sentence by concatenating the word embeddings and POS tag embeddings of the word and the predicate head. Given these input features, the model learns whether the current word is part of argument of the particular predicate. At inference time, they first identify verbs and verb nominalization as candidate predicates and generate an input instance with each candidate predicate head.

Stanford Open IE is heavily based on dependency parsers. A classifier is learned for splitting a sentence into a set of logically entailed shorter clauses by recursively traversing its dependency tree and predicts whether an edge should yield an independent clause or not. In order to increase the usefulness of the extracted propositions, each self-contained clause is then maximally shortened by running natural logic inference over it. In the end, a set of 14 handcrafted patterns are used to extract a predicate-argument triple from each utterance.

OpenIE 5 is a combination of four Open IE systems CALMIE (Saha et al., 2018), BONIE (Saha et al., 2017b), RelNoun (Pal et al., 2016) and SRLIE (Christensen et al., 2011). SRLIE converts the output of a SRL system into an Open IE extraction by treating the verb as the relational phrase, and taking its role-labeled arguments as the arguments of the relation. On the other hand, RelNoun is a nominal Open IE system that extracts relations from compound noun phrases. BONIE focuses on extracting tuples where one of the arguments is a number or a quantity-unit phrase. CALMIE extracts information from conjunctive sentences by using language model based scoring and several linguistic constraints to search over hierarchical conjunct boundaries.

UKG was developed by some of this paper's authors as a tool to construct a knowledge graph for the cybersecurity domain, which contains information about cyber-incidents involving malware, campaign, and IoCs (Indicators of Compromise). It extracts verbal binary relations based on noun phrase detection, named entity recognition, dependency parsing. UKG currently extracts verbal binary relations from three dependency structures, 'NP-VP-NP', 'NP-VP-PP' and 'VP-NP-PP'. Named entity extraction is performed to detect cybersecurity-specific entities (e.g., malware names) and constrain the extractions to only cybersecurity-related relations (those with at least one argument being a cybersecurity entity). Further, UKG employs a coreference resolution, and coordination and apposition analysis to increase the recall of the extraction. To make UKG similar to other OpenIE systems for the evaluation, we did not run the cybersecurity named entity extraction but used all noun phrases as candidate arguments. Also, we did not apply the coreference resolution as other systems produce pronouns, not the referring nouns, as arguments.

Majority Votes is another baseline system that we compared with *SenseOIE*. In this system we simply take majority votes from three different IE systems that we used to generate input feature for *SenseOIE*.

3.2 Experiment Data

We use four different benchmark datasets to train and test the models. The datasets are AW-OIE (Stanovsky et al., 2018), WEB and NYT (de Sá Mesquita et al., 2013) and PENN (Xu et al., 2013). Table 2 presents more details on these datasets.

Data Set	# of Sentences	# of Tuples
AW-OIE	3,300	17,165
AW-OIE-C	3,300	13,056
WEB	500	461
NYT	222	222
PENN	100	51

Table 2: Data sets used in this work

AW-OIE corpus was created by extending the OIE2016 corpus released by (Stanovsky and Dagan, 2016). OIE2016 (Stanovsky and Dagan, 2016) was created by an automatic translation from question-answering driven semantic role labeling annotations (He et al., 2015). (Stanovsky et al., 2018) extended these techniques and apply them to the QAMR corpus (Michael et al., 2018) to create AW-OIE. This dataset is the largest dataset available for supervised open information extraction.

However, when we observe the information extracted from this dataset, we notice that the dataset is not accurate enough to be considered as a benchmark dataset. We often find missing relations and noise introduced during the automatic generation process. To solve this problem, we manually inspect the dataset and find several patterns causing this noise in the dataset. We use these patterns to filter out noisy and missing relations from the dataset and call the cleaned data set 'AW-OIE-C'.

The WEB dataset represents the challenges of dealing with web text. This contains many incomplete and grammatically unsound sentences. NYT contains formal, well written news stories from the New York Times Corpus. The PENN dataset was created from PENN Tree Bank. We use AW-OIE-C for training and testing purpose and other three datasets only for testing. We use 8,000 instances from AW-OIE-C to train *SenseOIE* and 1,456 instances to test all the models. We set aside 3,600 instances for a new experiment described in Section 3.4.

3.3 Performance Evaluation

In this section, we report the utility of our model by comparing its performance with the baseline systems on the four datasets (AW-OIE-C, WEB, NYT and PENN).

Evaluation Metric and Matching Function We compare the systems using precision, recall and F1-score. In order to compute the measures, we need to match the automated extractions by the systems and the ground truth extractions. In this work, we compute the measures based on tuple-level matching and word-level matching. Word-level matching has been used for the evaluation metric for many NER systems. For each word, we match the tag generated by the system with the word's label.

Tuple-level matching is used in other Open IE systems (Stanovsky et al., 2018; Cui et al., 2018). It is done by mapping extracted tuples with their corresponding benchmark tuples. One strategy for tuple matching would be to enforce an exact match by matching the boundaries of the extracted and benchmark tuples in text. However, as noted in earlier works (Stanovsky et al., 2018; Schneider et al., 2017), this method penalizes different but equally valid arguments, which are resulted from different annotation styles employed by different Open IE systems. Therefore, dealing with multiple OIE systems requires a less restrictive matching strategy. (Schneider et al., 2017) introduced *relaxed containment strategy*. With this strategy, extractions are counted correct as long as they contain all gold standard arguments. (Stanovsky et al., 2018) used a partial matching strategy allowing some variability (e.g., omissions of prepositions or auxiliaries) in the predicted tuples.

Following these works, we also use a partial matching strategy that allows all these kind of variabilities. We consider each argument or predicate correct, if it partially matches with the benchmark data over a certain threshold. This threshold can control the leniency or strictness of the matching function. This metric allows a more balanced and fair comparison between systems which can extract potentially correct arguments beyond benchmark extraction.

Comparison with the Baseline Systems Table 3 shows the tuple-level F1-score of *SenseOIE* and the benchmark systems. As we can see, *SenseOIE* outperforms all baseline systems with a large difference. On the AE-OIE-C dataset, *SenseOIE* achieves the highest F1-score of 0.79. In comparison with the unsupervised Open IE methods, the performance gain of *SenseOIE* ranges from 66% to 315%. *SenseOIE* outperforms OpenIE5 by 36% to 56%. When compared to UKG, *SenseOIE*'s performance gain ranges from 92% to 186%. In terms of *SenseOIE*'s performance over the different datasets, it's worth noting the differences in annotations in the different

	AW-OIE-C	Web	NYT	PENN	AW-OIE
SenseOIE	**0.79**	0.66	**0.41**	**0.52**	**0.72**
RnnOIE	-	**0.67**	0.35	0.44	0.62
OpenIE5	0.58	0.46	0.29	0.34	-
Stanford OpenIE	0.19	0.24	0.21	0.31	-
UKG	0.41	0.23	0.15	0.21	-
Majority Votes	0.40	0.42	0.24	0.27	-

Table 3: Performance (F1-score) comparison of *SenseOIE* and the baseline systems

datasets. As the test data from AW-OIE-C follows the same annotation style as the training data, the performance of *SenseOIE* is much higher on this dataset compared to other datasets.

Figure 3 shows the comparison results based on the word level F1-scores. The results also demonstrate that *SenseOIE* works better than the other systems. Especially, *SenseOIE* shows much higher accuracy in detecting words belonging to the arguments and the relation, but a slightly lower accuracy for other words.

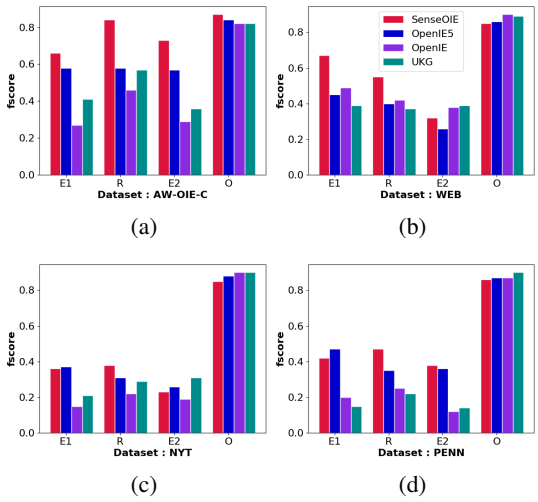

Figure 3: Word level F1-score comparison

Feature Ablation Study To investigate the contribution of each feature type on *SenseOIE*, we conducted a feature ablation study. Table 4 shows the F1-scores of several variations built with a different subset of our features. We note that the performance of *SenseOIE* is, on aevrage, 92% higher than the model using only the 'Embedding Features', which is similar to the features used in other supervised Open IE systems (Stanovsky et al., 2018; Cui et al., 2018). Overall the performance gain ranges from 13% to 156%. This performance boost proves that using an ensemble of multiple unsupervised OpenIE systems is very effective. The results also show that the ensemble of unsupervised Open IE results is more effective than the embedding features, and the combined features of the embeddings and Open IE results produce the best results. Surprisingly model without features from dependency parse tree outperforms *SenseOIE* in 2 out of 4 datasets. This might be indicator that simple concatenation is not the best way to include features from dependency tree.

3.4 *SenseOIE* as Annotator

Since *SenseOIE* outperforms the baseline systems by a large margin, we investigate if *SenseOIE* can be used to bootstrap a supervised Open IE model for new domains by automatically producing annotated data. Previously, (Cui et al., 2018) used OpenIE4 (Mausam, 2016b), an earlier version of OpenIE5, to automatically create a training dataset. The limitation of their approach is that using only one OpenIE system's extraction as ground truth will result in biased and low coverage of extracted relations. As each of the unsupervised OpenIE systems has it's own rules to extract different relations, applying only one system might miss other potential relations that can be extracted by other Open IE systems. However, since *SenseOIE* learns from multiple existing Open IE systems, it can extract many different relation types.

For this purpose, we run *SenseOIE* on the 3,600 instances from AW-OIE-C and use its extraction results as the ground truth to train a supervised model. We name this new model *SupervisedOIE* to differentiate it from *SenseOIE*. The model is quite similar to *SenseOIE* using LSTM to aggregate features and classify the labels of a sequence of words. The input features for each word are word embedding, pos embedding, syntactic role embedding, dependency tree information and label of previous word. During training label of pre-

	AW-OIE-C	Web	NYT	PENN

Embedding + Open IE Result Features	0.78	**0.69**	**0.45**	0.51
All Features	**0.79**	0.66	0.41	**0.52**

Table 4: Performance (F1-score) comparison of different feature sets. 'Embedding Features' denotes the concatenated set of word embedding, POS embedding and syntactic role embedding. 'Open IE Result Features' include only the EOR tags generated by the three unsupervised Open IE systems. 'All Features' consists of all the features as described in Section 2.2.

vious word comes from ground truth and during testing this value is predicted by the model. This feature is useful to generate multiple sequences of extractions from a single sentence. However, note that this model does not use the results of unsupervised systems as features. Figure 4 shows the architecture and features of *SupervisedOIE*.

During the inference time, to extract multiple relations from a single sentence, we use beam search to find multiple possible labels for each word. Instead of greedily choosing the most likely next step as the sequence is constructed, the beam search expands all possible next steps and keeps the k most likely results, where k is a user-specified parameter and controls the number of beams or parallel searches through the sequence of probabilities. Figure 5 shows an example of beam search predicting multiple relation extraction sequences from one sentence.

To validate the effectiveness of *SenseOIE* as an annotator model, we compare *SupervisedOIE*'s performance when trained with the human labeled data and *SenseOIE*'s extractions. As with *SenseOIE*, both models are initialized with the pre-trained word embedding and randomly initialize the part-of-speech and syntactic role embeddings. In this experiments, we set the beam size to 3 which gives an overall best performance. Table 5 shows the results from these two models. We can see that both models achieve similar F1-scores on the four test dataset. These results supports *SenseOIE*'s role as a digital annotator for unlabeled dataset.

4 Related Work

Early Open IE systems apply handcrafted rules or self-supervised learning paradigm, where the extraction results which satisfy a set of syntactic constraints are considered as positive examples and the results which do not satisfy the constrains are considered as negative examples. *TextRunner* (Banko et al., 2007) is the first domain-independent Open IE system. *ReVerb* (Fader et al., 2011) extracts verbal propositions from part of speech tags using a logistic regression classifier. OLLIE (Mausam et al., 2012) is built on *ReVerb* and extracts relations from syntactic and lexical dependency patterns. *ClausIE* (Corro and Gemulla, 2013) first classifies clauses into clause types and extract tuples based on the clause type using predefined rules. Followed by these systems, Stanford OpenIE (Angeli et al., 2015) and OpenIE5 are developed by combining several different approaches as described in details in Section 3.1. Further, several systems focusing on a specialized constructs were developed, including noun-mediated relations (Pal and Mausam, 2016), n-ary relations (Akbik and Löser, 2012), nested propositions (Bhutani et al., 2016) and numerical Open IE (Saha et al., 2017a).

Recently, there have been efforts to apply deep learning methods to Open IE. *RnnOIE* (Stanovsky et al., 2018) is the first attempt to apply a supervised learning approach for Open IE using the labeled data set from (Stanovsky and Dagan, 2016) (See Section 3.1). (Cui et al., 2018) propose an encoder-decoder framework with an attention-based copying mechanism to extract binary relation tuples. They formulated Open IE as a sequence-to-sequence generation problem. Instead of relying on manually labeled data,

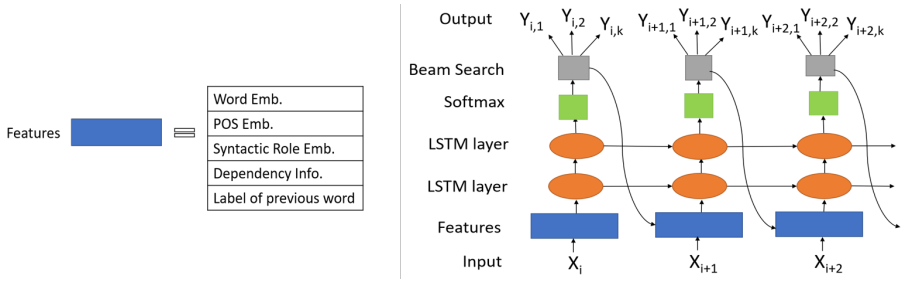

Figure 4: Model Architecture of a new *SupervisedOIE*

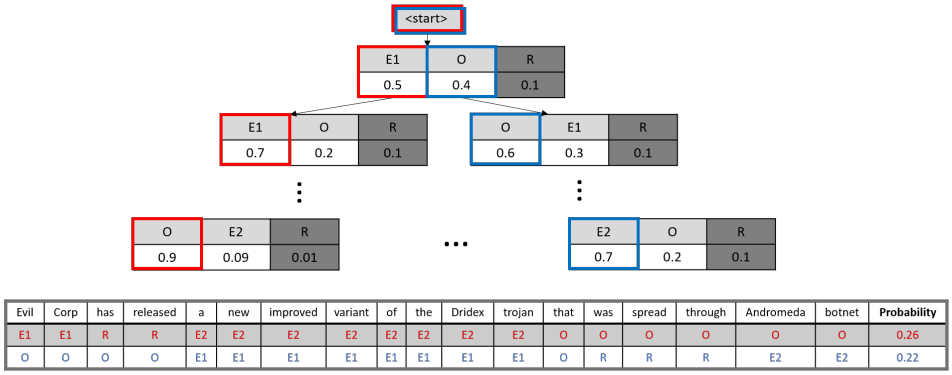

Figure 5: Example of beam search predicting multiple relation extraction sequences from one sentence

they train the model using the results of OpenIE4 (Mausam, 2016a) as labeled training data and evaluate the model using the human-labeled data from (Stanovsky and Dagan, 2016) as *RnnOIE* (Stanovsky et al., 2018). (Sun et al., 2018) present a supervised neural Open IE model for Chinese information extraction. They apply an attention-based sequence-to-sequence learning similarly to (Cui et al., 2018). However, they use the gated dependency attention mechanism based on the shortest path between a pair of words in the sentence's dependency tree. We do not compare our model with this system because it supports different target types and languages.

5 Conclusion

We propose a new Open IE paradigm which combines supervised learning and unsupervised Open IE systems. Our model uses the results of existing Open IE systems as features in addition to other linguistic features and then optimize the model using a small amount of labeled data. Validation using several benchmark data sets generated for the Open IE task shows that our method is very effective outperforming both other supervised and unsupervised Open IE systems.

Further, we investigate if our model can be applied to automatically generate annotated data to train a new supervised model for a new task. The experiment shows that a supervised model trained with the model-generated data performes similarly as the model trained with human labeled data. This result shows that our approach can overcome the cold-start problem in machine learning by leveraging existing unsupervised systems.

Abstract

The scarcity in annotated data poses a great challenge for event detection (ED). Cross-lingual ED aims to tackle this challenge by transferring knowledge between different languages to boost performance. However, previous cross-lingual methods for ED demonstrated a heavy dependency on parallel resources, which might limit their applicability. In this paper, we propose a new method for cross-lingual ED, demonstrating a minimal dependency on parallel resources. Specifically, to construct a lexical mapping between different languages, we devise a context-dependent translation method; to treat the word order difference problem, we propose a shared syntactic order event detector for multilingual co-training. The efficiency of our method is studied through extensive experiments on two standard datasets. Empirical results indicate that our method is effective in 1) performing cross-lingual transfer concerning different directions and 2) tackling the extremely annotation-poor scenario.

1 Introduction

Event detection (ED) is a crucial natural language processing problem that aims to identify event triggers in texts (Ahn, 2006; Nguyen and Grishman, 2015). For example, in the sentence: "*A man* **died** *when a tank* **fired** *on the hotel*", ED requires a system to identify two event triggers, **died** and **fired**, along with their types `Die` and `Attack`.

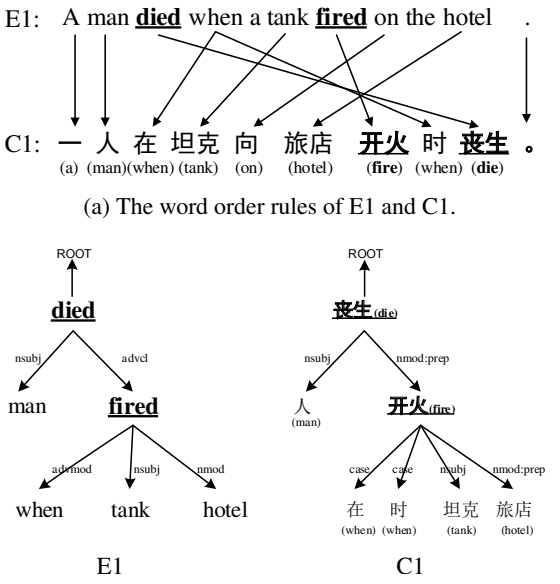
Generally, training an ED system requires to obtain a considerably large amount of labeled data. However, owing to the complexity and high costs of annotation, existing event resources are scarce and unbalanced across languages (Hsi et al., 2016), which prevents us from building an ED system in languages with insufficient training data. Cross-lingual ED (Ji, 2009; Chen and Ji, 2009; Zhu et al., 2014; Hsi et al., 2016; Liu et al., 2018a) aims to tackle this challenge by transferring knowledge cross languages to boost performance. However, previous cross-lingual ED methods rely on either high-performance machine translation (MT) systems trained on large numbers of parallel sentences or manually aligned documents to achieve a decent performance — the required parallel resources may only exist for a small fraction of language pairs (Koehn et al., 2007), which greatly limits the applicability of these methods.

In this paper, we propose a new simple but effective method for cross-lingual ED, which can overcome the data scarcity problem in annotation-poor languages by jointly training with resources in other languages. Compared with previous methods, our approach demonstrates a minimal dependency on parallel resources, which may fit with language pairs that do not have large bitexts.

To achieve cross-lingual transfer, two challenges exist: 1) how to build lexical mappings between different languages, and 2) how to handle the word order difference problem (Xie et al., 2018). For the first challenge, previous studies (Guo et al., 2015; Ni et al., 2017; Mayhew et al., 2017; Xie et al., 2018; Lample et al., 2018) have investigated embedding projection-based method in cross-lingual applications and achieved promising results. For example, (Xie et al., 2018) proposed a novel "cheap translation" based method which has greatly advanced the performance in zero-shot named entity recognition (NER). However, these methods may not directly fit with cross-lingual ED, as the lexical mapping in ED is usually context-dependent but not deterministic as in other tasks. Consider the following English-to-Chinese lexical mapping examples. To preserve its original meaning, the trigger word "fire" in "*gangsters* fire *at a policeman*" (which evokes an `Attack`

*Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 738–748, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics



event), and "*the house caught* fire" (which evokes an NA event) should be translated as different Chinese words "开 火(open fire)" and "着 火(be on fire)" respectively. But in previous lexical mapping methods, the "fired" is always having the same transferred representation irrespective of its contexts. This problem might introduce noise for cross-lingual ED.

To address the above issues, in this paper, we devise a content-dependent lexical mapping method for cross-lingual ED. Similar to (Xie et al., 2018), for each source word, we first project it into a shared embedding space, but instead of adopting a deterministic word-to-word translation, we retrieve different translation candidates by looking for its nearest neighbors, and we then adopt a context-aware selective attention mechanism to rank these candidates to find the best-suited translation. Compared with previous methods, our approach can obtain content-dependent translations for each word in the source training data, which may be more suitable for cross-lingual ED.

Considering the word order difference, to our best knowledge, (Xie et al., 2018) is the only work which adopted a self-attention mechanism (Vaswani et al., 2017) to tackle this problem (in cross-lingual NER). Difference with them, we propose a shared syntactic order event detector for cross-lingual ED, which explores the syntactic similarity of resources in different languages and circumvents the word order difference problem in performing multilingual co-training.

To illustrate our motivation, consider an English example E1 and its parallel Chinese translation C1 in Figure 1. As shown, E1 and C1 have rather different word orders (Figure 1a), but they share a similar syntactic structure which captures enough generality for identifying event triggers (Figure 1b). This observation motivates us to explore the syntactic similarity to achieve multilingual co-training. To achieve this goal, we propose a shared syntactic order event detector based on Graph Convolutional Networks (GCNs) (Kipf and Welling, 2016), which can provide each word a contextual feature based on its immediate neighbors in the syntactic graph irrespective of its original position in the sentence. This decoder allows us to train a model on multilingual resources effectively, which circumvents the word order different problem.

To estimate our method, we have conducted

(a) The word order rules of E1 and C1.

(b) The syntactic structures of E1 and C1.

Figure 1: The comparison of word orders and syntactic structures of an annotated English sentence E1 and its parallel Chinese sentence C1.

extensive experiments on two standard datasets, using English, Chinese, and Spanish as experimental languages respectively. The experimental results demonstrate that: 1) our model can perform cross-lingual transfer between different language pairs. Especially, the improvement in Chinese ED is large, with an absolute 3.8% in F1 over the monolingual approaches. 2) Our model is robust in the extreme annotation-poor scenario where a language has very limited training data, which demonstrates a definite advantage over previous monolingual models. Additionally, compared with MT-based methods, our model achieves competitive results but requires much less parallel resource.

This paper is organized as follows: Section 2 briefly introduces the task description and terminologies used in ED; Section 3 elaborates details of our approach; Section 4 reports on our experimental results and other analysis; Section 5 reviews related work; Section 6 concludes the paper and illustrates future work.

2 Task Description

Event detection (ED) is a subtask defined in the overall Event Extraction (EE) evaluation in Automatic Content Extraction (ACE) 2005 program. We first introduce some ACE terminologies to facilitate the understanding of ED task.

In ACE, 1) an **event mention** refers to a phrase/sentence within which an event is described. 2) **Event trigger** refers to a specific word in an event mention which is considered the most representative of the event. Each event trigger has a certain type corresponding to the event mention. 3) **Event arguments** are participants of the event.

With these definitions, the goal of ED is to locate event triggers and categorize their types. For example, in sentence "*The old man* **died** in the *hospital*", ED requires a system to detect a `Die` event along with the event trigger **died**. The detection of event arguments *The old man* (role=`Person`) and *hospital* (role=`Place`) is not involved in the ED task.

Following previous work (Nguyen and Grishman, 2015; Liu et al., 2016), we formulate ED as a token-level multi-class classification task. Namely, given a sentence, we treat every token in it as a trigger candidate, and we aim to classify each candidate into one of 34 categories (33 event types defined in ACE in addition to an `NA` type indicating "not an event trigger").

3 Methodology

This study focuses on cross-lingual ED, which aims to transfer knowledge from a source language with abundant labeled data to a target language with insufficient training data.

Figure 2 visualizes the overall architecture of our model, which consists of three main components: (1) Monolingual embedding layer, which transforms each token into a continuous vector representation. (2) Context-dependent lexical mapping, which maps each word in the source language to its best-suited translation in the target language, by examining its contextual representation and imposing a selective attention over different translation candidates. (3) Shared syntactic order event detector, which employs a Graph Convolutional Networks (GCNs) to explore syntactic similarity of resources of different languages, in order to achieve multilingual co-training.

For the sake of convenience, in the following illustrations, we assume the source language is English and the target language is Chinese, and we use an English sentence $s = \{w_1, w_2, \ldots, w_n\}$ to illustrate our idea.

3.1 Monolingual Embedding Layer

In the monolingual embedding layer, each word is assigned to a distributed vector as its representation. Specifically, we first train English/Chinese word embeddings on the corresponding Wikipedia dumps via Skip-gram model (Mikolov et al., 2013) with a dimensional size $d = 300$. And then we transform each token into its word embedding as its vectorized feature representation.

In this way, s is transformed into an embedding matrix $\boldsymbol{E}_s = [\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n]^T$, where $\boldsymbol{x}_i \in \mathbb{R}^d$ indicates the word embedding of the token w_i.

3.2 Context-Dependent Lexical Mapping

For each token w_i in s, context-dependent lexical mapping aims to search for its best-suited word translation according to its contextual representation. This process involves: 1) learning multilingual alignment, 2) retrieving translation candidates, and 3) ranking translation words via a selective attention mechanism.

3.2.1 Learning Multilingual Alignment

Let $\boldsymbol{X}$ and $\boldsymbol{Y}$ be the English and Chinese embedding spaces. In order to achieve multilingual alignment, we learn a mapping $\boldsymbol{W} \in \mathbb{R}^{d \times d}$ from $\boldsymbol{X}$ to $\boldsymbol{Y}$ via a seed dictionary with a size of m, by optimizing:

$$\boldsymbol{W}^* = \underset{\boldsymbol{W} \in M_d(\mathbb{R})}{\arg\min} ||\boldsymbol{W}\boldsymbol{X}_{dic} - \boldsymbol{Y}_{dic}||_F \quad (1)$$

where $M_d(\mathbb{R})$ is the space of $d \times d$ matrices; $\boldsymbol{X}_{dic}$, $\boldsymbol{Y}_{dic} \in \mathbb{R}^{d \times m}$ are two matrices containing the aligned embeddings of words in the seed dictionary; $||\cdot||_F$ indicates the Frobenius norm. To get a closed form solution, following (Xing et al., 2015; Lample et al., 2018), we impose an orthogonality constraint on $\boldsymbol{W}$ (i.e.,$\boldsymbol{W}\boldsymbol{W}^T$=$\boldsymbol{W}^T\boldsymbol{W}$=$\boldsymbol{I}$), and in this way, the optimized solution of $\boldsymbol{W}$ corresponds to the singular value decomposition (SVD) of $\boldsymbol{Y}_{dic}\boldsymbol{X}_{dic}^T$, i.e.,

$$\boldsymbol{W}^* = \underset{\boldsymbol{W} \in O_d(\mathbb{R})}{\arg\min} ||\boldsymbol{W}\boldsymbol{X}_{dic} - \boldsymbol{Y}_{dic}||_F = \boldsymbol{U}\boldsymbol{V}^T \quad (2)$$

where $\boldsymbol{U}\boldsymbol{\Sigma}\boldsymbol{V}^T = \mathrm{SVD}(\boldsymbol{Y}_{dic}\boldsymbol{X}_{dic}^T)$.

3.2.2 Retrieving Translation Candidates

Next, we retrieve translation candidates for each token w_i in s. Specifically, we first project w_i into the aligned embedding space (i.e., by applying $\boldsymbol{W}$ on $\boldsymbol{x}_i$), and then we explore its neighborhood to find the nearest Chinese words as its translation candidates. In order to measure the distance

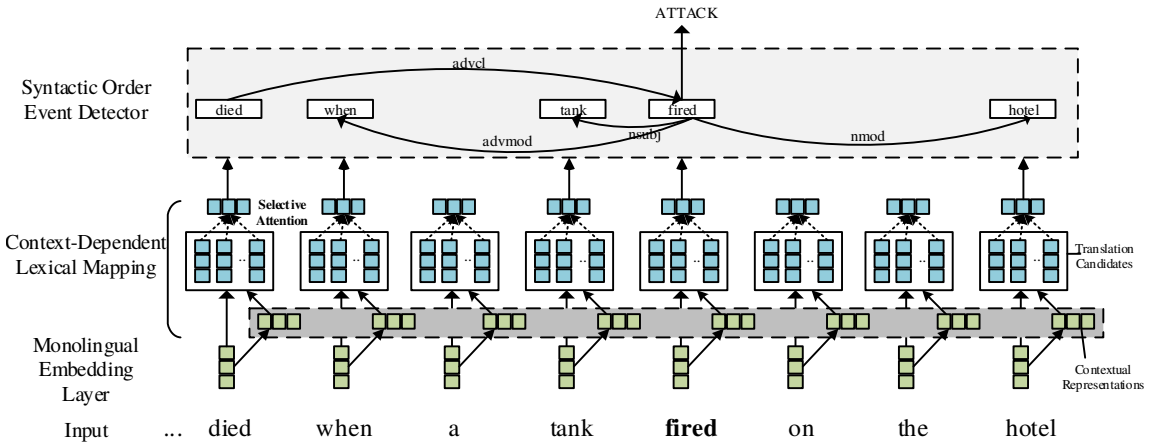


Figure 2: The overview architecture of our model. The figure illustrates the process of performing cross-lingual transfer for an English sentence "A man died when a tank fired on the hotel" into Chinese and using the shared syntactic order event detector to predict the event type for the word "fired".

of w_i and a Chinese word y in the aligned space, we adopt the cross-domain similarity local scaling (CSLS) metric (Lample et al., 2018):

$$\begin{aligned}\text{CSLS}(\boldsymbol{W}\boldsymbol{x}_i, \boldsymbol{y}) =& 2\cos(\boldsymbol{W}\boldsymbol{x}_i, \boldsymbol{y}) \\ & - r_{\boldsymbol{Y}}(\boldsymbol{W}\boldsymbol{x}_i) - r_{\boldsymbol{X}}(\boldsymbol{y})\end{aligned} \tag{3}$$

where $\boldsymbol{y}$ denotes the (Chinese) word embedding of y; $r_{\boldsymbol{Y}}(\boldsymbol{W}\boldsymbol{x}_i)$ indicates the mean cosine similarity between $\boldsymbol{W}\boldsymbol{x}_i$ and its K neighbors in $\boldsymbol{Y}$, which is defined as: $r_{\boldsymbol{Y}}(\boldsymbol{W}\boldsymbol{x}_i) = \frac{1}{K}\sum_{\boldsymbol{y}' \in \mathcal{N}_{\boldsymbol{Y}}(\boldsymbol{W}\boldsymbol{x}_i)} \cos(\boldsymbol{W}\boldsymbol{x}_i, \boldsymbol{y}')$ where $\mathcal{N}_{\boldsymbol{Y}}(\boldsymbol{W}\boldsymbol{x}_i)$ denotes the neighborhood associate with $\boldsymbol{W}\boldsymbol{x}_i$ in $\boldsymbol{Y}$. In our method, for w_i, we take J Chinese words which have the smallest CSLSs as its translation candidates. We denote by $T^{(w_i)}$ the set of translation candidates for w_i, where $T_j^{(w_i)}$ indicates the jth element of $T^{(w_i)}$.

3.2.3 Content-Aware Selective Attention

Finally, for each token w_i, we perform a context-aware selective attention mechanism to weigh each translation candidate in $T^{(w_i)}$ and get the best-suited translation for it.

Learning Contextual Representation. We employ the self-attention mechanism (Vaswani et al., 2017) to learn context representation of w_i. Specifically, given $\boldsymbol{E}_s = [\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_n]^T$, we use different single-layer neural networks to learn queries $\boldsymbol{Q}$, keys $\boldsymbol{K}$, values $\boldsymbol{V}$ respectively. For example, $\boldsymbol{Q} = \tanh(\boldsymbol{E}_s\boldsymbol{W}_m + \boldsymbol{b}_m)$, where $\boldsymbol{W}_m \in \mathbb{R}^{d\times d}$ and $\boldsymbol{b} \in \mathbb{R}^d$ are parameter matrix and bias respectively. Then, we compute a self-attention matrix by computing:

$$\boldsymbol{C}_s = \text{softmax}(\frac{\boldsymbol{Q}\boldsymbol{K}^\top}{\sqrt{d}})\boldsymbol{V} \tag{4}$$

$$= [\boldsymbol{c}_1, \boldsymbol{c}_2, \ldots, \boldsymbol{c}_n]^T \tag{5}$$

where d indicates the word embedding dimension. We take $\boldsymbol{c}_i$ as the contextual representation of w_i.

Learning Selective Attention. For each token w_i, after obtaining its translation candidates list $T^{(w_i)}$ and contextual representation $\boldsymbol{c}_i$, we impose a selective attention mechanism to automatically weigh each candidate. Specifically, the weight of the jth candidate $T_j^{(w_i)}$ is computed as:

$$\alpha_j = \frac{\exp(m_j)}{\sum_{i=1}^{J}\exp(m_i)} \tag{6}$$

where m_j measures the semantic relatedness of $\boldsymbol{c}_i$ and $T_j^{(w_i)}$, which is computed by:

$$m_j = \tanh([\boldsymbol{c}_i; \boldsymbol{y}_j^{(w_i)}]\boldsymbol{W}_r + b_r) \tag{7}$$

where [;] indicates the concatenation operations; $\boldsymbol{y}_j^{(w_i)}$ denotes the Chinese word embedding of $T_j^{(w_i)}$; $\boldsymbol{W}_r \in \mathbb{R}^{d\times 1}$ and $b_r \in \mathbb{R}$ are parameter matrix and bias respectively. Finally, we select the candidate which has the maximal attention weight as the best-suited translation for w_i, which is denoted by w_i'. In this way, the original sentence s is transfer into a Chinese word sequences $t = \{w_1', w_2', \ldots, w_n'\}$ with a same length.

3.3 Shared Syntactic Order Event Detector

As English and Chinese usually have different word orders, the transferred result t might be seen

as a corrupted sentences from Chinese, which could introduce noise for multilingual co-training. We tackle this problem by proposing a Graph Convolutional Neural Networks (GCNs) (Kipf and Welling, 2016) based syntactic order event detector, which provides each word with a feature vector based on its immediate neighbors in the syntactic graph irrespective of its position in the sentence. This allows our model to train with the translated data t and the other labeled data in Chinese indiscriminately.

3.3.1 Extracting Graph Convolution Feature

Specifically, for each token w_i, our model computes a graph convolution feature vector based on its immediate neighbors in the syntactic graph. Figure 3 illustrates the process of extracting the feature for "fired".

Let $\mathcal{N}(w_i)$ denote the set of neighbors of w_i in the syntactic graph, and $L(w_i, v)$ indicate the label of the dependency arc $(w_i \rightarrow v)$ (For example, L("fired", "hotel") = nmod in the example in Figure 3). The original GCNs compute a graph convolution vector for w_i at (k+1)th layer by:

$$\boldsymbol{h}_{w_i}^{k+1} = g\Big(\sum_{v \in \mathcal{N}(w_i)} (\boldsymbol{W}_{L(w_i,v)}^{k} \boldsymbol{h}_{v}^{k}) + \boldsymbol{b}_{L(w_i,v)}^{k}\Big) \tag{8}$$

where g denotes the ReLU function; $\boldsymbol{W}_{L(w_i,v)}^{k}$ and $\boldsymbol{b}_{L(w_i,v)}^{k}$ are parameters of the dependency label $L(w_i, v)$ in the kth layer. However, retaining parameters for every dependency label is space-consuming and compute-intense (there are approximately 50 labels), in our model, we limit $L(w_i, v)$ to have only three types of labels 1) an original edge, 2) a self loop edge, and 3) an added inverse edge, as suggested in (Nguyen and Grishman, 2018). Additionally, since the generated syntactic parsing structures usually contain noise, we apply attention gates on the edges to weigh their individual importances:

$$\alpha_{(w_i,v)}^{k} = \sigma(\boldsymbol{h}_{u}^{k} \boldsymbol{U}_{L(w_i,v)}^{k} + \boldsymbol{d}_{L(w_i,v)}^{k}) \tag{9}$$

where σ is the logistic sigmoid function. $\boldsymbol{U}_{L(w_i,v)}^{k}$ and $\boldsymbol{d}_{(w_i,v)}^{k}$ are the weight matrix and the bias of the gate. With this gating mechanism, the final syntactic GCNs computation in our model is:

$$\boldsymbol{h}_{\boldsymbol{u}}^{k+1} = g\Big(\sum_{\boldsymbol{v} \in \mathcal{N}(\boldsymbol{u})} \alpha_{\boldsymbol{u},\boldsymbol{v}}^{k} (\boldsymbol{W}_{L(\boldsymbol{u},\boldsymbol{v})}^{k} \boldsymbol{h}_{\boldsymbol{v}}^{k}) + \boldsymbol{b}_{L(\boldsymbol{u},\boldsymbol{v})}^{k}\Big) \tag{10}$$

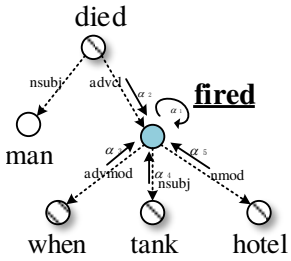

Figure 3: The illustration of using GCNs to compute the order-invariant feature for the word "fired".

We set the initial vectors $\boldsymbol{h}_{w_i}^{0}$ for w_i as the Chinese word embedding of w_i' (its translated word), and we stack 2 layers of GCNs (i.e., k = 2) to obtain the final feature for w_i, denoted as $\mathbf{f_i}$.

3.4 Event Type Classification

Our model incorporates a logistic regression classifier to predict w_i's event type. Specifically, we compute a prediction vector for w_i by taking $\boldsymbol{f}_i$ as the input:

$$\boldsymbol{out} = \text{softmax}(\boldsymbol{W}_o \boldsymbol{f}_i + \boldsymbol{b}_o) \tag{11}$$

where $\boldsymbol{W}_o \in \mathbb{R}^{d \times c}$ and $\boldsymbol{b}_o \in \mathbb{R}^{c}$ are parameters, and c is the total number of event types (i.e., 34 in this study). The probability of t-th class type is denoted as $P(t|w_i)$, which corresponds to the t-th element of $\boldsymbol{out}$.

3.5 Multilingual Co-Training

To enable multilingual co-training, we adopt the cross-entropy loss, and we use λ to balance the contribution of multilingual resources (which is set as 0.7 through a grid search):

$$J(\Theta) = -\lambda \sum_{w_e'} \log P(l_{w_e'}|w_e') - \sum_{w_c} \log P(l_{w_c}|w_c) \tag{12}$$

where Θ denotes all the parameters in our model; w_e' ranges over each token in the translated examples and w_c enumerate each token in the original Chinese training set; $l_{w_e'}$ and l_{w_c} denote the ground-truth event types of w_e' and w_c respectively. We adopt Adam rules (Kingma and Ba, 2014) to update our model's parameters and add dropout layers to prevent over-fitting.

4 Experiments

4.1 Datasets and Evaluation

Our main experiments are conducted on ACE 2005 and TAC KBP 2017, two widely used ED

datasets which contain annotated documents in English and Chinese (The documents are not parallel). For ACE English ED, we split the dataset to training/development/test set as suggested in (Li et al., 2013; Nguyen and Grishman, 2015). For ACE Chinese ED, we perform a 10-fold cross-validation as suggested in (Chen and Ji, 2009; Lin et al., 2018). For TAC KBP 2017 English and Chinese, we use the official test sets for testing, and we split the remaining data with a ratio of 9:1 for training and developing. The bilingual dictionary is obtained from the MUSE project[1] with a size of $5k$. The number of candidate translations J (in Section 3.2.2) is set as 3. We use the Stanford CoreNLP (Manning et al., 2014) to obtain syntactic trees for each language.

Precision (Pre.), Recall (Rec.), and F1-score (F1) are used as evaluation metrics, same as previous ED studies to ensure compatibility. Significant tests (with p=0.05) were conducted using method described in (Yeh, 2000).

4.2 Experimental Results

We conduct two groups of experiments to investigate the ability of our model in 1) performing cross-lingual transfer concerning different language directions, and 2) handling the annotation-poor scenario.

4.2.1 Cross-Lingual Transfer Concerning Different Language Directions

We investigate both English-to-Chinese and Chinese-to-English transfers to investigate whether cross-lingual transfer is feasible concerning different language directions. In these experiments, we jointly train on the translated data with all the labeled data in target language.

We compare our cross-lingual approach (*CL_Trans*) with our monolingual approach (*Monolingual*, which only uses the training data of the target language) and the existing state-of-the-art monolingual ED models (*Monolingual_SOTA*). In ACE ED, we take models proposed in (Nguyen and Grishman, 2015) and (Lin et al., 2018) as the SOTA English and Chinese ED systems respectively. In TAC KBP ED, we take the top systems reported in the official evaluation (Mitamura et al., 2017) as *Monolingual_SOTA*. We also include a vanilla embedding projection based method for comparison (denoted as *Embedding_proj*).

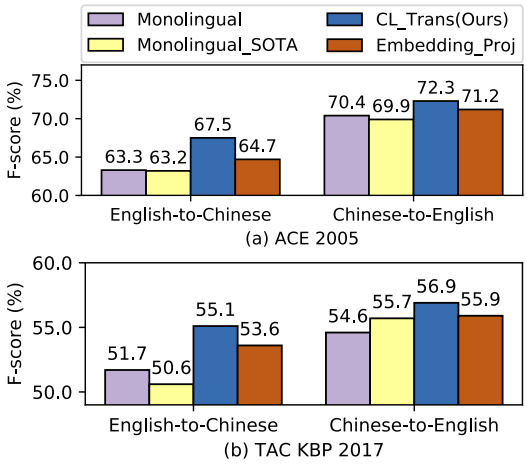

Figure 4: Experimental results on investigating cross-lingual transfer concerning different language directions.

Figure 4 summarizes the results. From the results, 1) our cross-lingual approach *CL_Trans* outperforms two monolingual systems (+2.95% on F1 on the average) and the vanilla embedding projection based method (+1.60% on F1), in the four evaluations. This justifies the effectiveness of our approach concerning cross-lingual in different language directions. 2) Additionally, our cross-lingual approach is more effective for Chinese (+3.80% on F1) than for English (+2.10% on F1). This is understandable as the number of English examples is much larger than that of Chinese examples (5,285 v.s. 2,710 in ACE 2005, and 24,979 v.s. 10,630 in TAC KBP 2017). 3) We obtain interesting findings by investigating each event type. For example, in TAC KBP 2017, the type of "contact/correspondence" has only 167 samples in Chinese but 996 samples in English. By adopting cross-lingual training, our approach leads to an improvement of 15.3% (from 10.3% to 25.6%) in Chinese ED for this type, compared with the monolingual approach. This proves that our method can handle the annotation sparseness problem in the target language.

4.2.2 Exploring the Annotation-Scarce Scenario

We next investigate the annotation-poor scenario, where the source language is set as English and the target language is set as Chinese to compare with previous works. In this scenario, we assume that only a few of annotated documents are available in

[1] https://github.com/facebookresearch/MUSE

Chinese.

In Comparison to Monolingual ED Models. We first compare our cross-lingual approach with the existing monolingual ED models, including *CNN* (Nguyen and Grishman, 2015) which employs Convolutional Neural Networks for the task and *Hbrid* (Feng et al., 2016) which combines CNN with Recurrent Neural Networks (RNN) for ED. Figure 5 presents the experimental results, where the number of the available Chinese documents ranges from 0 to 50.

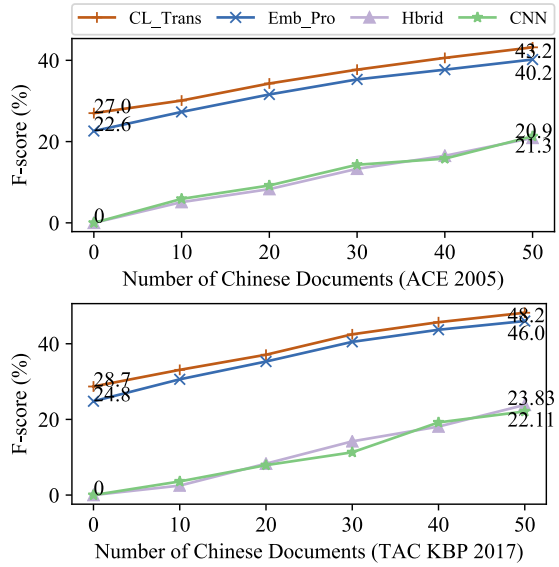

Figure 5: The comparison to monolingual ED models for Chinese ED in the annotation-poor scenario.

From the results, our approach demonstrates a definite advantage over monolingual ED models in the annotation-poor scenario. Particularly, when there is no Chinese training document available (i.e., in the unsupervised cross-lingual transfer scenario), our model achieves a performance of 27.0% on F1 in ACE, and 28.7% on F1 in TAC KBP, while supervised ED methods completely fail. Additionally, our approach can consistently outperform the embedding-projection method.

In Comparison to Cross-Lingual Models. We next compare our model to the existing cross-lingual ED methods, including 1) LexMap (Hsi et al., 2016), which combines embedding projection method with multilingual feature extraction to perform cross-lingual ED, and 2) MTED (Zhu et al., 2014), which uses a MT system to translate the training examples in source language to obtain additional data for training. In our re-implementation, we employ OpenNMT (Klein et al.) as the translation model and we use OpenSubtitles (Lison and Tiedemann, 2016) to train it. To ensure comparability of results, we use the setting of (Hsi et al., 2016) (i.e., using one-fold data (64 annotated documents) for training) to conduct the experiments.

Method	Pre.	Rec.	F1
LexMap (2016) (5k dict.)	**63.5**	28.8	39.6
MTBased (50k sent.)	11.3	16.8	13.5
MTBased (200k sent.)	42.4	26.1	32.3
MTBased (400k sent.)	54.7	**36.2**	43.7
CL_Trans (5k dict.)	62.5	35.7	**45.4**

Table 1: The comparison to cross-lingual ED models for Chinese ED in ACE 2005. (50k sent.) means using 50k parallel sentences to train the MT system.

Table 1 gives the results. From the results, 1) our method outperforms LexMap by a rather large margin (+5.8% on F1). The poor performance of LexMap might be attributed to its feature engineering process, which is often very difficult and requires expert knowledge. 2) Our model behaves competitively to machine translation based method (which are trained on 400k parallel sentences) yet relies on much less parallel resources (a dictionary with a size of 5k).

4.2.3 Ablation Study

We conduct ablation study to explore the effects of our different model components. We limit our study in the extremely annotation-poor scenario, that is, we assume there is no training data in the target language (Chinese).

Exploring Lexical Mapping Method. To explore our lexical mapping method, we compare the performance of several variant systems retrieving a different number of candidates (ranging from 1 to 5) and the embedding-projection method (Embedding_proj). Note the system retrieving only one candidate actually takes the nearest Chinese neighbor as the word translation. The lexical mapping in it is still context-independent. Table 2 summarizes the results.

From the results, we observe that 1) even though both of CL_Trans (1 cand.) and Embedding_proj are content-independent mapping methods, the former outperforms the latter by a margin (+3.2% on F1). This implies that the embedding-projection method might suffer from the misalignment in the shared embedding space, and enforcing a word-to-word alignment (as in CL_Trans (1 cand.)) could alleviate this problem to some ex-

Method	Pre.	Rec.	F1
Embbeding_Proj	26.0	20.0	22.6
CL_Trans (1 cand.)	31.2	21.4	25.4
CL_Trans (2 cand.)	31.7	22.3	26.2
CL_Trans (3 cand.)	**32.0**	23.4	**27.0**
CL_Trans (4 cand.)	30.7	**23.6**	26.7
CL_Trans (5 cand.)	30.2	**23.6**	26.5

Table 2: Experimental results in exploring different lexical mapping methods.

Model	Pre.	Rec.	F1
CL_Trans_MLP	20.3	16.3	18.1
CL_Trans_CNN	32.5	16.3	21.7
CL_Trans_Hbrid	30.4	17.6	22.3
CL_Trans_Self.	**34.9**	18.3	24.0
CL_Trans_GCN (ours)	32.0	**23.4**	**27.0**
CL_Trans_GCN_Self	32.1	23.0	26.8

Table 3: Experimental results in exploring the shared syntactic order event detector.

English	Chinese Translation Candidates
36,000	5.76, 98.8%, 2.53
people	**人(people)**, 人们(folk), 青年人(youngs)
died	**死(die)**, 死亡(death), 死去(dying)
every	**每个(every)**, 所有(all), 都(all)
year	**年(year)**, 年代(years), 年龄(age)
from	以外(beyond), **从(from)**, 外(except)
the	这(this), 整个(total), 完全(completely)
flu	感染(inflection), **流感(flu)**, 疾病(disease)

Table 4: Translation candidates of each English word. Bold indicates the best-suited translation.

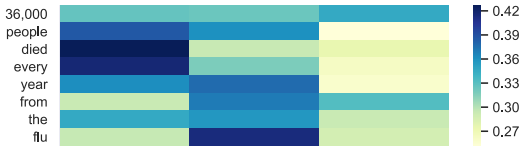

Figure 6: The learned attention weights. Darker color indicates higher weight.

tent. 2) Retrieving more translation candidates could consistently improve Recall. But when too many candidates (e.g., 5) are added, the Precision drops, which harms the overall F1 measure.

Exploring the Syntactic Order Event Detector. We compare our syntactic order event detector (CL_Trans_GCN) with several event detectors, including 1) *CL_Trans_MLP*, which employs a feed-forward network as event detector; 2) CL_Trans_CNN, which uses CNNs as the event detector; 3) CL_Trans_Hbrid, which use a hybrid network (Feng et al., 2016) for event detection. We also compared our model with several variants including 4) CL_Trans_Self., which replaces the GCNs with a self-attention network, and 5) CL_Trans_GCN_Self, which combines GCNs with a self-attention network. We train these models on the same translated English data. Table 3 shows the results.

From the results, 1) CL_Trans_MLP, CL_Trans_CNN, and CL_Trans_Hbrid behave poorly, as expected. The reason might be that these models usually employ order-sensitive structures (e.g., CNNs) for ED, which would suffer the word order inconsistency problem when trained on the translated data. 2) CL_Trans_Self. yields relatively good performance. The reason might be that self-attention network could provide each word with a feature vector based on all the words of a sentence, which is also irrespective of the words' positions in a sentence. This could address the word order difference to some extent. 3) Our syntactic order event detector yields the best performance. While, we do not observe salient advantages by combining GCNs with a self-attention network (by comparing CL_Trans_GCN with CL_Trans_GCN_Self).

4.3 Beyond English-Chinese Pair

We conduct additional experiments on Spanish to investigate cross-lingual transfer beyond English-Chinese transfer. The Spanish corpus is in TAC-KBP solely, with much smaller size and fewer publish evaluations. Experimental results demonstrate that, our model, without any modification, surpasses the best-reported Spanish system (42.8 (Mitamura et al., 2017) with F1 scores of 44.0 and 43.8 concerning EN $\rightarrow$ SP and CH $\rightarrow$ SP transfer. The value changes to 20.8 and 18.9 in zero transfer scenarios. This demonstrates that our approach is language-independent.

4.4 Case Study

We give a case study on the cross-lingual transfer process of a real example in ACE: "*36,000 people* **died** *every year from the flu*". Table 4 and Figure 6 gives the Chinese translation candidates and the learned attention weights respectively.

From the results, the best-suited translations indeed often correspond to larger attention weights, which implies the validity of our approach. In the above example, the Chinese words "从(from)" and "流感(flu)" do not correspond to the nearest

neighbor of “from” and ”flu”, but our content-dependent lexical mapping method enable us to successfully obtain them as the translations.

The case study also poses several future directions for this work. For example, one is how to address the one-to-many mapping between different languages. In the above example, the correct Chinese translation of “every year” should be one single word “每年”, not the combination of two words “每个(every)” and “年(year)”. This calls for more advanced lexical mapping methods.

5 Related Work

Event detection (ED) is a hot topic in natural language processing, which has attracted extensive attention in the past few years. Traditionally, the study of ED has focused on monolingual training. The proposed models can be divided into feature-based methods which employ fine-grained features (Ahn, 2006; Ji and Grishman, 2008; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2013; Li and Ji, 2014), and deep learning-based methods which employ neural networks to automatically learn features for the task (Chen et al., 2015; Nguyen and Grishman, 2015; Nguyen et al., 2016; Liu et al., 2018b; Orr et al., 2018; Liu et al., 2019). Usually, their performance is limited by the amount of labeled data in a specific language.

Cross-lingual ED attempts transfer knowledge between different languages to boost performance. To name a few, (Chen and Ji, 2009) used an English detector to label events on parallel documents to obtain additional data for boosting Chinese ED; (Zhu et al., 2014; Liu et al., 2018a) used machine translation to obtain additional labeled data for training; (Hsi et al., 2016) combined the embedding-projection method with multilingual feature extraction for bilingual ED. Nevertheless, the heavily dependency on parallel resources often limits the applicability of these methods.

Our study also relates to cross-lingual studies in other applications (Guo et al., 2015; Ni et al., 2017; Mayhew et al., 2017; Xie et al., 2018; Lample et al., 2018). These approaches adopted embedding projection based method to achieve cross-lingual transfer and achieved prosing results. However, since the lexical mapping in these methods is usually deterministic and irrespective of contexts, they might not directly fit with cross-lingual ED, where the cross-lingual transfer should be context-dependent.

6 Conclusions and Future Work

In this paper, we propose a new cross-lingual approach for event detection, which demonstrates a minimal dependency on parallel resources. Specifically, we propose a context-dependent lexical mapping method to obtain content-dependent translation, and we devise a shared syntactic order event detector to explore the syntactic similarity for multilingual co-training. Experiments demonstrate the effectiveness of our method.

Currently, as our approach is predicated on the availability of syntax trees of training examples, it might not fit with languages which lack syntactic parsers. In the future, we plan to investigate more language-independent patterns in cross-lingual transfer to circumvent this dependency.

Abstract

KnowledgeNet is a benchmark dataset for the task of automatically populating a knowledge base (Wikidata) with facts expressed in natural language text on the web. KnowledgeNet provides text exhaustively annotated with facts, thus enabling the holistic end-to-end evaluation of knowledge base population systems as a whole, unlike previous benchmarks that are more suitable for the evaluation of individual subcomponents (e.g., entity linking, relation extraction). We discuss five baseline approaches, where the best approach achieves an F1 score of 0.50, significantly outperforming a traditional approach by 79% (0.28). However, our best baseline is far from reaching human performance (0.82), indicating our dataset is challenging. The KnowledgeNet dataset and baselines are available at https://github.com/diffbot/knowledge-net

1 Introduction

Knowledge Bases (KBs) are valuable resources for developing intelligent applications, including search, question answering, data integration, and recommendation systems. High-quality KBs still rely almost exclusively on human-curated structured or semi-structured data. Such a reliance on human curation is a major obstacle to the creation of comprehensive, always-up-to-date KBs.

KB population (KBP) is the task of automatically augmenting a KB with new facts. Traditionally, KBP has been tackled with datasets for individual components to be arranged in a pipeline, typically: (1) entity discovery and linking (Ji et al., 2017; Shen et al., 2015) and (2) relation extraction (Angeli et al., 2015; Zhang et al., 2017). Entity discovery and linking seeks to recognize and disambiguate proper names in text that refer to entities (e.g., people, organizations and locations) by linking them to a reference KB. Relation extraction seeks to detect facts involving two entities (or an entity and a literal, such as a number or date).

KnowledgeNet is a benchmark dataset for populating a KB (Wikidata) with facts expressed in natural language on the web. KnowledgeNet facts are of the form (*subject*; property; *object*), where *subject* and *object* are linked to Wikidata. For instance, the dataset contains text expressing the fact (*Gennaro Basile*[1]; RESIDENCE; *Moravia*[2]), in the passage:

> "Gennaro Basile was an Italian painter, born in Naples but active in the German-speaking countries. *He* settled at Brünn, in *Moravia*, and lived about 1756..."

KnowledgeNet's main goal is to evaluate the overall task of KBP rather than evaluating its subcomponents in separate. We refer to this type of evaluation as *end-to-end*. The dataset supports the end-to-end evaluation of KBP systems by exhaustively annotating all facts in a sentence. For instance, the dataset contains all RESIDENCE facts (two) from the sentence "He settled at Brünn, in Moravia, and lived about 1756". This allows our evaluation to assess precision and recall of RESIDENCE facts extracted from this sentence.

A popular initiative to evaluate KBP is the Text Analysis Conference, or TAC (Getman et al., 2018). TAC evaluations are performed manually and are hard to reproduce for new systems. Unlike TAC, KnowledgeNet employs an automated and reproducible way to evaluate KBP systems at any time, rather than once a year. We hope a faster evaluation cycle will accelerate the rate of improvement for KBP.

In addition to providing an evaluation benchmark, KnowledgeNet's long-term goal is to provide exhaustively annotated training data at large

scale. Our goal for the coming years is to annotate *100,000 facts for 100 properties*. To accomplish this goal, we propose a new framework for annotating facts with high accuracy and low effort.

Contributions. Our contributions are as follows. We introduce KnowledgeNet, a benchmark dataset for end-to-end evaluation of KBP systems (Section 3). We propose a new framework for exhaustive yet efficient annotation of facts (Section 3.1). We implement five baseline approaches that build upon state-of-the-art KBP systems (Section 4). Finally, we present an experimental analysis of our baseline approaches, comparing their performance to human performance (Section 5).

2 Related Work

KBP has traditionally been tackled with pipeline systems. For instance, Stanford's TAC 2015 winning system employs the following pipeline: named entity recognition (NER) → entity linking → relation extraction (Angeli et al., 2015). Stanford's latest TAC system continues to use the same pipeline architecture with one additional component: coreference resolution (Chaganty et al., 2017).

The main shortcoming of pipeline systems is error propagation. Mistakes made by components in the beginning of the pipeline are propagated to the final output of the system, negatively affecting the overall precision and recall. For instance, our experiments show that the pipeline employed by Stanford's TAC 2015 winning system can achieve a maximum recall of 0.32 in KnowledgeNet[3].

End-to-end systems (Liu et al., 2018; Miwa and Bansal, 2016) are a promising solution for addressing error propagation. However, a major roadblock for the advancement of this line of research is the lack of benchmark datasets. We hope KnowledgeNet can help support this line of research.

2.1 Datasets

TAC is a series of evaluation workshops organized as several tracks by NIST (Getman et al., 2018). The Cold Start track provides an end-to-end evaluation of KBP systems, while other tracks focus on subtasks (e.g., entity disambiguation and linking). The Cold Start track is the current standard to evaluate KBP systems. To compete in this track, participants have a limited time window to submit the results of their KBP systems. After this window, the systems are evaluated by pooling facts extracted by the contestants. Despite its effectiveness for running a contest, this methodology has been shown to be biased against new systems, which are not part of the pooling (Chaganty et al., 2017). TAC also manually evaluates a system's "justification", a span of text provided as evidence for a fact. A correct fact with an incorrect justification is considered invalid. Therefore, reproducing TAC's evaluation for new systems is challenging.

We propose KnowledgeNet as an automated and reproducible alternative to TAC's evaluation. Before creating KnowledgeNet, we considered using one of the datasets presented in Table 1. We compare these datasets according to five criteria that we consider desirable for a KBP benchmark dataset:

- **Human annotation**: the dataset should be annotated by (multiple) humans to support accurate evaluation.
- **Exhaustive annotation:** for each property, the dataset should exhaustively enumerate all facts of that property that are expressed in the text. Exhaustive annotation allows measuring true precision and recall for a system.
- **Text annotation:** the dataset should contain text spans for entities involved in a fact. This allows evaluating whether the text expresses an extracted fact (as alternative to TAC's manual justification assessments).
- **Links to reference KB:** the dataset should contain a link to the reference KB for entities involved in every fact (or indicate that such an entity doesn't exist in the KB). This allows the evaluation to confirm that the reference KB is being correctly populated.
- **Cross-sentence facts:** the dataset should contain facts involving entities whose *names* never appear in the same sentence. This is because a significant portion of facts expressed in text require coreference resolution of entity mentions spanning multiple sentences.

ACE 2005[4] is a popular dataset for end-to-end relation extraction systems (Li and Ji, 2014;

[3]Maximum recall is the recall of candidate facts, which are used as input to the last component of the pipeline (relation extraction).

[4]https://catalog.ldc.upenn.edu/LDC2006T06

Dataset	**KnowledgeNet**	ACE	TAC	TACRED	FewRel	DocRED	GoogleRE	T-REx
Human annotation	yes	yes	yes	yes	yes	yes	yes	no
Exhaustive annotation	yes	yes	no	no	no	no	no	no
Exhaus. anno. sentences	9,000	11,000	N/A	N/A	N/A	N/A	N/A	N/A
Text span annotation	yes	yes	no	yes	yes	yes	no	yes
Links to reference KB	yes	yes	yes	no	yes	no	yes	yes
Cross-sentence facts	yes	yes	yes	no	no	yes	yes	yes
Annotated facts	13,000	8,000	84,000	22,000	56,000	56,000	40,000	11M
Properties	15	18	41	41	100	96	5	353
New KB facts annotated	77%	100%	100%	100%	0%	100%	0%	0%

Table 1: A dataset comparison according to our criteria for a desirable KBP benchmark dataset. "Exhaus. anno. sentences" shows the number of exhaustively annotated sentences. "New KB facts annotated" shows the percentage of annotated facts that can be found in the reference KB. Most datasets contain only facts with no links to a reference KB (100% new facts) or contain only facts that exist in the KB (0% new facts).

Miwa and Bansal, 2016). According to our criteria, ACE might seem the most complete benchmark dataset for end-to-end evaluation of KBP. It exhaustively annotates every sentence of 599 documents with mentions, coreference chains and facts for 18 properties. Also, ACE has been independently extended with links to Wikipedia (Bentivogli et al., 2010). However, a closer look at ACE's annotations reveals that most of them are ill-suited for general-purpose KBs. These annotations include facts about broad properties (e.g., part-whole, physical location) or mentions that do not refer to named entities (e.g., "two Moroccan men", "women on the verge of fainting", "African immigrants who came ashore Thursday"). Perhaps not coincidently, we are unaware of any work using it for the purpose of evaluating a KBP system.

Our annotation framework (Section 3.1) is inspired by ACE's framework but tailored towards KBP. First, we only annotate mentions that refer to named entities. Second, while our annotation is exhaustive, we focus on annotating sentences rather than documents, eliminating the need to annotate every fact described in the entire document. Such a requirement creates a significant imbalance in the number of annotations per property. For instance, the most popular property from ACE has 1,400 annotated facts, while the majority of properties from ACE have less than 300 annotated facts. This might explain why most relation extraction evaluations use only 6 properties from ACE.

Annotating every sentence with facts for all properties is also detrimental to the incremental nature of KnowledgeNet. Adding one property to the dataset would require an annotator to re-annotate every sentence in the dataset. In contrast, our framework selects a limited set of sentences to be annotated for a particular property. The remaining sentences are ignored during annotation and evaluation. As a consequence, our annotation framework allows incremental annotation of new properties and is better suited for the goal of annotating 100,000 facts for 100 properties.

Datasets employing non-exhaustive annotation. Recent datasets like T-REx automatically annotate facts in text as a way to produce training data cheaply. This is performed by aligning facts in the KB to sentences referring to them (Elsahar et al., 2018). Other datasets go further and use human annotators to label every alignment as correct or incorrect. These semi-supervised datasets include TACRED (Zhang et al., 2017), GoogleRE[5], FewRel (Han et al., 2018) and DocRED (Yao et al., 2019). Annotations created in this way are useful for training KBP systems. However, they do not provide an exhaustive annotation of facts, which is needed for end-to-end evaluation of KBP. For instance, Zhang et al. (2017) train their KBP system with TACRED, but rely on TAC to evaluate the system.

3 KnowledgeNet Dataset

This section discusses the first release of KnowledgeNet and our annotation framework. The documents in this first release are either DBpedia abstracts (i.e., first paragraphs of a Wikipedia page) or short biographical texts about a person or organization from the web. These web texts were collected using the Diffbot Knowledge Graph[6].

Table 2 presents the number of annotated facts for each property. We chose 9,073 sentences

[5] https://code.google.com/archive/p/relation-extraction-corpus/downloads

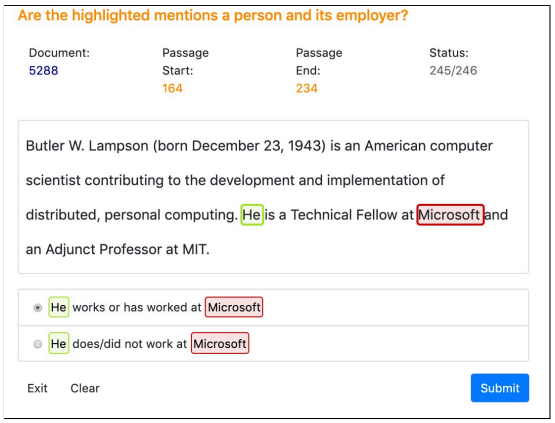
Total	13,425	9,073	5,423

Table 2: KnowledgeNet properties and their number of annotated facts and sentences. "Relevant" indicates the number of relevant sentences (i.e., those with one or more annotated facts). Subjects and objects belong to one of the following types: person, organization, location and date.

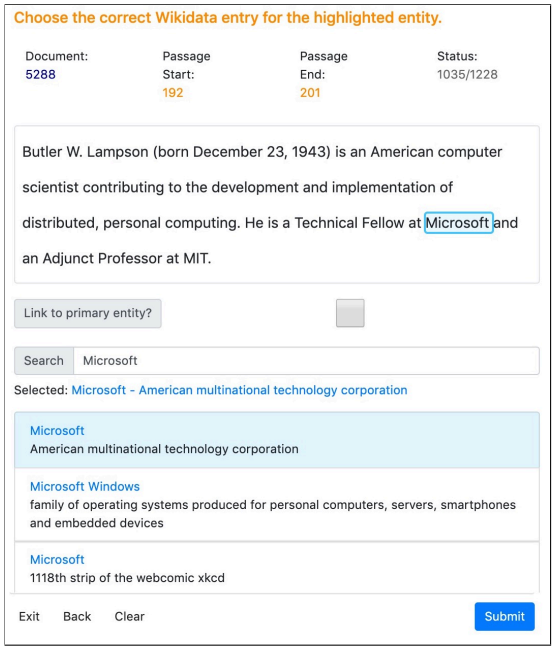
from 4,991 documents to be exhaustively annotated with facts about a particular property of interest. Because our annotation is exhaustive, negative examples of facts can be automatically generated. In total, KnowledgeNet comprises 13,425 facts from 15 properties.

Holdout test set. We split the documents into five folds in a round-robin manner, keeping the fifth fold (20% of the dataset) as the test set. To preserve the integrity of the results, we will release the test set without annotations and will provide a service through which others can evaluate their KBP systems. In our experiments, we used folds 1-3 for training and fold 4 for development and validation, including hyperparameter tuning.



3.1 Dataset Annotation

The dataset has been generated by multiple annotators using a new multi-step framework. We conjecture our framework can help annotators produce higher quality annotations by allowing them to focus on one small, more specific task at a time. The annotation consists of four different steps: (1) fetch sentences, (2) detect mentions, (3) classify facts and (4) link entities.



Step 1: Fetch sentences. We employ two methods of choosing a sentence for annotation. The first method leverages T-REx's automatic alignments (Elsahar et al., 2018) to find sentences that are likely to describe facts from Wikidata. The

(a) Interface to detect mentions of an entity type.

(b) Interface to classify facts.

(c) Interface to link a mention to a Wikidata entity.

Figure 1: Interface for Steps 2-4 of our framework. Step 1 fetches sentences to be exhaustively annotated for one property. The remaining steps guide annotators to detect entity mentions, facts and links in each sentence.

second method chooses sentences that contain a keyword that might indicate the presence of a fact for a property (e.g., *"born"* for DATE_OF_BIRTH). We have chosen these keywords by leveraging Wikidata's "also known as" values for properties as well as WordNet synonyms. By using these keywords, we prevent the dataset to be exclusively annotated with facts that are known in Wikidata. In fact, only 23% of facts annotated in this release are present in Wikidata.

For each fetched sentence, an annotator decides whether the sentence is *relevant* for the property of interest (i.e., whether this sentence describes one or more facts for this property). Relevant sentences go through steps 2 through 4; while irrelevant sentences are kept to be used for detecting incorrectly extracted facts (i.e., false positives).

It is worth noting that this step might not fetch some relevant sentences. Our framework does not require all relevant sentences to be annotated and does not penalize systems for extracting facts from sentences that were not annotated.

Step 2: Detect mentions. In this step, we ask annotators to highlight entity names (Figure 1a). We consider only entities whose type is relevant to the property being annotated. For instance, an annotator will only be asked to highlight names of people and organizations when annotating the property FOUNDED_BY. Pronouns are automatically annotated with a gazetteer. To decrease the likelihood of missing a mention, we consider the *union* of mentions highlighted by two annotators for the following step.

Step 3: Classify facts. We ask annotators to classify a candidate fact (i.e., a pair of mentions) in a sentence as a positive or negative example for a property (Figure 1b). Each candidate fact is annotated by at least two annotators. A third annotator breaks the tie when the first two annotators disagree.

We follow ACE's *reasonable reader rule*, which states that a fact should only be annotated when there is no reasonable interpretation of the sentence in which the fact does not hold. In other words, annotators are asked to only annotate facts that are either explicitly stated in the sentence or inferred with absolute certainty from the sentence alone (i.e., without using external world knowledge).

Step 4: Link entities. Finally, we ask annotators to link every mention involved in a fact to a single Wikidata entity. In this step, annotators can read the entire document and resolve mentions (e.g., pronouns) that refer to names in other sentences. Every mention is annotated by at least two annotators. When there is disagreement, we ask other annotators to join in the process until consensus is reached. In total, excluding the properties having literal objects (Table 2) we can assign a link to both subject and object for 52% of the facts.

Inter-annotator agreement. A total of five annotators have contributed to KnowledgeNet so far. In Step 3, the initial two annotators have annotated 33,165 candidate facts with 96% agreement. They disagreed on 1,495 candidate facts, where 599 have been deemed positive by a third annotator. In Step 4, the initial two annotators have annotated 13,453 mentions with agreement of 93%. The remaining 7% of mentions were resolved with additional annotators.

Timing. On average, annotating a sentence for one property takes 3.9 minutes. This total time includes two annotators (plus additional annotators for tiebreaking). It also includes inspecting sentences that express no facts and therefore do not go through steps 2-4 (but are included in the dataset and are helpful for assessing false positives). The most expensive step is Step 3 (40% of the total time), followed by Step 4 (28%), Step 2 (22%) and Step 1 (10%).

3.2 Limitations

Our first release is comparable to other benchmarks in size (e.g., ACE 2005), but it is perhaps insufficient to train data-hungry models. This is by design. Most organizations do not have the resources to produce tens of thousands of examples for each property of interest. As we expand the number of properties to achieve our goal of annotating 100,000 facts, we expect to keep the number of facts per property to around a thousand. In this way, we hope to promote approaches that can learn from multiple properties, requiring less annotations per property. We also hope to promote approaches using KnowledgeNet together with semi-supervised or unsupervised datasets for training.

Another limitation of our first release is the focus on individual sentences. Currently, our framework can only annotate a fact when the subject and

the object are explicitly mentioned by a name or pronoun in a sentence. Others have reported that the majority of facts fall into this category. For example, the authors of DocRED report that 41% of facts require reasoning over multiple sentences in a document (Yao et al., 2019). This indicates that a fact's subject and object are mentioned by their full name in a single sentence 59% of the time. The percentage of facts that can be annotated in KnowledgeNet is significantly higher than 59%. This is because our framework can also annotate facts that require resolving (partial) names and pronouns referring to full names in other sentences. These facts are particularly common in our document collection.

4 Baseline Approaches

This section presents five baseline approaches for KBP. We evaluate these approaches and compare their performance relative to human annotators in Section 5.

Figure 2 illustrates the architecture shared by our five baseline approaches. We start by splitting a given document into sentences. For each sentence, we detect entity mentions using a named entity recognizer (NER) and a gazetteer for pronoun mentions and their type (e.g., person, organizations, location). We also detect coreference chains, that is, groups of mentions within a document that refer to the same entity. Figure 2 illustrates how coreference chains help disambiguate pronouns and partial names by clustering them together with the full name of an entity. Finally, we link these coreference chains to Wikidata entities.

Next, we produce candidate facts by considering pair of mentions from the same sentence, as illustrated in Figure 2. The relation extraction component makes the final decision on whether a candidate fact is expressed by the text.

4.1 Relation Extraction

Figure 2 illustrates our relation extraction model. This model follow the literature by using a Bi-LSTM network (Miwa and Bansal, 2016; Xu et al., 2015; Zhou et al., 2016; Zhang et al., 2017), which is effective in capturing long-distance dependencies between words. We train a single multi-task model for all properties using both positive examples (i.e., annotated facts) and automatically generated negative examples.

The model outputs two values for each property. The first value represents the likelihood of the subject and object *mentions* (i.e., text spans) to be correct, while the second value represents the likelihood of the subject and object *links* to be correct. We learn individual thresholds for each value and property. When both values are above the threshold, the system outputs the fact with links. When the first value is above the threshold and the second value is below the threshold, we output the fact without links.

Features. Figure 3 illustrates features encoding syntactic and positional information, which are concatenated to the embedding of every word.

1. **Enriched NER:** NER label for names (using a NER system) and pronouns (using gazetteers for each type).
2. **Mention distance:** distance between each word and the subject and object mention, following Zhang et al. (2017).
3. **Shortest dependency path (SDP) length:** number of edges in the SDP between the word and the subject and object.
4. **SDP distance:** number of edges separating the word to the closest word in the SDP between the subject and object.
5. **Coreference confidence:** confidence score of the coreference resolution system that a word refers to the subject and object.
6. **Coreference distance:** distance to the closest mention in the coreference chain of the subject and object.
7. **Coreference SDP length:** number of edges in the SDP between the word and the closest mention in the subject and object chain.
8. **Coreference SDP distance:** number of edges separating the word to the closest word in the SDP between the subject and object coreference chains.
9. **KB entity types:** entity types for the subject and object from Wikidata.
10. **KB properties:** the property p where (*subject*; p; *object*) exists in Wikidata (when both the subject and object have links).

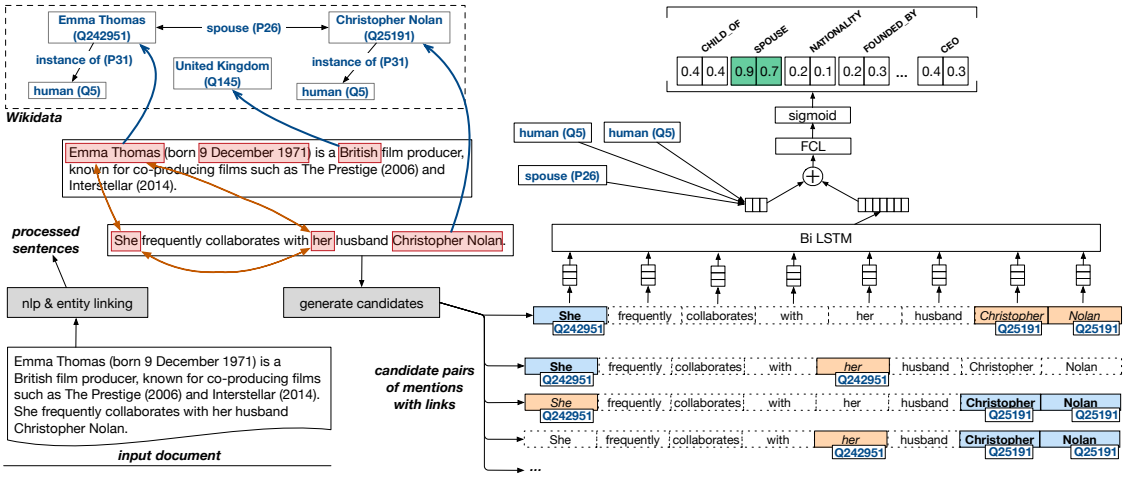


Figure 2: The architecture of our baseline approaches, illustrated with an example. Red arrows and boxes represent coreference chains and blue arrows represent links to Wikidata. The subject and object of candidate facts are highlighted in bold (blue) and italics (orange), respectively.

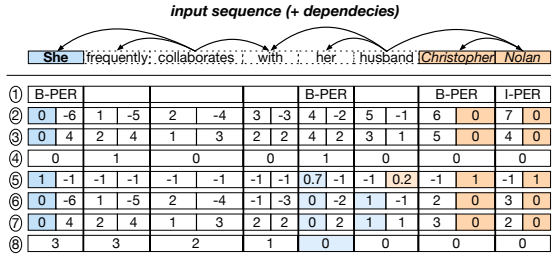

Figure 3: Features representing the relationships between the words. Significant relationships with the subject and object are highlighted in blue and orange, respectively.

Features 9 and 10 are generated by querying Wikidata and are relative to a single entity pair. We concatenate those features to the Bi-LSTM output, as illustrated in Figure 2.

4.2 Baseline Approaches

We propose five baselines obtained by improving the candidate generation and relation extraction components.

Baseline 1. Our first baseline is a standard pipeline approach inspired by the TAC 2015 Cold Start winning system (Angeli et al., 2015). It generates candidate mentions by using NER and the pronoun gazetteers. For mentions of the correct type (e.g., person for the property SPOUSE), the system then links these mentions using an entity linking system. The relation extraction component uses features 1-4.

Baseline 2. Our second baseline adds coreference resolution. This baseline is inspired by Stanford's TAC 2017 system (Chaganty et al., 2017). We leverage coreference chains to both increase the number of candidate mentions linked to KB entities (e.g., pronouns) as well as to introduce additional features. This model uses features 1-8.

Baseline 3. Our third baseline adds features 9 and 10 to the relation extraction model. These features leverage Wikidata information for the linked entities, such as entity types and known facts.

Baseline 4. Our fourth baseline seeks to decrease error propagation by allowing more candidate facts to be evaluated by the relation extraction component. This is done in two ways. First, Baseline 4 uses all mentions regardless of their NER type when creating candidate facts. Second, this baseline adds a candidate link to mentions that had no candidate link in Baseline 1-3 (due to incorrect coreference chains). This is done by choosing a link outside of the mention's coreference chain that maximizes a combination of entity linking score and coreference resolution score.

Baseline 5. Our final baseline seeks to improve the relation extraction component by employing BERT's pre-trained representations (Devlin et al., 2018) in addition to all other features. To produce a contextual representation for every word, we learn a linear weighted combination of BERT's 12 layers, following Peters et al. (2019).

4.3 Implementation

All our baseline systems follow the same architecture (Figure 2). We use spaCy[7] for the NLP pipeline (sentence splitting, tokenization, POS tagging, dependency parsing, NER), Hugging Face's coreference resolution system[8], and the Diffbot Entity Linker[9] for entity linking.

For relation extraction we implement a standard BiLSTM network with two 500-dimensional hidden layers. We use spaCy pre-trained word embeddings (size 300) concatenated with additional features illustrated in Figure 3. The output of the BiLSTM network is concatenated with features from Wikidata (Features 9-10).

We train all the networks using mini-batches of 128 examples and Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.001. We use the fourth fold of the dataset as validation set, selecting the model that minimize the loss function value. The same validation set is used to find thresholds for the output values that maximize the F1 score for each property.

5 Experiments

Table 3 presents the performance of our baseline systems compared to the human performance. We report precision (P), recall (R) and F-score ($F1$):

$$P = \frac{\text{correctly extracted facts}}{\text{extracted facts}},$$

$$R = \frac{\text{correctly extracted facts}}{\text{annotated facts}},$$

$$F1 = \frac{2 \cdot P \cdot R}{P + R}.$$

We evaluate our baseline systems from two perspectives. The *text evaluation* deems an extracted fact correct when the text spans of the subject and object overlap with the text spans of a ground truth fact. The *link evaluation* deems an extracted fact correct when the links of the subject and object match the links of a ground truth fact. In the link evaluation, we consider only facts where both the subject and object links are present.

Human performance. To measure the human performance on the end-to-end KBP task, one of our annotators was asked to enumerate all facts described in a sample of the test sentences. We report the performance of our annotator in Table 3.

[7] https://spacy.io/
[8] https://huggingface.co/coref/
[9] https://diffbot.com/

System	Text evaluation			Link evaluation		
	P	R	F1	P	R	F1
Baseline 1	0.44	0.64	0.52	0.31	0.26	0.28
Baseline 2	0.49	0.64	0.55	0.37	0.32	0.34
Baseline 3	0.47	0.66	0.55	0.35	0.37	0.36
Baseline 4	0.60	0.65	0.62	0.51	**0.48**	0.49
Baseline 5	**0.68**	**0.70**	**0.69**	**0.53**	**0.48**	**0.50**
Human	0.88	0.88	0.88	0.81	0.84	0.82

Table 3: The performance of our baseline approaches is well below human performance.

A closer look at the annotator's mistakes shows that 32% of the mistakes are due to incorrect annotations in KnowledgeNet (i.e., the annotator is actually correct). The remaining mistakes (68%) are mostly due to the annotator entering an incorrect fact (30%) or missing a link on a correct fact (18%). These results show that our annotation framework produces significantly better annotations than individual annotators working without our framework.

Baseline performance. Table 3 presents the performance of our baselines. Our best baseline (Baseline 5) significantly outperforms the standard pipeline approach (Baseline 1) in both the text and link evaluation. However, the performance of Baseline 5 is well below the human performance. The most impactful improvements over Baseline 1 are due to (a) incorporating coreference when choosing candidate links for pronouns in Baseline 2; (b) allowing more candidate facts and links to be classified by the relation extraction component in Baseline 4; and (c) incorporating BERT's pre-trained model in Baseline 5.

Table 4 shows the "maximum recall" for each baseline (i.e., recall of candidate facts used as input for the relation extraction component). These results indicate that error propagation significantly limits recall. Our best baseline shows higher maximum recall due to coreference resolution (introduced in Baseline 2) and removing the filtering of candidate facts based on NER types (introduced in Baseline 4). The low maximum recall for link evaluation is mainly due to incorrect candidate links, which can only be omitted (but not fixed) in our baselines.

6 Conclusion

We introduce KnowledgeNet, an end-to-end benchmark dataset for populating Wikidata with facts expressed in natural language text on the

System	Text evaluation	Link evaluation
	Maximum Recall	Maximum Recall
Baseline 1	0.80	0.33
Baseline 2	0.80	0.37
Baseline 3	0.80	0.37
Baseline 4	0.90	0.59
Baseline 5	0.90	0.59

Table 4: The relation extraction component's recall is limited by error propagation. Maximum recall is the recall of the candidate facts used as input for the relation extraction component on the dev set.

web. We build KnowledgeNet using a new multi-step framework that helps human annotators to produce high-quality annotations efficiently. We also introduce five baseline systems and evaluate their performance. Our best baseline outperforms a traditional pipeline approach by 79% (F1 score of 0.50 vs. 0.28). Human performance is significantly higher (0.82), indicating that KnowledgeNet can support further research to close this gap.

Our experiments show that the traditional pipeline approach for KB population is notably limited by error propagation. Performance gains achieved by our best baseline are mainly due to more candidates being passed along to the final pipeline component (relation extraction), allowing this component to fix errors made by previous components. A closer inspection reveals that even our best baseline is fairly limited by error propagation and can only achieve a maximum recall of 0.59. These results indicate that end-to-end models might be a promising alternative to the traditional pipeline approach.

Acknowledgments

We would like to thank Veronica Romualdez and Geraldine Fajardo for their diligent annotation work. We would also like to thank Mike Tung, Zhaochen Guo, Sameer Singh and the anonymous reviewers for their helpful comments. A Beyond Binary Relationships

While it would be convenient to express all facts as (*subject*; property; *object*) triples, this is not always possible. Many facts require further annotations to be sufficiently and accurately expressed in the KB. Take for instance (*United States*; head_of_government; *Barack Obama*), which only holds true in the past.

Qualifiers allow facts to be expanded or contextualized beyond what can be expressed with binary relationships. More specifically, qualifiers can be used to constrain the validity of a fact in time or space, e.g., (*employment fact*; end_time; *2017*); represent n-ary relationships, e.g., (*casting fact*; character_role; *Tony Stark*); and track provenance.

This release contains 4,518 facts annotated with three *temporal qualifiers*: IS_CURRENT, START_TIME and END_TIME. We use one of our baseline system to obtain facts to be annotated with qualifiers, along with the the sentence where each fact was found. Given a fact and a sentence, human annotators must decide the value of a qualifier (*true* or *false* for IS_CURRENT or a time expression for START_TIME, END_TIME). A third option *unclear* can be chosen in the case of uncertainty. To be included in the dataset, each fact must be annotated by two annotators in agreement. While preliminary experiments show promising results for qualifier extraction, they are out-of-scope of this work.

Effective Use of Transformer Networks for Entity Tracking

Aditya Gupta and **Greg Durrett**
Department of Computer Science
The University of Texas at Austin
{agupta,gdurrett}@cs.utexas.edu

Abstract

Tracking entities in procedural language requires understanding the transformations arising from actions on entities as well as those entities' interactions. While self-attention-based pre-trained language encoders like GPT and BERT have been successfully applied across a range of natural language understanding tasks, their ability to handle the nuances of procedural texts is still untested. In this paper, we explore the use of pre-trained transformer networks for entity tracking tasks in procedural text. First, we test standard lightweight approaches for prediction with pre-trained transformers, and find that these approaches underperform even simple baselines. We show that much stronger results can be attained by restructuring the input to guide the transformer model to focus on a particular entity. Second, we assess the degree to which transformer networks capture the process dynamics, investigating such factors as merged entities and oblique entity references. On two different tasks, ingredient detection in recipes and QA over scientific processes, we achieve state-of-the-art results, but our models still largely attend to shallow context clues and do not form complex representations of intermediate entity or process state.[1]

1 Introduction

Transformer based pre-trained language models (Devlin et al., 2019; Radford et al., 2018, 2019; Joshi et al., 2019; Yang et al., 2019) have been shown to perform remarkably well on a range of tasks, including entity-related tasks like coreference resolution (Kantor and Globerson, 2019) and named entity recognition (Devlin et al., 2019). This performance has been generally attributed to the robust transfer of lexical semantics to downstream tasks. However, these models are still better at capturing syntax than they are at more entity-focused aspects like coreference (Tenney et al., 2019a,b); moreover, existing state-of-the-art architectures for such tasks often perform well looking at only local entity mentions (Wiseman et al., 2016; Lee et al., 2017; Peters et al., 2017) rather than forming truly global entity representations (Rahman and Ng, 2009; Lee et al., 2018). Thus, performance on these tasks does not form sufficient evidence that these representations strongly capture entity semantics. Better understanding the models' capabilities requires testing them in domains involving complex entity interactions over longer texts. One such domain is that of procedural language, which is strongly focused on tracking the entities involved and their interactions (Mori et al., 2014; Dalvi et al., 2018; Bosselut et al., 2018).

This paper investigates the question of how transformer-based models form entity representations and what these representations capture. We expect that after fine-tuning on a target task, a transformer's output representations should somehow capture relevant entity properties, in the sense that these properties can be extracted by shallow classification either from entity tokens or from marker tokens. However, we observe that such "post-conditioning" approaches don't perform significantly better than rule-based baselines on the tasks we study. We address this by proposing entity-centric ways of structuring input to the transformer networks, using the entity to guide the intrinsic self-attention and form entity-centric representations for all the tokens. We find that our proposed methods lead to a significant improvement in performance over baselines.

Although our entity-specific application of transformers is more effective at the entity track-

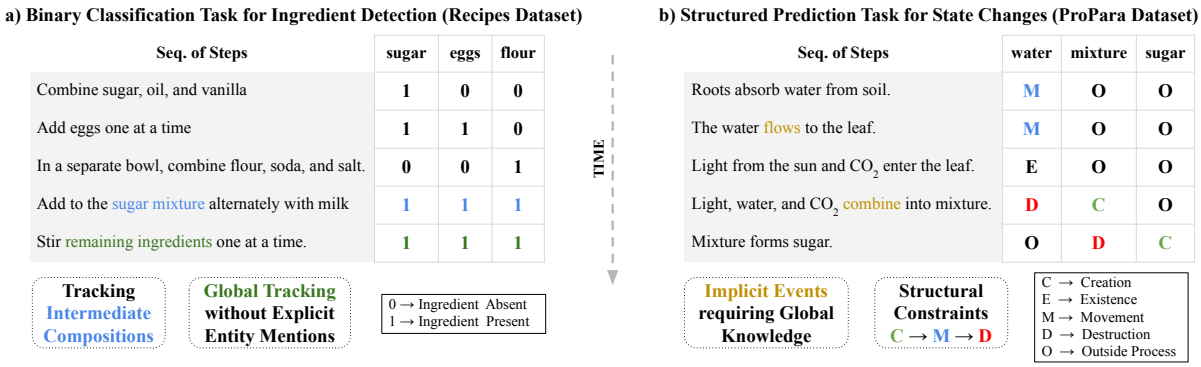

Figure 1: Process Examples from (a) RECIPES as a binary classification task of ingredient detection, and (b) PROPARA as a structured prediction task of identifying state change sequences. Both require cross-sentence reasoning, such as knowing what components are in a *mixture* and understanding verb semantics like *combine*.

ing tasks we study, we perform additional analysis and find that these tasks still do not encourage transformers to form truly deep entity representations. Our performance gain is largely from better understanding of verb semantics in terms of associating process actions with entity the paragraph is conditioned on. The model also does not specialize in "tracking" composed entities per se, again using surface clues like verbs to identify the components involved in a new composition.

We evaluate our models on two datasets specifically designed to invoke procedural understanding: (i) RECIPES (Kiddon et al., 2016), and (ii) PROPARA (Dalvi et al., 2018). For the RECIPES dataset, we classify whether an ingredient was affected in a certain step, which requires understanding when ingredients are combined or the focus of the recipe shifts away from them. The PROPARA dataset involves answering a more complex set of questions about physical state changes of components in scientific processes. To handle this more structured setting, our transformer produces potentials consumed by a conditional random field which predicts entity states over time. Using a unidirectional GPT-based architecture, we achieve state-of-the-art results on both the datasets; nevertheless, analysis shows that our approach still falls short of capturing the full space of entity interactions.

2 Background: Process Understanding

Procedural text is a domain of text involved with understanding some kind of process, such as a phenomenon arising in nature or a set of instructions to perform a task. Entity tracking is a core component of understanding such texts.

Dalvi et al. (2018) introduced the **PROPARA** dataset to probe understanding of scientific processes. The goal is to track the sequence of physical state changes (creation, destruction, and movement) entites undergo over long sequences of process steps. Past work involves both modeling entities across time (Das et al., 2019) and capturing structural constraints inherent in the processes (Tandon et al., 2018; Gupta and Durrett, 2019) Figure 1b shows an example of the dataset posed as a structured prediction task, as in (Gupta and Durrett, 2019). For such a domain, it is crucial to capture implicit event occurrences beyond explicit entity mentions. For example, in *fuel goes into the generator. The generator converts mechanical energy into electrical energy*", the *fuel* is implicitly destroyed in the process.

Bosselut et al. (2018) introduced the task of detecting state changes in recipes in the **RECIPES** dataset and proposed an entity-centric memory network neural architecture for simulating action dynamics. Figure 1a shows an example from the RECIPES dataset with a grid showing ingredient presence. We focus specifically on this core problem of ingredient detection; while only one of the sub-tasks associated with their dataset, it reflects some complex semantics involving understanding the current state of the recipe. Tracking of ingredients in the cooking domain is challenging owing to the compositional nature of recipes whereby ingredients mix together and are aliased as intermediate compositions.

We pose both of these procedural understanding tasks as classification problems, predicting the state of the entity at each timestep from a set of pre-defined classes. In Figure 1, these classes cor-

respond to either the presence (1) or absence (0) or the sequence of state changes create (C), move (M), destroy (D), exists (E), and none (O).

State-of-the-art approaches on these tasks are inherently entity-centric. Separately, it has been shown that entity-centric language modeling in a continuous framework can lead to better performance for LM related tasks (Clark et al., 2018; Ji et al., 2017). Moreover, external data has shown to be useful for modeling process understanding tasks in prior work (Tandon et al., 2018; Bosselut et al., 2018), suggesting that pre-trained models may be effective.

With such tasks in place, a strong model will ideally learn to form robust entity-centric representation at each time step instead of solely relying on extracting information from the local entity mentions. This expectation is primarily due to the evolving nature of the process domain where entities undergo complex interactions, form intermediate compositions, and are often accompanied by implicit state changes. We now investigate to what extent this is true in a standard application of transformer models to this problem.

3 Studying Basic Transformer Representations for Entity Tracking

3.1 Post-conditioning Models

The most natural way to use the pre-trained transformer architectures for the entity tracking tasks is to simply encode the text sequence and then attempt to "read off" entity states from the contextual transformer representation. We call this approach *post-conditioning*: the transformer runs with no knowledge of which entity or entities we are going to make predictions on, but we only condition on the target entity after the transformer stage.

Figure 3 depicts this model. Formally, for a labelled pair $(\{s_1, s_2, \ldots, s_t\}, y_{et})$, we encode the tokenized sequence of steps up to the current timestep (the sentences are separated by using a special `[SEP]` token), independent of the entity. We denote by $X = [h_1, h_2, \ldots, h_m]$ the contextualized hidden representation of the m input tokens from the last layer, and by $g_e = \sum_{\text{ent toks}} emb(e_i)$ the entity representation for post conditioning. We now use one of the following two ways to make an entity-specific prediction:

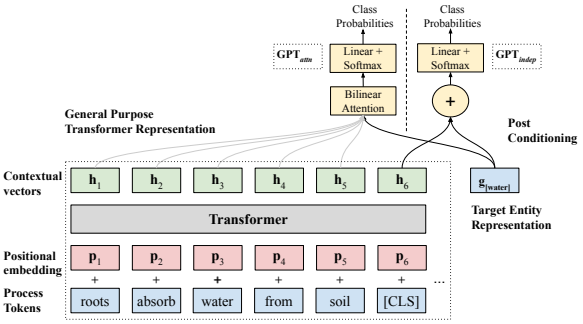

Figure 2: Post-conditioning entity tracking models. Bottom: the process paragraph is encoded in an entity-independent manner with transformer network and a separate entity representation $g_{[water]}$ for post-conditioning. Top: the two variants for the conditioning: (i) GPT$_{attn}$, and (ii) GPT$_{indep}$.

Task Specific Input Token We append a `[CLS]` token to the input sequence and use the output representation of the `[CLS]` token denoted by $h_{\texttt{[CLS]}}$ concatenated with the learned BPE embeddings of the entity as the representation $c_{e,t}$ for our entity tracking system. We then use a linear layer over it to get class probabilities:

$$c_{e,t} = [h_{\texttt{[CLS]}}; g_e]$$
$$P(y_t|s_t, s_{t-1}, \ldots, s_1, e) = \text{softmax}(c_{e,t}W_{task})$$

The aim of the `[CLS]` token is to encode information related to general entity related semantics participating in the recipe (*sentence priors*). We then use a single linear layer to learn sentence priors and entity priors independently, without strong interaction. We call this model GPT$_{indep}$.

Entity Based Attention Second, we explore a more fine-grained way of using the GPT model outputs. Specifically, we use bilinear attention between g_e and the transformer output for the process tokens X to get a contextual representation $c_{e,t}$ for a given entity. Finally, using a feed-forward network followed by softmax layer gives us the class probabilities:

$$a_i = g_e^T * W_{sim} * h_i$$
$$\alpha = \text{softmax}(a)$$
$$c_{e,t} = \sum \alpha_i * h_i$$

$$P(y_t|s_t, s_{t-1}, \ldots, s_1, e) = \text{softmax}(c_{e,t}W_{task})$$

The bilinear attention over the contextual representations of the process tokens allows the model to fetch token content relevant to that particular entity. We call this model GPT$_{attn}$.

Variant	Template
Sentence, Entity First	[START] **Target Entity** [SEP] Steps 1 to $t-1$ [SEP] Step t [CLS]
Sentence, Entity Last	[START] Steps 1 to $t-1$ [SEP] Step t [SEP] **Target Entity** [CLS]
Document, Entity First	[START] **Target Entity** [SEP] Step 1 [CLS] Step 2 [CLS] ... Step T [CLS]
Document, Entity Last	[START] Step 1 [SEP] **Target Entity** [CLS] ... Step T [SEP] **Target Entity** [CLS]

Table 1: Templates for different proposed entity-centric modes of structuring input to the transformer networks.

3.2 Results and Observations

We evaluate the discussed post-conditioning models on the ingredient detection task of the RECIPES dataset.[2] To benchmark the performance, we compare to three rule-based baselines. This includes (i) *Majority Class*, (ii) *Exact Match* of an ingredient e in recipe step s_t, and (iii) *First Occurrence*, where we predict the ingredient to be present in all steps following the first exact match. These latter two baselines capture natural modes of reasoning about the dataset: an ingredient is used when it is directly mentioned, or it is used in every step after it is mentioned, reflecting the assumption that a recipe is about incrementally adding ingredients to an ever-growing mixture. We also construct a LSTM baseline to evaluate the performance of ELMo embeddings (ELMo$_{token}$ and ELMo$_{sent}$) (Peters et al., 2018) compared to GPT.

Table 2 compares the performance of the discussed models against the baselines, evaluating per-step entity prediction performance. Using the ground truth about ingredient's state, we also report the uncombined (UR) and combined (CR) recalls, which are per-timestep ingredient recall distinguished by whether the ingredient is explicitly mentioned (uncombined) or part of a mixture (combined). Note that *Exact Match* and *First Occ* baselines represent high-precision and high-recall regimes for this task, respectively.

As observed from the results, the post-conditioning frameworks underperform compared to the *First Occ* baseline. While the CR values appear to be high, which would suggest that the model is capturing the addition of ingredients to the mixture, we note that this value is also lower than the corresponding value for *First Occ*. This result suggests that the model may be approximating the behavior of this baseline, but doing so poorly. The unconditional self-attention mechanism of the transformers does not seem sufficient to capture the entity details at each time step beyond simple presence or absence. Moreover, we see that GPT$_{indep}$ performs somewhat comparably to GPT$_{attn}$, suggesting that consuming the transformer's output with simple attention is not able to really extract the right entity representation.

[2]We discuss training details more in Section 4.1, but largely use a standard GPT training protocol (Radford et al., 2018).

Model	P	R	F_1	Acc	UR	CR
Performance Benchmarks						
Majority	-	-	-	57.27	-	-
Exact Match	**84.94**	20.25	32.70	64.39	73.42	4.02
First Occ	65.23	**87.17**	**74.60**	**74.65**	**84.88**	**87.79**
Models						
GPT$_{attn}$	63.94	71.72	67.60	70.63	54.30	77.04
GPT$_{indep}$	67.05	69.07	68.04	72.28	47.09	75.79
ELMo$_{token}$	64.96	76.64	70.32	72.35	69.14	78.94
ELMo$_{sent}$	69.09	72.88	70.90	74.48	57.05	77.71

Table 2: Performance of the rule-based baselines and the post conditioned models on the ingredient detection task of the RECIPES dataset. These models all underperform *First Occ*.

For PROPARA, we observe similar performance trends where the post-conditioning model performed below par with the state-of-the-art architectures.

4 Entity-Conditioned Models

The post-conditioning framework assumes that the transformer network can form strong representations containing entity information accessible in a shallow way based on the target entity. We now propose a model architecture which more strongly conditions on the entity as a part of the intrinsic self-attention mechanism of the transformers.

Our approach consists of structuring input to the transformer network to use and guide the self-attention of the transformers, conditioning it on the entity. Our main mode of encoding the input, the **entity-first** method, is shown in Figure 3. The input sequence begins with a [START] token, then the entity under consideration, then a [SEP] token. After each sentence, a [CLS] to-

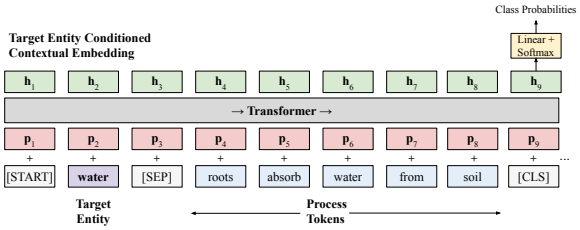

Figure 3: Entity conditioning model for guiding self-attention: the entity-first, sentence-level input variant fed into a left-to-right unidirectional transformer architecture. Task predictions are made at `[CLS]` tokens about the entity's state after the prior sentence.

ken is used to anchor the prediction for that sentence. In this model, the transformer can always observe the entity it should be primarily "attending to" from the standpoint of building representations. We also have an **entity-last** variant where the entity is primarily observed just before the classification token to condition the `[CLS]` token's self-attention accordingly. These variants are naturally more computationally-intensive than post-conditioned models, as we need to rerun the transformer for each distinct entity we want to make a prediction for.

Sentence Level vs. Document Level As an additional variation, we can either run the transformer once per document with multiple `[CLS]` tokens (a **document-level** model as shown in Figure 3) or specialize the prediction to a single timestep (a **sentence-level** model). In a sentence level model, we formulate each pair of entity e and process step t as a separate instance for our classification task. Thus, for a process with T steps and m entities we get $T \times m$ input sequences for fine tuning our classification task.

4.1 Training Details

In most experiments, we initialize the network with the weights of the standard pre-trained GPT model, then subsequently do either domain specific LM fine-tuning and supervised task specific fine-tuning.

Domain Specific LM fine-tuning For some procedural domains, we have access to additional unlabeled data. To adapt the LM to capture domain intricacies, we fine-tune the transformer network on this unlabeled corpus.

Supervised Task Fine-Tuning After the domain specific LM fine-tuning, we fine-tune our network parameters for the end task of entity tracking. For fine-tuning for the task, we have a labelled dataset which we denote by $\mathcal{C}$, the set of labelled pairs $(\{s_1, s_2, \ldots, s_t\}, y_{et})$ for a given process. The input is converted according to our chosen entity conditioning procedure, then fed through the pre-trained network.

In addition, we observed that adding the language model loss during task specific fine-tuning leads to better performance as well, possibly because it adapts the LM to our task-specific input formulation. Thus,

$$\mathcal{L}_{total} = \mathcal{L}_{task} + \lambda \mathcal{L}_{lm}$$

4.2 Experiments: Ingredient Detection

We first evaluate the proposed entity conditioned self-attention model on the RECIPES dataset to compare the performance with the post-conditioning variants.

4.2.1 Systems to Compare

We use the pre-trained GPT architecture in the proposed entity conditioned framework with all its variants. BERT mainly differs in that it is bidirectional, though we also use the pre-trained `[CLS]` and `[SEP]` tokens instead of introducing new tokens in the input vocabulary and training them from scratch during fine-tuning. Owing to the lengths of the processes, all our experiments are performed on BERT$_{BASE}$.

Neural Process Networks The most significant prior work on this dataset is the work of Bosselut et al. (2018). However, their data condition differs significantly from ours: they train on a large noisy training set and do not use any of the high-quality labeled data, instead treating it as dev and test data. Consequently, their model achieves low performance, roughly 56 F_1 while ours achieves 82.5 F_1 (though these are not the exact same test set). Moreover, theirs underperforms the first occurrence baseline, which calls into question the value of that training data. Therefore, we do not compare to this model directly. We use the small set of human-annotated data for our probing task. Our train/dev/test split consists of 600/100/175 recipes, respectively.

4.2.2 Results

Table 3 compares the overall performances of our proposed models. Our best ET$_{GPT}$ model achieves an F_1 score of 82.50. Comparing to

Model	P	R	F_1	Acc	UR	CR
Rule Based Benchmarks						
Majority	-	-	-	57.27	-	-
Exact	84.94	20.25	32.70	64.39	73.42	4.02
First	65.23	87.17	74.60	74.65	84.88	87.79
Post Conditioning Models						
GPT$_{attn}$	63.94	71.72	67.60	70.63	54.30	77.04
GPT$_{concat}$	67.05	69.07	68.04	72.28	47.09	75.79
ELMo$_{token}$	64.96	76.64	70.32	72.35	69.14	78.94
ELMo$_{sent}$	69.09	72.88	70.90	74.48	57.05	77.71
Entity-Centric Models						
ET$_{BERT}$	72.49	80.09	76.10	78.50	84.30	78.82
ET$_{GPT}$ ⓈⓁ	75.27	83.85	79.33	81.32	87.28	82.81
ET$_{GPT}$ ⓈⒻ	76.70	83.98	80.17	82.26	88.20	82.69
ET$_{GPT}$ ⒹⓁ	79.19	83.82	81.44	83.67	88.11	82.51
ET$_{GPT}$ ⒹⒻ	**79.85**	**84.19**	**81.96**	**84.16**	**87.91**	**83.05**

Table 3: Performances of different baseline models discussed in Section 3, the ELMo baselines, and the proposed entity-centric approaches with the (D)ocument v (S)entence level variants formulated with both entity (F)irst v. (L)ater. Our ET$_{GPT}$ variants all substantially outperform the baselines.

the baselines (*Majority* through *First*) and post-conditioned models, we see that the early entity conditioning is critical to achieve high performance.

Although the *First* model still achieves the highest CR, due to operating in a high-recall regime, we see that the ET$_{GPT}$ models all significantly outperform the post-conditioning models on this metric, indicating better modeling of these compositions. Both recall and precision are substantially increaesd compared to these baseline models. Interestingly, the ELMo-based model underperforms the first-occurrence baseline, indicating that the LSTM model is not learning much in terms of recognizing complex entity semantics grounded in long term contexts.

Comparing the four variants of structuring input in proposed architectures as discussed in Section 4, we observe that the **document-level, entity-first model** is the best performing variant. Given the left-to-right unidirectional transformer architecture, this model notably forms target-specific representations for all process tokens, compared to using the transformer self-attention only to extract entity specific information at the end of the process.

4.2.3 Ablations

We perform ablations to evaluate the model's dependency on the context and on the target ingredient. Table 4 shows the results for these ablations.

Model	P	R	F_1	Acc	UR	CR
ET$_{GPT}$ ⒹⒻ						
w/o ing.	67.47	60.46	63.77	70.64	35.82	67.97
w/ ing.	79.85	84.19	81.96	84.16	87.91	83.05
ET$_{GPT}$ ⓈⒻ						
w/o context	67.88	75.91	71.67	74.36	87.00	72.52
w/ context	76.70	83.98	80.17	82.26	88.20	82.69

Table 4: Top: we compare how much the model degrades when it conditions on no ingredient at all (w/o ing.), instead making a generic prediction. Bottom: we compare how much using previous context beyond a single sentence impacts the model.

Ingredient Specificity In the "no ingredient" baseline (w/o ing.), the model is not provided with the specific ingredient information. Table 4 shows that while not being a strong baseline, the model achieves decent overall accuracy with the drop in UR being higher compared to CR. This indicates that there are some generic indicators (*mixture*) that it can pick up to try to guess at overall ingredient presence or absence.

Context Importance We compare with a "no context" model (w/o context) which ignore the previous context and only use the current recipe step in determining the ingredient's presence. Table 4 shows that the such model is able to perform surprisingly well, nearly as well as the first occurrence baseline.

This is because the model can often recognize words like verbs (for example, *add*) or nouns (for example, *mixture*) that indicate many ingredients are being used, and can do well without really tracking any specific entity as desired for the task.

4.3 State Change Detection (ProPara)

Next, we now focus on a structured task to evaluate the performance of the entity tracking architecture in capturing the structural information in the continuous self-attention framework. For this, we use the ProPara dataset and evaluate our proposed model on the comprehension task.

Figure 1b shows an example of a short instance from the ProPara dataset. The task of identifying state change follows a structure satisfying the existence cycle; for example, an entity can not be created after destruction. Our prior work (Gupta and Durrett, 2019) proposed a structured model for the task that achieved state-of-the-art perfor-

mance. We adapt our proposed entity tracking transformer models to this structured prediction framework, capturing creation, movement, existence (distinct from movement or creation), destruction, and non-existence.

We use the standard evaluation scheme of the PROPARA dataset, which is framed as answering the following categories of questions: (Cat-1) **Is** *e* created (destroyed, moved) in the process?, (Cat-2) **When** (step #) is *e* created (destroyed, moved)?, (Cat-3) **Where** is *e* created/destroyed/moved from/to)?

4.3.1 Systems to Compare

We compare our proposed models to the previous work on the PROPARA dataset. This includes the entity specific MRC models, EntNet (Henaff et al., 2017), QRN (Seo et al., 2017), and KG-MRC (Das et al., 2019). Also, Dalvi et al. (2018) proposed two task specific models, ProLocal and ProGlobal, as baselines for the dataset. Finally, we compare against our past neural CRF entity tracking model (NCET) (Gupta and Durrett, 2019) which uses ELMo embeddings in a neural CRF architecture.

For the proposed GPT architecture, we use the task specific `[CLS]` token to generate tag potentials instead of class probabilities as we did previously. For BERT, we perform a similar modification as described in the previous task to utilize the pre-trained `[CLS]` token to generate tag potentials. Finally, we perform a Viterbi decoding at inference time to infer the most likely valid tag sequence.

4.3.2 Results

Table 5 compares the performance of the proposed entity tracking models on the sentence level task. Since, we are considering the classification aspect of the task, we compare our model performance for Cat-1 and Cat-2. As shown, the structured document level, entity first ET_{GPT} and ET_{BERT} models achieve state-of-the-art results. We observe that the major source of performance gain is attributed to the improvement in identifying the exact step(s) for the state changes (Cat-2). This shows that the model are able to better track the entities by identifying the exact step of state change (Cat-2) accurately rather than just detecting the presence of such state changes (Cat-1). This task is more highly structured and in some ways more non-local than ingredient prediction; the high performance here shows that the ET_{GPT} model is able to capture document level structural information effectively. Further, the structural constraints from the CRF also aid in making better predictions. For example, in the process *"higher pressure causes the sediment to heat up. the heat causes chemical processes. the material becomes a liquid. is known as oil."*, the *material* is a by-product of the chemical process but there's no direct mention of it. However, the material ceases to exist in the next step, and because the model is able to predict this correctly, maintaining consistency results in the model finally predicting the entire state change correctly as well.

Model	Cat-1	Cat-2	Ma-Avg	Mi-Avg

Table 5: Performance of the proposed models on the PROPARA dataset. Our models outperform strong approaches from prior work across all metrics.

5 Challenging Task Phenomena

Based on the results in the previous section, our models clearly achieve strong performance compared to past approaches. We now revisit the challenging cases discussed in Section 2 to see if our entity tracking approaches are modeling sophisticated entity phenomena as advertised. For both datasets and associated tasks, we isolate the specific set of challenging cases grounded in tracking (i) intermediate compositions formed as part of combination of entities leading to no explicit mention, and (ii) implicit events which change entities' states without explicit mention of the affects.

5.1 Ingredient Detection

For RECIPES, we mainly want to investigate cases of ingredients getting re-engaged in the recipe not in a raw form but in a combined nature with other ingredients and henceforth no explicit mention. For example, *eggs* in step 4 of Figure 1a exem-

plifies this case. The performance in such cases is indicative of how strongly the model can track compositional entities. We also examine the performance for cases where the ingredient is referred by some other name.

Intermediate Compositions Formally, we pick the set of examples where the ground truth is a transition from $0 \rightarrow 1$ (not present to present) *and* the 1 is a "combined" case. Table 6 shows the model's performance on this subset of cases, of which there are 1049 in the test set. The model achieves an accuracy of 51.1% on these bigrams, which is relatively low given the overall model performance. In the error cases, the model defaults to the $1 \rightarrow 1$ pattern indicative of the *First Occ* baseline.

	$0 \rightarrow 0$	$0 \rightarrow 1$	$1 \rightarrow 0$	$1 \rightarrow 1$
#preds	179	**526**	43	301

Table 6: Model predictions from the document level entity first GPT model in 1049 cases of intermediate compositions. The model achieves only 51% accuracy in these cases.

Hypernymy and Synonymy We observe the model is able to capture ingredients based on their hypernyms (*nuts* $\rightarrow$ *pecans*, *salad* $\rightarrow$ *lettuce*) and rough synonymy (*bourbon* $\rightarrow$ *scotch*). This performance can be partially attributed to the language model pre-training. We can isolate these cases by filtering for *uncombined* ingredients when there is no matching ingredient token in the step. Out of 552 such cases in the test set, the model predicts 375 correctly giving a recall of 67.9. This is lower than overall UR; if pre-training behaves as advertised, we expect little degradation in this case, but instead we see performance significantly below the average on uncombined ingredients.

Impact of external data One question we can ask of the model's capabilities is to what extent they arise from domain knowledge in the large pre-trained data. We train transformer models from scratch and additionally investigate using the large corpus of unlabeled recipes for our LM pre-training. As can be seen in Table 7, the incorporation of external data leads to major improvements in the overall performance. This gain is largely due to the increase in combined recall. One possible reason could be that external data leads to better understanding of verb semantics and in turn the specific ingredients forming part of the intermediate compositions. Figure 4 shows that verbs are a critical clue the model relies on to make predictions. Performing LM fine-tuning on top of GPT also gives gains.

Model	**P**	**R**	F_1	**Acc**	**UR**	**CR**
No pre-training, 8 heads, 8 layers, 512 embedding size						
No LM	66.52	73.48	69.83	72.87	79.20	71.73
20k	72.53	80.32	76.23	78.59	79.49	80.58
50k	74.40	81.80	77.92	80.19	81.90	81.77
Standard GPT pre-training						
No LM	79.85	84.19	81.96	84.16	87.91	83.05
20k	**80.14**	**85.01**	**82.50**	**84.59**	**88.83**	**83.84**

Table 7: Performance for using unsupervised data for LM training.

5.2 State Change Detection

For PROPARA, Table 5 shows that the model does not significantly outperform the SOTA models in state change detection (Cat-1). However, for those correctly detected events, the transformer model outperforms the previous models for detecting the exact step of state change (Cat-2), primarily based on verb semantics. We do a finer-grained study in Table 8 by breaking down the performance for the three state changes: creation (C), movement (M), and destruction (D), separately. Across the three state changes, the model suffers a loss of performance in the movement cases. This is owing to the fact that the movement cases require a deeper compositional and implicit event tracking. Also, a majority of errors leading to false negatives are due to the the formation of new sub-entities which are then mentioned with other names. For example, when talking about *weak acid* in *"the water becomes a weak acid. the water dissolves limestone"* the *weak acid* is also considered to move to the *limestone*.

Model	**Cat-1**			**Cat-2**		
	C	M	D	C	M	D
ET_{BERT}	78.51	61.60	71.50	76.68	54.12	58.62
ET_{GPT}	79.82	56.27	73.83	77.24	50.82	56.27

Table 8: Results for each state change type. Performance on predicting creation and destruction are highest, partially due to the model's ability to use verb semantics for these tasks.

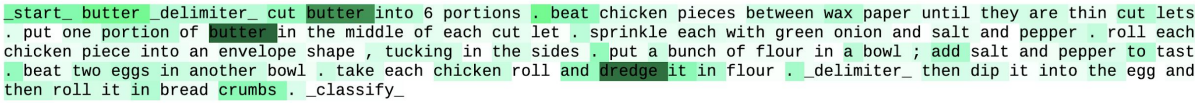

Figure 4: Gradient of the classification loss of the gold class with respect to inputs when predicting the status of *butter* in the last sentence. We follow a similar approach as Jain and Wallace (2019) to compute associations. Exact matches of the entity receive high weight, as does a seemingly unrelated verb *dredge*, which often indicates that the *butter* has already been used and is therefore present.

6 Analysis

The model's performance on these challenging task cases suggests that even though it outperforms baselines, it may not be capturing deep reasoning about entities. To understand what the model actually does, we perform analysis of the model's behavior with respect to the input to understand what cues it is picking up on.

Gradient based Analysis One way to analyze the model is to compute model gradients with respect to input features (Sundararajan et al., 2017; Jain and Wallace, 2019). Figure 4 shows that in this particular example, the most important model inputs are verbs possibly associated with the entity *butter*, in addition to the entity's mentions themselves. It further shows that the model learns to extract shallow clues of identifying actions exerted upon only the entity being tracked, regardless of other entities, by leveraging verb semantics.

In an ideal scenario, we would want the model to track constituent entities by translating the "focus" to track their newly formed compositions with other entities, often aliased by other names like *mixture, blend, paste* etc. However, the low performance on such cases shown in Section 5 gives further evidence that the model is not doing this.

Input Ablations We can study which inputs are important more directly by explicitly removing specific certain words from the input process paragraph and evaluating the performance of the resulting input under the current model setup. We mainly did experiments to examine the importance of: (i) verbs, and (ii) other ingredients.

Table 9 presents these ablation studies. We only observe a minor performance drop from 84.59 to 82.71 (accuracy) when other ingredients are removed entirely. Removing verbs dropped the performance to 79.08 and further omitting both leads to 77.79. This shows the models dependence on verb semantics over tracking the other ingredients.

Input	Accuracy
Complete Process	84.59
w/o Other Ingredients	82.71
w/o Verbs	79.08
w/o Verbs & Other Ingredients	77.79

Table 9: Model's performance degradation with input ablations. We see that the model's major source of performance is from verbs than compared to other ingredient's explicit mentions.

7 Conclusion

In this paper, we examined the capabilities of transformer networks for capturing entity state semantics. First, we show that the conventional framework of using the transformer networks is not rich enough to capture entity semantics in these cases. We then propose entity-centric ways to formulate richer transformer encoding of the process paragraph, guiding the self-attention in a target entity oriented way. This approach leads to significant performance improvements, but examining model performance more deeply, we conclude that these models still do not model the intermediate compositional entities and perform well by largely relying on surface entity mentions and verb semantics.

Abstract

Pre-training has proven to be effective in unsupervised machine translation due to its ability to model deep context information in cross-lingual scenarios. However, the cross-lingual information obtained from shared BPE spaces is inexplicit and limited. In this paper, we propose a novel cross-lingual pre-training method for unsupervised machine translation by incorporating explicit cross-lingual training signals. Specifically, we first calculate cross-lingual n-gram embeddings and infer an n-gram translation table from them. With those n-gram translation pairs, we propose a new pre-training model called Cross-lingual Masked Language Model (CMLM), which randomly chooses source n-grams in the input text stream and predicts their translation candidates at each time step. Experiments show that our method can incorporate beneficial cross-lingual information into pre-trained models. Taking pre-trained CMLM models as the encoder and decoder, we significantly improve the performance of unsupervised machine translation. Our code is available at https://github.com/Imagist-Shuo/CMLM.

1 Introduction

Unsupervised machine translation has become an emerging research interest in recent years (Artetxe et al., 2017; Lample et al., 2017, 2018; Artetxe et al., 2018b; Marie and Fujita, 2018; Ren et al., 2019; Lample and Conneau, 2019). The common framework of unsupervised machine translation builds two initial translation models at first (i.e., source to target and target to source), and then does iterative back-translation (Sennrich et al., 2016a; Zhang et al., 2018) with the two models using pseudo data generated by each other. The initialization process is crucial to the final translation performance as pointed in Lample et al. (2018), Artetxe et al. (2018b) and Ren et al. (2019).

Previous approaches benefit mostly from cross-lingual n-gram embeddings, but recent work proves that cross-lingual language model pre-training could be a more effective way to build initial unsupervised machine translation models (Lample and Conneau, 2019). However, in their method, the cross-lingual information is mostly obtained from shared Byte Piece Encoding (BPE) (Sennrich et al., 2016b) spaces during pre-training, which is inexplicit and limited. Firstly, although the same BPE pieces from different languages may share the same semantic space, the semantic information of n-grams or sentences in different languages may not be shared properly. However, cross-lingual information based on n-gram level is crucial to model the initialization of unsupervised machine translation (Lample et al., 2018; Artetxe et al., 2018b), which is absent in the current pre-training method. Secondly, BPE sharing is limited to languages that share much of their alphabet. For language pairs that are not the case, the above pre-training method may not provide much useful cross-lingual information.

In this paper, by incorporating explicit cross-lingual training signals, we propose a novel cross-lingual pre-training method based on BERT (Devlin et al., 2018) for unsupervised machine translation. Our method starts from unsupervised cross-lingual n-gram embeddings, from which we infer n-gram translation pairs. Then, we propose a new pre-training objective called Cross-lingual Masked Language Model (CMLM), which masks the input n-grams randomly and predicts their corresponding n-gram translation candidates inferred above. To solve the mismatch between different lengths of the masked source and predicted target n-grams, IBM models are introduced (Brown et al., 1993) to derive the training loss at each

*Contribution during internship at MSRA.

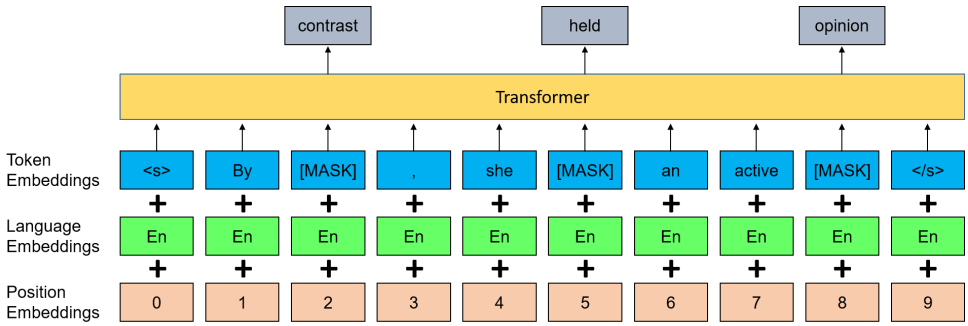

Figure 1: Masked Language Model (MLM) for BERT training. For a given sentence, this task is to predict randomly masked tokens, i.e., "contrast", "held" and "opinion". In practice, it is implemented based on BPE.

time step. In this way, we can guide the model with more explicit and strong cross-lingual training signals, and meanwhile, leverage the potential of BERT to model context information. We then use two pre-trained cross-lingual language models as the encoder and decoder respectively to build desired machine translation models. Our method can be iteratively performed with the n-gram translation table updated by downstream tasks. Experiments show that our method can produce better cross-lingual representations and significantly improve the performance of unsupervised machine translation. Our contributions are listed as follows.

- We propose a novel cross-lingual pre-training method to incorporate explicit cross-lingual information into pre-trained models, which significantly improves the performance of unsupervised machine translation.
- We introduce IBM models to calculate the step-wise training loss for CMLM, which breaks the limitation that masked n-grams and predicted ones have to be the same length during BERT training.
- We produce strong context-aware cross-lingual representations with our pre-training method, which helps in word alignment and cross-lingual classification tasks.

2 Background

2.1 BERT

BERT (Devlin et al., 2018), short for Bidirectional Encoder Representations from Transformers, is a powerful pre-training method for natural language processing and breaks records of many NLP tasks after corresponding fine-tuning. The core idea of BERT is pre-training a deep bidirectional Transfomer encoder (Vaswani et al., 2017) with two training tasks. The first one is Masked Language Model (MLM) referring to the *Cloze* task (Taylor, 1953), which takes a straightforward approach of masking some percentage of the input tokens at random, and then predicting them with the corresponding Transformer hidden states, as shown in Figure 1. The second one is Next Sentence Prediction, which means to predict whether two sentences are adjacent or not. This task is designed for some tasks that need modeling the relationship between two sentences such as Question Answering (QA) and Natural Language Inference (NLI).

2.2 XLM

Based on BERT, Lample and Conneau (2019) propose a cross-lingual version called XLM and reach the state-of-the-art performance on some cross-lingual NLP tasks including cross-lingual classification (Conneau et al., 2018), machine translation, and unsupervised cross-lingual word embedding. The basic points of XLM are mainly two folds. The first one is to use a shared vocabulary of BPE (Sennrich et al., 2016b) to provide potential cross-lingual information between two languages just as mentioned in Lample et al. (2018), in an inexplicit way though. The second point is a newly proposed training task called Translation Language Modeling (TLM), which extends MLM by concatenating parallel sentences into a single training text stream. In this way, the model can leverage the cross-lingual information provided by parallel sentences to predict the masked tokens. However, for unsupervised machine translation, TLM cannot be used due to the lack of parallel sentences. Different from them, we are motivated to give the model more explicit and strong cross-lingual information and propose a new pre-training method by (1) masking source n-grams and (2) predicting their corresponding translation candidates.

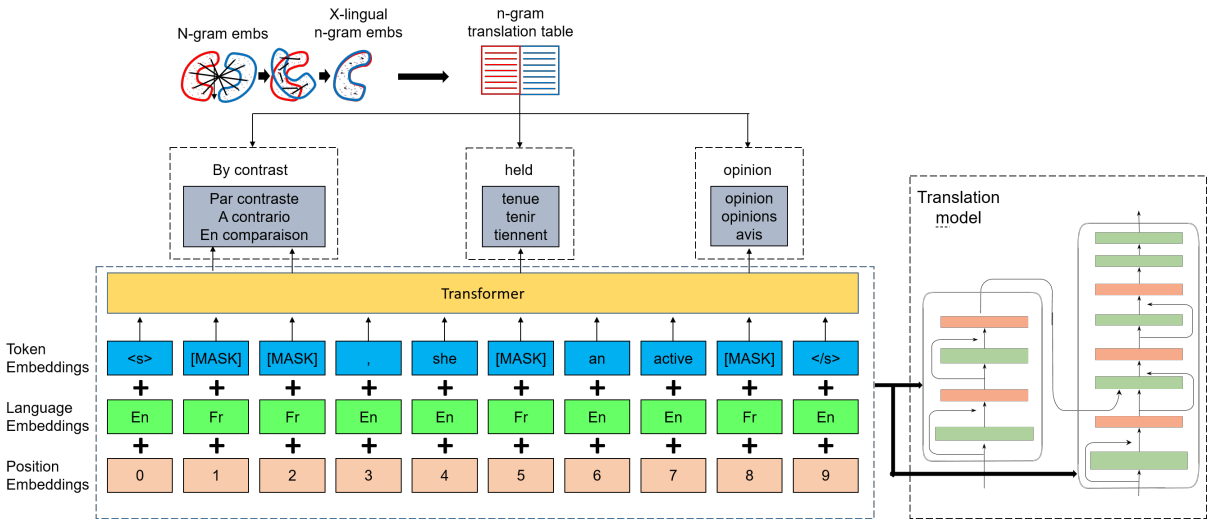

Figure 2: Method overview. Our method consists of three steps. The first one is the n-gram translation table inferring. The second one is pre-training with our proposed objective Cross-lingual Masked Language Model (CMLM) which is to predict the translation candidates of randomly masked n-grams. The last step is to leverage the pre-trained cross-lingual language models as the encoder and decoder of a neural machine translation model and fine-tune the translation model iteratively.

3 Method

3.1 Overview

Our method can be divided into three steps as shown in Figure 2. Given two languages X and Y, we first get unsupervised cross-lingual n-gram embeddings of them, from which we infer n-gram translation tables (source-to-target and target-to-source). The n-gram translation pairs inferred in this way have proven to be instructive for initial unsupervised machine translation models (Artetxe et al., 2018b; Lample et al., 2018; Marie and Fujita, 2018; Ren et al., 2019). Then, we pre-train cross-lingual BERT language models with our proposed Cross-lingual Masked Language Model (CMLM) objective. Specifically, we randomly choose n-grams in the monolingual sentences and predict corresponding translation candidates in the n-gram translation table inferred in the first step. In this way, we can guide the model with explicit and strong cross-lingual training signals. Finally, two pre-trained cross-lingual language models are used to initialize the encoder and decoder respectively, based on which, denoising auto-encoder and iterative back-translation are leveraged to fine-tune the unsupervised machine translation models.

The above process is repeated by updating the n-gram table with the n-gram translation pairs extracted from the pseudo data generated by the translation models. In the following subsections, we will give details of each step.

3.2 N-gram Translation Table Inferring

Following previous work of unsupervised machine translation (Artetxe et al., 2018b; Lample et al., 2018; Ren et al., 2019), given two languages X and Y, we build our n-gram translation tables as follows. First, we obtain monolingual n-gram embeddings using fastText (Bojanowski et al., 2017) and then get cross-lingual n-gram embeddings using vecmap (Artetxe et al., 2018a) in a fully unsupervised way. Based on that, we calculate the similarity score of n-grams x and y in two languages respectively with the marginal-based scoring method (Conneau et al., 2017; Artetxe and Schwenk, 2018). Specifically, given the cross-lingual embeddings of x and y, denoted as e_x and e_y, the similarity score is calculated as:

$$\text{sim}(x, y) = \text{margin}(\cos(e_x, e_y), \sum_{z \in \text{NN}_n(x)} \frac{\cos(e_x, e_z)}{2n} + \sum_{z \in \text{NN}_n(y)} \frac{\cos(e_y, e_z)}{2n}) \quad (1)$$

where $\text{margin}(a, b)$ is a marginal scoring function and $\text{NN}_n(x)$ denotes x's k-nearest neighbors in the other language. In our experiments, n is 5 and $\text{margin}(a, b) = \frac{a}{b}$.

We take the above similarity scores as the translation probabilities between x and y in the n-gram table. For each top frequent n-gram in the source language, we retrieve top-k n-gram translation candidates in the target language.

3.3 Cross-lingual Masked Language Model

In this section, we introduce our proposed method for pre-training cross-lingual language models based on BERT. Unlike the masked language model (MLM) described in Section 2.2 which masks several tokens in the input stream and predict those tokens themselves, we randomly select some percentage of n-grams in the input source sentence, and predict their translation candidates retrieved from Section 3.2. We call our proposed pre-training objective "Cross-lingual Masked Language Model" (CMLM) as shown in Figure 2. The difficulty for BERT to predict target phrases during training is that the lengths of the translation candidates are sometimes different from the source n-grams. To deal with this problem, we turn to IBM Model 2 (Brown et al., 1993) to calculate the training loss at each time step. Our proposed method breaks the limitation that masked n-grams and predicted ones have to be the same length during BERT training.

Specifically, according to IBM Model 2, given a source n-gram x_1^l and a target one y_1^m, where l and m are the numbers of tokens in the source and target n-grams respectively, the translation probability from x_1^l to y_1^m is calculated as:

$$\mathbf{Pr}(y_1^m|x_1^l) = \epsilon \prod_{j=1}^{m} \sum_{i=0}^{l} a(i|j,l,m) p(y_j|x_i) \quad (2)$$

where $\epsilon = p(m|x_1^l)$, i.e. the probability that the translation of x_1^l consists of m tokens; $a(j|i,l,m)$ is the probability that the i^{th} source token is aligned with the j^{th} target token conditioned on the lengths l and m, while $p(y_j|x_i)$ is the translation probability from the source token x_i to the target token y_i. Based on the IBM Model 2, the loss function of our CMLM is defined as

$$\begin{aligned} \mathcal{L}_{cmlm} &= -\log \mathbf{Pr}(y_1^m|x_1^l) \\ &= -\log \epsilon - \sum_{j=1}^{m} \log \sum_{i=0}^{l} a(i|j,l,m) p(y_j|x_i) \end{aligned} \quad (3)$$

The derived gradient w.r.t model parameters θ at each time step can be calculated as follows:

$$\begin{aligned} &\nabla_\theta \mathcal{L}_{cmlm} \\ &= -\sum_{j=1}^{m} \frac{a(i|j,l,m) p(y_j|x_i)}{\sum_{i=0}^{l} a(i|j,l,m) p(y_j|x_i)} \nabla_\theta \log p(y_j|x_i) \end{aligned} \quad (4)$$

Since the target n-gram y_1^m is predicted with our modified BERT, in practice, the source word x_i in Eq.(4) is replaced with its context-sensitive embedding $\mathrm{C}(x_1^l)$, which is the corresponding hidden state of the top Transformer layer. The alignment probability $a(i|j,l,m)$ cannot be learned during training because of the absence of bilingual corpus. Therefore, cross-lingual BPE embeddings are leveraged to calculate the normalized $\mathrm{sim}(x_i, y_j)$ to approximate $a(i|j,m,l)$. $p(y_j|x_i)$ is the model prediction in Softmax outputs. For each source n-gram, all of the retrieved k translation candidates are used to calculate the cross entropy loss, which are weighted with their translation probabilities in the n-gram table.

Given a language pair $X - Y$, we process both languages with the same shared BPE vocabulary using their monolingual sentences together during pre-training. Following Devlin et al. (2018); Lample and Conneau (2019), in our CMLM objective, we randomly sample 15% of the BPE n-grams from the text streams, and replace them by [MASK] tokens 70% of the time. During pre-training, in each iteration, a batch is composed of sentences sampled from the same language, and we alternate between MLM and CMLM objectives. Different from the original MLM in BERT, in the half of the MLM time, we randomly choose some source n-grams in the input text stream, and replace them with their translation candidates to construct code-switching sentences. Our final pre-training loss is defined as

$$\mathcal{L}_{pre} = \mathcal{L}_{cmlm} + \mathcal{L}_{mlm} \quad (5)$$

3.4 Unsupervised Machine Translation

Taking two cross-lingual language models pre-trained with the above method as the encoder and decoder, we build an initial unsupervised neural machine translation model. Then, we train the model with monolingual data until convergence via denoising auto-encoder and iterative back-translation, as described in Artetxe et al. (2017); Lample et al. (2017, 2018). Different from them, we step further and make another iteration with updated n-gram translation tables. Specifically, we translate the monolingual sentences with our latest translation model and run GIZA++ (Och and Ney, 2003) on the generated pseudo parallel data to extract updated n-gram translation pairs, which are used to tune the encoder as Section 3.3, together with the back-translation within a multi-task learn-

ing framework. Experimental results show that running another iteration can further improve the translation performance.

It is also interesting to explore the usage of pre-trained decoders in the translation model. It seems that pre-training decoders has a smaller effect on the final performance than pre-training encoders (Lample and Conneau, 2019), one reason for which could be that the encoder-to-decoder attention is not pre-trained. Therefore, the parameters of the decoder need to be re-adjusted substantially in the following tuning process for MT task. In our experiments, we explore some other usage of pre-trained decoders, i.e., we use the pre-trained decoder as the feature extractor and feed the outputs into a new decoder consisting of several Transformer layers with the attention to the encoder. We find this method improves the performance of some language translation directions.

4 Experiments

In this section, we conduct experiments to evaluate our proposed pre-training method. In Section 4.1, we will introduce the setup of our experiments, followed by the overall results of the final unsupervised MT models. Then, in Section 4.3, we will discuss another usage of pre-trained decoders for translation models. To evaluate the cross-lingual modeling capacity of our pre-trained encoders, in Section 4.4, we conduct experiments on word alignment and cross-lingual classification tasks. Finally, we do the ablation study to check the performance contribution of each component in our proposed method.

4.1 Setup

Data and Preprocess

In our experiments, we consider three language pairs, English-French (en-fr), English-German (en-de) and English-Romanian (en-ro). For each language, we use all the available sentences in NewsCrawl till 2018, monolingual datasets from WMT. The NewsCrawl data are used in both pre-training and the following unsupervised NMT iteration process. Our CMLM is optimized based on the pre-trained models released by Lample and Conneau (2019)[1], which are trained with Wikipedia dumps. For fair comparison, we use *newstest* 2014 as the test set for en-fr, and *newstest* 2016 for en-de and en-ro.

We use Moses scripts for tokenization, and use fastBPE[2] to split words into subword units with their released BPE codes[1]. The number of shared BPE codes for each language pair is 60,000.

Implementation Details

Our implementation is based on the released code of XLM[1] (Paszke et al., 2017). Specifically, we use a Transformer architecture with 1024 hidden units, 8 heads, GELU activations (Hendrycks and Gimpel, 2016), with a dropout rate of 0.1. The models are trained with the Adam optimizer (Kingma and Ba, 2014), a linear warmup (Vaswani et al., 2017) and the learning rates varying from 10^4 to 5×10^4.

For both of the MLM and CMLM objectives, we use streams of 256 tokens and mini-batches of size 64. We use the averaged perplexity over languages as a stopping criterion for training. For machine translation, we use 6 Transformer layers, and we create mini-batches of 2000 tokens.

Baselines

Our method is compared with six baselines of unsupervised MT systems listed in the upper part of Table 1. The first two baselines (Artetxe et al., 2017; Lample et al., 2017) use a shared encoder and different decoders for two languages with the training methods of denoising auto-encoder and iterative back-translation. The third baseline (Artetxe et al., 2018b) is an unsupervised PBSMT model, which uses the initial PBSMT models built with language models and n-gram translation tables inferred from cross-lingual embeddings, followed with the iterative back-translation. The fourth baseline (Lample et al., 2018) is a hybrid method of unsupervised NMT and PBSMT by combining the pseudo data generated by PBSMT models into the final iteration of NMT. The fifth baseline (Ren et al., 2019) is also a hybrid method of NMT and PBSMT but different from Lample et al. (2018), they leverage PBSMT as posterior regularization in each NMT iteration. The last baseline is XLM described in Section 2.2.

4.2 Overall Results

The overall comparison results of unsupervised machine translation are shown in Table 1. From the table, we find that our proposed method significantly outperforms previous methods on all language pairs by the average BLEU score of 1.7,

	Iter 2	**34.9**	**35.4**	**35.6**	27.7	**34.1**	**34.9**

Table 1: Comparison of the final unsupervised MT performance (BLEU). In this table, "Iter 2" means we do the whole process with another iteration as described in Section 3.4.

and both the improvements of en2fr and ro2en are over 2 BLEU points. The results indicate that the explicit cross-lingual information incorporated by our proposed CMLM is beneficial to the unsupervised machine translation task. Notice that by doing another iteration ("Iter 2") with updated n-gram tables as described in Section 3.4, we further improve the performance a bit for most translation directions with the improvements of en2fr and ro2en bigger than 0.5 BLEU point, which confirms the potential that fine-tuned machine translation models contain more beneficial cross-lingual information than the initial n-gram translation tables, which can be used to enhance the pre-trained model iteratively.

The improvement made by Lample and Conneau (2019) compared with the first five baselines shows that cross-lingual pre-training can be necessary for unsupervised MT. However, the cross-lingual information learned with this method during pre-training is mostly from the shared subword space, which is inexplicit and not strong enough. Our proposed method can give the model more explicit and strong cross-lingual training signals so that the pre-trained model contains much beneficial cross-lingual information for unsupervised machine translation. As a result, we can further improve the translation performance significantly, compared with Lample and Conneau (2019) (with the significance level of $p<0.01$).

4.3 Usage of Pre-trained Decoder

As mentioned in Section 3.4, it is interesting to explore the different usage of pre-trained decoders in the MT task. According to our intuition, directly using the pre-trained model as the decoder may not work well because parameters of the decoder need substantial adjustment due to the attention part between the encoder and the decoder. Therefore, we treat the pre-trained decoder as the feature extractor and add several Transformer layers with the encoder-to-decoder attention on top of it. We also try to fix the pre-trained decoder and just fine-tune the encoder and the added decoder part. The experiments are conducted based on "Iter 1" with the results reported in Table 2.

From this table, we can see that directly using the pre-trained model as the decoder may be the best choice for most of the time, with the exceptions of en2fr and ro2en. By adding 6 Transformer layers on top of the original pre-trained decoder can achieve higher performance for en2fr and ro2en, but not significant. The reason could be that it is difficult to train the additional Transformer layers from scratch in the unsupervised scenario. There is also an interesting phenomenon that if we fix the pre-trained part of the decoder and only tune the added Transformer layers, the final performance will drop drastically, which indicates that the representation space of the decoder requires substantial adaptation, even though the pre-trained models already contain cross-lingual information. We think that further deep research on the decoder initialization could be a necessary and interesting topic in the future.

4.4 Evaluation of Cross-lingual Pre-trained Encoder

Word Alignment

To evaluate the cross-lingual modeling capacity of our pre-trained models, we first conduct experiments on the English-French (en-fr) dataset of the HLT/NAACL 2003 alignment shared task (Mihalcea and Pedersen, 2003). Given two parallel sentences in English and French respectively, we feed each sentence into the pre-trained cross-lingual encoder and get its respective outputs. Then, we calculate the similarities between the outputs of the two sentences and choose target words with max similarity scores as the alignments of corre-

Decoder type	fr2en	en2fr	de2en	en2de	ro2en	en2ro
Pre-trained	**34.8**	34.5	**35.5**	**27.9**	33.4	**34.7**
Pre-trained + 4 TF layers	34.2	33.9	34.9	26.8	32.5	33.2
Pre-trained + 6 TF layers	34.6	**34.9**	34.9	27.5	**33.6**	34.1
Pre-trained (fix) + 4 TF layers	26.8	22.0	23.9	19.2	24.7	25.9
Pre-trained (fix) + 6 TF layers	28.2	22.4	24.2	19.7	25.1	26.2

Table 2: Test BLEU scores with different usage of the pre-trained decoder.

sponding source words.

We compare the context-unaware method (i.e., directly calculating the similarity scores between unsupervised cross-lingual embeddings (Artetxe et al., 2018a) of source and target words), XLM (Lample and Conneau, 2019) and our proposed CMLM pre-training method in the Table 3. In this experiment, we leave out all the OOV words and those torn apart by the BPE operations.

Method	P	R	F	AER
Context-unaware	0.3860	0.1854	0.2505	0.6061
XLM	0.5480	0.3178	0.4023	0.4302
Ours	**0.5898**	**0.3497**	**0.4391**	**0.4016**

Table 3: Results of word alignment tasks using different cross-lingual word embeddings. In this table, "P" means "precision", "R" means recall", "F" means "F-measure" and "AER" means the "alignment error rate".

From this table, we find that, based on BERT, both XLM and our method can model cross-lingual context information, indicating that context information can greatly enhance the cross-lingual mapping between the source and target words. By leveraging the explicit cross-lingual information in the model training, our CMLM can outperform XLM significantly. This confirms that our CMLM does better to connect the source and target representation space, with which as pre-trained models, the performance of unsupervised NMT can be improved.

Cross-lingual Classification

We also conduct experiments on the cross-lingual classification task (Conneau et al., 2018) using the cross-lingual language inference (XNLI) dataset (Conneau et al., 2018). Specifically, we add a linear classification layer on top of the first hidden state of our pre-trained model and fine-tune its parameters on the English NLI dataset. Without using any labeled data for French (fr) and Germany (de) languages, we only report the zero-shot classification results for them as shown in Table 4. We can find that our method reaches a new record of the zero-shot cross-lingual classification task on languages of French (fr) and Germany (de), which confirms again that our CMLM works better on modeling cross-lingual information than previous methods in the unsupervised scenario.

Method	en	fr	de
(Conneau et al., 2018)	73.7	67.7	67.7
(Devlin et al., 2018)	81.4	-	70.5
(Lample and Conneau, 2019)	83.2	76.5	74.2
Ours	**83.4**	**77.1**	**74.7**

Table 4: Results of zero-shot cross-lingual classification (on XNLI test sets).

4.5 Ablation Study

In this section, we will discuss the different settings of our method. Firstly, the training loss of our pre-trained method contains two parts, i.e., CMLM and MLM, just as Eq.(5) shows. To study the respective influences of these two parts, we remove the MLM loss from it and compare the performance on en-fr and en-de translation tasks. Since our CMLM task differs from XLM in two aspects during pre-training. The first one is that we randomly choose n-grams to mask in the input text stream rather than BPE tokens, and the second one is that we predict the translation candidates of a source n-gram rather than predicting the source n-gram itself. Although the first one has proven to be beneficial during pre-training to some NLP tasks, we want to check how much its influence is to our final translation performance. Therefore, we disable those two modifications in CMLM one by one and report the translation results. Our experiments are conducted based on "Iter 1" with the results in Table 5.

From Table 5, we can find that the combination of CMLM and MLM can improve the translation performance by about 0.6 to 0.7 BLEU compared with any one only. This confirms the monolingual context modeling capacity of the MLM, which is quite useful for unsupervised machine translation. By combining CMLM and MLM, we can enforce

	fr2en	en2fr	de2en	en2de
CMLM + MLM	**34.8**	**34.9**	**35.5**	**27.9**
CMLM	34.1	34.3	35.1	27.2
- translation prediction	33.7	33.9	34.8	26.6
- - n-gram mask	33.3	33.4	34.3	26.4

Table 5: Ablation study. "CMLM + MLM" means we use $\mathcal{L}_{pre}$ as the pre-training loss; "CMLM" means we only use $\mathcal{L}_{cmlm}$ as the pre-training loss; "- translation prediction" means we predict the masked n-grams themselves rather than their translation candidates during pre-training; "- - n-gram mask" means we randomly mask BPE tokens rather than n-grams based on "- translation prediction" during pre-training, which degrades our method to XLM.

our model to learn both monolingual and cross-lingual information during pre-training. Besides, we find the two modifications(translation prediction and n-gram mask) made by CMLM have nearly equal contributions to the translation performance, except for en2de, where the "n-gram mask" has little influence.

5 Related Work

Unsupervised machine translation dates back to Klementiev et al. (2012); Nuhn et al. (2012), but becomes a hot research topic in recent years. As the pioneering methods, Artetxe et al. (2017); Lample et al. (2017); Yang et al. (2018) are mainly the modifications of the encoder-decoder structure. The core idea is to constrain outputs of encoders of two languages into a same latent space with a weight sharing mechanism such as using a shared encoder. Denoising auto-encoder (Vincent et al., 2010) and adversarial training methods are also leveraged. Besides, they apply iterative back-translation to generated pseudo data for cross-lingual training. In addition to NMT methods for unsupervised machine translation, some following work shows that SMT methods and the hybrid of NMT and SMT can be more effective (Artetxe et al., 2018b; Lample et al., 2018; Marie and Fujita, 2018; Ren et al., 2019). They all build unsupervised PBSMT systems, and all of their models are initialized with language models and phrase tables inferred from cross-lingual word or n-gram embeddings and then use the initial PBSMT models to do iterative back-translation. Lample et al. (2018) also build a hybrid system by combining the best pseudo data that SMT models generate into the training of the NMT model while Ren et al. (2019) alternately train SMT and NMT models with the framework of posterior regularization.

More recently, Lample and Conneau (2019) reach new state-of-the-art performance on unsupervised en-fr and en-de translation tasks. They propose a cross-lingual language model pre-training method based on BERT (Devlin et al., 2018), and then treat two cross-lingual language models as the encoder and decoder to finish the translation. Leveraging much more monolingual data from Wikipedia, their work shows a big potential of pre-training for unsupervised machine translation. However, the cross-lingual information is obtained mostly from the shared BPE space during their pre-training method, which is inexplicit and limited. Therefore, we figure out a new pre-training method that gives the model more explicit and stronger cross-lingual information.

In the recent work of Song et al. (2019), they also mask several consecutive tokens in the source sentence, but jointly pre-train the encoder and decoder by making the decoder to predict those masked tokens in both the source and target sides. Their method is a good case of pre-training for seq-to-seq tasks but the cross-lingual information incorporated with their method is from BPE sharing, which is also implicit. Our proposed method can be combined with their method within a multi-task framework, which could be done in the future.

6 Conclusion

In this paper, we propose a novel cross-lingual pre-training method for unsupervised machine translation. In our method, we leverage Cross-lingual Masked Language Model (CMLM) to incorporate explicit and strong cross-lingual information into pre-trained models. Experimental results on en-fr, en-de, and en-ro language pairs demonstrate the effectiveness of our proposed method.

In the future, we may apply our pre-training method to other language pairs and delve into the performance of the pre-trained encoders on other NLP tasks, such as Name Entity Recognition.

Abstract

Learning target side syntactic structure has been shown to improve Neural Machine Translation (NMT). However, incorporating syntax through latent variables introduces additional complexity in inference, as the models need to marginalize over the latent syntactic structures. To avoid this, models often resort to greedy search which only allows them to explore a limited portion of the latent space.

In this work, we introduce a new latent variable model, LaSyn, that captures the co-dependence between syntax and semantics, while allowing for effective and efficient inference over the latent space. LaSyn decouples direct dependence between successive latent variables, which allows its decoder to exhaustively search through the latent syntactic choices, while keeping decoding speed proportional to the size of the latent variable vocabulary. We implement LaSyn by modifying a transformer-based NMT system and design a neural expectation maximization algorithm that we regularize with part-of-speech information as the latent sequences. Evaluations on four different MT tasks show that incorporating target side syntax with LaSyn improves both translation quality, and also provides an opportunity to improve diversity.

1 Introduction

Syntactic information has been shown to improve the translation quality in NMT models. On the source side, syntax can be incorporated in multiple ways — either directly during encoding (Chen et al., 2018; Sennrich and Haddow, 2016; Eriguchi et al., 2016), or indirectly via multi-task learning to produce syntax informed representations (Eriguchi et al., 2017; Baniata et al., 2018; Niehues and Cho, 2017; Zaremoodi et al., 2018). On the target side, however, incorporating the syntax is more challenging due to the additional complexity in inference when decoding over latent states. To avoid this, existing methods resort to approximate inference over the latent states using a two-step decoding process (Gū et al., 2018; Wang et al., 2018a; Wu et al., 2017; Aharoni and Goldberg, 2017). Typically, the first stage decoder produces a beam of latent states, which serve as conditions to feed into the second stage decoder to obtain the target words. Thus, training and inference in these models can only explore a limited sub-space of the latent states.

In this work, we introduce LaSyn, a new target side syntax model that allows exhaustive exploration of the latent states to ensure a better translation quality. Similar to prior work, LaSyn approximates the co-dependence between syntax and semantics of the target sentences by modeling the joint conditional probability of the target words and the syntactic information at each position. However, unlike prior work, LaSyn eliminates the sequential dependence between the latent variables and simply infers the syntactic information at a given position based on the source text and the partial translation context. This allows LaSyn to search over a much larger set of latent state sequences. In terms of time complexity, unlike typical latent sequential models, LaSyn only introduces an additional term that is linear in the size of latent variable vocabulary and the length of the sentence.

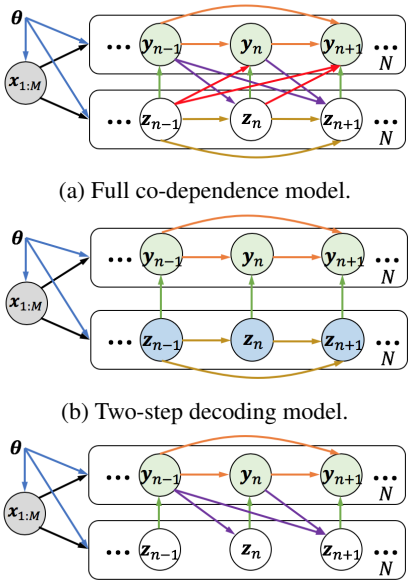
We implement LaSyn by modifying a transformer-based encoder-decoder model. The implementation uses a hybrid decoder that predicts two posterior distributions: the probability of syntactic choices at each position $P(\mathbf{z}_n|\mathbf{x}, \mathbf{y}_{<n})$, and the probability of the word choices at each position conditioned on each of the possible values for the latent states $P(\mathbf{y}_n|\mathbf{z}_n, \mathbf{x}, \mathbf{y}_{<n})$. The model cannot be trained by directly optimizing the data log-likelihood

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 780–790, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

because of its non-convex property. We devise a neural expectation maximization (NEM) algorithm, whose E-step computes the posterior distribution of latent states under current model parameters, and M-step updates model parameters using gradients from back-propagation. Given some supervision signal for the latent variables, we can modify this EM algorithm to obtain a regularized training procedure. We use parts-of-speech (POS) tag sequences, automatically generated by an existing tagger, as the source of supervision.

Because the decoder is exposed to more latent states during training, it is more likely to generate diverse translation candidates. To obtain diverse sequences, we can decode the most likely translations for different POS tag sequences. This is a more explicit and effective way of performing diverse translation than other methods based on diverse or re-ranking beam search (Vijayakumar et al., 2018; Li and Jurafsky, 2016), or coarse codes planning (Shu and Nakayama, 2018).

We evaluate LaSyn on four translation tasks. Evaluations show that LaSyn outperforms models that only use partial exploration of the latent states for incorporating target side syntax. A diversity based evaluation also shows that when using different POS tag sequences during inference, LaSyn produces more diverse and meaningful translations compared to existing models.



2 A Latent Syntax Model for Decoding

In a standard sequence-to-sequence model, the decoder directly predicts the target sequence $\mathbf{y}$ conditioned on the source input $\mathbf{x}$. The translation probability $P(\mathbf{y}|\mathbf{x})$ is modeled directly using the probability of each target word $\mathbf{y}_n$ at time step n conditioned on the source sequence $\mathbf{x}$ and the current partial target sequence $\mathbf{y}_{<n}$ as follows:

$$P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) = \prod_{n=1}^{N} P(\mathbf{y}_n|\mathbf{x},\mathbf{y}_{<n};\boldsymbol{\theta}) \qquad (1)$$

where, $\boldsymbol{\theta}$ denotes the parameters of both the encoder and the decoder.

In this work, we model syntactic information of target tokens using an additional sequence of variables, which captures the syntactic choices[1] at each time step. There are multiple ways of incorporating this additional information in a sequence-to-sequence model.

(a) Full co-dependence model.

(b) Two-step decoding model.

(c) LaSyn: Our Latent syntax model

Figure 1: Target-side Syntax Models: (a) An ideal solution that captures full co-dependence between syntax and semantics. (b) A widely-used two-step decoding model (Wang et al., 2018a; Wu et al., 2017; Aharoni and Goldberg, 2017). (c) LaSyn, our latent syntax model that uses non-sequential latent variables for exhaustive search of latent states.

An ideal solution should capture the co-dependence between syntax and semantics. In a sequential translation process, the word choices at each time step depend on both the semantics and the syntax of the words generated at the previous time steps. The same dependence also holds for the syntactic choices at each time step. Figure 1a shows a graphical model that captures this *full* co-dependence between the syntactic variable sequence $\mathbf{z}_1, \ldots, \mathbf{z}_N$ and the output word sequence $\mathbf{y}_1, \ldots, \mathbf{y}_N$. Such a model can be implemented using two decoders, one to decode syntax and the other to decode output words. The main difficulty, however, is that inference in this model is intractable since it involves marginalizing over the latent $\mathbf{z}$ sequences.

To keep inference tractable, existing approaches treat syntactic choices $\mathbf{z}$ as observed sequential variables (Gū et al., 2018; Wang et al., 2018a; Wu et al., 2017; Aharoni and Goldberg, 2017), as shown in Figure 1b. These models use a two-stage decoding process, where for each time step they

[1]The variables can be used to model any linguistic information that can be expressed as choices for each word position (e.g., morphological choices).

first produce most likely latent state $\mathbf{z}_n$ and then use this as input to a second stage that decodes words. However, this process is unsatisfactory in two respects. First, the inference of syntactic choices is still approximate as it does not explore the full space of $\mathbf{z}$. Second, these models are not well-suited for controllable or diverse translations. Using such a model to decode from an arbitrary $\mathbf{z}$ sequence is a divergence from its training, where it only learns to decode from a limited space of $\mathbf{z}$ sequences.

2.1 Model Description

Our goal is to design a model that allows for exhaustive search over syntactic choices. We introduce LaSyn, a new latent model shown in Figure 1c. The syntactic choices are modeled as *true latent variables* i.e., unobserved variables. Compared to the ideal model in Figure 1a, LaSyn includes two simplifications for tractability: (i) The dependence between successive syntactic choices is modeled indirectly, via the word choices made in the previous time steps. (ii) The word choice at each position depends only on the syntactic choice at the current position and the previous predicted words. Dependence on previous syntactic choices is modeled indirectly.

Under this model, the joint conditional probability of the target word $\mathbf{y}_n$ together with its corresponding latent syntactic choice $\mathbf{z}_n$[2] is given by:

$$P(\mathbf{y}_n, \mathbf{z}_n | \mathbf{x}, \mathbf{y}_{<n}) = P(\mathbf{y}_n | \mathbf{z}_n, \mathbf{x}, \mathbf{y}_{<n}) \times P(\mathbf{z}_n | \mathbf{x}, \mathbf{y}_{<n}) \quad (2)$$

We implement LaSyn by modifying the Transformer-based encoder-decoder architecture (Vaswani et al., 2017). As shown in Figure 2, LaSyn consists of a shared encoder for encoding source sentence $\mathbf{x}$ and a hybrid decoder that manages the decoding of the latent sequence $\mathbf{z}$ (left branch) and the target sentence $\mathbf{y}$ (right branch) separately.

The encoder consists of the standard self-attention layer, which generates representations of each token in the source sentence $\mathbf{x}$. The hybrid decoder consists of a self-attention layer that encodes the output generated thus far (i.e., the partial translation), followed by a inter-attention layer

[2]Note that $\mathbf{z}_n \in V_\mathbf{z}$, where $V_\mathbf{z}$ is the vocabulary of latent syntax for the target, which differs from language to language.

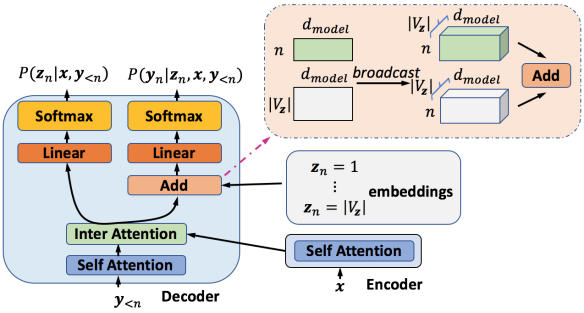


Figure 2: The architecture of LaSyn.

which computes the attention across the encoder and decoder representations.

The decoder's left branch predicts the latent variable distribution $P(\mathbf{z}_n | \mathbf{x}, \mathbf{y}_{<n})$ by applying a simple linear transformation and softmax on the inter-attention output, which contains information about the encoded input $\mathbf{x}$ and the partial translation $\mathbf{y}_{<n}$.

The right branch predicts the target word distribution $P(\mathbf{y}_n | \mathbf{z}_n, \mathbf{x}, \mathbf{y}_{<n})$ using the inter-attention output and the embeddings of all the available choices for $\mathbf{z}_n$. The choices for $\mathbf{z}_n$ are represented as embeddings that can be learned during training. We then combine the inter-attention output and the latent choice embeddings through an `Add` operation, which is a simple composition function that captures all combinations of additive interactions between the two. The dimension of the inter-attention is $n \times d_{model}$ and that of the latent embeddings is $|V_\mathbf{z}| \times d_{model}$, where $|V_\mathbf{z}|$ is the total number of choices for $\mathbf{z}_n$ or the size of the latent variable vocabulary. We broadcast them to the same dimension $n \times |V_\mathbf{z}| \times d_{model}$ and then simply add them together point-wise as shown in Figure 2. This is then fed to a linear transform and softmax over the target word vocabulary.

2.2 Inference with Exhaustive Search for Latent States

When using additional variables to model target side syntax, exact inference requires marginalizing over these additional variables.

$$P(\mathbf{y}|\mathbf{x}) = \sum_{\mathbf{z} \in F(\mathbf{z})} P(\mathbf{y}|\mathbf{z}, \mathbf{x}) P(\mathbf{z}|\mathbf{x}) \quad (3)$$

To avoid this exponential complexity, prior works use a two-step decoding process with models similar to the one shown in Figure 1b. They use greedy or beam search to explore a subset $B(\mathbf{z})$ of

the latent space to compute the posterior distribution as follows:

$$P(\mathbf{y}|\mathbf{x}) \simeq \sum_{\mathbf{z}\in B(\mathbf{z})} P(\mathbf{y}|\mathbf{z},\mathbf{x})P(\mathbf{z}|\mathbf{x}) \quad (4)$$

Finding the most likely translation using LaSyn also requires marginalizing over the latent states. However, because the latent states in LaSyn don't directly depend on each other, we can exhaustively search over the latent states. In particular, we can show that when $\mathbf{y}$ is fixed (observed), the $\{\mathbf{z}_n\}_{n=1}^{N}$ variables are d-separated (Bishop, 2006) i.e., are mutually independent. As a result, the time complexity for searching latent sequence $\mathbf{z}$ drops from $|V_\mathbf{z}|^N$ to $N|V_\mathbf{z}|$.

The posterior distribution for the translation probability at a time step n can be computed as follows:

$$\begin{aligned} &P(\mathbf{y}_n|\mathbf{x},\mathbf{y}_{<n}) \\ &= \sum_{\mathbf{z}_n\in F(\mathbf{z}_n)} P(\mathbf{y}_n,\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n}) \\ &= \sum_{\mathbf{z}_n\in F(\mathbf{z}_n)} P(\mathbf{y}_n|\mathbf{z}_n,\mathbf{x},\mathbf{y}_{<n}) \times P(\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n}) \end{aligned} \quad (5)$$

where, $F(\mathbf{z}_n)$ is the full search space of latent states $\mathbf{z}_n$ and the joint probability is factorized as specified in Equation 2.

For decoding words, we use standard beam search[3] with $P(\mathbf{y}_n,\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n})$ as the beam cost. With this inference scheme, we can easily control decoding for diversity, by feeding different $\mathbf{z}$ sequences to the right branch of the decoder and decode diverse $\mathbf{y}_n$ by directly using $P(\mathbf{y}_n|\mathbf{z}_n,\mathbf{x},\mathbf{y}_{<n})$ as the beam cost. Unlike the two-step decoding models which only evaluate a small number of $\mathbf{z}_n$ values at each time step (constrained by beam size), LaSyn evaluates all possible values for $\mathbf{z}_n$ at each time step, while avoiding the evaluation of all possible sequences.

2.3 Training with Neural Expectation Maximization

The log-likelihood of LaSyn's parameters $\boldsymbol{\theta}$[4] computed on one training pair $\langle\mathbf{x},\mathbf{y}\rangle \in D$ is given by:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\theta}) &= \log P(\mathbf{y}|\mathbf{x};\boldsymbol{\theta}) \\ &= \sum_{n=1}^{N} \log P(\mathbf{y}_n|\mathbf{x},\mathbf{y}_{<n};\boldsymbol{\theta}) \\ &= \sum_{n=1}^{N} \log \sum_{\mathbf{z}_n\in V_\mathbf{z}} P(\mathbf{y}_n,\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n}) \end{aligned} \quad (6)$$

Directly optimizing the log-likelihood function (equation 6) with respect to model parameter $\boldsymbol{\theta}$ is challenging because of the highly non-convex function $P(\mathbf{y}_n,\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n})$ and the marginalization over $\mathbf{z}_n$.[5] Alternatively, we optimize the system parameters by Expectation Maximization (EM).

Using Jensen's inequality, equation (6) can be re-written as:

$$\begin{aligned} \mathcal{L}(\boldsymbol{\theta}) &= \sum_{n=1}^{N} \log \sum_{\mathbf{z}_n\in V_\mathbf{z}} Q(\mathbf{z}_n) \frac{P(\mathbf{y}_n,\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n})}{Q(\mathbf{z}_n)} \\ &\geq \sum_{n=1}^{N} \sum_{\mathbf{z}_n\in V_\mathbf{z}} Q(\mathbf{z}_n) \log \frac{P(\mathbf{y}_n,\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n})}{Q(\mathbf{z}_n)} \\ &= \mathcal{L}_{lower}(Q,\boldsymbol{\theta}) \end{aligned} \quad (7)$$

where $\mathcal{L}_{lower}(Q,\boldsymbol{\theta})$ is the lower bound of the log-likelihood and Q is any auxiliary probability distribution defined on $\mathbf{z}_n$. $\boldsymbol{\theta}$ is omitted from the expression for simplicity.

We set $Q(\mathbf{z}_n) = P(\mathbf{z}_n|\mathbf{x},\mathbf{y}_{\leq n};\boldsymbol{\theta}^{old})$, the probability of the latent state computed by the decoder (shown in the left branch in Figure 2). Substituting this in equation (7), we obtain the lower bound as

$$\begin{aligned} &\mathcal{L}_{lower}(Q,\boldsymbol{\theta}) = \\ &\sum_{n=1}^{N} \sum_{\mathbf{z}_n\in V_\mathbf{z}} P(\mathbf{z}_n|\mathbf{x},\mathbf{y}_{\leq n};\boldsymbol{\theta}^{old}) \times \log P(\mathbf{y}_n,\mathbf{z}_n|\mathbf{x},\mathbf{y}_{<n};\boldsymbol{\theta}) \\ &- P(\mathbf{z}_n|\mathbf{x},\mathbf{y}_{\leq n};\boldsymbol{\theta}^{old}) \times \log P(\mathbf{z}_n|\mathbf{x},\mathbf{y}_{\leq n};\boldsymbol{\theta}^{old}) \\ &= \mathcal{Q}(\boldsymbol{\theta},\boldsymbol{\theta}^{old}) + C \end{aligned} \quad (8)$$

[3]Note our primary goal is to perform exhaustive search in the latent space. Search in the target vocabulary space remains exponential in our model.

[4]This includes the trainable parameters of the encoder, decoder, and the latent state embeddings.

[5]Note that marginalization is an issue during training, unlike in inference. As $P(y_n,z_n)$ is already an non-convex function with respect to θ, summing $P(y_n,z_n)$ over different values of z_n makes the function more complicated. Besides, we also need to compute gradients to update the parameters and computing the gradient of a log-of-sum function is costly and unstable. During the translation, we only need to compute the value of $\mathcal{L}(\theta)$ as score for beam searching. Therefore, the marginalization is not an issue.

where

$$\mathcal{Q}(\boldsymbol{\theta}, \boldsymbol{\theta}^{old}) = \sum_{n=1}^{N} \sum_{\mathbf{z}_n \in V_{\mathbf{z}}} P(\mathbf{z}_n | \mathbf{x}, \mathbf{y}_{\leq n}; \boldsymbol{\theta}^{old}) \times \log P(\mathbf{y}_n, \mathbf{z}_n | \mathbf{x}, \mathbf{y}_{<n}; \boldsymbol{\theta}) \quad (9)$$

EM algorithm for optimizing $\mathcal{Q}(\boldsymbol{\theta}, \boldsymbol{\theta}^{old})$ consists of two major steps. In the E-step, we compute the posterior distribution of $\mathbf{z}_n$ with respect to $\boldsymbol{\theta}^{old}$ by

$$\gamma(\mathbf{z}_n = i) = P(\mathbf{z}_n = i | \mathbf{x}, \mathbf{y}_{\leq n}) = \frac{P(\mathbf{y}_n, \mathbf{z}_n = i | \mathbf{x}, \mathbf{y}_{<n})}{\sum_{\mathbf{z}_n = j} P(\mathbf{y}_n, \mathbf{z}_n = j | \mathbf{x}, \mathbf{y}_{<n})} \quad (10)$$

where $\gamma(\mathbf{z}_n = i)$ is the responsibility of $\mathbf{z}_n = i$ given $\mathbf{y}_n$, and can be calculated by equation (2).

In the M-step, we aim to find the configuration of $\boldsymbol{\theta}$ that would maximize the expected log-likelihood using the posteriors computed in the E-step. In conventional EM algorithm for shallow probabilistic graphical model, the M-step is generally supposed to have closed-form solution. However, we model the probabilistic dependencies by deep neural networks, where $\mathcal{Q}(\boldsymbol{\theta}, \boldsymbol{\theta}^{old})$ is highly non-convex and non-linear with respect to network parameters $\boldsymbol{\theta}$. Therefore, there exists no analytical solution to maximize it. However, since deep neural network is differentiable, we can update $\boldsymbol{\theta}$ by taking a gradient ascent step:

$$\boldsymbol{\theta}^{new} = \boldsymbol{\theta}^{old} + \eta \frac{\partial \mathcal{Q}(\boldsymbol{\theta}, \boldsymbol{\theta}^{old})}{\partial \boldsymbol{\theta}}, \quad (11)$$

The resulting algorithm belongs to the class of *generalized EM algorithms* and is guaranteed (for a sufficiently small learning rate η) to converge to a (local) optimum of the data log likelihood (Wu, 1983).

2.4 Regularized EM training

The EM training we derived does not assume any supervision for the latent variables $\mathbf{z}$. This can be seen as inferring the latent syntax of the target sentences by clustering the target side tokens into $|V_{\mathbf{z}}|$ different categories. Given some token-level syntactic information, we can modify the training procedure to regularize the generation of latent sequence $P(\mathbf{z}_n | \mathbf{x}, \mathbf{y}_{<n})$ such that true latent sequences have higher probabilities under the model. In this work, we consider parts-of-speech sequences of the target sentences for regularization.

The regularized EM training objective is thus redefined as

$$\mathcal{L}_{total}(\boldsymbol{\theta}) = \mathcal{L}_{lower}(\boldsymbol{\theta}) + \lambda \mathcal{L}_{\mathbf{z}}(\boldsymbol{\theta}), \quad (12)$$

where $\mathcal{L}_{lower}(\boldsymbol{\theta})$ is the EM lower bound in equation (7) and $\mathcal{L}_{\mathbf{z}}(\boldsymbol{\theta})$ denotes cross entropy loss between $P(\mathbf{z}_n | \mathbf{x}, \mathbf{y}_{<n})$ and the true POS tag sequences and λ is a hyper-parameter that controls the impact of the regularization.

This regularized training algorithm is shown in Algorithm 1.

Algorithm 1 Training NMT with latent POS tag sequences through Regularized Neural EM

Objective: Maximize the log likelihood function $\mathcal{Q}(\boldsymbol{\theta}, \boldsymbol{\theta}^{old})$ with respect to $\boldsymbol{\theta}$ over observed variable $\mathbf{y}$ and latent variable $\mathbf{z}$, governed by parameters $\boldsymbol{\theta}$.
Input: Parallel corpus training data $\langle \mathbf{x}, \mathbf{y} \rangle$; POS tag sequence $\mathbf{z}$ of target sentence; the number of EM update steps per batch K.
Initialize: Initialize random values for the parameters $\boldsymbol{\theta}^{old}$.
while Training loss has not converged **do**
  Select $\langle \mathbf{x}, \mathbf{y} \rangle \in D$, parse $\mathbf{z}$ of $\mathbf{y}$.
  for $k \leftarrow 1$ to K **do**
    1. E-step: Evaluate $\gamma(\mathbf{z}_n = i)$ for $i \leq |V_{\mathbf{z}}|$.
    2. M-step: Evaluate $\boldsymbol{\theta}^{new}$ given by equation (11).
    3. Let $\boldsymbol{\theta}^{old} \leftarrow \boldsymbol{\theta}^{new}$.
  end for
end while

3 Evaluation

We evaluate LaSyn on four translation tasks, including three with moderate sized datasets IWSLT 2014 (Cettolo et al., 2015) German-English (De-En), English-German (En-De), English-French (En-Fr), and one with a relatively larger dataset, the WMT 2014 English-German (En-De). We describe the datasets in more details in the appendix.

We compare against three types of baselines: (i) general Seq2Seq models that use no syntactic information, (ii) models that incorporate source side syntax directly, and multitask learning models which include syntax indirectly, and (iii) models that use syntax on the target side. We also define a LaSyn **Empirical Upper Bound (EUB)**, which is our proposed model using true POS tag sequences for inference.

We use BLEU as the evaluation metric (Papineni et al., 2002) for translation quality. For diverse translation evaluation, we utilize *distinct-1* score (Li et al., 2016) as the evaluation metric,

which is the number of distinct unigrams divided by total number of generated words.

For all translation tasks, we choose the *base* configuration of Transformer with $d_{model} = 512$. During training, we choose Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ with initial learning rate is 0.0002 with 4000 warm-up steps. We describe additional implementation and training details in the Appendix.

3.1 Results on IWSLT'14 Tasks

Table 1 compares LaSyn versions against some of the state-of-the-art models on the IWSLT'14 dataset. LaSyn-K rows show results when varying the number of EM update steps per batch (K).

On the De-En task, LaSyn provides a 1.7 points improvements over the Transformer baseline, demonstrating that the LaSyn's improvements come from incorporating target side syntax effectively. This result is also better than a transformer-based source side syntax model by 1.5 points. LaSyn results are also better than the published numbers for LSTM-based models that use multi-task learning for source side and models that uses target side syntax. Note that since the underlying architectures are different, we only present these results to show that the results with LaSyn are comparable with other models that have incorporated syntax.

On the En-De task, our model achieves 29.2 in terms of BLEU score, with 2.6 points improvement over the Transformer baseline and 2.4 points improvement over Transformer-based Source Side Syntax model. Compared with NPMT (Huang et al., 2018), which is a BiLSTM based model, we achieve 3.84 point improvement.

On the En-Fr task, our model set a new state-of-the-art with a BLEU score of 40.6, which is 1.7 points improvement over the second best model which uses Transformer to incorporate source side syntax knowledge. Our model also surpasses the basic Transformer model by about 2.1 points.

We notice that across all tasks, the performance of our model improves with number of EM update steps per batch (K). With larger K values, we get better lower bounds $\mathcal{L}_{lower}(\boldsymbol{\theta})$ on each training batch, thus leading to better optimization. For update steps beyond $K > 5$, the performance does not improve any more.

Last, the EUB row indicates the performance that can be obtained when feeding in the true POS tags. The large improvement here shows the potential for improvement when modeling target side syntax.

Table 2 shows one example where LaSyn produces correct translations for a long input sentence. The output of LaSyn is close to the reference and the output of LaSyn when given the gold POS tag sequence is even better, demonstrating the benefits of modeling syntax. The transformer model however fails to decode the later portions of the long input accurately.

3.2 Speed

We compare the speeds of our (un-optimized) implementation of LaSyn with a vanilla transformer with no latents in its decoder. Table 3 shows the training time per epoch, and the inference time for the whole test set. computed on the IWSLT'14 De-En task. When $K = 1$, LaSyn takes almost twice as much time as the vanilla transformer for training. Increasing K increases training time further. For inference, LaSyn takes close to four times as much time compared to the vanilla Transformer. In terms of complexity, LaSyn only adds a linear term (in POS tag size to the decoding complexity. Specifically, its decoding complexity is $B \times O(m) \times O(|V_{\mathbf{z}}| \times N)$ where B is beam size, m is a constant proportional to the tag set size and N is output size. As the table shows, empirically, our current implementation incurs $m \simeq 4$. We leave further optimizations for future work.

3.3 Diversity

We compare the diversity of translations using *distinct-1* score (Li et al., 2016), which is simply the number of distinct unigrams divided by total number of generated words. We use our model to generate 10 translations for each source sentence of the test dataset. We then compare our results with baseline Transformer. The result is shown in Table 4. Much like translation quality, LaSyn's diversity increases with number of EM updates and is better than diversity of the transformer and a source side encoder model.

3.3.1 Controlling Diversity with POS Sequences

One of the main strengths of LaSyn is that it can generate translations conditioned on a given POS sequence. First, we present some examples that we generate by decoding over different POS tag sequences. Given a source sentence, we use

Method Type	Model	BLEU		
		De-En	En-De	En-Fr
BiLSTM	BiLSTM (Denkowski and Neubig, 2017)	–	–	34.8

LaSyn to provide the most-likely target pos tag sequence. Then, we obtain a random set of valid POS tag sequences that differ from this maximum likely sequence by some edit distance. For each of these randomly sampled POS tag sequences, we let LaSyn generate a translation that fits the sequence. Table 5 shows some example sentences. LaSyn is able to generate diverse translations that reflect the sentence structure implied by the input POS tags. However, in trying to fit the translation into the specified sequence, it deviates somewhat from the ideal translation.

To understand how diversity plays against translation quality, we also conduct a small scale quantitative evaluation. We pick a subset of the test dataset, and for each source sentence in this subset, we sample 10 POS tag sequences whose edit distance to their corresponding Top-1 POS tag sequence equal to a specific value, we then use them

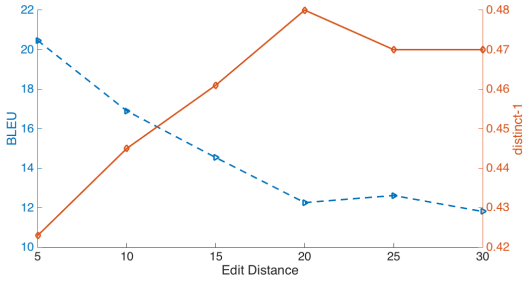

Figure 3: Diversity vs. Translation Quality: BLEU and *distinct-1* scores for targets decoded using POS sequences of increasing edit distance.

to decode W translations. We calculate their final BLEU and *distinct-1* scores. The results are shown in Figure: 3. As the edit distance increases, diversity increases dramatically but at the cost of translation quality. Since the POS tag sequence acts as a template for generation, as we move further from the most likely template, the model struggles to fit the content accurately. Understanding this trade-off can be useful for re-ranking or other scoring functions.

3.4 Results on WMT'14 En-De

To assess the impact on a larger dataset, we show results on the WMT'14 English-German in table 6. Compared to the previously reported systems, we see that our transformer implementation is a strong baseline. LaSyn produces small gains, with the best gain at K=5 – a BLEU score improvement of 0.6. This demonstrates that syntactic information can contribute more to the increase of translation quality on a smaller dataset.

4 Related Work

Attention-based Neural Machine Translation (NMT) models have shown promising results in various large scale translation tasks (Bahdanau et al., 2015; Luong et al., 2015; Sennrich et al., 2016; Vaswani et al., 2017) using an `Seq2Seq` structure. Many Statistical Machine Translation (SMT) approaches have leveraged benefits from modeling syntactic information (Chiang et al., 2009; Huang and Knight, 2006; Shen et al., 2008). Recent efforts have demonstrated that incorporating syntax can also be useful in neural methods as well.

Model	BLEU

LaSyn (K=3) (base)	27.8
LaSyn (K=5) (base)	**27.9**

Table 6: **WMT'14 English-German results** - shown are the BLEU scores of various models on TED talks translation tasks. We highlight the **best** model in bold.

One branch uses features on the source side to help improve the translation performance (Sennrich and Haddow, 2016; Morishita et al., 2018; Eriguchi et al., 2016). Sennrich *et al.* (2016) explored linguistic features like lemmas, morphological features, POS tags and dependency labels and concatenate their embeddings with sentence features to improve the translation quality. In a similar vein, Morishita *et al.* (2018) and Eriguchi *et al.* (2016), incorporated hierarchical subword features and phrase structure into the source side representations. Despite the promising improvements, these approaches are limited in that the trained translation model requires the availability of external tools during inference – the source text needs to be processed first to extract syntactic structure (Eriguchi et al., 2017).

Another branch uses multitask learning, where the encoder of the NMT model is trained to produce multiple tasks such as POS tagging, named-entity recognition, syntactic parsing or semantic parsing (Eriguchi et al., 2017; Baniata et al., 2018; Niehues and Cho, 2017; Zaremoodi et al., 2018). These can be seen as models that implicitly generate syntax informed representations during encoding. With careful model selection, these methods have demonstrate some benefits in NMT.

The third branch directly models the syntax of

the target sentence during decoding (Gū et al., 2018; Wang et al., 2018a; Wu et al., 2017; Aharoni and Goldberg, 2017; Bastings et al., 2017; Li et al., 2018). Aharoni *et al.* (2017) treated constituency trees as sequential strings and trained a `Seq2Seq` model to translate source sentences into these tree sequences. Wang *et al.* (2018a) and Wu *et al.* (2017) proposed to use two RNNs, a Rule RNN and a Word RNN, to generate a target sentence and its corresponding tree structure. Gu *et al.* (2018) proposed a model to translate and parse at the same time. However, apart from the complex tree structure to model, they all have a similar architecture as shown in Figure 1b, which limits them to only exploring a small portion of the syntactic space during inference.

LaSyn uses simpler parts-of-speech information in a latent syntax model, avoiding the typical exponential search complexity in the latent space with a linear search complexity and is optimized by EM. This allows for better translation quality as well as diversity. Similar to our work, (Shankar et al., 2018) and (Shankar and Sarawagi, 2019) proposed a latent attention mechanism to further reduce the complexity of model implementation by taking a top-K approximation instead of the EM algorithm as in LaSyn.

5 Conclusion

Modeling target-side syntax through true latent variables is difficult because of the additional inference complexity. In this work, we presented LaSyn, a latent syntax model that allows for efficient exploration of a large space of latent sequences. This yields significant gains on four translation tasks, IWSLT'14 English-German, German-English, English-French and WMT'14 English-German. The model also allows for better decoding of diverse translation candidates. This work only explored parts-of-speech sequences for syntax. Further extensions are needed to tackle tree-structured syntax information.

Abstract

While back-translation is simple and effective in exploiting abundant monolingual corpora to improve low-resource neural machine translation (NMT), the synthetic bilingual corpora generated by NMT models trained on limited authentic bilingual data are inevitably noisy. In this work, we propose to quantify the confidence of NMT model predictions based on model uncertainty. With word- and sentence-level confidence measures based on uncertainty, it is possible for back-translation to better cope with noise in synthetic bilingual corpora. Experiments on Chinese-English and English-German translation tasks show that uncertainty-based confidence estimation significantly improves the performance of back-translation. [1]

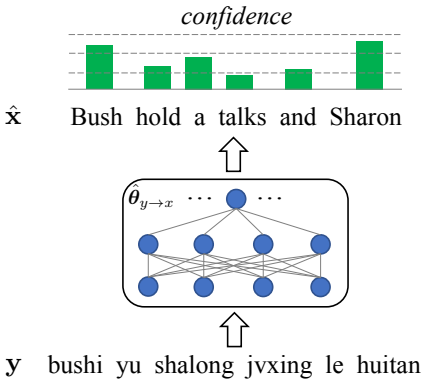

Figure 1: Confidence estimation for back-translation. Back-translation generates a source (e.g., English) sentence for a ground-truth target (e.g., Chinese) sentence. Such synthetic sentence pairs are used to train NMT models. As the model prediction (i.e., $\hat{\mathbf{x}}$) is often noisy, our work aims to quantify the prediction confidence using model uncertainty to alleviate error propagation.

1 Introduction

The past several years have witnessed the rapid development of end-to-end neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017), which leverages neural networks to map between natural languages. Capable of learning representations from data, NMT has significantly outperformed conventional statistical machine translation (SMT) (Koehn et al., 2003) and been widely deployed in large-scale MT systems in the industry (Wu et al., 2016; Hassan et al., 2018).

Despite the remarkable success, NMT suffers from the data scarcity problem. For most language pairs, large-scale, high-quality, and wide-coverage bilingual corpora do not exist. Even for the top handful of resource-rich languages, the major sources of available parallel corpora are often restricted to government documents or news articles.

Therefore, improving NMT under small-data training conditions has attracted extensive attention in recent years (Sennrich et al., 2016a; Cheng et al., 2016; Zoph et al., 2016; Chen et al., 2017; Fadaee et al., 2017; Ren et al., 2018; Lample et al., 2018). Among them, back-translation (Sennrich et al., 2016a) is an important direction. Its basic idea is to use an NMT model trained on limited authentic bilingual corpora to generate synthetic bilingual corpora using abundant monolingual data. The authentic and synthetic bilingual corpora are then combined to re-train NMT models. Due to its simplicity and effectiveness, back-translation has been widely used in low-resource language translation. However, as the synthetic corpora generated by the NMT model are inevitably noisy, translation errors can be propagated to subsequent steps and prone to hinder the

performance (Fadaee and Monz, 2018; Poncelas et al., 2018).

In this work, we propose a method to quantify the confidence of NMT model predictions to enable back-translation to better cope with translation errors. The central idea is to use *model uncertainty* (Buntine and Weigend, 1991; Gal and Ghahramani, 2016; Dong et al., 2018; Xiao and Wang, 2019) to measure whether the model parameters can best describe the data distribution. Based on the expectation and variance of word- and sentence-level translation probabilities calculated by Monte Carlo Dropout (Gal and Ghahramani, 2016), we introduce various confidence measures.

Different from most previous quality estimation studies that require feature extraction (Blatz et al., 2004; Specia et al., 2009; Salehi et al., 2014) or post-edited data (Kim et al., 2017; Wang et al., 2018; Ive et al., 2018) to train external confidence estimators, all our approach needs is the NMT model itself. Hence, it is easy to apply our approach to arbitrary NMT models trained for arbitrary language pairs. Experiments on Chinese-English and English-German translation tasks show that our approach significantly improves the performance of back-translation.

2 Background

Let $\mathbf{x} = x_1 \dots x_I$ be a source-language sentence and $\mathbf{y} = y_1 \dots y_J$ be a target-language sentence. We use $P(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{x\to y})$ to denote a source-to-target NMT model (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) parameterized by $\boldsymbol{\theta}_{x\to y}$. Similarly, the target-to-source NMT model is denoted by $P(\mathbf{x}|\mathbf{y}, \boldsymbol{\theta}_{y\to x})$.

Let $\mathcal{D}_b = \{\langle \mathbf{x}^{(m)}, \mathbf{y}^{(m)} \rangle\}_{m=1}^{M}$ be an *authentic* bilingual corpus that contains M sentence pairs and $\mathcal{D}_m = \{\mathbf{y}^{(n)}\}_{n=1}^{N}$ be a monolingual corpus that contains N target sentences. The first step of back-translation (Sennrich et al., 2016a) is to train a target-to-source model on the authentic bilingual corpus $\mathcal{D}_b$ using maximum likelihood estimation:

$$\hat{\boldsymbol{\theta}}_{y\to x} = \underset{\boldsymbol{\theta}_{y\to x}}{\operatorname{argmax}} \Big\{ L(\mathcal{D}_b, \boldsymbol{\theta}_{y\to x}) \Big\}, \quad (1)$$

where the log-likelihood is defined as

$$L(\mathcal{D}_b, \boldsymbol{\theta}_{y\to x}) = \sum_{m=1}^{M} \log P(\mathbf{x}^{(m)}|\mathbf{y}^{(m)}, \boldsymbol{\theta}_{y\to x}). \quad (2)$$

The second step is to use the trained model $\hat{\boldsymbol{\theta}}_{y\to x}$ to translate the monolingual corpus $\mathcal{D}_m$:

$$\hat{\mathbf{x}}^{(n)} = \underset{\mathbf{x}}{\operatorname{argmax}} \Big\{ P(\mathbf{x}|\mathbf{y}^{(n)}, \hat{\boldsymbol{\theta}}_{y\to x}) \Big\}, \quad (3)$$

where $\hat{\mathbf{x}}^{(n)} = \hat{x}_1^{(n)} \dots \hat{x}_I^{(n)}$. The word-level decision rule is given by

$$\hat{x}_i^{(n)} = \underset{x}{\operatorname{argmax}} \Big\{ P(x|\mathbf{y}^{(n)}, \hat{\mathbf{x}}_{<i}^{(n)}, \hat{\boldsymbol{\theta}}_{y\to x}) \Big\}. \quad (4)$$

The resulting translations $\{\hat{\mathbf{x}}^{(n)}\}_{n=1}^{N}$ can be combined with $\mathcal{D}_m$ to generate a *synthetic* bilingual corpus $\tilde{\mathcal{D}}_b = \{\langle \hat{\mathbf{x}}^{(n)}, \mathbf{y}^{(n)} \rangle\}_{n=1}^{N}$.

The third step is to train a source-to-target model $P(\mathbf{y}|\mathbf{x}, \boldsymbol{\theta}_{x\to y})$ on the combination of authentic and synthetic bilingual corpora:

$$\hat{\boldsymbol{\theta}}_{x\to y} = \underset{\boldsymbol{\theta}_{x\to y}}{\operatorname{argmax}} \Big\{ L(\mathcal{D}_b \cup \tilde{\mathcal{D}}_b, \boldsymbol{\theta}_{x\to y}) \Big\}. \quad (5)$$

This three-step process can iterate until convergence (Hoang et al., 2018; Cotterell and Kreutzer, 2018).

A problem with back-translation is that model predictions are inevitably erroneous. Translation errors can be propagated to subsequent steps and impair the performance of back-translation, especially when $\tilde{\mathcal{D}}_b$ is much larger than $\mathcal{D}_b$ (Pinnis et al., 2017; Fadaee and Monz, 2018; Poncelas et al., 2018). Therefore, it is crucial to develop principled solutions to enable back-translation to better deal with the error propagation problem.

3 Approach

This work aims to find solutions to the two following problems:

1. How to quantify the confidence of model predictions at both word and sentence levels?

2. How to leverage confidence to improve back-translation?

Section 3.1 introduces how to calculate model uncertainty, which lays a foundation for designing uncertainty-based word- and sentence-level confidence measures in Section 3.2. Section 3.3 describes confidence-aware training for NMT models on noisy bilingual corpora.

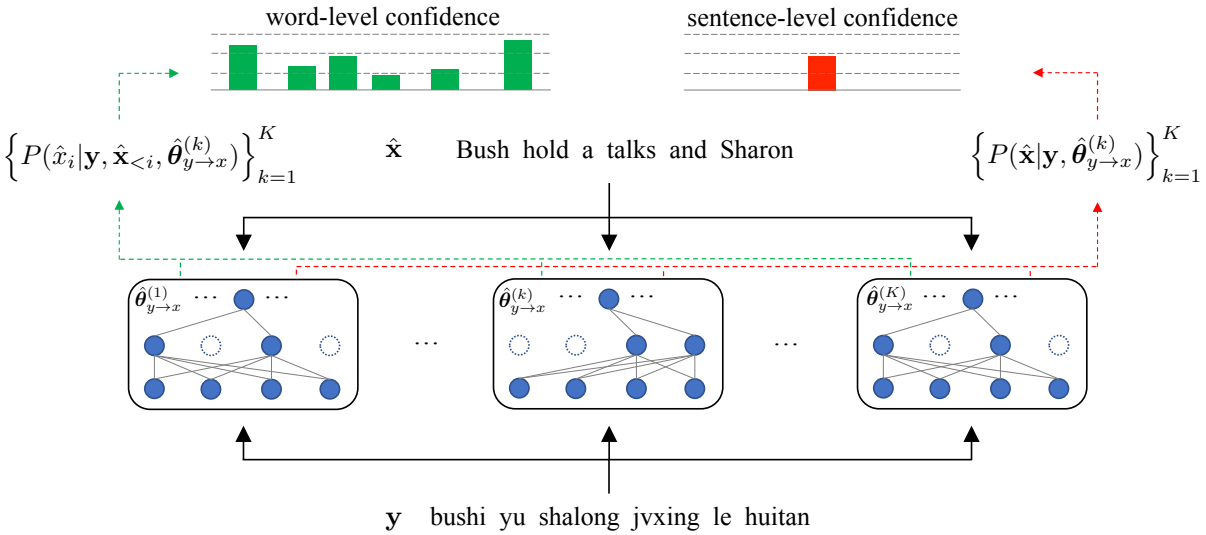

Figure 2: Illustration of uncertainty calculation. Given a target sentence $\mathbf{y}$ and the model prediction $\hat{\mathbf{x}}$, our approach treats word- and sentence-level translation probabilities as random variables and uses Monte Carlo Dropout to draw samples. These samples are used to calculate the expectations and variances of translation probabilities.

3.1 Calculating Uncertainty

Uncertainty quantification, which quantifies how confident a certain mapping is with respect to different inputs, has made significant progress due to the recent advances in Bayesian deep learning (Kendall et al., 2015; Gal and Ghahramani, 2016; Kendall and Gal, 2017; Xiao and Wang, 2019; Oh et al., 2019; Geifman et al., 2019; Lee et al., 2019). In this work, we aim to calculate *model uncertainty* (Kendall and Gal, 2017; Dong et al., 2018; Xiao and Wang, 2019), which measures whether a model can best describe the data distribution, for NMT using approximate inference methods widely used in Bayesian neural networks.

Given the authentic bilingual corpus $\mathcal{D}_b$, Bayesian neural networks aim at finding the posterior distribution over model parameters $P(\boldsymbol{\theta}_{y\to x}|\mathcal{D}_b)$. With a target sentence $\mathbf{y}$ in the monolingual corpus $\mathcal{D}_m$ and its translation $\hat{\mathbf{x}}$, the translation probability is given by

$$P(\hat{\mathbf{x}}|\mathbf{y}, \mathcal{D}_b) = \int P(\hat{\mathbf{x}}|\mathbf{y}, \boldsymbol{\theta}_{y\to x}) P(\boldsymbol{\theta}_{y\to x}|\mathcal{D}_b) d\boldsymbol{\theta}_{y\to x}. \quad (6)$$

In particular, we are interested in calculating the variance of the distribution $P(\hat{\mathbf{x}}|\mathbf{y}, \boldsymbol{\theta}_{y\to x})$ that reflects our ignorance over model parameters, which is referred to as *model uncertainty*. As exact inference is intractable, a number of variational inference methods (Graves, 2011; Blundell et al., 2015; Gal and Ghahramani, 2016) have been proposed to find an approximation to $P(\boldsymbol{\theta}_{y\to x}|\mathcal{D}_b)$. In this work, we leverage the widely used Monte Carlo Dropout (Gal and Ghahramani, 2016) to obtain samples of word- and sentence-level translation probabilities.

Figure 2 illustrates the key idea of our approach. Given an authentic target sentence $\mathbf{y}$, an NMT model made its prediction $\hat{\mathbf{x}}$ via a standard decoding process (see Eq. (3) and Eq. (4)). To quantify how confident the model was when making the prediction, our approach treats word- and sentence-level translation probabilities as random variables. [2] Drawing samples can be done by randomly deactivating part of neurons of the NMT model and re-calculating translation probabilities while keeping $\mathbf{y}$ and $\hat{\mathbf{x}}$ fixed. This stochastic feed-forward is repeated K times and generates K samples for both word- and sentence-level translation probabilities, respectively. We use $\hat{\boldsymbol{\theta}}^{(k)}_{y\to x}$ to denote the model parameters derived from $\hat{\boldsymbol{\theta}}_{y\to x}$ by deactivation in the k-th pass.

Intuitively, if the variance of translation probability is low, it is highly likely that the model was confident in making the prediction. Given K samples $\{P(\hat{\mathbf{x}}|\mathbf{y}, \hat{\boldsymbol{\theta}}^{(k)}_{y\to x})\}_{k=1}^{K}$, the expectation

[2] Unlike prior studies that calculate model uncertainty during inference (Xiao and Wang, 2019), our approach computes uncertainty after the NMT model has made the prediction for two reasons. First, our goal is to quantify the confidence of model prediction rather than using uncertainty to improve model prediction. Second, using Monte Carlo Dropout during decoding is very slow because of the autoregressive property of standard NMT models.

of sentence-level translation probability can be approximated by

$$\mathbb{E}\Big[P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x})\Big] \approx \frac{1}{K}\sum_{k=1}^{K} P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}^{(k)}_{y\to x}). \quad (7)$$

The variance of sentence-level translation probability can be approximated by

$$\begin{aligned}&\mathrm{Var}\Big[P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x})\Big]\\ &\approx \frac{1}{K}\sum_{k=1}^{K} P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}^{(k)}_{y\to x})^2 - \mathbb{E}\Big[P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x})\Big]^2, \quad (8)\end{aligned}$$

which is also referred to as *model uncertainty*.

The expectation and variance of word-level translation probabilities can also be calculated similarly using K samples.

3.2 Confidence Measures

We use $C(\mathbf{y},\hat{\mathbf{x}}_{<i},\hat{x}_i,\hat{\boldsymbol{\theta}}_{y\to x})$ to denote the *word-level confidence* for the model to generate $\hat{x}_i$ and $C(\mathbf{y},\hat{\mathbf{x}},\hat{\boldsymbol{\theta}}_{y\to x})$ to the denote the *sentence-level confidence* for the model to generate $\hat{\mathbf{x}}$.

Intuitively, when making predictions, the more confident an NMT model is, the higher expectation and lower variance of translation probability are. For comparison reasons, we used the following four types of confidence measures at the sentence level in our experiments:

1. *Predicted translation probability* (PTP). The translation probability of model prediction during standard decoding (Eq. (3)):

$$C_{\mathrm{PTP}}(\mathbf{y},\hat{\mathbf{x}},\hat{\boldsymbol{\theta}}_{y\to x}) = P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x}). \quad (9)$$

2. *Expected translation probability* (EXP). The expectation of translation probability:

$$C_{\mathrm{EXP}}(\mathbf{y},\hat{\mathbf{x}},\hat{\boldsymbol{\theta}}_{y\to x}) = \mathbb{E}\Big[P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x})\Big]. \quad (10)$$

3. *Variance of translation probability* (VAR). The variance of translation probability:

$$\begin{aligned}&C_{\mathrm{VAR}}(\mathbf{y},\hat{\mathbf{x}},\hat{\boldsymbol{\theta}}_{y\to x})\\ &= \Big(1 - \mathrm{Var}\Big[P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x})\Big]\Big)^{\alpha}. \quad (11)\end{aligned}$$

4. *Combination of expectation and variance* (CEV). The combination of expectation and variance:

$$\begin{aligned}&C_{\mathrm{CEV}}(\mathbf{y},\hat{\mathbf{x}},\hat{\boldsymbol{\theta}}_{y\to x})\\ &= \left(1 - \frac{\mathrm{Var}\big[P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x})\big]}{\mathbb{E}\big[P(\hat{\mathbf{x}}|\mathbf{y},\hat{\boldsymbol{\theta}}_{y\to x})\big]}\right)^{\beta}. \quad (12)\end{aligned}$$

where α and β are hyper-parameters to control the gap between confidence values of sentences of different quality. Larger values of α and β lead to bigger gaps. [3]

In Eq. (12), our approach tries to combine the merits of expectation and variance by using variance divided by expectation because smaller variance and bigger expectation are expected to result in higher confidence. There may exist more sophisticated ways to estimate prediction confidence using model uncertainty (Dong et al., 2018). As we find that the measures mentioned above are easy-to-implement and prove to be effective in our experiments, we leave the investigation of more complex confidence measures for future work.

The word-level confidence measures can be defined similarly.

3.3 Confidence-aware Training for NMT

We propose confidence-aware training for NMT to enable NMT to make better use of noisy data. Word- and sentence-level confidence measures are complementary: while word-level confidence can provide more fine-grained information than the sentence-level counterpart, it is unable to cope with word omission errors that can only be captured at the sentence level. As a result, our approach incorporates both word- and sentence-level confidence measures into the training process. [4]

Using Sentence-level Confidence

It is easy to integrate sentence-level confidence into back-translation by modifying the likelihood function in Eq. (5):

$$\begin{aligned}&L(\mathcal{D}_b \cup \tilde{\mathcal{D}}_b, \boldsymbol{\theta}_{x\to y})\\ =\ &\sum_{m=1}^{M} \log P(\mathbf{y}^{(m)}|\mathbf{x}^{(m)},\boldsymbol{\theta}_{x\to y}) +\\ &\sum_{n=1}^{N} C(\mathbf{y}^{(n)},\hat{\mathbf{x}}^{(n)},\hat{\boldsymbol{\theta}}_{y\to x}) \times\\ &\log P(\mathbf{y}^{(n)}|\hat{\mathbf{x}}^{(n)},\boldsymbol{\theta}_{x\to y}). \quad (13)\end{aligned}$$

[3] Note that all confidence measures are between 0 and 1. Clearly, both the expectation and variance of a probability are between 0 and 1. It can be proved that the variance of a probability is no greater than the corresponding expectation. As a result, $C_{\mathrm{CEV}}(\cdot)$ is also between 0 and 1.

[4] Instead of applying confidence estimation to the second pass of decoding (Luong et al., 2017), we directly integrate confidence scores into the training process. These two kinds of methods are complementary.

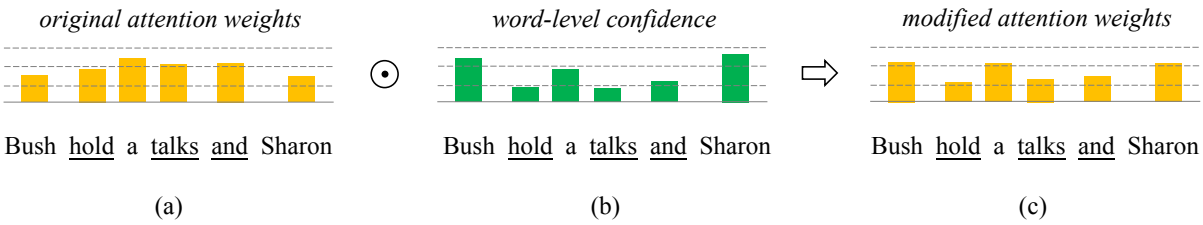

Figure 3: Using word-level confidence in confidence-aware training. The basic idea is to use confidence to modify attention weights to pay less attention to erroneous words highlighted in underline. (a) The original attention weights of the NMT model; (b) the word-level confidence of the noisy source sentence; (c) the attention weights modified by the word-level confidence, which focus more on words with high confidence. $\odot$ is a broadcast product. See Eq. (15) for details.

Serving as a weight assigned to each synthetic sentence pair, sentence-level confidence is expected to help to minimize the negative effect of estimating parameters on sentences with lower confidence. Note that the confidence of an authentic sentence pair in $\mathcal{D}_b$ is 1.

Using Word-level Confidence

As the source side instead of the target side of the synthetic bilingual corpus is noisy, word-level confidence cannot be integrated into back-translation in a similar way to sentence-level confidence. This is because the word-level confidence associated with each source word does not get involved in backpropagation during training.

Alternatively, we build a real-valued word-level confidence vector:

$$\mathbf{c} = \left\{ C\left(\mathbf{y}^{(n)}, \hat{\mathbf{x}}^{(n)}_{<i}, \hat{x}_i, \hat{\boldsymbol{\theta}}_{y \to x}\right) \right\}_{i=1}^{I}. \quad (14)$$

Due to the wide use of attention (Bahdanau et al., 2015; Vaswani et al., 2017) in NMT, we use the confidence vector $\mathbf{c} \in \mathbb{R}^{1 \times I}$ to modify attention weights and enable the model to focus more on words with high confidence. Figure 3 shows an example. Figure 3(a) gives a source sentence in the synthetic bilingual corpus, in which erroneous words "hold", "talks", and "and" receive high attention weights, deteriorating the parameter estimation on this sentence pair. By multiplying with word-level confidence (Figure 3(b)), the weights are modified to pay less attention to erroneous words (Figure 3(c)).

More formally, the modified attention function is given by

$$\begin{aligned} &\mathrm{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}, \mathbf{c}) \\ &= \left(\mathrm{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{D}} \right) \odot \mathbf{c} \right) \mathbf{V}, \end{aligned} \quad (15)$$

where $\mathbf{Q} \in \mathbb{R}^{I \times D}$, $\mathbf{K} \in \mathbb{R}^{I \times D}$, and $\mathbf{V} \in \mathbb{R}^{I \times D}$ are query, key, and value matrices and D is the hidden size. $\odot$ is a broadcast product.

Since the integration of sentence- and word-level confidence measures are independent of each other, it is easy to use both of them in back-translation.

4 Experiments

4.1 Setup

We evaluated our approach on Chinese-English and English-German translation tasks. The evaluation metric is BLEU (Papineni et al., 2001) as calculated by the `multi-bleu.perl` script. We use the paired bootstrap resampling (Koehn, 2004) for significance testing.

For the Chinese-English task, the training set contains 1.25M sentence pairs from LDC[5] with 27.8M Chinese words and 34.5M English words. To build the monolingual corpus for back-translation, we extracted the English side of the training set of the WMT 2017 Chinese-English news translation task. After removing sentences longer than 256 words, we randomly selected 10M English sentences as the monolingual corpus. NIST06 is used as the development set and NIST02, 03, 04, 05, and 08 datasets as test sets.

For the English-German task, we used the dataset of the WMT 2014 English-German translation task. The training set consists of 4.47M sentence pairs with 116M English words and 110M German words. We randomly selected 4.5M German sentences from the 2012 News Crawl corpus of WMT 2014 to construct the monolingual corpus for back-translation. We use newstest 2013 as

[5]The training set includes LDC2002E18, LDC2003E07, LDC2003E14, part of LDC2004T07, LDC2004T08 and LDC2005T06.

the development set and newstest 2012, 2014, and 2015 as test sets.

Chinese sentences were segmented by an open-source toolkit THULAC[6] . German and English sentences were tokenized by the tokenizer in Moses (Koehn et al., 2007). We used byte pair encoding (Sennrich et al., 2016b) to perform sub-word segmentation with 32k merge operations for Chinese-English and 35k merge operations for English-German. Sentence pairs are batched together by approximate length and each batch has roughly 25,000 source and target tokens. We distinguish between three kinds of translations of the monolingual corpus:

1. NONE: there is no translation and only the authentic bilingual corpus is used;

2. SEARCH: the translations are generated by beam search (Sennrich et al., 2016a);

3. SAMPLE: the translations are generated by sampling (Edunov et al., 2018).

As neural quality estimation (Kim et al., 2017; Wang et al., 2018) can also give word- and sentence-level confidences for the output of NMT models when labeled data is available, we distinguish between two kinds of confidence estimation methods:

1. NEURALQE: the confidences are given by an external neural quality estimator;

2. UNCERTAINTY: the proposed uncertainty-based confidence estimation method.

For NEURALQE, we used the Predictor-Estimator architecture (Kim et al., 2017) implemented by OpenKiwi (Kepler et al., 2019), which is an open source software officially recommended by the QE shared task of WMT. Following the guide of OpenKiwi, we used a German-English parallel corpus containing 2.09M sentence pairs to train the predictor and a post-edited corpus containing 25k sentence triples to train the estimator. All the data used to train QE models are provided by WMT. As there are no post-edited corpora for the Chinese-English task, NEURALQE can only be used in the English-German task in our experiments. For NEURALQE, both word- and sentence- level quality scores were considered.

We implemented our method on the top of THUMT (Zhang et al., 2017). The NMT model we use is Transformer (Vaswani et al., 2017). We used the base model for the Chinese-English task and the big model for the English-German task. We used the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$ to optimize model parameters. We used the same warm-up strategy for learning rate as Vaswani et al. (2017) with $\text{warmup_steps} = 4,000$. During training, the hyper-parameter of label smoothing was set as $\epsilon_{ls} = 0.1$ (Szegedy et al., 2016; Pereyra et al., 2017). During training and the Monte Carlo Dropout process, the hyper-parameter of dropout was set to 0.1 and 0.3 for Transformer base and big models, respectively. K was set to 20. Through experiments, we find our method works best when the α and β are set to 2. All experiments were conducted on 8 NVIDIA GTX 1080Ti GPUs.

4.2 Comparison of Confidence Measures

Table 1 shows the comparison of confidence measures on the Chinese-English development set. We find that using either the translation probabilities outputted by the model (i.e., "PTP") or the expectation of translation probabilities (i.e., "EXP") deteriorates the translation quality, which suggests that translation probabilities themselves can not help NMT models better cope with synthetic data.

Table 3: BLEU scores on the NIST Chinese-English translation task. The ratio of authentic data to synthetic data is 1:1. NONE: only the authentic bilingual corpus is used. SEARCH: the translations of the monolingual corpus are generated by beam search (Sennrich et al., 2016a). SAMPLE: the translations of the monolingual corpus are generated by sampling (Edunov et al., 2018). "CE": confidence estimation method. "U": the proposed uncertainty-based confidence estimation. "All": the combination of all test sets. "+": significantly better than SEARCH without CE ($p < 0.05$). "++": significantly better than SEARCH without CE ($p < 0.01$). "‡‡": significantly better than SAMPLE without CE ($p < 0.01$).

In contrast, using the variance or model uncertainty (i.e., "VAR") increases translation quality. Combining variance and expectation (i.e., "CEV") leads to a further improvement. In the following experiments, we use CEV as the default setting.

4.3 Comparison between Word- and Sentence-level Confidence Measures

Table 2 shows the comparison between word- and sentence-level CEV (i.e., combination of expectation and variance) confidence measures on the Chinese-English development set. It is clear that using either sentence-level or word-level confidence measures improves the translation performance. Thanks to more fine-grained quantification of uncertainty, using word-level confidence achieves a higher BLEU score than using sentence-level confidence. Combining the sentence- and word-level of confidences leads to a further improvement, suggesting that they are complementary to each other. In the following experiments, we use the combination of word- and sentence-level confidences as the default setting.

4.4 Main Results

The Chinese-English Task

Table 3 shows the results of the Chinese-English task. Back-translation, either generating translations using beam search (i.e., SEARCH) or using sampling (i.e., SAMPLE), does lead to significant improvements over using only the authentic bilingual corpus (i.e., NONE). We find that SAMPLE is more effective than SEARCH, which confirms the finding of Edunov et al. (2018). Using uncertainty-based confidence (i.e., "U") significantly improves over both SEARCH and SAMPLE on the combination of all test sets ($p < 0.01$). As there is no Chinese-English labeled data to train neural quality estimation models, we did not report the result of NEURALQE in this experiment.

The English-German Task

Table 4 shows the results of the English-German task. We find that using quality estimation, either NEURALQE (i.e., "N") or UNCERTAINTY (i.e., "U"), improves over SEARCH and SAMPLE. UNCERTAINTY even achieves better performance than NEURALQE, although NEURALQE uses additional labeled training data. As NEURALQE heavily relies on post-edited corpora and labeled data to train QE models, it can only be used in a handful of language pairs. In contrast, it is easier to apply our approach to arbitrary language pairs since it does not need any labeled data to estimate confidence.

4.5 Effect of Training Corpus Size

Figure 4 shows the effect of training corpus size. The X-axis is the size of the total training data (i.e., $\mathcal{D}_b \cup \tilde{\mathcal{D}}_b$ in Eq. (5)). The BLEU scores were calculated on the Chinese-English development set. We find that the translation performance of SEARCH rises with the increase of monolingual corpus size in the beginning. However, further enlarging the monolingual corpus hurts the translation performance. In contrast, our approach can still obtain further improvements when adding more synthetic bilingual sentence pairs. Similar findings are also observed for SAMPLE.

Data	CE	news2013	news2012	news2014	news2015	All
NONE	-	26.57	22.09	28.42	30.26	26.31

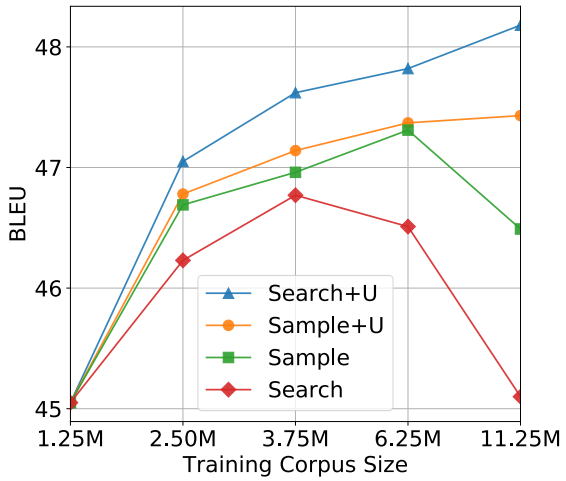

Figure 4: Effect of training corpus size.

4.6 Effect of Data Selection

Instead of randomly selecting monolingual sentences to generate synthetic data, we also used the method proposed by (Fadaee and Monz, 2018) to select monolingual data by targeting difficult words. In this series of experiments, we used the same amount of monolingual data that was derived from a larger monolingual corpus using different data selection methods.

Results on NIST06 show that targeting difficult words improves over randomly selecting monolingual data (46.23 → 46.60 BLEU), confirming the finding of Fadaee and Monz (2018). Using uncertainty-based confidence can further improve the translation performance (46.60 → 47.18 BLEU), indicating that our approach can be combined with advanced data selection methods.

4.7 Case Study

Figure 5 shows an example of model prediction and its corresponding word- and sentence-level confidence measures for the English-German task. We observe that the PTP and EXP measures are unable to give low confidence to erroneous words. In contrast, variance-based measures such as VAR and CEV can better quantify how confident the model is to make its prediction.

5 Related work

Our work is closely related to three lines of research: (1) back-translation, (2) confidence estimation, and (3) uncertainty quantification.

5.1 Back-translation

Back-translation is a simple and effective approach to leveraging monolingual data for NMT (Sennrich et al., 2016a). There has been a growing body of literature that analyzes and extends back-translation recently. Currey et al. (2017) show that low-resource NMT can benefit from the synthetic data generated by simply copying target monolingual data to the source side. Imamura et al. (2018) and Edunov et al. (2018) demonstrate that it is more effective to generate source sentences via sampling rather than beam search. Cotterell and Kreutzer (2018) and Hoang et al.

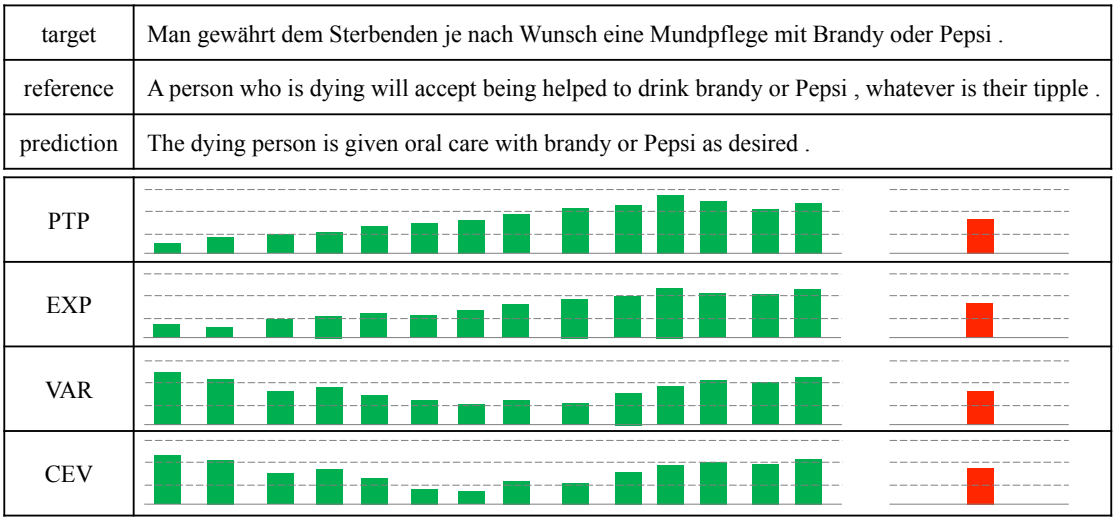

Figure 5: Example of confidence measures.

(2018) find that iterative back-translation can further improve the performance of NMT. Fadaee and Monz (2018) show that words with high predicted loss during training benefit most. Our work differs from existing methods in that we propose to use confidence estimation to enable back-translation to better cope with noisy synthetic data, which can be easily combined with previous works. Our experiments show that both neural and uncertainty-based confidence estimation methods benefit back-translation.

5.2 Confidence Estimation

Estimating the confidence or quality of the output of MT systems (Ueffing and Ney, 2007; Specia et al., 2009; Bach et al., 2011; Salehi et al., 2014; Rikters and Fishel, 2017; Kepler et al., 2019) is important for enabling downstream applications such as post-editing and interactive MT to better cope with translation mistakes. While existing methods rely on external models to estimate confidence, our approach leverages model uncertainty to derive confidence measures. The major benefit is that our approach does not need labeled data.

5.3 Uncertainty Quantification

Reliable uncertainty quantification is key to building a robust artificial intelligent system. It has been successfully applied to many fields, including computer vision (Kendall et al., 2015; Kendall and Gal, 2017), time series prediction (Zhu and Laptev, 2017), and natural language processing (Dong et al., 2018; Xiao and Wang, 2019). Our work differs from previous work in that we are interested in calculating uncertainty after the model has made the prediction rather during inference. Ott et al. (2018) also analyze the inherent uncertainty of machine translation. The difference is that they focus on the existence of multiple correct translations for a single sentence while we aim to quantify the uncertainty of NMT models.

6 Conclusions

We have presented a method for qualifying model uncertainty for neural machine translation and use uncertainty-based confidence measures to improve back-translation. The key idea is to use Monte Carlo Dropout to sample translation probabilities to calculate model uncertainty, without the need for manually labeled data. As our approach is transparent to model architectures, we plan to further verify the effectiveness of our approach on other downstream applications of NMT such as post-editing and interactive MT in the future.

Abstract

In this study, we first investigate a novel capsule network with dynamic routing for linear time Neural Machine Translation (NMT), referred as CAPSNMT. CAPSNMT uses an aggregation mechanism to map the source sentence into a matrix with pre-determined size, and then applys a deep LSTM network to decode the target sequence from the source representation. Different from the previous work (Sutskever et al., 2014) to store the source sentence with a passive and bottom-up way, the dynamic routing policy encodes the source sentence with an iterative process to decide the credit attribution between nodes from lower and higher layers. CAPSNMT has two core properties: it runs in time that is linear in the length of the sequences and provides a more flexible way to aggregate the part-whole information of the source sentence. On WMT14 English-German task and a larger WMT14 English-French task, CAPSNMT achieves comparable results with the Transformer system. To the best of our knowledge, this is the first work that capsule networks have been empirically investigated for sequence to sequence problems.[1]

1 Introduction

Neural Machine Translation (NMT) is an end-to-end learning approach to machine translation which has recently shown promising results on multiple language pairs (Luong et al., 2015; Shen et al., 2015; Wu et al., 2016; Gehring et al., 2017a; Kalchbrenner et al., 2016; Sennrich et al., 2015; Vaswani et al., 2017). Unlike conventional Statistical Machine Translation (SMT) systems (Koehn et al., 2003; Chiang, 2005) which consist of multiple separately tuned components, NMT aims at building upon a single and large neural network to directly map input text to associated output text (Sutskever et al., 2014).

In general, there are several research lines of NMT architectures, among which the Enc-Dec NMT (Sutskever et al., 2014) and the Enc-Dec Att NMT are of typical representation (Bahdanau et al., 2014; Wu et al., 2016; Vaswani et al., 2017). The Enc-Dec represents the source inputs with a fixed dimensional vector and the target sequence is generated from this vector word by word. The Enc-Dec, however, does not preserve the source sequence resolution, a feature which aggravates learning for long sequences. This results in the computational complexity of decoding process being $\mathcal{O}(|S| + |T|)$, with $|S|$ denoting the source sentence length and $|T|$ denoting the target sentence length. The Enc-Dec Att preserves the resolution of the source sentence which frees the neural model from having to squash all the information into a fixed represention, but at a cost of a quadratic running time. Due to the attention mechanism, the computational complexity of decoding process is $\mathcal{O}(|S| \times |T|)$. This drawbacks grow more severe as the length of the sequences increases.

Currently, most work focused on the Enc-Dec Att, while the Enc-Dec paradigm is less emphasized on despite its advantage of linear-time decoding (Kalchbrenner et al., 2016). The linear-time approach is appealing, however, the performance lags behind the Enc-Dec Att. One potential issue is that the Enc-Dec needs to be able to compress all the necessary information of the input source sentence into context vectors which are fixed during decoding. Therefore, a natural question was raised, *Will carefully designed aggregation operations help the Enc-Dec paradigm to achieve the best performance?*

In recent promising work of capsule network, a dynamic routing policy is proposed and proven to

[1]The work is partially done when the first author worked at Tencent.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 803–812,

effective (Sabour et al., 2017; Zhao et al., 2018; Gong et al., 2018). Following a similar spirit to use this technique, we present CAPSNMT, which is characterized by capsule encoder to address the drawbacks of the conventional linear-time approaches. The capsule encoder processes the attractive potential to address the aggregation issue, and then introduces an iterative routing policy to decide the credit attribution between nodes from lower (child) and higher (parent) layers. Three strategies are also proposed to stabilize the dynamic routing process. We empirically verify CAPSNMT on WMT14 English-German task and a larger WMT14 English-French task. CAPSNMT achieves comparable results with the state-of-the-art Transformer systems. Our contributions can be summarized as follows:

- We propose a sophisticated designed linear-time CAPSNMT which achieved comparable results with the Transformer framework. To the best of our knowledge, CAPSNMT is the first work that capsule networks have been empirically investigated for sequence-to-sequence problems.

- We propose several techniques to stabilize the dynamic routing process. We believe that these technique should always be employed by capsule networks for the best performance.

2 Linear Time Neural Machine Translation

From the perspective of machine learning, the task of linear-time translation can be formalized as learning the conditional distribution $p(\mathbf{y}|\mathbf{x})$ of a target sentence (translation) $\mathbf{y}$ given a source sentence $\mathbf{x}$. Figure 1 gives the framework of our proposed linear time NMT with capsule encoder, which mainly consists of two components: a constant encoder that represents the input source sentence with a fixed-number of vectors, and a decoder which leverages these vectors to generate the target-side translation. Please note that due to the fixed-dimension representation of encoder, the time complexity of our model could be linear in the number of source words.

Constant Encoder with Aggregation Layers Given the input source sentence $\mathbf{x} = x_1, x_2 \cdots, x_L$, Then, we introduce capsule networks to transfer

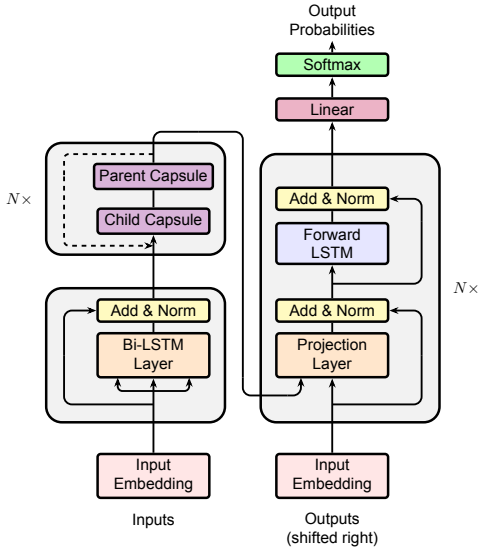

Figure 1: CAPSNMT:Linear time neural machine translation with capsule encoder

$$\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \cdots, \mathbf{x}_L] \in \mathbb{R}^{L \times d_x}.$$

The goal of the constant encoder is to transfer the inputs $\mathbf{X} \in \mathbb{R}^{L \times d_v}$ into a pre-determined size representation

$$\mathbf{C} = [\mathbf{c}_1, \mathbf{c}_2, \cdots, \mathbf{c}_M] \in \mathbb{R}^{M \times d_c}.$$

where $M < L$ is the pre-determined size of the encoder output, and d_c is the dimension of the hidden states.

We first introduce a bi-directional LSTM (BiLSTM) as the primary-capsule layer to incorporate forward and backward context information of the input sentence:

$$\begin{aligned} \overrightarrow{\mathbf{h}_t} &= \overrightarrow{\mathbf{LSTM}}(\mathbf{h}_{t-1}, \mathbf{x}_t) \\ \overleftarrow{\mathbf{h}_t} &= \overleftarrow{\mathbf{LSTM}}(\mathbf{h}_{t+1}, \mathbf{x}_t) \\ \mathbf{h}_t &= [\overrightarrow{\mathbf{h}_t}, \overleftarrow{\mathbf{h}_t}] \end{aligned} \quad (1)$$

Here we produce the sentence-level encoding $\mathbf{h}_t$ of word $\mathbf{x}_t$ by concatenating the forward $\overrightarrow{\mathbf{h}_t}$ and backward output vector $\overleftarrow{\mathbf{h}_t}$. Thus, the output of BiLSTM encoder are a sequence of vectors $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_L]$ corresponding to the input sequence.

On the top of the BiLSTM, we introduce several aggregation layers to map the variable-length inputs into the compressed representation. To demonstrate the effectiveness of our encoder, we

compare it with a more powerful aggregation method, which mainly involves Max and Average pooling.

Both Max and Average pooling are the simplest ways to aggregate information, which require no additional parameters while being computationally efficient. Using these two operations, we perform pooling along the time step as follows:

$$\mathbf{h}^{max} = \max([\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_L]) \quad (2)$$

$$\mathbf{h}^{avg} = \frac{1}{L}\sum_{i=1}^{L}\mathbf{h}_i \quad (3)$$

Moreover, because the last time step state h_L and the first time step state h_1 provide complimentary information, we also exploit them to enrich the final output representation of encoder. Formally, the output representation of encoder consists of four vectors,

$$\mathbf{C} = [\mathbf{h}^{max}, \mathbf{h}^{avg}, \mathbf{h}_1, \mathbf{h}_L]. \quad (4)$$

The last time step state $\mathbf{h}_L$ and the first time step state $\mathbf{h}_1$ provide complimentary information, thus improve the performance. The compressed represention $\mathbf{C}$ is fixed for the subsequent translation generation, therefore its quality directly affects the success of building the Enc-Dec paradigm. In this work, we mainly focus on how to introduce aggregation layers with capsule networks to accurately produce the compressed representation of input sentences, of which details will be provided in Section 3.

LSTM Decoder The goal of the LSTM is to estimate the conditional probability $p(y_t|y_{<t}; x_1, x_2, \cdots, x_T)$, where $(x_1, x_2, \cdots, x_T)$ is the input sequence and $(y_1, y_2, \cdots, y_{T'})$ is its corresponding output sequence.

A simple strategy for general sequence learning is to map the input sequence to a fixed-sized vector, and then to map the vector to the target sequence with a conditional LSTM decoder(Sutskever et al., 2014):

$$\begin{aligned}\mathbf{s}_t &= \mathbf{LSTM}(\mathbf{s}_{t-1}, \mathbf{u}_t) \\ \mathbf{u}_t &= \mathrm{ATT}(\mathbf{C}, \mathbf{s}_{t-1}) + \mathbf{y}_t\end{aligned} \quad (5)$$

where $\mathbf{y}_t$ is the target word embedding of y_t, $\mathbf{u}_t$ is the inputs of LSTM at time step t, $\mathbf{C}$ is the concatenation of the source sentence representation and $\mathrm{ATT}(\cdot)$ is the traditional attention function.

At inference stage, we only utilize the top-most hidden states $\mathbf{s}_t$ to make the final prediction with a softmax layer:

$$p(y_t|y_{t-1}, \mathbf{x}) = \mathbf{softmax}(\mathbf{W}_o\mathbf{s}_t). \quad (6)$$

Similar as (Vaswani et al., 2017), we also employ a residual connection (He et al., 2016) around each of the sub-layers, followed by layer normalization (Ba et al., 2016).

3 Aggregation layers with Capsule Networks

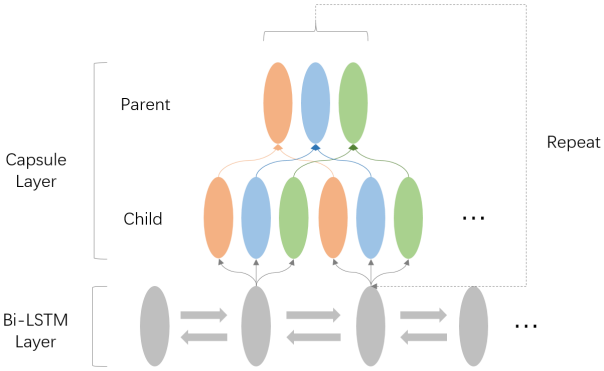

Figure 2: Capsule encoder with dynamic routing by agreement

The aggregation layers with capsule networks play a crucial role in our model. As shown in Figure 2, unlike the traditional linear-time approaches collecting information in a bottom-up approach without considering the state of the whole encoding, our capsule layer is able to iteratively decide the information flow, where the part-whole relationship of the source sentence can be effectively captured.

3.1 Child-Parent Relationships

To compress the input information into the representation with pre-determined size, the central issue we should address is to determine the information flow from the input capsules to the output capsules.

Capsule network is an ideal solution which is able to address the representational limitation and exponential inefficiencies of the simple aggregation pooling method. It allows the networks to automatically learn child-parent (or part-whole) relationships. Formally, $\mathbf{u}_{i\to j}$ denotes the information be transferred from the child capsule $\mathbf{h}_i$ into the

parent capsule $\mathbf{c}_j$:

$$\mathbf{u}_{i\to j} = \alpha_{ij}\mathbf{f}(\mathbf{h}_i, \boldsymbol{\theta}_j) \tag{7}$$

where $\alpha_{ij} \in \mathbb{R}$ can be viewed as the voting weight on the information flow from child capsule to the parent capsule; $\mathbf{f}(\mathbf{h}_i, \boldsymbol{\theta}_j)$ is the transformation function and in this paper, we use a single layer feed forward neural networks:

$$\mathbf{f}(\mathbf{h}_i, \boldsymbol{\theta}_j) = \mathbf{ReLU}(\mathbf{h}_i\mathbf{W}_j) \tag{8}$$

where $\mathbf{W}_j \in \mathbb{R}^{d_c\times d_c}$ is the transformation matrix corresponding to the position j of the parent capsule.

Finally, the parent capsule aggregates all the incoming messages from all the child capsules:

$$\mathbf{v}_i = \sum_{j=1}^{L} \mathbf{u}_{j\to i} \tag{9}$$

and then squashes $\mathbf{v}_i$ to $||\mathbf{v}_i|| \in (0, 1)$ confine. ReLU or similar non linearity functions work well with single neurons. However we find that this squashing function works best with capsules. This tries to squash the length of output vector of a capsule. It squashes to 0 if it is a small vector and tries to limit the output vector to 1 if the vector is long.

$$\begin{aligned}\mathbf{c}_i &= \mathbf{squash}(\mathbf{v}_i) \\ &= \frac{||\mathbf{v}_i||^2}{1+||\mathbf{v}_i||^2}\frac{\mathbf{v}_i}{||\mathbf{v}_i||}\end{aligned} \tag{10}$$

3.2 Dynamic Routing by Agreement

The dynamic routing process is implemented via an EM iterative process of refining the coupling coefficient α_{ij} , which measures proportionally how much information is to be transferred from $\mathbf{h}_i$ to $\mathbf{c}_j$.

At iteration t, the coupling coefficient α_{ij} is computed by

$$\alpha_{ij}^t = \frac{\exp(b_{ij}^{t-1})}{\sum_k \exp(b_{ik}^{t-1})} \tag{11}$$

where $\sum \alpha_j \alpha ij$. This ensures that all the information from the child capsule $\mathbf{h}_i$ will be transferred to the parent.

$$b_{ij}^t = b_{ij}^{t-1} + \mathbf{c}_j^t \cdot \mathbf{f}(\mathbf{h}_i^t, \boldsymbol{\theta}_j^t) \tag{12}$$

This coefficient b_{ij}^t is simply a temporary value that will be iteratively updated with the value b_{ij}^{t-1} of the previous iteration and the scalar product of $\mathbf{c}_j^{t-1}$ and $\mathbf{f}(\mathbf{h}_j^{t-1}, \boldsymbol{\theta}_j^{t-1})$, which is essentially the similarity between the input to the capsule and the output from the capsule. Likewise, remember from above, the lower level capsule will send its output to the higher level capsule with similar output. Particularly, b_{ij}^0 is initialized with 0. The coefficient depends on the location and type of both the child and the parent capsules, which iteratively refinement of b_{ij}. The capsule network can increase or decrease the connection strength by dynamic routing. It is more effective than the previous routing strategies such as max-pooling which essentially detects whether a feature is present in any position of the text, but loses spatial information about the feature.

Algorithm 1 Dynamic Routing Algorithm

procedure ROUTING($[\mathbf{h}_1, \mathbf{h}_2, \cdots, \mathbf{h}_L]$,$T$)
  Initialize $\mathbf{b}_{ij}^0 \leftarrow 0$
  for each $t \in$ range$(0 : T)$ **do**
    Compute the routing coefficients α_{ij}^t for all $i \in [1, L], j \in [1, M]$ ▷ From Eq.(11)
    Update all the output capsule $\mathbf{c}_j^t$ for all $j \in [1, M]$ ▷ From Eq.(7,8,9,10)
    Update all the coefficient $\mathbf{b}_{ij}^t$ for all $i \in [1, L], j \in [1, M]$ ▷ From Eq.(12)
  end for
  return $[\mathbf{c}_1, \mathbf{c}_2, \cdots, \mathbf{c}_M]$
end procedure

When an output capsule $\mathbf{c}_j^t$ receives the incoming messages $\mathbf{u}_{i\to j}^t$, its state will be updated and the coefficient α_{ij}^t is also re-computed for the input capsule $\mathbf{h}_i^{t-1}$. Thus, we iteratively refine the route of information flowing, towards an instance dependent and context aware encoding of a sequence. After the source input is encoded into M capsules, we map these capsules into vector representation by simply concatenating all capsules:

$$\mathbf{C} = [\mathbf{c}_1, \mathbf{c}_2, \cdots, \mathbf{c}_M] \tag{13}$$

Finally matrix $\mathbf{C}$ will then be fed to the final end to end NMT model as the source sentence encoder.

In this work, we also explore three strategies to improve the accuracy of the routing process.

Position-aware Routing strategy The routing process iteratively decides what and how much information is to be sent to the final encoding with considering the state of both the final outputs cap-

sule and the inputs capsule. In order to fully exploit the order of the child and parent capsules to capture the child-parent relationship more efficiently, we add "positional encoding" to the representations of child and parent capsules. In this way, some information can be injected according to the relative or absolute position of capsules in the sequence. In this aspect, there are many choices of positional encoding proposed in many NLP tasks (Gehring et al., 2017b; Vaswani et al., 2017). Their experimental results strongly demonstrate that adding positional information in the text is more effective than in image since there is some sequential information in the sentence. In this work, we follow (Vaswani et al., 2017) to apply sine and cosine functions of different frequencies.

Non-sharing Weight Strategy Besides, we explore two types of transformation matrices to generate the message vector $\mathbf{u}_{i\to j}$ which has been previously mentioned Eq.(7,8). The first one shares parameters $\boldsymbol{\theta}$ across different iterations. In the second design, we replace the shared parameters with the non-shared strategy $\boldsymbol{\theta}^t$ where t is the iteration step during the dynamic process. We will compare the effects of these two strategies in our experiments. In our preliminary, we found that non-shared weight strategy works slightly better than the shared one which is in consistent with (Liao and Poggio, 2016).

Separable Composition and Scoring strategy The most important idea behind capsule networks is to measure the input and output similarity. It is often modeled as a dot product function between the input and the output capsule, and the routing coefficient is updated correspondingly. Traditional capsule networks often resort to a straightforward strategy in which the "fusion" decisions (e.g., deciding the voting weight) are made based on the values of feature-maps. This is essentially a soft template matching (Lawrence et al., 1997), which works for tasks like classification, however, is undesired for maintaining the composition functionality of capsules. Here, we propose to employ separate functional networks to release the scoring duty, and let $\boldsymbol{\theta}$ defined in Eq.(7) be responsible for composition. More specifically, we redefined the iteratively scoring function in Eq.(12) as follow,

$$b_{ij}^t = b_{ij}^{t-1} + \mathbf{g}(\mathbf{c}_j^t) \cdot \mathbf{g}(\mathbf{h}_i^t). \qquad (14)$$

Here $\mathbf{g}(\cdot)$ is a fully connected feed-forward network, which consists of two linear transformations with a ReLU activation and is applied to each position separately.

4 Experiments

4.1 Datasets

We mainly evaluated CAPSNMT on the widely used WMT English-German and English-French translation task. The evaluation metric is BLEU. We tokenized the reference and evaluated the performance with multi-bleu.pl. The metrics are exactly the same as in previous work (Papineni et al., 2002).

For English-German, to compare with the results reported by previous work, we used the same subset of the WMT 2014 training corpus that contains 4.5M sentence pairs with 91M English words and 87M German words. The concatenation of news-test 2012 and news-test 2013 is used as the validation set and news-test 2014 as the test set.

To evaluate at scale, we also report the results of English-French. To compare with the results reported by previous work on end-to-end NMT, we used the same subset of the WMT 2014 training corpus that contains 36M sentence pairs. The concatenation of news-test 2012 and news-test 2013 serves as the validation set and news-test 2014 as the test set.

4.2 Training details

Our training procedure and hyper parameter choices are similar to those used by (Vaswani et al., 2017). In more details, For English-German translation and English-French translation, we use $50K$ sub-word tokens as vocabulary based on Byte Pair Encoding(Sennrich et al., 2015). We batched sentence pairs by approximate length, and limited input and output tokens per batch to 4096 per GPU.

During training, we employed label smoothing of value $\epsilon = 0.1$(Pereyra et al., 2017). We used a beam width of 8 and length penalty $\alpha = 0.8$ in all the experiments. The dropout rate was set to 0.3 for the English-German task and 0.1 for the English-French task. Except when otherwise mentioned, NMT systems had 4 layers encoders followed by a capsule layer and 3 layers decoders. We trained for 300,000 steps on 8 M40 GPUs, and averaged the last 50 checkpoints, saved at 30 minute intervals. For our base model, the dimensions of all the hidden states were set to 512 and

SYSTEM	Architecture	Time	EN-Fr BLEU	EN-DE BLEU

Big Model	CapsNMT+ KD	c$\|S\|$+c$\|T\|$	**40.6**	**27.6**

Table 1: Case-sensitive BLEU scores on English-German and English-French translation. KD indicates knowledge distillation (Kim and Rush, 2016).

for the big model, the dimensions were set to 1024. The capsule number is set to 6.

Sequence-level knowledge distillation is applied to alleviate multimodality in the training dataset, using the state-of-the-art transformer big models as the teachers(Kim and Rush, 2016). We decode the entire training set once using the teacher to create a new training dataset for its respective student.

4.3 Results on English-German and English-French Translation

The results on English-German and English-French translation are presented in Table 1. We compare CapsNMT with various other systems including the winning system in WMT'14 (Buck et al., 2014), a phrase-based system whose language models were trained on a huge monolingual text, the Common Crawl corpus. For Enc-Dec Att systems, to the best of our knowledge, GNMT is the best RNN based NMT system. Transformer (Vaswani et al., 2017) is currently the SOTA system which is about 2.0 BLEU points better than GNMT on the English-German task and 0.6 BLEU points better than GNMT on the English-French task. For Enc-Dec NMT, ByteNet is the previous state-of-the-art system which has 150 convolutional encoder layers and 150 convolutional decoder layers.

On the English-to-German task, our big CapsNMT achieves the highest BLEU score among all the Enc-Dec approaches which even outperform ByteNet, a relative strong competitor, by +3.9 BLEU score. In the case of the larger English-French task, we achieves the comparable BLEU score among all the with Big Transform, a relative strong competitor with a gap of only 0.4 BLEU score. To show the power of the capsule encoder, we also make a comparison with the simple aggregation version of the Enc-Dec model, and again yields a gain of +1.8 BLEU score on English-German task and +3.5 BLEU score on English-French task for the base model. The improvements is in consistent with our intuition that the dynamic routing policy is more effective than the simple aggregation method. It is also worth noting that for the small model, the capsule encoder approach get an improvement of +2.3 BLEU score over the Base Transform approach on English-French task. Knowledge also helps a lot to bridge the performance gap between CapsNMT and the state-of-the-art transformer model.

The first column indicates the time complexity of the network as a function of the length of the

sequences and is denoted by Time. The ByteNet, the RNN Encoder-Decoder are the only networks that have linear running time (up to the constant c). The RNN Enc-Dec, however, does not preserve the source sequence resolution, a feature that aggravates learning for long sequences. The Enc-Dec Att do preserve the resolution, but at a cost of a quadratic running time. The ByteNet overcomes these problem with the convolutional neural network, however the architecture must be deep enough to capture the global information of a sentence. The capsule encoder makes use of the dynamic routing policy to automatically learn the part-whole relationship and encode the source sentence into fixed size representation. With the capsule encoder, CAPSNMT keeps linear running time and the constant c is the capsule number which is set to 6 in our mainly experiments.

4.4 Ablation Experiments

In this section, we evaluate the importance of our main techniques for training CAPSNMT. We believe that these techniques are universally applicable across different NLP tasks, and should always be employed by capsule networks for best performance. From Table 2 we draw the following conclusions:

Model	BLEU
Base CAPSNMT	24.7
+ Non-weight sharing	25.1
+ Position-aware Routing Policy	25.3
+ Separable Composition and Scoring	25.7
+Knowledge Distillation	26.9

Table 2: English-German task: Ablation experiments of different technologies.

- **Non-weight sharing strategy** We observed that the non-weight sharing strategy improves the baseline model leading to an increase of 0.4 BLEU.
- **Position-aware Routing strategy** Adding the position embedding to the child capsule and the parent capsule can obtain an improvement of 0.2 BLEU score.
- **Separable Composition and Scoring strategy** Redefinition of the dot product function contributes significantly to the quality of the model, resulting in an increase of 0.4 BLEU score.
- **Knowledge Distillation** Sequence-level knowledge distillation can still achive an increase of +1.2 BLEU.

4.5 Model Analysis

In this section, We study the attribution of CAPSNMT.

Effects of Iterative Routing We also study how the iteration number affect the performance of aggregation on the English-German task. Figure 3 shows the comparison of $2-4$ iterations in the dynamic routing process. The capsule number is set to $2, 4, 6$ and 8 for each comparison respectively. We found that the performances on several different capsule number setting reach the best when iteration is set to 3. The results indicate the dynamic routing is contributing to improve the performance and a larger capsule number often leads to better results.

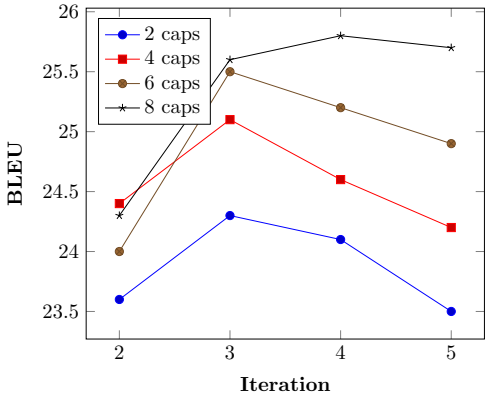

Figure 3: Effects of Iterative Routing with different capsule numbers

Model	Num	Latency(ms)
Transformer	-	225
CAPSNMT	4	146
CAPSNMT	6	153
CAPSNMT	8	168

Table 3: Time required for decoding with the base model. Num indicates the capsule number. Decoding indicates the amount of time in millisecond required for translating one sentence, which is averaged over the whole English-German newstest2014 dataset.

Analysis on Decoding Speed We show the decoding speed of both the transformer and CAP-

sNMT in Table 3. Thg results empirically demonstrates that CAPSNMT can improve the decoding speed of the transformer approach by $+50\%$.

Performance on long sentences A more detailed comparison between CAPSNMT and Transformer can be seen in Figure 4. In particular, we test the BLEU scores on sentences longer than $\{0, 10, 20, 30, 40, 50\}$. We were surprised to discover that the capsule encoder did well on medium-length sentences. There is no degradation on sentences with less than 40 words, however, there is still a gap on the longest sentences. A deeper capsule encoder potentially helps to address the degradation problem and we will leave this in the future work.

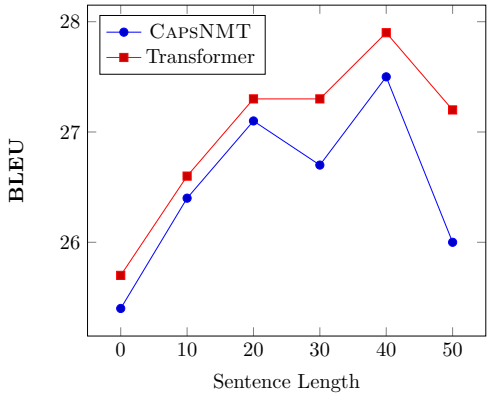

Figure 4: The plot shows the performance of our system as a function of sentence length, where the x-axis corresponds to the test sentences sorted by their length.

Orlando Bloom and Miranda Kerr still love each other
Orlando Bloom and Miranda Kerr still love each other
Orlando Bloom and Miranda Kerr still love each other

Table 4: A visualization to show the perspective of a sentence from 4 different capsules at the third iteration.

Visualization We visualize how much information each child capsule sends to the parent capsules. As shown in Table 4, the color density of each word denotes the coefficient α_{ij} at iteration 3 in Eq.(11). At first iteration, the α_{ij} follows a uniform distribution since b_{ij} is initialized to 0, and α_{ij} then will be iteratively fitted with dynamic routing policy. It is appealing to find that afte 3 iterations, the distribution of the voting weightsα_{ij} will converge to a sharp distribution and the values will be very close to 0 or 1. It is also worth mentioning that the capsule seems able to capture some structure information. For example, the information of phrase *still love each other* will be sent to the same capsule. We will make further exploration in the future work.

5 Related Work

Linear Time Neural Machine Translation Several papers have proposed to use neural networks to directly learn the conditional distribution from a parallel corpus(Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014; Kalchbrenner et al., 2016). In (Sutskever et al., 2014), an RNN was used to encode a source sentence and starting from the last hidden state, to decode a target sentence. Different the RNN based approach, Kalchbrenner et al., (2016) propose ByteNet which makes use of the convolution networks to build the liner-time NMT system. Unlike the previous work, the CAPSNMT encodes the source sentence with an iterative process to decide the credit attribution between nodes from lower and higher layers.

Capsule Networks for NLP Currently, much attention has been paid to how developing a sophisticated encoding models to capture the long and short term dependency information in a sequence. Gong et al., (2018) propose an aggregation mechanism to obtain a fixed-size encoding with a dynamic routing policy. Zhao et al., (2018) explore capsule networks with dynamic routing for multi-task learning and achieve the best performance on six text classification benchmarks. Wang et al., (2018) propose RNN-Capsule, a capsule model based on Recurrent Neural Network (RNN) for sentiment analysis. To the best of our knowledge, CAPSNMT is the first work that capsule networks have been empirically investigated for sequence-to-sequence problems.

6 Conclusion

We have introduced CAPSNMT for linear-time NMT. Three strategies were proposed to boost the performance of dynamic routing process. The emperical results show that CAPSNMT can achieve state-of-the-art results with better decoding latency in several benchmark datasets.

Modeling Multi-mapping Relations for Precise Cross-lingual Entity Alignment

Xiaofei Shi[1], **Yanghua Xiao**[1,2,3]

Abstract

Entity alignment aims to find entities in different knowledge graphs (KGs) that refer to the same real-world object. An effective solution for cross-lingual entity alignment is crucial for many cross-lingual AI and NLP applications. Recently many embedding-based approaches were proposed for cross-lingual entity alignment. However, almost all of them are based on TransE or its variants, which have been demonstrated by many studies to be unsuitable for encoding multi-mapping relations such as 1-N, N-1 and N-N relations, thus these methods obtain low alignment precision. To solve this issue, we propose a new embedding-based framework. Through defining dot product-based functions over embeddings, our model can better capture the semantics of both 1-1 and multi-mapping relations. We calibrate embeddings of different KGs via a small set of pre-aligned seeds. We also propose a weighted negative sampling strategy to generate valuable negative samples during training and we regard prediction as a bidirectional problem in the end. Experimental results (especially with the metric *Hits@1*) on real-world multilingual datasets show that our approach significantly outperforms many other embedding-based approaches with state-of-the-art performance.

1 Introduction

Knowledge bases in the form of knowledge graphs (KGs) contain lots of facts of the real world. In recent years, KGs have been successfully explored to serve many AI and NLP applications such as question answering, information extraction, semantic search and recommender systems. Multilingual KGs such as BabelNet (Navigli and Ponzetto, 2012), YAGO3 (Mahdisoltani et al., 2013) and DBpedia (Lehmann et al., 2015) play essential roles in many cross-lingual applications. However, for multilingual KGs, each language-specific part is constructed by different parties with different data sources. Thus these language-specific KGs contain different but complementary facts. To support cross-lingual applications, it is essential for us to integrate these language-specific KGs into a unified KG. Fortunately, existing inter-lingual links (ILLs) that link equivalent entities or relations can help us to achieve this goal. However, as Chen et al. (2017) and Sun et al. (2017) pointed out, the existing cross-lingual alignments usually account for a small proportion of the total. Therefore, it is valuable to find more cross-lingual entity alignment pairs to bridge the language gap in multilingual KGs.

Entity alignment is the task of finding entity pairs in different KGs that refer to the same real-world object. An effective solution for entity alignment is vital for integrating multiple KGs. In this paper, we focus on cross-lingual entity alignment. Our goal is to find more cross-lingual entity alignments based on existing alignment seeds.

Various methods have been explored for cross-lingual entity alignment. Traditional approaches rely on machine translation or feature engineering to find cross-lingual matching pairs. The effectiveness of these methods heavily depends on the quality of translations and defined features. Recently, many embedding-based approaches were proposed for cross-lingual entity alignment. Embedding-based approaches embed entities and relations as low-dimensional vectors, such that the similarity between entities or relations can be calculated via their vectors. For example, MTransE (Chen et al., 2017) embeds entities and relations separately in each KG and then learns the cross-lingual transitions between different language-specific embedding spaces. JAPE (Sun et al., 2017) encodes both structures of KGs and types of attribute values. GCN-EA (Wang et al., 2018) employs GCNs as its embedding model to encode entities.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 813–822, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

Though these methods have made great progress in cross-lingual entity alignment, there are still several key issues worth study. To the best of our knowledge, almost all of the existing methods encode knowledge in KGs based on the well-known TransE (Bordes et al., 2013) and its variants (Sun et al., 2017; Zhu et al., 2017). Given a relational triple $\tau = (h, r, t)$, where r represents a specific relation between the head entity h and the tail entity t, TransE and its variants expect $\vec{v_h} + \vec{v_r} - \vec{v_t} \approx \vec{0}$, where $\vec{v_h}$, $\vec{v_r}$ and $\vec{v_t}$ denote the embeddings for h, r and t, respectively. However, as Wang et al. (2014) and Ebisu and Ichise (2018) pointed out: 1) TransE and its variants neglect some mapping properties of relations; and 2) TransE and its variants force entity embeddings to be on a sphere in the embedding space, which conflicts with the expectation of TransE and warps embeddings obtained by TransE. Thus TransE and its variants don't do well in modeling multi-mapping relations, such as 1-N, N-1 and N-N relations.

As the majority of relations in real KGs are multi-mapping relations, previous entity alignment approaches obtain low accuracy, especially with the metric *Hits@1*. And the gap between alignment results with the metric *Hits@1* and *Hits@10* in these methods is large. This means previous methods can cluster similar entities together, however, they don't have enough ability to distinguish which is the true counterpart. Although following works such as TransH (Wang et al., 2014), TransR (Lin et al., 2015b) and TransD (Ji et al., 2015) have extended TransE on modeling multi-mapping relations, we experimentally found these methods also have low performances for cross-lingual entity alignment. And though the GCN-based approach avoids the flaw in TransE and its variants, GCN-EA (Wang et al., 2018) only encodes entities in KGs. It doesn't distinguish among relations and the absence of relation embeddings results in low alignment precision, too.

Besides, most previous works use uniform sampling to generate negative samples during training, which often generates too many easy examples that contribute little to learning embeddings. Although Boot-EA (Sun et al., 2018) proposes a truncated method to select hard negative samples based on the semantic similarity, it only considers hard examples (easy ones are truncated) that only account for a small proportion of all examples, which can lead to overfitting and low accuracy in practice (since easy examples are also useful).

To address the above issues, we propose a new embedding-based framework to do cross-lingual entity alignment in this paper. Motivated by the success of multiplicative approaches (Yang et al., 2015; Trouillon et al., 2016) in knowledge representation learning, we propose a new embedding approach for multilingual KGs. The score function of our method is based on multiplication instead of subtraction. Unlike TransE and its variants giving a strong constraint to embeddings, dot products of embeddings in our method scale well and can naturally handle both 1-1 and multi-mapping relations. Besides, we propose a weighted sampling strategy to pay more attention to harder examples than easier ones during the process of negative samples generating. We summarize the main contributions of this paper as follows:

- We propose a new KG embedding framework to jointly embed entities and relations from different KGs into a unified embedding space using a small set of pre-aligned alignment pairs obtained from inter-lingual links.
- We discuss the problem that generating too many easy negative examples during training hurts alignment performance and then we propose a weighted sampling strategy for hard negative example generation.
- We regard the alignment prediction as a bidirectional selection problem, and we propose to combine ranking matrices from both directions to align entities.
- We evaluate the proposed approach on three real-world cross-lingual datasets. Experimental results (especially with the metric *Hits@1*) show that our approach significantly outperforms four representative embedding-based methods for cross-lingual entity alignment.

2 Related Work

2.1 KG Embedding

In the past few years, many KG embedding methods have been proposed for modeling the semantics of KGs. TransE (Bordes et al., 2013)

interprets a relation as the translation from its head entity to its tail entity and achieves great success in many AI-related tasks. Following TransE, TransH (Wang et al., 2014), TransR (Lin et al., 2015b) and TransD (Ji et al., 2015) were proposed to extend TransE on modeling multi-mapping relations. PTransE (Lin et al., 2015a) and RTransE (García-Durán et al., 2015) extend TransE on modeling multi-step relation paths. There are also non-translation-based methods. ComplEx (Trouillon et al., 2016) learns embeddings via defining product-based functions over embeddings. And some methods utilizing extra resources, i.e. visual information (Xie et al., 2017) and entity descriptions (Xie et al., 2016; Xiao et al., 2017), were also proposed to improve embedding performance.

2.2 Cross-lingual Entity Alignment

Conventional methods for cross-lingual entity alignment rely on machine translation and handcrafted features, which often need extra resources as input and are difficult to reuse. By contrast, embedding-based approaches are simple and easy to reuse. In recent years, many embedding-based methods have been proposed and achieved promising results in cross-lingual entity alignment.

Due to the simplicity and effectiveness of TransE, almost all of the existing cross-lingual entity alignment works employ TransE or its variants to encode knowledge. JE (Hao et al., 2016) employs a modified TransE to encode entities and relations. It bridges different KGs by adding a loss of alignment seeds in its objective function. MTransE (Chen et al., 2017) encodes entities and relations for each language-specific KG separately based on TransE, and then employs five strategies to learn cross-lingual transitions through pre-aligned triples. JAPE (Sun et al., 2017) learns structure embedding using a variant of TransE which adds weight to negative samples in its objective function. It also borrows the idea from Skip-gram model to learn attribute correlations and then leverages attribute correlations to refine structure embedding. To overcome the heterogeneity and language gap between different KGs, JAPE only considers the range types of attribute values, with the specific attribute values discarded.

There are also some efforts have been devoted to solving the problem of lacking enough training data. IPTransE (Zhu et al., 2017) and BootEA (Sun et al., 2018) propose to expand training set from alignment results iteratively. KDCoE (Chen et al., 2018) performs co-training of a KG embedding model and an entity description embedding model.

Besides, GCN-EA (Wang et al., 2018) employs GCNs to embed entities and attributes as low-dimensional vectors.

Different from the above methods, in this paper, we propose a new approach to jointly learn embeddings for both entities and relations from different KGs.

3 Problem Formulation

We begin with the problem definition. A knowledge graph (KG) usually contains a large number of triples in the form of (h, r, t), where r represents a relation between the head entity h and the tail entity t. Formally, a KG can be represented as $KG = (E, R, T)$, where E, R, T are the set of entities, relations and triples respectively.

Now suppose we have two heterogenous and language-specific KGs to be aligned, where $KG_1 = (E_1, R_1, T_1)$ and $KG_2 = (E_2, R_2, T_2)$. And in many cases, we already have a set of pre-aligned entities $S_e = \{(e_1, e_2)|e_1 \in E_1, e_2 \in E_2\}$ and relations $S_r = \{(r_1, r_2)|r_1 \in R_1, r_2 \in R_2\}$ as alignment seeds. The task of entity alignment is to automatically find new entity alignments based on the existing alignment seeds.

4 The Proposed Approach

Our approach consists of two steps. The first step is to learn embeddings for entities and relations, and we will introduce a new method to do this task. The second step is to align entities between the two input KGs based on the learned embeddings. In this section, we will introduce the two parts in details.

4.1 Multilingual KG Embedding

DistMA: The goal of KG embedding is to embed entities and relations into a unified vector space such that low-dimensional vectors of entities or relations can represent their semantics. A powerful KG embedding approach should embed similar entities or relations to have similar embeddings, such that the semantics of knowledge graphs can be well captured.

The most widely used approaches to encode entities and relations by previous works are

TransE (Bordes et al., 2013) and its variants. Given one triple $\tau = (h, r, t)$ in a knowledge graph, TransE and its variants define the energy function for this triple as $E(\tau) = \|\vec{v_h}+\vec{v_r}-\vec{v_t}\|_{1/2}$, where $\vec{v_h}, \vec{v_r}, \vec{v_t} \in \mathbb{R}^d$ represent the d-length vectors for h, r and t respectively. Then they optimize margin-based ranking losses so that the energy for positive triples is lower than negative ones. As discussed in Section 1, they don't do well in modeling multi-mapping relations, we need to explore new approaches to better capture the semantics of multi-mapping relations.

In this paper, we propose a new approach to encode both entities and relations in knowledge graphs. Our approach defines the energy function for a triple τ as:

$$E_1(h, r, t) = \langle \vec{v_h}, \vec{v_r} \rangle + \langle \vec{v_r}, \vec{v_t} \rangle + \langle \vec{v_h}, \vec{v_t} \rangle \quad (1)$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product.

Besides, instead of using a margin-based loss function, we employ the logistic loss with L_2 regularization on model parameters Θ. The objective function is defined as:

$$\begin{aligned} O_1 = &- \sum_{(h,r,t)\in\mathbb{T}^+} \log \sigma(E_1(h, r, t)) \\ &- \sum_{(h',r,t')\in\mathbb{T}^-} \log \sigma(-1 \cdot E_1(h', r, t')) + \lambda\|\Theta\|_2^2 \end{aligned} \quad (2)$$

where σ is the sigmoid function. $\mathbb{T}^+$ and $\mathbb{T}^-$ are positive and negative triples set, respectively. λ is a hyper-parameter that controls the influence of regularization. The value of $\sigma(E(h, r, t))$ measures the plausibility of the triple (h, r, t). This means our method expects positive triples to have high energy scores and negative ones to have low scores. Compared with TransE and its variants, dot products of embeddings scale well and can naturally handle both 1-1 and multi-mapping relations, which is helpful for capturing the semantics of KGs. We define the negative triples set $\mathbb{T}^-$ as:

$$\begin{aligned} \mathbb{T}^- = &\{(h', r, t)|h' \in E\} \cup \\ &\{(h, r, t')|t' \in E\}, (h, r, t) \in \mathbb{T}^+ \end{aligned} \quad (3)$$

where E denotes the set of entities.

ComplEx: The energy function of DistMA doesn't distinguish between head entities and tail entities. This means DistMA can model symmetric relations like $similar_to$, has_friend well but maybe unfriendly to some antisymmetric relations like is_father_of, $part_of$. To improve the ability of our model to encode such relations, we utilize the ComplEx (Trouillon et al., 2016). Instead of real-valued vectors, ComplEx gives complex-valued vectors to entities and relations. That is, for each entity e or relation r, let $\vec{w_e} \in \mathbb{C}^k$ or $\vec{w_r} \in \mathbb{C}^k$ be the corresponding complex-valued vector, i.e. $\vec{w_e} = Re(\vec{w_e}) + iIm(\vec{w_e})$ with $Re(\vec{w_e}) \in \mathbb{R}^k$ and $Im(\vec{w_e}) \in \mathbb{R}^k$ being the real and imaginary parts of $\vec{w_e}$, where $\mathbb{R}$, $\mathbb{C}$ represent the real and complex vector spaces respectively, and i denotes the square root of -1. Then the energy for a triple (h, r, t) is defined as follows:

$$E_2(h, r, t) = Re(\langle \vec{w_h}, \vec{w_r}, \vec{\bar{w}_t} \rangle) \quad (4)$$

where $\langle \cdot, \cdot, \cdot \rangle$ denotes the generalized inner product and $\vec{\bar{w}_t}$ represents the conjugate of $\vec{w_t}$: $\vec{\bar{w}_t} = Re(\vec{w_t}) - iIm(\vec{w_t})$. One can easily verify that Equation (4) can be expanded and written as:

$$\begin{aligned} E_2(h, r, t) = &\langle Re(\vec{w_h}), Re(\vec{w_r}), Re(\vec{w_t}) \rangle \\ &+ \langle Re(\vec{w_h}), Im(\vec{w_r}), Im(\vec{w_t}) \rangle \\ &+ \langle Im(\vec{w_h}), Re(\vec{w_r}), Im(\vec{w_t}) \rangle \\ &- \langle Im(\vec{w_h}), Im(\vec{w_r}), Re(\vec{w_t}) \rangle \end{aligned} \quad (5)$$

With this energy function, we use the same Equation (2) to calculate loss O_2 as O_1.

Joint Embedding: With ComplEx, we refine the final energy function for each triple as:

$$E(h, r, t) = E_1(h, r, t) + E_2(h, r, t) \quad (6)$$

Then the final loss O to optimize can be defined by Equation (2) using Equation (6) as the energy function.

We will evaluate each part of our method in the experiments.

Parameter Sharing: The aforementioned embedding model is trained separately in each KG. As our final goal is to align entities between two KGs, we need to calibrate the embeddings of the two KGs into a unified embedding space based on the existing seed alignment. A natural and effective assumption is: the pre-aligned pair should share embedding to bridge different KGs. Under this assumption, the semantic loss between equivalent entity or relation pair is zero. This idea has also been mentioned in Sun et al. (2017) and Zhu et al. (2017).

4.2 Weighted Negative Sampling

Most previous works (Bordes et al., 2013; Sun et al., 2017; Zhu et al., 2017; Wang et al., 2018) use uniform sampling to generate negative triples $\mathbb{T}^-$, that is, replacing the head or tail entity of a positive triple with a random entity. Despite the simplicity of this method, it can be blind in many cases. For example, suppose we have a positive triple $(David\ Hilbert, nationality, Germany)$ and randomly replace the tail entity with an arbitrary entity. Maybe we can get one negative triple $(David\ Hilbert, nationality, Barack\ Obama)$. This is not a good choice because such a ridiculous triple contributes little to learning embeddings. Since such an obviously false triple is "too easy" and can easily obtain low plausibility during training. In contrast, a negative triple like $(David\ Hilbert, nationality, France)$ is more valuable, since $France$ has similar semantics with $Germany$, but $France$ can't replace $Germany$. Such a negative triple can help the model to learn the underlying semantics difference between entities rather than types solely.

We propose a weighted sampling strategy to generate valuable negative samples. Take the tail entity for example, given a positive triple (h, r, t), we replace t with t' obtained from the following probability distribution:

$$P((h,r,t')|(h,r,t)) = \frac{exp(sim(t,t'))}{\sum_{e\in E} exp(sim(t,e))} \tag{7}$$

where E denotes the entity set and $sim(\cdot,\cdot)$ calculates the similarity between two entities. Here we employ the cosine similarity measure. This means our sampling method is more likely to replace one entity with its similar entities. Since these entities have strong semantic correlations with the original entity but don't express the original entity, which helps the model learn to distinguish. Note that our method also generates a few easy examples, which are also useful for learning embeddings.

4.3 Bidirectional Alignment

We regard alignment prediction as a ranking problem. That is, suppose we need to align the entities in KG_1 to KG_2, for each entity e_i in KG_1 , we rank each entity e_j in KG_2 based on the similarity between e_i and e_j. The similarity can be calculated via their embeddings, which we define by cosine similarity measure as follows:

$$sim(e_i, e_j) = \langle [\vec{v_{e_i}}]_1, [\vec{v_{e_j}}]_1 \rangle \tag{8}$$

where $[\cdot]_1$ denotes the normalized vector. Finally, we will get a similarity matrix $\mathbf{S_{12}}$ between the two KGs. Then we can get a ranking matrix $\mathbf{M_{12}}$ for KG_1 with $\mathbf{M_{12}}(i,j)$ denoting the index of e_j in the ranking list of e_i.

One thing that hurts the alignment precision is the difference of knowledge distribution between different KGs. Considering the following fact during the entity alignment process. Suppose we select the first ranked entity e_j in the ranking list of e_i to be the counterpart of e_i. It is reasonable because, from the view of e_i, e_j is the most similar entity in KG_2. However, this can be misleading sometimes. For example, from the view of e_j, e_i may not rank first in the ranking list of e_j, and even rank at dozens. In such a case, we don't think e_j is the desired candidate for e_i. This means, instead of single direction in previous works, that the alignment prediction process should consider both directions of KGs. We combine ranking matrices from both directions to accomplish this goal.

From both views of KG_1 and KG_2, we refine the ranking matrix $\mathbf{M_{12}}$ as:

$$\mathbf{M_{12}} = \mathbf{M_{12}} + \mathbf{M_{21}^T} \tag{9}$$

where $\mathbf{M_{21}^T}$ denotes the transpose of the ranking matrix of KG_2.

4.4 Implementation Details

We initialize all embeddings for both DistMA and ComplEx based on the uniform distribution. We set d = 150 for DistMA and k = 75 for ComplEx so that the length of embeddings in DistMA and ComplEx are all equal to 150. Before predicting, we concatenate the embeddings in DistMA and ComplEx such that each entity is represented as a 300-dimensional vector in the end. Besides, during training, we sample ten negative triples for each positive one. Since the weighted negative sampling is time-consuming, to speed it up, we calculate Equation (7) every five epochs. We use the self-adaptive optimization method Adam (Kingma and Ba, 2015) for all trainings and we implement our model with Tensorflow [1].

5 Evaluation

5.1 Datasets

We evaluate our proposed method on DBP15K datasets (Sun et al., 2017; Wang et al., 2018).

[1] https://www.tensorflow.org/

The datasets contain three cross-lingual real-world datasets: DBP_{ZH-EN} (Chinese to English), DBP_{FR-EN} (French to English), DBP_{JA-EN} (Japanese to English). In which each was built with 15 thousand ILLs from multilingual versions of DBpedia. The average number of entities, relations and relational triples of the three datasets are 166,255/4,291/420,025 respectively.

5.2 Baseline Methods

We select four representative methods as baselines for cross-lingual entity alignment. These methods can be categorized as:

- Translation-based methods where relations are modeled as translation operators in the embedding space, including JE (Hao et al., 2016), MTransE (Chen et al., 2017) and JAPE (Sun et al., 2017). For MTransE, it develops five variants in its alignment model, where the fourth obtains the best results according to the experiments of its authors. Thus, we choose this variant to represent MTransE. For JAPE, it learns both structure and attribute embeddings. We report the results of its full model.

- To the best of our knowledge, GCN-EA (Wang et al., 2018) is the only one method employing non-translation-based embedding technique. GCN-EA uses GCNs as its encoding network to encode entities and attributes. We report the results of its full model.

5.3 Evaluation Metrics

By convention, we use *Hits@k* and *Mean Reciprocal Rank (MRR)* as our metrics. *Hits@k* measures the percentage of correctly aligned entities ranked in the top-k. Generally, *Hits@1* indicates precision. *MRR* is the average of the reciprocal ranks of all test instances. Higher *Hits@k* and *MRR* indicate better performance.

5.4 Model Selection

We select hyper-parameters with the following values: learning rate $\eta \in \{0.001, 0.003, 0.005, 0.01, 0.1\}$, L_2 regularization factor $\lambda \in \{1e{-}5, 1e{-}4, 5e{-}4, 1e{-}3\}$, batch size $B \in \{2000, 5000, 10000, 20000, 30000\}$. The optimal hyper-parameters are: $\eta = 0.005$, $\lambda = 1e{-}4$ and $B = 20000$. We use these values in all experiments. The total number of epochs is set to 3000, within which we test alignment every ten epochs and save embeddings when obtaining better *Hits@1* performances.

5.5 Results and Analysis

Following Sun et al. (2017) and Wang et al. (2018), we use 30% of the gold standards for training and the rest 70% for testing. The results of four compared baselines and our approach are shown in Table 1. Among the four baselines, JAPE and GCN-EA obtain better results, since semantic loss happens when learning the translations between embedding spaces in the other two methods. GCN-EA is the most powerful method. It doesn't encode relations but it achieves a better performance except for the dataset DBP15K_{ZH-EN}.

However, we can easily see our method significantly outperforms all the four baselines, especially with the metric *Hist@1*, which indicates our method can better capture the semantics of different KGs. As discussed in Section 1, baseline methods all obtain low performance. And the *Hits@3* results of our method are comparable to the *Hits@10* results of all the baselines. Besides, we observe that the gap between the results with metrics *Hits@1* and *Hits@10* of our method is much smaller than the other methods (average 20.24% *vs.* 29.34%), which means our method has stronger ability to distinguish between target counterparts and error ones which have strong semantic similarity with target counterparts.

We also find the results after applying bidirectional alignment have a large improvement compared with single directional alignment under all the metrics, especially for *Hits@1*. This is due to the fact that entity alignment is essentially a bidirectional selection process. Bidirectional selection can soften the impact of unbalanced data distribution between different KGs, making the alignment prediction more reasonable.

Evaluation of Weighted Negative Sampling: Here we come to evaluate the effectiveness of our proposed weighted negative sampling strategy. We compare with uniform sampling with the negative sampling rate neg = 1 and neg = 10 (1 and 10 negative triples per positive triple), respectively. Table 2 shows the testing results with metrics *Hits@1* and *MRR*.

We summarize Table 2 in three aspects. Firstly, we can see that both sampling methods obtain

DBP15K$_{ZH-EN}$	$ZH-EN$				$EN-ZH$

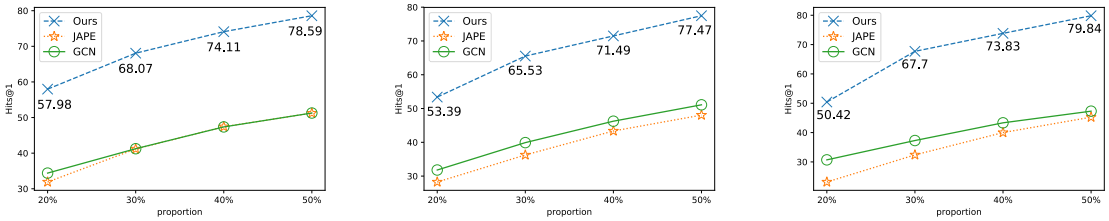
Table 1: Results comparison. (* marks the results copied from Sun et al. (2017). † marks the results reported by its authors. - marks the unreported results. *Bid.* indicates bidirectional alignment.)

better performance with the increase of the negative sampling rate. This shows that more negative samples can assist model to better capture the semantics of KGs. Secondly, we can find that, compared with uniform negative sampling, our weighted sampling strategy gets better performance for all the three datasets. This is because our sampling method can generate more valuable negative samples to assist model to learn correct embeddings. Besides, we observe our method is more effective with a smaller negative sampling rate (neg = 1). Because when neg is large, it is likely to generate a few valuable negative samples though using uniform sampling. But when neg is small, the uniform sampling method can't generate enough valuable samples, which seriously hurts the final performance. However, our sampling strategy can pay more attention to valuable samples, generating many valuable negative samples even when the amount of total samples is small.

Ablation Study: For ablation study, we separate two variants from our approach. The first one only optimizes the objective function O_1, called DistMA. And the second one only optimizes O_2, called ComplEx. Table 3 shows the results of the two variants and the overall method.

As expected, Table 3 shows that each variant gets better results compared with four baselines. The DistMA can model symmetric relations well and the ComplEx can improve the ability in modeling antisymmetric relations. The overall method gets the best results due to its strong ability in modeling both relations.

Training with Different Sizes of Seed Alignment: We further investigate how the size of the training data affects the performance of our proposed approach. Here we use different proportions of seed alignment, which ranges from 20% to 50% with step 10%. And we choose two strong baselines JAPE and GCN-EA for comparison. Figure 1 illustrates the *Hits@1* results of the three approaches.



From Figure 1 we can see that the results for

all the three approaches become better with the increase of proportion of training data, because more seed alignment can provide more information to bridge different KGs. And we can also see that our approach consistently outperforms the other two methods under different proportions. Moreover, only with 20% seed alignment, our approach achieves comparable performances for all the three datasets with the other two methods using 50% seed alignment. When using 30% seed alignment, our approach largely outperforms the other two methods using 50% seed alignment. All these results show the robustness and effectiveness of our method.

Hits@1 Results by Mapping Properties of Relations: To better know how effective our method is for different relations, compared with JAPE (Sun et al., 2017), we evaluate the improvement of *Hits@1* results by mapping properties of relations. To do this, we first divide all relations into 1-N, N-1, 1-1 and N-N relations [2]. Then we evaluate the *Hits@1* alignment results for head entities and tail entities of the four kinds of relations respectively.

The results are shown in Table 4. We can see that the result of N-N relations has the greatest improvement (with 111.4% average relative increase for head entities and 93.6% for tail entities). In addition, there are two points are also remarkable: the head entities of N-1 relations (96.2%) and the tail entities of 1-N relations (79.3%), which suggests the superiority of our method in modeling multi-mapping relations.

6 Conclusion and Future Work

This paper presents a simple and effective embedding framework for multilingual KGs which successfully improves the performance of cross-

[2]Following Wang et al. (2014), for each relation r, we compute the average number of tails per head (tph_r) and the average number of head per tail (hpt_r). If $tph_r \geq 1.5$ and $hpt_r < 1.5$, r is treated as 1-N; if $tph_r < 1.5$ and $hpt_r \geq 1.5$, r is treated as N-1; if $tph_r < 1.5$ and $hpt_r < 1.5$, r is treated as 1-1; if $tph_r \geq 1.5$ and $hpt_r \geq 1.5$, r is treated as a N-N.

lingual entity alignment. We also propose a weighted sampling strategy to generate hard negative examples during training. Moreover, we propose to align entities from both directions. Experimental results on real-world datasets show that our method significantly outperforms four competitors, especially with the metric *Hits@1*.

Our proposed embedding framework can be easily applied to other tasks, i.e. link prediction and triple classification. And the idea of weighted negative sampling can be helpful for many AI and NLP tasks such as relation extraction and classification. For future work, we plan to explore more powerful KG embedding methods. And we also have the idea of using categorical attributes or hierarchical types to guide the negative sampling process.

Supervised and Nonlinear Alignment of Two Embedding Spaces for Dictionary Induction in Low Resourced Languages

Masud Moshtaghi

mmasud@amazon.com

Abstract

Enabling cross-lingual NLP tasks by leveraging multilingual word embedding has recently attracted much attention. An important motivation is to support lower resourced languages, however, most efforts focus on demonstrating the effectiveness of the techniques using embeddings derived from similar languages to English with large parallel content. In this study, we present a noise tolerant piecewise linear technique to learn a non-linear mapping between two monolingual word embedding vector spaces. We evaluate our approach on inferring bilingual dictionaries. We show that our technique outperforms the state of the art in lower resourced settings with an average improvement of 3.7% for precision @10 across 14 mostly low resourced languages.

1 Introduction

Aligning two embedding spaces is a key component in many multilingual tasks in natural language processing such as unsupervised word and sentence translation (Ruder et al., 2017) and large-scale dictionary creation (Lample et al., 2018). Large scale dictionaries are used in many NLP tasks, for example, web data cleaning. The main feature of the two most successful methods for this task is based on dictionaries (Xu and Koehn, 2017; Koehn et al., 2018).

Initial success obtained in aligning two embedding spaces has created a flurry of research efforts into improving the task (Nakashole, 2018; Doval et al., 2018; Kementchedjhieva et al., 2018; Chen and Cardie, 2018; Joulin et al., 2018; Hoshen and Wolf, 2018; Artetxe et al., 2018), to name a few published in 2018. There are two main approaches for mapping a monolingual word embedding space into another (Ruder et al., 2017): 1) Supervised methods rely on a few anchor points to learn the matching of two spaces (Lample et al., 2018; Mikolov et al., 2013; Xing et al., 2015; Joulin et al., 2018) and; 2) Unsupervised methods mostly formulate the problem as an adversarial optimization problem (Lample et al., 2018; Zhang et al., 2017; Ruder et al., 2017; Chen and Cardie, 2018; Hoshen and Wolf, 2018). While for high density languages such as Spanish, German, French and Italian the accuracy of unsupervised techniques is comparable, or even higher, than supervised techniques, the accuracy of unsupervised techniques is significantly lower when lower resourced languages are considered. A number of the experiments featured in the recent publications reflect this fact (Søgaard et al., 2018; Irvine and Callison-Burch, 2017).

To place this work in the context of recent advances in the field, we divide the aspects targeted by researchers to improve the precision with some examples in Fig. 1. While some of the improvements in optimization and space-adjustments can be applied to almost (any) model, our goal is to improve the supervised mapping in low resourced setting. Since the conception of linear mapping between two spaces, there are only very small minor improvement in the supervised mapping function itself and largest improvements are obtained by updating the word translation retrieval in the shared space and normalization steps (Artetxe et al., 2018). Therefore, we test our method against the most widely cited and tested method by (Lample et al., 2018), which culminates the previous efforts in the area of the supervised mapping (Mikolov et al., 2013; Xing et al., 2015; Lazaridou et al., 2015; Dinu et al., 2015; Smith et al., 2017; Artetxe et al., 2017). The main idea of these methods is to use Procrustes analysis to determine a linear mapping between two spaces using a few anchor points, i.e., a small dictionary. An iterative method is used to expand the dictionary with the most promising candidates and

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 823–832, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

re-learn the mapping (Artetxe et al., 2017; Lample et al., 2018). However, the main success of these methods was obtained on linguistically similar languages where a large volume of monolingual data from compatible sources is available. A recent study showed that a simple linear mapping is not enough for low resourced languages (Nakashole, 2018). However, the proposed method in this study, NorMA, came short in solving the problem showing significant gains in mapping precision for Russian-English and Chinese-English, compared not to the best model in (Lample et al., 2018), while underperforming in Spanish-English French-English and German-English. Due to the limited set of experiments and inconsistent results across multiple languages we defer comparison with this method until a more mature version is developed. Here, we only acknowledge that our method achieves 1.5% better precision@1 compared to NorMA's results for Chinese.

The contributions of this work are three-fold. First, we introduce a noise tolerant form of *Generalized Procrustes* (GP) which corrects for rotation, geometrical translation [1] and dilation. Second, we adapt an existing technique for piecewise linear regression to instead perform piecewise linear mapping. This allows subspaces to have different mapping functions. Finally, we conduct a large-scale evaluation and show that our model systematically outperforms the state of the art (Lample et al., 2018) in dictionary inference task with the average gain of 3.7% in precision @10 across 14 languages.

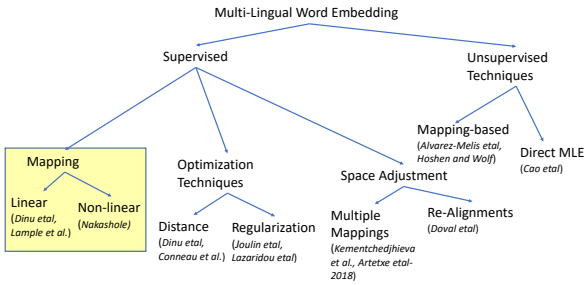

Figure 1: A breakdown of the main area of research focus for dictionary induction task.

[1] Note the difference between the translation of a word and translation as a geometrical transformation of a vector space.

2 Problem Statement

We first provide a formal definition of multilingual word embedding task using a mapping function, then we explain the intuition on why this method can be used to create dictionaries.

2.1 Definition

Given source and target embedding vector spaces V_s and V_o, we are looking for a mapping $V_o \xrightarrow{f} V_s$ that minimize $\|f(V_o) - V_s\|_F$, where $\|.\|_F$ is the Frobenius norm (a matrix norm calculated by the square root of the sum of squares of its elements). Function f performs two tasks, a permutation task to find the matching of vectors and a mapping task to map the permuted vectors in V_o to space spanned by the vectors in V_s. In this general form, the problem is not convex. The supervised solutions for this problem add two assumptions to the problem to make it tractable. First, they assume a set of anchor points are available $\bar{V}_s \subseteq V_s$ and $\bar{V}_o \subseteq V_o$ for which we know a one-to-one matching, i.e., from a small dictionary. The second assumption is that the difference between the two spaces is only in rotation. In this paper, we relax the assumption about f and propose a non-linear mapping, which in addition to the rotational difference, it corrects for dilation and translation between two embedding vector spaces.

2.2 Intuition

We first give an intuition about why we can map a word embedding space into another. Word2Vec (or similar) embedding processes capture the correlation between words (Mikolov et al., 2013) and embed the words in a vector space so that the distances between them are representative of this correlation. If the word embeddings are computed over comparable corpora, a word and its translation have similar correlated words. Hence, these words form similar neighborhood structures in their own monolingual spaces. A reasonable assumption is that the words in this neighborhood should also be a (dictionary) translation of each other. These two assumptions of the similarity of neighborhood structure and the assumption that the neighborhood consists of words that are translations of each other are crucial to the success of mapping methods. The similarity of the corpora used in the initial embeddings in terms of size and content significantly contributes to the validity of the assumptions. This effect is highlighted

in multiple studies (Lample et al., 2018; Søgaard et al., 2018; Grave et al., 2018). That is why the embeddings calculated on high resourced languages, with a similar parallel content to English, are mapped to English embedding space with very high accuracy as the embedding spaces have similar structures. Søgaard *et al.* highlight the language pair, the comparability of the monolingual corpora, and the parameters of the word embedding algorithms as key aspects affecting the performance of unsupervised methods. The performance of supervised methods is also tightly tied to these factors but they are less affected by the virtue of having the extra source of supervision.

If the initial two assumptions hold and since affine mappings, such as orthogonal rotation, do not change the structure of the space, minimizing the distance between the vectors should force the words with the same meaning to end up close to each other. In low resourced languages with a significantly lower amount of data compared to the English corpora structural similarities of the two spaces are not guaranteed leading to weak initial assumptions. This is also true in languages with lower similarity to English such as Slavic and Asian languages (Nakashole, 2018; Nakashole and Flauger, 2018). Nakashole and Flauger showed that word neighborhoods require different linear mappings to correctly capture the word relation. However, the proposed method by (Nakashole, 2018), NorMA, learns a dictionary of neighborhoods and reconstruct the word embedding using a linear combination of the dictionary items which does not guarantee locality in the mapping, , i.e., many dictionary items can contribute to representation of a word.

3 Proposed Method

Our proposed method tackles two problems with the existing mapping techniques. First, instead of only fixing the rotational differences between the two embedding vector spaces, the model also accounts for geometrical translation and dilation. Second, our model, which we call *LLMap*, has different linear mapping functions in subspaces which allows us to have different levels of corrections in different regions of the embedding space. We achieve this goal by incorporating a *Robust Generalized Procrustes* (RGP) mapping into a Locally Linear Model (LLNF).

3.1 Robust Generalized Procrustes Analysis

We borrow the concept Generalized Procrustes and introduce a noise tolerant version, which we name *Robust Generalized Procrustes* (RGP), to solve the first problem with the existing mapping techniques. RGP adds translation and dilation to the vanilla Procrustes. Note that Generalized Procrustes (GP) has been used to mean a different concept in (Kementchedjhieva et al., 2018) referring to a method that maps multiple spaces together.

3.1.1 Procrustes Problem

Procrustes analysis has been used in many different fields for analyzing the relationship between two datasets. The *Orthogonal Procrustes Problem* (*OPP*) (Koschat and Swayne, 1991; Crosilla, 2003), aka Procrustes Rotation, used in current supervised multilingual mapping techniques (Lample et al., 2018; Smith et al., 2017) is defined as,

Definition 1: Given two matrices $\bar{V_s}$ and $\bar{V_o} \in \Re^{n \times p}$ with rank p, the OPP is defined as the following optimization problem.

$$\min_{W} \left\| \bar{V_o} W - \bar{V_s} \right\|_F^2, \text{subject to } W^T W = I_{p \times p} \tag{1}$$

The above optimization function has a closed form solution given by $W^T = UV^*$ where $UDV^* = SVD(\bar{V_s}^T \bar{V_o})$. The Generalized Procrustes Problem (GPP) formulates the problem as a general linear mapping, correcting for other types of disturbances, i.e., translation and dilation.

Definition 2: Given two matrices $\bar{V_s}$ and $\bar{V_o} \in \Re^{n \times p}$ with rank p, the GPP is defined as the following optimization problem.

$$\begin{aligned} &\min_{W} \left\| \left(\bar{V_o} K W + I_{n \times 1} b \right) - \bar{V_s} \right\|_F^2, \\ &\qquad \text{subject to } W^T W = I_{p \times p} \\ &\textit{where } K \in \Re^{p \times p} (\textit{dilation}),\ b \in \Re^{1 \times p} (\textit{translation}), \\ &\qquad W \in \Re^{p \times p} (\textit{rotation}) \end{aligned} \tag{2}$$

The solutions for the three components of this optimization problem, i.e., K (diagonal (zero off diagonal) positive matrix), b and W are shown in Eq. (3). Let $m_s = mean(\bar{V_s})$, $m_o = mean(\bar{V_o})$,

$\bar{V}_o^* = \bar{V}_o - m_o$ and $\bar{V}_s^* = \bar{V}_s - m_s$

$$
\begin{aligned}
W^T &= UV^*, UDV^* = SVD(K^{-1}\bar{V}_s^{*T}\bar{V}_o^*) \\
K_{jj} &= \frac{(\bar{V}_s^*)_j^T(\bar{V}_o^*W)_j}{(\bar{V}_o^*W)_j^T(\bar{V}_o^*W)_j} \\
b &= m_s - m_oKW
\end{aligned}
\tag{3}
$$

where $(.)_j$ denote the j^{th} column vector of the matrix.

The translation factor b in Eq. 3 does not appear in the calculation of rotation and dilation while the other two have interdependencies. Centering all vectors prior to mapping makes the translation vector zero. But it affects the flexibility of subspaces to have different translation factor. Hence, we operate on the original embedding space without centering the vectors.

For the other two factors, Koschar and Swayne (Koschat and Swayne, 1991) suggested using an iterative algorithm starting with $K = I_{p\times p}$ and computing W, then using W updating the values of K and iterate between the two until reaching convergence. We use 3 iterations in all of our experiments as the values converge rapidly. We expect to have noisy embedding vectors, so we use the truncated SVD algorithm to calculate the rotation matrix, i.e., discarding eigenvectors corresponding to small eigenvalues to make the mapping robust to outliers.

In the next section, we introduce how this linear mapping can be incorporated into the LLNF model to learn a piecewise linear mapping between two vector spaces.

3.2 Locally Linear Neural Model for Mapping (LLMap)

The inaccuracies in the embedding process due to lack of data, and inherent language family differences reduce structural similarities in (some) regions of the embedding space. In this case, a global minimization of the distance between the vectors using structure preserving mappings (Procrustes) could create undesired artifacts. We devise a piecewise linear mapping between the two spaces based on a Locally Linear Neural (LLNF) model with soft switching between the neurons (Babuška and Verbruggen, 2003) to increase the flexibility of the models when dealing with different levels of structural similarities in the embedding space. In this work, we update the neuron definition in the standard LLNF model to perform localized mapping using RGP, which guarantees a reduction in terms of the *Sum of Squared Errors* (SSE).

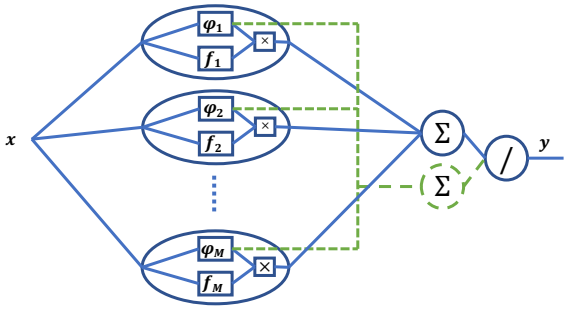

Figure 2: The network structure of an LLNF model. The green dotted line is used to normalize the output of neurons. Each neuron contains a membership function ϕ that controls the contribution of the neuron function f to the final output.

First, we provide a brief introduction to the LLNF model followed by the description of our method, LLMap. LLMap replaces the linear regression function in the LLNF neurons with RGP while exploiting the training algorithm of the LLNF model for parameter estimation.

3.2.1 Introduction to LLNF Models

The LLNF model is a specific form of Radial Basis Function Networks (RBF) with an expanded linear model in each neuron. This model is a general function approximator (Nelles, 2001). An LLNF input-output model with input vector $x \in \Re^p$, output $y \in \Re$ and M neurons has the following form:

$$
y = \frac{\sum_{i=1}^{M} \phi_i(x) f_i(x)}{\sum_{i=1}^{M} \phi_i(x)} \tag{4}
$$

where $f : \Re^p \rightarrow \Re$ is a linear function and $\phi : \Re^p \rightarrow [0\ ,\ 1]$ is called a membership function. Fig. 2 shows a pictorial form of these networks. These networks typically contain one hidden layer. Each neuron has a membership function that controls the output of the neuron generated by a linear regression function inside the neuron. The final output is the weighted average of all the neurons.

The two most common membership functions are the Gaussian and trapezoidal functions. The Gaussian membership function with spherical contours

is defined as

$$\phi(x) = \prod_{j=1}^{p} e^{-\frac{(x_j - c_j)^2}{2\sigma_j^2}}, \tag{5}$$

where $c \in \Re^p$ and $\sigma \in \Re^p$ are the center and standard deviation of the neuron. When p is large the Gaussian function can result in numerical instability and usually a trapezoidal function is preferred in this case. In one dimensional form a trapezoidal function is defined by a quadruple (a, b, c, d) with the following function.

$$\phi(x_j)_j = \begin{cases} 0 & x_j < a \text{ or } x_j \geq d, \\ \frac{x_j - a_j}{b - a_j} & a \leq x_j < b, \\ 1 & b \leq x_j < c, \\ \frac{d - x_j}{d - c} & c \leq x_j < d. \end{cases} \tag{6}$$

An extension to a multidimensional function can be achieved by defining $\phi(x) = \min_j(\phi(x_j)_j)$. We use this membership function our model.

The non-linearity of the LLNF comes from ϕ_i functions. If these functions are predefined, the estimation of f_i parameters is simplified to solving a weighted regression problem. The weight for input vector x at neuron q is $\phi_q(x)/\sum_{i=1}^{M}\phi_i(x)$, i.e., the normalized membership of the vector to the neuron. There are a number of strategies for determining the number of neurons and the ϕ_i functions. A widely used approach is called Locally Linear Model Tree (LoLiMoT), which follows a greedy tree construction algorithm.

LoLiMoT- The LoLiMoT algorithm (Nelles, 2001) creates hyper-rectangular partitions over the input space and centers a neuron in the middle of each partition. The parameters of the neuron are set proportional to the size of the rectangle. In Section 3.2.2, we describe how the parameters of the model are set in our experiments. The algorithm works in a greedy manner. It starts with one hyper-rectangle covering the whole space. Then, it enters a loop to optimize the number of partitions where it finds the rectangle that contributes the most to the estimation error and split the rectangle in the dimension that decreases the estimation error the most as shown in Algorithm 1. The splitting of each neuron is performed using axis-parallel partition of the space into two equal subspaces with a neuron at the center of each subspace. Fig. 3 shows a schematic 2-dimensional view of how the LoLiMoT algorithm partitions the input space.

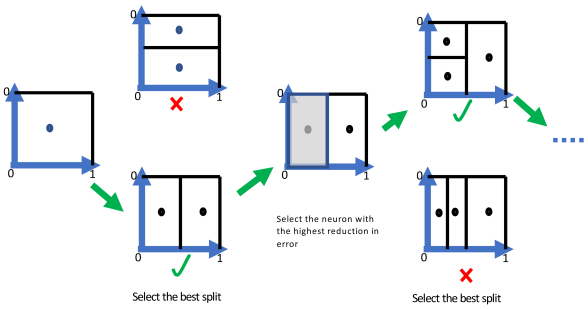

Figure 3: LoLiMoT structure optimization algorithm in 2 dimensions.

3.2.2 LLNF for Mapping

While LLNF models are used for regression and classification (Nelles, 2001), we aim to use these models for mapping by replacing the linear regression component in each neuron with an RGP. We leverage the LoLiMoT algorithm to optimize the network structure. This is achieved by replacing the function f_i in Eq. 4 with a linear mapping function. This results in having a weighted RGP problem to estimate the parameters of f_i. The weighted RGP can also be solved in closed-form (Crosilla, 2003; Koschat and Swayne, 1991) by updating the Eq. 3 to include a diagonal weight matrix L_q where $\ell_{xx} = \phi_q(x_x)/\sum_{i=1}^{M}\phi_i(x)$ is the weight for each input vector at neuron q. The updated formula is written as,

$$\begin{aligned} W_q^T &= UV^*, UDV^* = SVD(K^{-1}(L_q\bar{V}_s^{*T})(L_q\bar{V}_o^*)) \\ K_{jj} &= \frac{(\bar{V}_s^*)_j^T(\bar{V}_o^*W_q)_j}{(\bar{V}_o^*W_q)_j^T(\bar{V}_o^*W_q)} \\ b_q &= m_s - m_oKW_q \end{aligned} \tag{7}$$

The LLNF model in Eq. 4 computes a mapping of each input vector when Eq. 7 is used in place of f_i. With this change, the LoLiMoT algorithm can still be used to optimize the structure of the network.

In this paper, we consider a fixed setup in our experiments for certain hyperparameters of the LLMap to focus the discussion on the main model. These parameters can be potentially tuned to increase the performance. The following setup is used in all of the experiments in this paper.

1. Eq. 7 requires the number of iterations between calculation of rotation and dilation

Input: Matrices $\bar{V}_s$ and $\bar{V}_o$, D = # of dimensions, itr = # of splits
LLMap = `Initialize` (*One neuron covering the entire space*)
while $itr \geq 1$ **do**
  `// Use Eq.(7) for each neuron in LLMap`
  Error = LLMap.`Fit` ($\bar{V}_s$,$\bar{V}_o$)
  foreach $N \in LLMap$ **do**
    `// ` L_q `is a diag. matrix of membership values`
    N.Error = Error*N.L_q
  end
  N_Sel = *N in LLMap with Maximum Error*
  LLMap_Sel = LLMap
  MaxError = Error.`Sum` ()
  foreach $j \in D$ **do**
    LLMap_New = LLMap - N_Sel
    N1, N2 = N_Sel.`Split` (j)
    LLMap_New.`Add` (*N1, N2*)
    Error = LLMap_New.`Fit` ($\bar{V}_s, \bar{V}_o$)
    if *Error.*`Sum` *()* $<$ *MaxError* **then**
      MaxError = Error.`Sum` ()
      LLMap_Sel = LLMap_New
    end
  end
  $itr --$
  LLMap = LLMap_Sel
end

Algorithm 1: LLMap Algorithm

matrices. We use 3 iterations in all experiments.

2. To define the quadruple (a, b, c, d) for each neuron, we use two parameters (α, δ) and define $a = \alpha - 4\delta, b = \alpha - \delta, c = \alpha + \delta, d = \alpha + 4\delta$. For the first neuron $\alpha = m_o$ (the mean of input vectors) and $\delta = (max\{\bar{V}_o\} - min\{\bar{V}_o\})/4$. This ensures that the activation function of the first neuron is non-zero for all the values in the space.

3. We set the stopping criterion for the LoLiMoT algorithm to 4 neurons. We impose this restriction to allow the model and the data to fit in GPU memory. In addition, the small number of neurons prevents the vanilla LoLiMoT from overfitting and removing the need for a validation set.

4. To calculate the rotation parameter W, we discard eigenvectors in U, V with corresponding eigenvalue smaller than 0.5 up to a maximum of 50 vectors. This maximum number is used to ensure that as the number of neurons increases LLMap does not remove too many eigenvectors.

4 Experiments

The purpose of the experiments is to compare the performance of our algorithm in low resourced languages for dictionary generation in a supervised setting with the best existing supervised technique. To this end, we compare our model with the supervised MUSE algorithm (Lample et al., 2018).

4.1 Data

We use the dictionaries made publicly available through the MUSE library [2]. This library contains 110 bilingual dictionaries of varied sized, mostly with English as the target languages. We also use the 300-dimensional word embeddings pre-trained on Wikipedia using the skip-gram method with default parameters described in (Bojanowski et al., 2017). [3] This library contains 294 languages.

We select 14 languages from low resourced languages including a wide range of languages including Asian and Slavic and European languages plus Spanish. Our selection mix is focused on low resourced and languages with low structural similarity to English. We use 200,000 most frequent tokens in the embedding file.

4.2 Experimental setup

The goal of dictionary inference using multilingual word embedding is to map the monolingual word embedding spaces onto each other and to infer the translation of a word by looking at the neighborhood of that word. We use the *Cross-Domain Similarity Local Scaling* (CSLS) distance introduced in (Lample et al., 2018) to find the top k. Given a source word, v, and its set of translations, V', any sense retrieval measures the percentage of time that at least one $v' \in V'$ is in the top k-neighbors of v. In all senses retrieval the results

Table 1: The comparison between the proposed methods LLMap and RGP, and the MUSE supervised method. The values are average precision over 10 random 90-10 splits of the dictionaries, statistically significant results between LLMap and MUSE are shown in bold and between LLMap and RGP are underlined.

are measured by the percentage of time each individual $v' \in V'$ appearing in the top k-neighbors of v.

While MUSE supervised was tested for any sense retrieval using a pre-split train-test, the performance of the dictionary inference task for $k > 1$ is better to be measured by all senses retrieval. Any sense retrieval is considered a significantly easier task, e.g. in Spanish precision@5 of the MUSE algorithm goes up from 71% to 91% when any sense is considered. Also, best experimental design practices suggest using cross validation to account for variation in the data.

Considering these shortcomings, we use a different experimental setup. We create 10 random 90-10 splits of the big dictionaries for training and testing of the systems to capture the variations due to random splits. We also report the precision@5 using the pre-split for compatibility with previously published results on this dataset for both any and all senses of a word.

We use double sided paired t-test and p-value at 0.05 to test for statistical significance in the results. We used 4 refinement steps in the supervised MUSE mapping and used the best result on the test data as the performance of the algorithm. For our algorithm, we report the final test result after adding the 4th neuron. We compare the results of RGP and LLMap to quantify the contribution of each addition that we made to improve the mapping.

4.3 Results

Table 1 shows the average of precision over the 10 random splits $@k = 1, 5$ and 10. The bold values are statistically significant results between LLMap and the MUSE supervised method. The RGP column refers to our model without the piecewise mapping, which we discuss later in this section.

In all cases, except Czech (CS) and Bulgarian (BG) @1 where MUSE has a slight edge over LLMap, our method achieved higher precision on average over 10-fold cross-validation than the MUSE algorithm. In the majority of the cases the improvements are statistically significant. We can see the most significant improvements (over 8%) are observed in Japanese (JA) language and Chinese (ZH). The other languages mostly see between 1%-3% improvement in the precision. The average gain in precision @10 sits at 3.7%.

The gains achieved by our method become larger by increasing the k. It shows that LLMap can create a better proximity neighborhood around the words as it is more flexible to handle multiple

Table 2: The comparison between the proposed method LLMap and MUSE on pre-split train and test dictionaries for any and all senses recovery by the algorithms for precision@5. Last row shows the average improvement achieved by LLMap over MUSE

senses of a word. In Spanish the gains are not statistically significant at any k, pointing to the fact that in high resourced languages with large similarities with English the mapping cannot create a significant advantage over simpler mappings.

Table 2 shows the precision@5 for the pre-split dictionaries. In all 14 languages the LLMap outperforms the MUSE algorithm for recovering both all senses and any sense of a word with significant gains in Chinese and Japanese. These results are consistent with the more comprehensive cross-validation settings. Note that the any sense recovery is on average higher than all senses, pointing to the same fact the model is better at creating a better neighborhood around words where at least one sense of a word can be recovered.

The improvements that we observed compared to the state of the art are the culmination of two main changes to the baseline OPP in the mapping calculation, namely using RGP and the piecewise linear mapping. A vanilla RGP method is an LLMap model with one neuron. Table 1 shows how much increasing the non-linearity in the mapping by increasing the number of neurons from 1 to 4 contributes to the overall precision. LLMap has statistically significant (underlined values) higher precision than the vanilla RGP in most cases. However, in the two languages with the largest improvements compared to MUSE, RGP accounts for most of the gains. LLMap contributes to an overall average of 1% increase in the precision on top of RGP.

4.4 Discussions

The computational complexity of the mapping increases linearly with the number of neurons. In terms of training, finding the best dimension to split is the most time-consuming part, which increases the complexity of the algorithm from $O(n^2p)$ in OPP to $O(n^2p^2)$ in LLMap. This step requires creating p (number of dimensions) models and estimate the error of each model. In our implementation, each split took approximately 5 minutes to complete on an Amazon AWS EC2 p3.2xlarge. This task is usually done offline as a pre-processing step. Therefore, the training time complexity would not be a barrier to this approach. While MUSE uses a simpler mapping, the iterations require identifying promising candidates to add to the dictionary, which results in a similar 5 minutes run-time on a GPU.

We limit the number of neurons in our algorithm to 4 for experimental purposes. This allows us to have the models, data and top-k calculation on a single GPU for quick (10-15 minutes) run-time.

The framework presented in this work, is a general framework that can accommodate other mappings and improvements to the distance functions. However, so far to the best of our knowledge, structure preserving mapping such GP outperforms non-linear mappings that change the structure of the underlying space. Regularized and weighted mapping functions that do not have closed-form solutions can also be incorporated in this structure with a back-propagation optimization technique. In this work, we focused our discussion on the generalized mapping function as opposed to other areas of improving this task.

4.5 Comments

We have added this section to explain the The reviewers requested comparison of LLMap with a stronger baseline to compare the supervised mapping, suggesting vanilla VecMap (Artetxe et al., 2018) as a potential baseline. In the introduction, we argued that in terms of mapping function MUSE has the strongest and most widely applicable mapping function. Most of improvements after this work, including the ones in VecMap,

are obtained by updating the translation retrieval and/or normalization around the mapping function. To ensure the validity of our argument, we ran VecMap with normalization, whitening and reweighting turned off and it produced nearly identical numbers to MUSE when CSLS is used as the retrieval method.

5 Conclusion

In this research, we introduced a non-linear mapping between two embedding spaces for dictionary induction. The embedding space created for low resourced languages are noisier than their English counterpart and introduce challenges for simple rotational mapping used in the current techniques. We showed that our piecewise linear model systematically improves the precision of existing Procrustian mapping for dictionary induction using in a large-scale cross-validation setting by over 3% on average. This approach has applications beyond the scope of this paper and can be used in any applications requiring solving OPP or GPP.

Beto, Bentz, Becas: The Surprising Cross-Lingual Effectiveness of BERT

Shijie Wu and **Mark Dredze**
Department of Computer Science
Johns Hopkins University
shijie.wu@jhu.edu, mdredze@cs.jhu.edu

Abstract

Pretrained contextual representation models (Peters et al., 2018; Devlin et al., 2019) have pushed forward the state-of-the-art on many NLP tasks. A new release of BERT (Devlin, 2018) includes a model simultaneously pretrained on 104 languages with impressive performance for zero-shot cross-lingual transfer on a natural language inference task. This paper explores the broader cross-lingual potential of mBERT (multilingual) as a zero-shot language transfer model on 5 NLP tasks covering a total of 39 languages from various language families: NLI, document classification, NER, POS tagging, and dependency parsing. We compare mBERT with the best-published methods for zero-shot cross-lingual transfer and find mBERT competitive on each task. Additionally, we investigate the most effective strategy for utilizing mBERT in this manner, determine to what extent mBERT generalizes away from language-specific features, and measure factors that influence cross-lingual transfer.

1 Introduction

Pretrained language representations with self-supervised objectives have become standard in a variety of NLP tasks (Peters et al., 2018; Howard and Ruder, 2018; Radford et al., 2018; Devlin et al., 2019), including sentence-level classification (Wang et al., 2018), sequence tagging (e.g. NER) (Tjong Kim Sang and De Meulder, 2003) and SQuAD question answering (Rajpurkar et al., 2016). Self-supervised objectives include language modeling, the cloze task (Taylor, 1953) and next sentence classification. These objectives continue key ideas in word embedding objectives like CBOW and skip-gram (Mikolov et al., 2013a).

At the same time, cross-lingual embedding models have reduced the amount of cross-lingual supervision required to produce reasonable models; Conneau et al. (2017); Artetxe et al. (2018) use identical strings between languages as a pseudo bilingual dictionary to learn a mapping between monolingual-trained embeddings. Can jointly training contextual embedding models over multiple languages without explicit mappings produce an effective cross-lingual representation? Surprisingly, the answer is (partially) yes. BERT, a recently introduced pretrained model (Devlin et al., 2019), offers a multilingual model (mBERT) pretrained on concatenated Wikipedia data for 104 languages *without any cross-lingual alignment* (Devlin, 2018). mBERT does surprisingly well compared to cross-lingual word embeddings on zero-shot cross-lingual transfer in XNLI (Conneau et al., 2018), a natural language inference dataset. **Zero-shot cross-lingual transfer**, also known as single-source transfer, refers *trains and selects* a model in a source language, often a high resource language, then transfers directly to a target language.

While XNLI results are promising, the question remains: does mBERT learn a cross-lingual space that supports zero-shot transfer? We evaluate mBERT as a zero-shot cross-lingual transfer model on five different NLP tasks: natural language inference, document classification, named entity recognition, part-of-speech tagging, and dependency parsing. We show that it achieves competitive or even state-of-the-art performance with the recommended fine-tune all parameters scheme (Devlin et al., 2019). Additionally, we explore different fine-tuning and feature extraction schemes and demonstrate that with parameter freezing, we further outperform the suggested fine-tune all approach. Furthermore, we explore the extent to which mBERT generalizes away from a specific language by measuring accuracy on language ID

Code is available at https://github.com/shijie-wu/crosslingual-nlp

using each layer of mBERT. Finally, we show how subword tokenization influences transfer by measuring subword overlap between languages.

2 Background

(Zero-shot) Cross-lingual Transfer Cross-lingual transfer learning is a type of transductive transfer learning with different source and target domain (Pan and Yang, 2010). A cross-lingual representation space is assumed to perform the cross-lingual transfer. Before the widespread use of cross-lingual word embeddings, task-specific models assumed coarse-grain representation like part-of-speech tags, in support of a delexicalized parser (Zeman and Resnik, 2008). More recently cross-lingual word embeddings have been used in conjunction with task-specific neural architectures for tasks like named entity recognition (Xie et al., 2018), part-of-speech tagging (Kim et al., 2017) and dependency parsing (Ahmad et al., 2019).

Cross-lingual Word Embeddings. The quality of the cross-lingual space is essential for zero-shot cross-lingual transfer. Ruder et al. (2017) surveys methods for learning cross-lingual word embeddings by either joint training or post-training mappings of monolingual embeddings. Conneau et al. (2017) and Artetxe et al. (2018) first show two monolingual embeddings can be aligned by learning an orthogonal mapping with only identical strings as an initial heuristic bilingual dictionary.

Contextual Word Embeddings ELMo (Peters et al., 2018), a deep LSTM (Hochreiter and Schmidhuber, 1997) pretrained with a language modeling objective, learns contextual word embeddings. This contextualized representation outperforms standalone word embeddings, e.g. Word2Vec (Mikolov et al., 2013b) and Glove (Pennington et al., 2014), with the same task-specific architecture in various downstream tasks. Instead of taking the representation from a pretrained model, GPT (Radford et al., 2018) and Howard and Ruder (2018) also fine-tune all the parameters of the pretrained model for a specific task. Also, GPT uses a transformer encoder (Vaswani et al., 2017) instead of an LSTM and jointly fine-tunes with the language modeling objective. Howard and Ruder (2018) propose another fine-tuning strategy by using a different learning rate for each layer with learning rate warmup and gradual unfreezing.

Concurrent work by Lample and Conneau (2019) incorporates bitext into BERT by training on pairs of parallel sentences. Schuster et al. (2019) aligns pretrained ELMo of different languages by learning an orthogonal mapping and shows strong zero-shot and few-shot cross-lingual transfer performance on dependency parsing with 5 Indo-European languages. Similar to multilingual BERT, Mulcaire et al. (2019) trains a single ELMo on distantly related languages and shows mixed results as to the benefit of pretaining.

Parallel to our work, Pires et al. (2019) shows mBERT has good zero-shot cross-lingual transfer performance on NER and POS tagging. They show how subword overlap and word ordering effect mBERT transfer performance. Additionally, they show mBERT can find translation pairs and works on code-switched POS tagging. In comparison, our work looks at a larger set of NLP tasks including dependency parsing and ground the mBERT performance against previous state-of-the-art on zero-shot cross-lingual transfer. We also probe mBERT in different ways and show a more complete picture of the cross-lingual effectiveness of mBERT.

3 Multilingual BERT

BERT (Devlin et al., 2019) is a deep contextual representation based on a series of transformers trained by a self-supervised objective. One of the main differences between BERT and related work like ELMo and GPT is that BERT is trained by the Cloze task (Taylor, 1953), also referred to as masked language modeling, instead of right-to-left or left-to-right language modeling. This allows the model to freely encode information from both directions in each layer. Additionally, BERT also optimizes a next sentence classification objective. At training time, 50% of the paired sentences are consecutive sentences while the rest of the sentences are paired randomly. Instead of operating on words, BERT uses a subword vocabulary with WordPiece (Wu et al., 2016), a data-driven approach to break up a word into subwords.

Fine-tuning BERT BERT shows strong performance by fine-tuning the transformer encoder followed by a softmax classification layer on various sentence classification tasks. A sequence of shared softmax classifications produces sequence tagging models for tasks like NER. Fine-tuning usually takes 3 to 4 epochs with a relatively small learning rate, for example, 3e-5.

Multilingual BERT mBERT (Devlin, 2018) follows the same model architecture and training procedure as BERT, except with data from Wikipedia in 104 languages. Training makes no use of explicit cross-lingual signal, e.g. pairs of words, sentences or documents linked across languages. In mBERT, the WordPiece modeling strategy allows the model to share embeddings across languages. For example, "DNA" has a similar meaning even in distantly related languages like English and Chinese [1]. To account for varying sizes of Wikipedia training data in different languages, training uses a heuristic to subsample or oversample words when running WordPiece as well as sampling a training batch, random words for cloze and random sentences for next sentence classification.

Transformer For completeness, we describe the Transformer used by BERT. Let $\mathbf{x}, \mathbf{y}$ be a sequence of subwords from a sentence pair. A special token `[CLS]` is prepended to $\mathbf{x}$ and `[SEP]` is appended to both $\mathbf{x}$ and $\mathbf{y}$. The embedding is obtained by

$$\begin{aligned}\hat{h}_i^0 &= E(x_i) + E(i) + E(\mathbb{1}_{\mathbf{x}}) \\ \hat{h}_{j+|\mathbf{x}|}^0 &= E(y_j) + E(j+|\mathbf{x}|) + E(\mathbb{1}_{\mathbf{y}}) \\ h_{\cdot}^0 &= \text{Dropout}(\text{LN}(\hat{h}_{\cdot}^0))\end{aligned}$$

where E is the embedding function and LN is layer normalization (Ba et al., 2016). M transformer blocks are followed by the embeddings. In each transformer block,

$$\begin{aligned}h_{\cdot}^{i+1} &= \text{Skip}(\text{FF}, \text{Skip}(\text{MHSA}, h_{\cdot}^i)) \\ \text{Skip}(f, h) &= \text{LN}(h + \text{Dropout}(f(h))) \\ \text{FF}(h) &= \text{GELU}(h\mathbf{W}_1^\top + \mathbf{b}_1)\mathbf{W}_2^\top + \mathbf{b}_2\end{aligned}$$

where GELU is an element-wise activation function (Hendrycks and Gimpel, 2016). In practice, $h^i \in \mathbb{R}^{(|\mathbf{x}|+|\mathbf{y}|)\times d_h}$, $\mathbf{W}_1 \in \mathbb{R}^{4d_h \times d_h}$, $\mathbf{b}_1 \in \mathbb{R}^{4d_h}$, $\mathbf{W}_2 \in \mathbb{R}^{d_h \times 4d_h}$, and $\mathbf{b}_2 \in \mathbb{R}^{d_h}$. MHSA is the multi-heads self-attention function. We show how one new position $\hat{h}_i$ is computed.

$$\begin{aligned}[\cdots, \hat{h}_i, \cdots] &= \text{MHSA}([h_1, \cdots, h_{|\mathbf{x}|+|\mathbf{y}|}]) \\ &= \mathbf{W}_o \text{Concat}(h_i^1, \cdots, h_i^N) + \mathbf{b}_o\end{aligned}$$

In each attention, referred to as attention head,

$$\begin{aligned}h_i^j &= \sum_{k=1}^{|\mathbf{x}|+|\mathbf{y}|} \text{Dropout}(\alpha_k^{(i,j)})\mathbf{W}_V^j h_k \\ \alpha_k^{(i,j)} &= \frac{\exp \frac{(\mathbf{W}_Q^j h_i)^\top \mathbf{W}_K^j h_k}{\sqrt{d_h/N}}}{\sum_{k'=1}^{|\mathbf{x}|+|\mathbf{y}|} \exp \frac{(\mathbf{W}_Q^j h_i)^\top \mathbf{W}_K^j h_{k'}}{\sqrt{d_h/N}}}\end{aligned}$$

where N is the number of attention heads, $h_i^j \in \mathbb{R}^{d_h/N}$, $\mathbf{W}_o \in \mathbb{R}^{d_h \times d_h}$, $\mathbf{b}_o \in \mathbb{R}^{d_h}$, and $\mathbf{W}_Q^j, \mathbf{W}_K^j, \mathbf{W}_V^j \in \mathbb{R}^{d_h/N \times d_h}$.

4 Tasks

Does mBERT learn a cross-lingual representation, or does it produce a representation for each language in its own embedding space? We consider five tasks in the zero-shot transfer setting. We assume labeled training data for each task in English, and transfer the trained model to a target language. We select a range of different tasks: document classification, natural language inference, named entity recognition, part-of-speech tagging, and dependency parsing. We cover zero-shot transfer from English to 38 languages in the 5 different tasks as shown in Tab. 1. In this section, we describe the tasks as well as task-specific layers.

4.1 Document Classification

We use MLDoc (Schwenk and Li, 2018), a balanced subset of the Reuters corpus covering 8 languages for document classification. The 4-way topic classification task decides between CCAT (Corporate/Industrial), ECAT (Economics), GCAT (Government/Social), and MCAT (Markets). We only use the first two sentences[2] of a document for classification due to memory constraint. The sentence pairs are provided to the mBERT encoder. The task-specific classification layer is a linear function mapping $h_0^{12} \in \mathbb{R}_h^d$ into $\mathbb{R}^4$, and a softmax is used to get class distribution. We evaluate by classification accuracy.

4.2 Natural Language Inference

We use XNLI (Conneau et al., 2018) which cover 15 languages for natural language inference. The 3-way classification includes entailment, neutral, and contradiction given a pair of sentences. We

[1] "DNA" indeed appears in the vocabulary of mBERT as a stand-alone lexicon.

[2] We only use the first sentence if the document only contains one sentence. Documents are segmented into sentences with NLTK (Perkins, 2014).

Table 1: The 39 languages used in the 5 tasks.

feed a pair of sentences directly into mBERT and the task-specific classification layer is the same as §4.1. We evaluate by classification accuracy.

4.3 Named Entity Recognition

We use the CoNLL 2002 and 2003 NER shared tasks (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) (4 languages) and a Chinese NER dataset (Levow, 2006). The labeling scheme is BIO with 4 types of named entities. We add a linear classification layer with softmax to obtain word-level predictions. Since mBERT operates at the subword-level while the labeling is word-level, if a word is broken into multiple subwords, we mask the prediction of non-first subwords. NER is evaluated by F1 of predicted entity (F1). Note we use a simple post-processing heuristic to obtain a valid span.

4.4 Part-of-Speech Tagging

We use a subset of Universal Dependencies (UD) Treebanks (v1.4) (Nivre et al., 2016), which cover 15 languages, following the setup of Kim et al. (2017). The task-specific labeling layer is the same as §4.3. POS tagging is evaluated by the accuracy of predicted POS tags (ACC).

4.5 Dependency parsing

Following the setup of Ahmad et al. (2019), we use a subset of Universal Dependencies (UD) Treebanks (v2.2) (Nivre et al., 2018), which includes 31 languages. Dependency parsing is evaluated by unlabelled attachment score (UAS) and labeled attachment score (LAS) [3]. We only predict the coarse-grain dependency label following Ahmad et al. We use the model of Dozat and Manning (2016), a graph-based parser as a task-specific layer. Their LSTM encoder is replaced by mBERT. Similar to §4.3, we only take the representation of the first subword of each word. We use masking to prevent the parser from operating on non-first subwords.

[3] Punctuations (PUNCT) and symbols (SYM) are excluded.

5 Experiments

We use the base cased multilingual BERT, which has $N = 12$ attention heads and $M = 12$ transformer blocks. The dropout probability is 0.1 and d_h is 768. The model has 179M parameters with about 120k vocabulary.

Training For each task, no preprocessing is performed except tokenization of words into subwords with WordPiece. We use Adam (Kingma and Ba, 2014) for fine-tuning with β_1 of 0.9, β_2 of 0.999 and L2 weight decay of 0.01. We warm up the learning rate over the first 10% of batches and linearly decay the learning rate.

Maximum Subwords Sequence Length At training time, we limit the length of subwords sequence to 128 to fit in a single GPU for all tasks. For NER and POS tagging, we additionally use the sliding window approach. After the first window, we keep the last 64 subwords from the previous window as context. In other words, for a non-first window, only (up to) 64 new subwords are added for prediction. At evaluation time, we follow the same approach as training time except for parsing. We threshold the sentence length to 140 words, including words and punctuation, following Ahmad et al. (2019). In practice, the maximum subwords sequence length is the number of subwords of the first 140 words or 512, whichever is smaller.

Hyperparameter Search and Model Selection We select the best hyperparameters by searching a combination of batch size, learning rate and the number of fine-tuning epochs with the following range: learning rate $\{2\times10^{-5}, 3\times10^{-5}, 5\times10^{-5}\}$; batch size $\{16, 32\}$; number of epochs: $\{3, 4\}$. Note the best hyperparameters and model are selected by development performance in *English*.

5.1 Question #1: Is mBERT Multilingual?

MLDoc We include two strong baselines. Schwenk and Li (2018) use MultiCCA, multilingual word embeddings trained with a bilingual dictionary (Ammar et al., 2016), and convolution neural networks. Concurrent to our work,

mBERT	**94.2**	80.2	**76.9**	72.6	72.6	68.9	56.5	**73.7**	74.5

Table 2: MLDoc experiments. ♠ denotes the model is pretrained with bitext, and † denotes concurrent work. Bold and underline denote best and second best.

Artetxe and Schwenk (2018) use bitext between English/Spanish and the rest of languages to pretrain a multilingual sentence representation with a sequence-to-sequence model where the decoder only has access to a max-pooling of the encoder hidden states.

mBERT outperforms (Tab. 2) multilingual word embeddings and performs comparably with a multilingual sentence representation, even though mBERT does not have access to bitext. Interestingly, mBERT outperforms Artetxe and Schwenk (2018) in distantly related languages like Chinese and Russian and under-performs in closely related Indo-European languages.

XNLI We include three strong baselines, Artetxe and Schwenk (2018) and Lample and Conneau (2019) are concurrent to our work. Lample and Conneau (2019) with MLM is similar to mBERT; the main difference is that it only trains with the 15 languages of XNLI, has 249M parameters (around 40% more than mBERT), and MLM+TLM also uses bitext as training data [4]. Conneau et al. (2018) use supervised multilingual word embeddings with an LSTM encoder and max-pooling. After an English encoder and classifier are trained, the target encoder is trained to mimic the English encoder with ranking loss and bitext.

In Tab. 3, mBERT outperforms one model with bitext training but (as expected) falls short of models with more cross-lingual training information. Interestingly, mBERT and MLM are mostly the same except for the training languages, yet we observe that mBERT under-performs MLM by a large margin. We hypothesize that limiting pretraining to only those languages needed for the downstream task is beneficial. The gap between Artetxe and Schwenk (2018) and mBERT in XNLI is larger than MLDoc, likely because XNLI is harder.

[4]They also use language embeddings as input and exclude the next sentence classification objective

NER We use Xie et al. (2018) as a zero-shot cross-lingual transfer baseline, which is state-of-the-art on CoNLL 2002 and 2003. It uses unsupervised bilingual word embeddings (Conneau et al., 2017) with a hybrid of a character-level/word-level LSTM, self-attention, and a CRF. Pseudo training data is built by word-to-word translation with an induced dictionary from bilingual word embeddings.

mBERT outperforms a strong baseline by an average of 6.9 points absolute F1 and an 11.8 point absolute improvement in German with a simple one layer 0^{th}-order CRF as a prediction function (Tab. 4). A large gap remains when transferring to distantly related languages (e.g. Chinese) compared to a supervised baseline. Further effort should focus on transferring between distantly related languages. In §5.4 we show that sharing subwords across languages helps transfer.

POS We use Kim et al. (2017) as a reference. They utilized a small amount of supervision in the target language as well as English supervision so the results are not directly comparable. Tab. 5 shows a large (average) gap between mBERT and Kim et al. Interestingly, mBERT still outperforms Kim et al. (2017) with 320 sentences in German (de), Polish (pl), Slovak (sk) and Swedish (sv).

Dependency Parsing We use the best performing model on average in Ahmad et al. (2019) as a zero-shot transfer baseline, i.e. transformer encoder with graph-based parser (Dozat and Manning, 2016), and dictionary supervised cross-lingual embeddings (Smith et al., 2017). Dependency parsers, including Ahmad et al., assume access to gold POS tags: a cross-lingual representation. We consider two versions of mBERT: with and without gold POS tags. When tags are available, a tag embedding is concatenated with the final output of mBERT.

Tab. 6 shows that mBERT outperforms the base-

line on average by 7.3 point UAS and 0.4 point LAS absolute improvement even without gold POS tags. Note in practice, gold POS tags are not always available, especially for low resource languages. Interestingly, the LAS of mBERT tends to weaker than the baseline in languages with less word order distance, in other words, more closely related to English. With the help of gold POS tags, we further observe 1.6 points UAS and 4.7 point LAS absolute improvement on average. It appears that adding gold POS tags, which provide clearer cross-lingual representations, benefit mBERT.

Summary Across all five tasks, mBERT demonstrate strong (sometimes state-of-the-art) zero-shot cross-lingual performance without any cross-lingual signal. It outperforms cross-lingual embeddings in four tasks. With a small amount of target language supervision and cross-lingual signal, mBERT may improve further; we leave this as future work. In short, mBERT is a surprisingly effective cross-lingual model for many NLP tasks.

5.2 Question #2: Does mBERT vary layer-wise?

The goal of a deep neural network is to abstract to higher-order representations as you progress up the hierarchy (Yosinski et al., 2014). Peters et al. (2018) empirically show that for ELMo in English the lower layer is better at syntax while the upper layer is better at semantics. However, it is unclear how different layers affect the quality of cross-lingual representation. For mBERT, we hypothesize a similar generalization across the 13 layers, as well as an abstraction away from a specific language with higher layers. Does the zero-shot transfer performance vary with different layers?

We consider two schemes. First, we follow the feature-based approach of ELMo by taking a learned weighted combination of all 13 layers of mBERT with a two-layer bidirectional LSTM with d_h hidden size (Feat). Note the LSTM is trained from scratch and mBERT is fixed. For sentence and document classification, an additional max-pooling is used to extract a fixed-dimension vector. We train the feature-based approach with Adam and learning rate 1e-3. The batch size is 32. The learning rate is halved whenever the development evaluation does not improve. The training is stopped early when learning rate drop below 1e-5. Second, when fine-tuning mBERT, we fix the bottom n layers (n included) of mBERT, where layer 0 is the input embedding. We consider $n \in \{0, 3, 6, 9\}$.

Freezing the bottom layers of mBERT, in general, improves the performance of mBERT in all five tasks (Fig. 1). For sentence-level tasks like document classification and natural language inference, we observe the largest improvement with $n = 6$. For word-level tasks like NER, POS tagging, and parsing, we observe the largest improvement with $n = 3$. More improvement in under-performing languages is observed.

In each task, the feature-based approach with LSTM under-performs fine-tuning approach. We hypothesize that initialization from pretraining with lots of languages provides a very good starting point that is hard to beat. Additionally, the LSTM could also be part of the problem. In Ahmad et al. (2019) for dependency parsing, an LSTM encoder was worse than a transformer when transferring

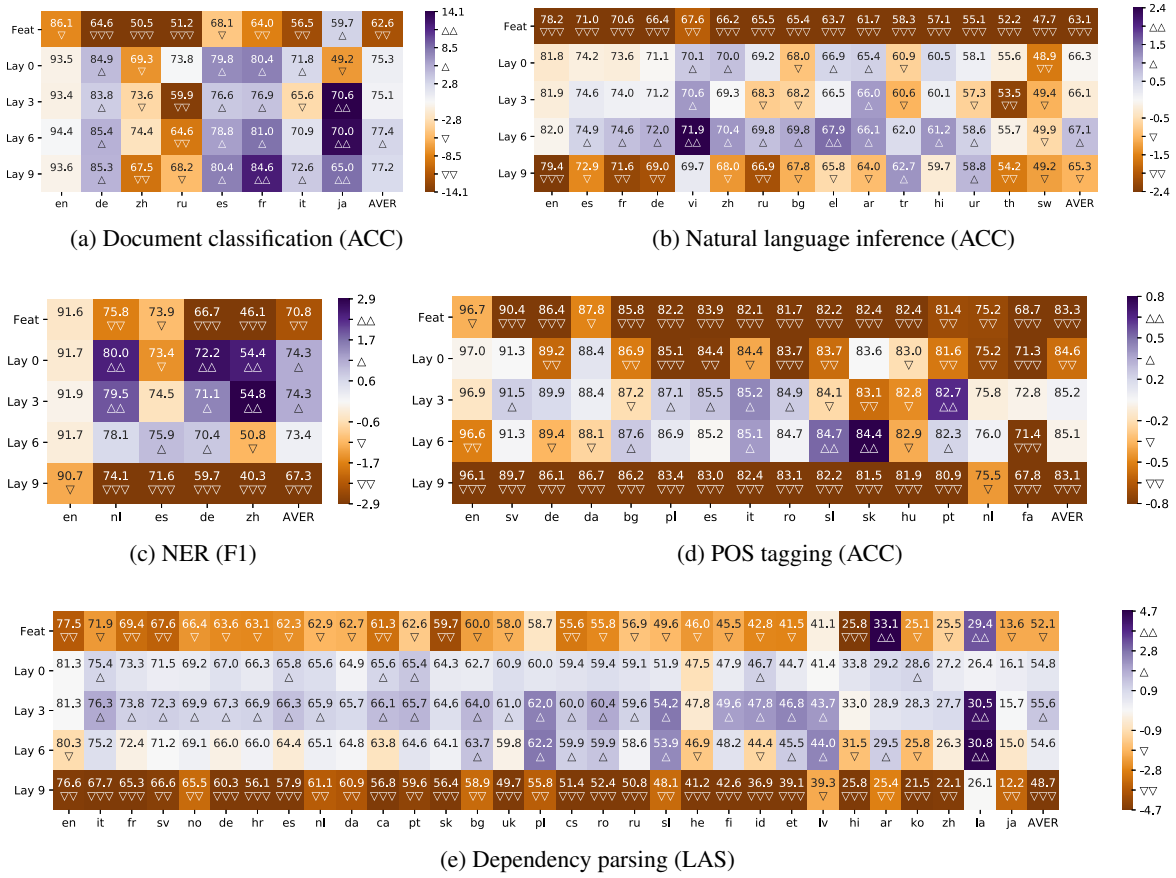
Table 6: Dependency parsing results by language (UAS/LAS). * denotes delexicalized parsing in the baseline. S and Z denotes supervised learning and zero-shot transfer. Bold and underline denotes best and second best. We order the languages by word order distance to English.

to languages with high word ordering distance to English.

5.3 Question #3: Does mBERT retain language specific information?

mBERT may learn a cross-lingual representation by abstracting away from language-specific information, thus losing the ability to distinguish between languages. We test this by considering language identification: does mBERT retain language-specific information? We use WiLI-2018 (Thoma, 2018), which includes over 200 languages from Wikipedia. We keep only those languages included in mBERT, leaving 99 languages [5]. We take various layers of bag-of-words mBERT representation of the first two sentences of the test paragraph and add a linear classifier with softmax. We fix mBERT and train *only* the classifier the same as the feature-based approach in §5.2.



All tested layers achieved around 96% accuracy (Fig. 2), with no clear difference between layers. This suggests each layer contains language-specific information; surprising given the zero-shot cross-lingual abilities. As mBERT generalizes its representations and creates cross-lingual representations, it maintains language-specific details. This may be encouraged during pretraining since mBERT needs to retain enough language-specific information to perform the cloze task.

5.4 Question #4: Does mBERT benefit by sharing subwords across languages?

As discussed in §3, mBERT shares subwords in closely related languages or perhaps in distantly related languages. At training time, the representation of a shared subword is explicitly trained to contain enough information for the cloze task in all languages in which it appears. During fine-tuning for zero-shot cross-lingual transfer, if a subword in the target language test set also appears in the source language training data, the supervision could be leaked to the target language explicitly. However, all subwords interact in a non-interpretable way inside a deep network, and subword representations could overfit to the source language and potentially hurt transfer performance. In these experiments, we investigate how sharing subwords across languages effects cross-lingual transfer.

To quantify how many subwords are shared

[5] Hungarian, Western-Punjabi, Norwegian-Bokmal, and Piedmontese are not covered by WiLI.

(a) Document classification (ACC)

(c) NER (F1)

(d) POS tagging (ACC)

(e) Dependency parsing (LAS)

Figure 1: Performance of different fine-tuning approaches compared with fine-tuning all mBERT parameters. Color denotes absolute difference and number in each entry is the evaluation in the corresponding setting. Languages are sorted by mBERT zero-shot transfer performance. Three downward triangles indicate performance drop more than the legends lower limit.

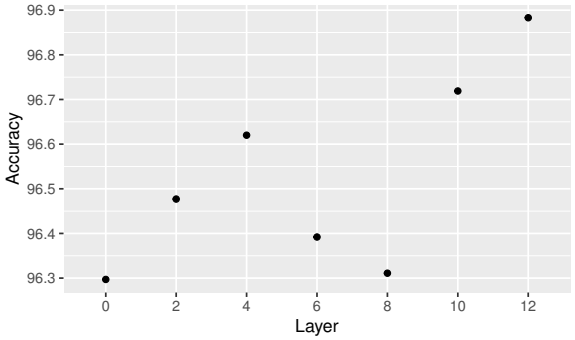

Figure 2: Language identification accuracy for different layer of mBERT. layer 0 is the embedding layer and the layer $i > 0$ is output of the i[th] transformer block.

across languages in any task, we assume $V^{\text{en}}_{\text{train}}$ is the set of all subwords in the English training set, V^{ℓ}_{test} is the set of all subwords in language ℓ test set, and c^{ℓ}_{w} is the count of subword w in test set of language ℓ. We then calculate the percentage of observed subwords at type-level p^{ℓ}_{type} and token-level p^{ℓ}_{token} for each target language ℓ.

$$p^{\ell}_{\text{type}} = \frac{|V^{\ell}_{\text{obs}}|}{|V^{\ell}_{\text{test}}|} \times 100$$

$$p^{\ell}_{\text{token}} = \frac{\sum_{w \in V^{\ell}_{\text{obs}}} c^{\ell}_{w}}{\sum_{w \in V^{\ell}_{\text{test}}} c^{\ell}_{w}} \times 100$$

where $V^{\ell}_{\text{obs}} = V^{\text{en}}_{\text{train}} \cap V^{\ell}_{\text{test}}$.

In Fig. 3, we show the relation between cross-lingual zero-shot transfer performance of mBERT and p^{ℓ}_{type} or p^{ℓ}_{token} for all five tasks with Pearson correlation. In four out of five tasks (not XNLI) we observed a strong positive correlation ($p < 0.05$) with a correlation coefficient larger than 0.5. In Indo-European languages, we observed p^{ℓ}_{token} is usually around 50% to 75% while p^{ℓ}_{type} is usually less than 50%. This indicates that subwords shared across languages are usually high frequency[6]. We

[6]With the data-dependent WordPiece algorithm, subwords that appear in multiple languages with high frequency are more likely to be selected.

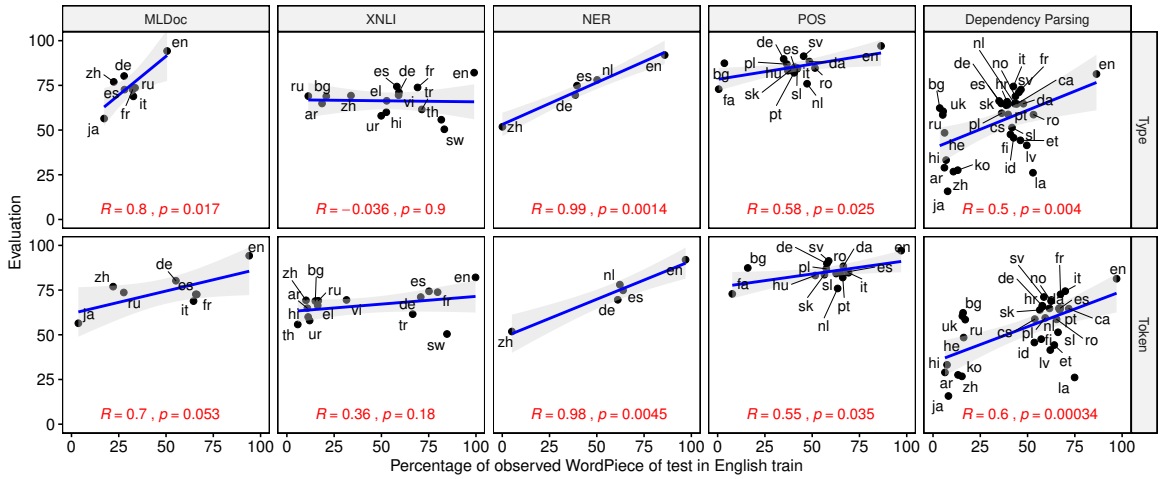

Figure 3: Relation between cross-lingual zero-shot transfer performance with mBERT and percentage of observed subwords at both type-level and token-level. Pearson correlation coefficient and p-value are shown in red.

hypothesize that this could be used as a simple indicator for selecting source language in cross-lingual transfer with mBERT. We leave this for future work.

6 Discussion

We show mBERT does well in a cross-lingual zero-shot transfer setting on five different tasks covering a large number of languages. It outperforms cross-lingual embeddings, which typically have more cross-lingual supervision. By fixing the bottom layers of mBERT during fine-tuning, we observe further performance gains. Language-specific information is preserved in all layers. Sharing subwords helps cross-lingual transfer; a strong correlation is observed between the percentage of overlapping subwords and transfer performance.

mBERT effectively learns a good multilingual representation with strong cross-lingual zero-shot transfer performance in various tasks. We recommend building future multi-lingual NLP models on top of mBERT or other models pretrained similarly. Even without explicit cross-lingual supervision, these models do very well. As we show with XNLI in §5.1, while bitext is hard to obtain in low resource settings, a variant of mBERT pretrained with bitext (Lample and Conneau, 2019) shows even stronger performance. Future work could investigate how to use weak supervision to produce a better cross-lingual mBERT, or adapt an already trained model for cross-lingual use. With POS tagging in §5.1, we show mBERT, in general, under-performs models with a small amount of supervision while Devlin et al. (2019) show that in English NLP tasks, fine-tuning BERT only needs a small amount of data. Future work could investigate when cross-lingual transfer is helpful in NLP tasks of low resource languages. With such strong cross-lingual NLP performance, it would be interesting to prob mBERT from a linguistic perspective in the future.

Abstract

Previous studies on the domain adaptation for neural machine translation (NMT) mainly focus on the one-pass transferring out-of-domain translation knowledge to in-domain NMT model. In this paper, we argue that such a strategy fails to fully extract the domain-shared translation knowledge, and repeatedly utilizing corpora of different domains can lead to better distillation of domain-shared translation knowledge. To this end, we propose an iterative dual domain adaptation framework for NMT. Specifically, we first pre-train in-domain and out-of-domain NMT models using their own training corpora respectively, and then iteratively perform bidirectional translation knowledge transfer (from in-domain to out-of-domain and then vice versa) based on knowledge distillation until the in-domain NMT model convergences. Furthermore, we extend the proposed framework to the scenario of multiple out-of-domain training corpora, where the above-mentioned transfer is performed sequentially between the in-domain and each out-of-domain NMT models in the ascending order of their domain similarities. Empirical results on Chinese-English and English-German translation tasks demonstrate the effectiveness of our framework.

1 Introduction

Currently, neural machine translation (NMT) has become dominant in the community of machine translation due to its excellent performance (Bahdanau et al., 2015; Wu et al., 2016; Vaswani et al., 2017). With the development of NMT, prevailing NMT models become more and more complex with large numbers of parameters, which often require abundant corpora for effective training. However, for translation tasks in most domains, domain-specific parallel sentences are often scarce. If we only use domain-specific data to train the NMT model for such a domain, the performance of resulting model is usually unsatisfying. Therefore, NMT for low-resource domains becomes a challenge in its research and applications.

To deal with this issue, many researchers have conducted studies on the domain adaptation for NMT, which can be classified into two general categories. One is to transfer the rich-resource domain (out-of-domain) translation knowledge to benefit the low-resource (in-domain) NMT model. The other is to use the mixed-domain training corpus to construct a unified NMT model for all domains. Here, we mainly focus on the first type of research, of which typical methods include fine-tuning (Luong and Manning, 2015; Zoph et al., 2016; Servan et al., 2016), mixed fine-tuning (Chu et al., 2017), cost weighting (Chen et al., 2017), data selection (Wang et al., 2017a,b; Zhang et al., 2019a) and so on. The underlying assumption of these approaches is that in-domain and out-of-domain NMT models share the same parameter space or prior distributions, and the useful out-of-domain translation knowledge can be completely transferred to in-domain NMT model in a one-pass manner. However, it is difficult to achieve this goal due to domain differences. Particularly, when the domain difference is significant, such conventional brute-force transfer may be unsuccessful, facing the similar issue as the domain adaptation for other tasks (Pan and Yang, 2010).

In this paper, to tackle the above problem, we argue that corpora of different domains should be repeatedly utilized to fully distill domain-shared translation knowledge. To this end, we propose a novel **I**terative **D**ual **D**omain **A**daptation (IDDA) framework for NMT. Under this framework, we first train in-domain and out-of-domain NMT models using their own training corpora re-

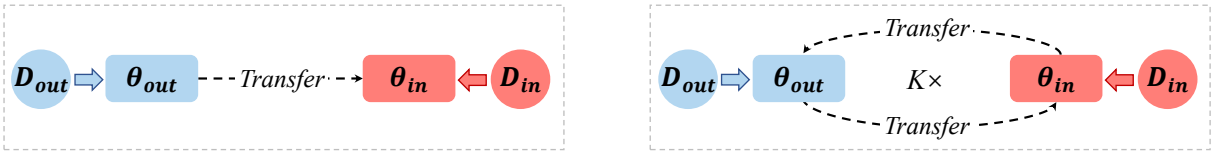
*Corresponding author.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 845–855, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

spectively, and then iteratively perform bidirectional translation knowledge transfer (from in-domain to out-of-domain and then vice versa). In this way, both in-domain and out-of-domain NMT models are expected to constantly reinforce each other, which is likely to achieve better NMT domain adaptation. Particularly, we employ a *knowledge distillation* (Hinton et al., 2015; Kim and Rush, 2016) based approach to transfer translation knowledge. During this process, the target-domain NMT model is first initialized with the source-domain NMT model, and then trained to fit its own training data and match the output of its previous best model simultaneously. By doing so, the previously transferred translation knowledge can be effectively retained for better NMT domain adaptation. Finally, we further extend the proposed framework to the scenario of multiple out-of-domain training corpora, where the above-mentioned bidirectional knowledge transfer is performed sequentially between the in-domain and each out-of-domain NMT models in the ascending order of their domain similarities.

The contributions of this work are summarized as follows:

- We propose an iterative dual domain adaptation framework for NMT, which is applicable to many conventional domain transfer approaches, such as fine-tune, mixed fine-tune. Compared with previous approaches, our framework is able to better exploit domain-shared translation knowledge for NMT domain adaptation.
- We extend our framework to the setting of multiple out-of-domain training corpora, which is rarely studied in machine translation. Moreover, we explicitly differentiate the contributions of different out-of-domain training corpora based on the domain-level similarity with in-domain training corpus.
- We provide empirical evaluations of the proposed framework on Chinese-English, German-English datasets for NMT domain adaptation. Experimental results demonstrate the effectiveness of our framework. Moreover, we deeply analyze impacts of various factors on our framework[1].



[1]We release code and results at https://github.com/DeepLearnXMU/IDDA.

2 Related Work

Our work is obviously related to the research on transferring the out-of-domain translation knowledge into the in-domain NMT model. In this aspect, fine-tuning (Luong and Manning, 2015; Zoph et al., 2016; Servan et al., 2016) is the most popular approach, where the NMT model is first trained using the out-of-domain training corpus, and then fine-tuned on the in-domain training corpus. To avoid overfitting, Chu et al. (2017) blended in-domain with out-of-domain corpora to fine-tune the pre-trained model, and Freitag and Al-Onaizan (2016) combined the fine-tuned model with the baseline via ensemble method. Meanwhile, applying data weighting into NMT domain adaptation has attracted much attention. Wang et al. (2017a) and Wang et al. (2017b) proposed several sentence and domain weighting methods with a dynamic weight learning strategy. Zhang et al. (2019a) ranked unlabeled domain training samples based on their similarity to in-domain data, and then adopts a probabilistic curriculum learning strategy during training. Chen et al. (2017) applied the sentence-level cost weighting to refine the training of NMT model. Recently, Vilar (2018) introduced a weight to each hidden unit of out-of-domain model. Chu and Wang (2018) gave a comprehensive survey of the dominant domain adaptation techniques for NMT. Gu et al. (2019) not only maintained a private encoder and a private decoder for each domain, but also introduced a common encoder and a common decoder shared by all domains.

Significantly different from the above methods, along with the studies of dual learning for NMT (He et al., 2016; Wang et al., 2018; Zhang et al., 2019b), we iteratively perform bidirectional translation knowledge transfer between in-domain and out-of-domain training corpora. To the best of our knowledge, our work is the first attempt to explore such a dual learning based framework for NMT domain adaptation. Furthermore, we extend our framework to the scenario of multiple out-of-domain corpora. Particularly, we introduce knowledge distillation into the domain adaptation for NMT and experimental results demonstrate its effectiveness, echoing its successful applications on many tasks, such as speech recognition (Hinton et al., 2015) and natural language processing (Kim and Rush, 2016; Tan et al., 2019).

Besides, our work is also related to the studies

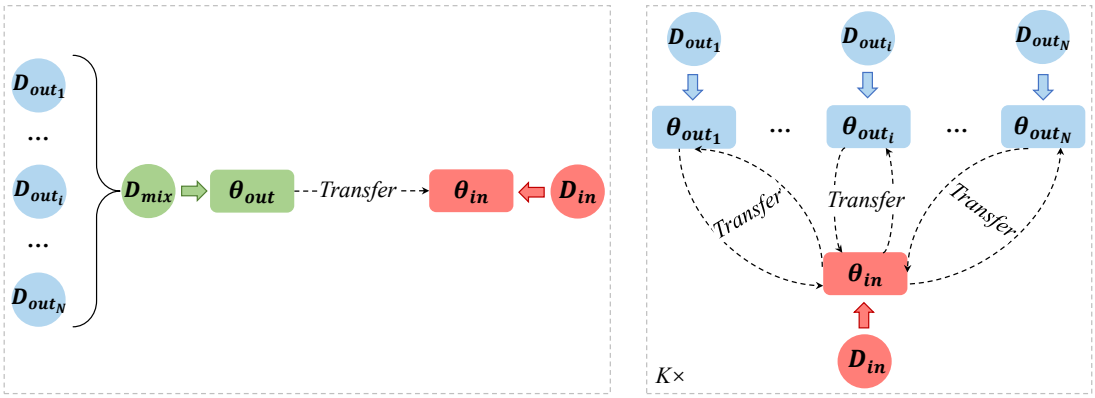
of multi-domain NMT, which focus on building a unified NMT model trained on the mixed-domain training corpus for translation tasks in all domains (Kobus et al., 2016; Tars and Fishel, 2018; Farajian et al., 2017; Pryzant et al., 2017; Sajjad et al., 2017; Zeng et al., 2018; Bapna and Firat, 2019). Although our framework is also able to refine out-of-domain NMT model, it is still significantly different from multi-domain NMT, since only the performance of in-domain NMT model is considered.

Finally, note that similar to our work, Tan et al. (2019) introduced knowledge distillation into multilingual NMT. However, our work is still different from (Tan et al., 2019) in the following aspects: (1) Tan et al. (2019) mainly focused on constructing a unified NMT model for multi-lingual translation task, while we aim at how to effectively transfer out-of-domain translation knowledge to in-domain NMT model; (2) Our translation knowledge transfer is bidirectional, while the procedure of knowledge distillation in (Tan et al., 2019) is unidirectional; (3) When using knowledge distillation under our framework, we iteratively update teacher models for better domain adaptation. In contrast, all language-specific teacher NMT models in (Tan et al., 2019) remain fixed.



3 Iterative Dual Domain Adaptation Framework

In this section, we first detailedly describe our proposed framework for conventional one-to-one NMT domain adaptation, and then extend this framework to the scenario of multiple out-of-domain corpora (many-to-one).

3.1 One-to-one Domain Adaptation

As shown in Figure 1(a), previous studies mainly focus on the one-pass translation knowledge transfer from one out-of-domain NMT model to the in-domain NMT model. Unlike these studies, we propose to conduct iterative dual domain adaptation for NMT, of which framework is illustrated in Figure 1(b).

To better describe our framework, we summarize the training procedure of our framework

(c) Non-iterative Domain Adaptation (d) Iterative Dual Domain Adaptation

Figure 2: Traditional approach vs IDDA framework for many-to-one NMT domain adaptation. D_{mix}: a mixed out-of-domain training corpus.

in Algorithm 1. Specifically, we first individually train the initial in-domain and out-of-domain NMT models, respectively denoted by $\theta_{in}^{(0)}$ and $\theta_{out}^{(0)}$, via minimizing the negative likelihood of their own training corpora D_{in} and D_{out} (**Line 3**):

$$\mathcal{L}_{in}^{(0)} = \sum_{(\mathbf{x},\mathbf{y})\in D_{in}} -logP(\mathbf{y}|\mathbf{x};\theta_{in}^{(0)}), \quad (1)$$

$$\mathcal{L}_{out}^{(0)} = \sum_{(\mathbf{x},\mathbf{y})\in D_{out}} -logP(\mathbf{y}|\mathbf{x};\theta_{out}^{(0)}). \quad (2)$$

Then, we iteratively perform bidirectional translation knowledge transfer to update both in-domain and out-of-domain NMT models, until the maximal iteration number K is reached (**Lines 5-14**). More specifically, at the k-th iteration, we first transfer the translation knowledge of the previous in-domain NMT model $\theta_{in}^{(k-1)}$ to the out-of-domain NMT model $\theta_{out}^{(k)}$ trained on D_{out} (**Line 6**), and then reversely transfer the translation knowledge encoded by $\theta_{out}^{(k)}$ to the in-domain NMT model $\theta_{in}^{(k)}$ trained on D_{in} (**Line 10**). During this process, we evaluate the new models $\theta_{in}^{(k)}$ and $\theta_{out}^{(k)}$ on their corresponding development sets, and then record the best model parameters as θ_{in}^{*} and θ_{out}^{*} (**Lines 7-9, 11-13**).

Obviously, during the above procedure, one of important steps is how to transfer the translation knowledge from one domain-specific NMT model to the other one. However, if we directly employ conventional domain transfer approaches, such as fine-tuning, as the iterative dual domain adaptation proceeds, the previously learned translation knowledge tends to be ignored. To deal with this issue, we introduce knowledge distillation (Kim and Rush, 2016) to conduct the translation knowledge transfer. Specifically, during the transfer process from $\theta_{out}^{(k)}$ to $\theta_{in}^{(k)}$, we first initialize $\theta_{in}^{(k)}$ with parameters of $\theta_{out}^{(k)}$, and then train $\theta_{in}^{(k)}$ not only to match the references of D_{in}, but also to be consistent with probability outputs of the previous best in-domain NMT model θ_{in}^{*}, which is considered as the teacher model. To this end, we define the loss function as

$$\mathcal{L}_{in}^{(k)} = \sum_{(\mathbf{x},\mathbf{y})\in D_{in}} [-(1-\lambda)\cdot logP(\mathbf{y}|\mathbf{x};\theta_{in}^{(k)}) + \lambda \cdot \mathrm{KL}(P(\mathbf{y}|\mathbf{x};\theta_{in}^{(k)})||P(\mathbf{y}|\mathbf{x};\theta_{in}^{*}))], \quad (3)$$

where λ is the coefficient used to trade off these two loss terms, and it can be tuned on the development set. Notably, when λ=0, only the term of likelihood function affects the model training, and thus our transfer approach degenerate into fine-tuning at each iteration.

In this way, we enable in-domain NMT model $\theta_{in}^{(k)}$ to not only retain the previously learned effective translation knowledge, but also fully absorb the useful translation knowledge from out-of-domain NMT model $\theta_{out}^{(k)}$. Similarly, we employ the above method to transfer translation knowledge from $\theta_{in}^{(k-1)}$ to $\theta_{out}^{(k)}$ using out-of-domain corpus D_{out} and the previous best out-of-domain model θ_{out}^{*}. Due to the space limitation, we omit the specific description of this procedure.

3.2 Many-to-one Domain Adaptation

Usually, in practical applications, there exist multiple available out-of-domain training corpora simultaneously. As shown in Figure 2(a), previous studies usually mix them into one out-of-domain

corpus, which is applicable for the conventional one-to-one NMT domain adaptation. However, various out-of-domain corpora are semantically related to in-domain corpus to different degrees, and thus intuitively, it is difficult to adequately play their roles without distinguishing them.

To address this issue, we extend the proposed framework to many-to-one NMT domain adaptation. Our extended framework is illustrated in Figure 2(b). Given an in-domain corpus and N out-of-domain corpora, we first measure the semantic distance between each out-of-domain corpus and the in-domain corpus using the proxy A-distance $\hat{d}_A$=$2(1-2\epsilon)$ (Ganin et al., 2015; Pryzant et al., 2017), where the ϵ is the generalization error of a linear bag-of-words SVM classifier trained to discriminate between the two domains. Then, we determine the transfer order of these out-of-domain NMT models as $\{\theta_{out_1}, \theta_{out_2}, ...\theta_{out_N}\}$, according to distances of their own training corpora to the in-domain corpus in a decreasing order. The reason behind this step is the translation knowledge of previously transferred out-of-domain NMT models will be partially forgotten during the continuous transfer. By setting transfer order according to their $\hat{d}_A$ values in a decreasing order, we enable the in-domain NMT model to fully preserve the translation knowledge transferred from the most relevant out-of-domain NMT model. Finally, we sequentially perform bidirectional knowledge transfer between the in-domain and each out-of-domain models, where this process will be repeated for K iterations.

4 Experiments

To verify the effectiveness of our framework, we first conducted one-to-one domain adaptation experiments on Chinese-English translation, where we further investigated impacts of various factors on our framework. Then, we carried out two-to-one domain adaptation experiments on English-German translation, so as to demonstrate the generality of our framework on different language pairs and multiple out-of-domain corpora.

4.1 Setup

Datasets. In the Chinese-English translation task, our in-domain training corpus is from IWSLT2015 dataset consisting of 210K *TED Talk* sentence pairs, and the out-of-domain training corpus contains 1.12M LDC sentence pairs related to *News* domain. For these two domains, we chose IWSLT dev2010 and NIST 2002 dataset as development sets. Finally, we used IWSLT tst2010, tst2011 and tst2012 as in-domain test sets. Particularly, in order to verify whether our framework can enable NMT models of two domains to benefit each other, we also tested the performance of out-domain NMT model on NIST 2003, 2004, 2005, 2006 datasets.

For the English-German translation task, our training corpora totally include one in-domain dataset: 200K *TED Talk* sentence pairs provided by IWSLT2015, and two out-of-domain datasets: 500K sentence pairs (*News* topic) extracted from WMT2014 corpus, and 500K sentence pairs (*Medical topic*) that are sampled from OPUS EMEA corpus[2]. As for development sets, we chose IWSLT tst2012, WMT tst2012 and 1K sampled sentence pairs of OPUS EMEA corpus, respectively. In addition, IWSLT tst2013, tst2014 were used as in-domain test sets, WMT news-test2014 (News topic) and 1K sampled sentence pairs of OPUS EMEA corpus were used as two out-of-domain test sets.

We first employed *Stanford Segmenter*[3] to conduct word segmentation on Chinese sentences and *MOSES script*[4] to tokenize English and German sentences. Then, we limited the length of sentences to 50 words in the training stage. Besides, we employed *Byte Pair Encoding* (Sennrich et al., 2016) to split words into subwords and set the vocabulary size for both Chinese-English and English-German as 32,000. We evaluated the translation quality with BLEU scores (Papineni et al., 2002) as calculated by `multi-bleu.perl` script .

Settings. We chose Transformer (Vaswani et al., 2017) as our NMT model, which exhibits excellent performance due to its flexibility in parallel computation and long-range dependency modeling. We followed Vaswani et al. (2017) to set the configurations. The dimensionality of all input and output layers is 512, and that of FFN layer is 2048. We employed 8 parallel attention heads in both encoder and decoder. Parameter optimization was performed using stochastic gradient descent, where *Adam* (Kingma and Ba, 2015) was used to automatically adjust the learning rate of

[2]http://opus.nlpl.eu/
[3]https://nlp.stanford.edu/
[4]http://www.statmt.org/moses/

each parameter. We batched sentence pairs by approximated length, and limited input and output tokens per batch to 25000 tokens. As for decoding we employed beam search algorithm and set the beam size as 4. Besides, we set the distillation coefficient λ as 0.4.

Contrast Models. We compared our framework with the following models, namely:

- **Single** A reimplemented Transformer only trained on a single domain-specific (in/out) training corpus.
- **Mix** A reimplemented Transformer trained on the mix of in-domain and out-of-domain training corpora.
- **Fine-tuning (FT)** (Luong and Manning, 2015). It first trains the NMT model on out-of-domain training corpus and then fine-tunes it using in-domain training corpus.
- **Mixed Fine-tuning (MFT)** (Chu et al., 2017). It also first trains the NMT model on out-of-domain training corpus, and then fine-tunes it using both out-of-domain and over-sampling in-domain training corpora.
- **Knowledge Distillation (KD)** (Kim and Rush, 2016). Using this method, we first train a out-of-domain and an in-domain NMT models using their own training corpus, respectively. Then, we use the in-domain training corpus to fine-tune the out-of-domain NMT model, supervised by the in-domain NMT model.

Besides, we reported the performance of some recently proposed multi-domain NMT models.

- **Domain Control (DC)** (Kobus et al., 2016). It is also based on the mix-domain NMT model. However, it adds an additional domain tag to each source sentence, incorporating domain information into source annotations.
- **Discriminative Mixing (DM)** (Pryzant et al., 2017). It jointly trains NMT with domain classification via multitask learning. Please note that it performs the best among three approaches proposed by Pryzant et al., (2017).
- **Word-level Domain Context Discrimination (WDCD)** (Zeng et al., 2018). It discriminates the source-side word-level domain specific and domain-shared contexts for multi-domain NMT by jointly modeling NMT and domain classifications.

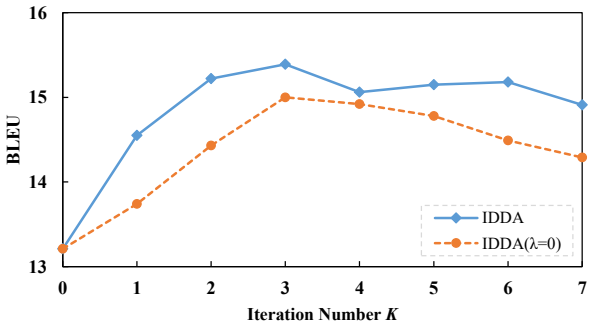


Figure 3: Effect of iteration number (K) on the Chinese-English in-domain development set.

4.2 Results on Chinese-English Translation

4.2.1 Effect of Iteration Number K

The iteration number K is a crucial hyper-parameter that directly determines the amount of the transferred translation knowledge under our framework. Therefore, we first inspected its impacts on the development sets. To this end, we varied K from 0 to 7 with an increment of 1 in each step, where our framework degrades to *Single* when K=0.

Figure 3 provides the experimental results using different Ks. We can observe that both *IDDA(λ=0)* and *IDDA* achieve the best performance at the 3-th iteration, respectively. Therefore, we directly used K=3 in all subsequent experiments.

4.2.2 Overall Performance

Table 1 shows the overall experimental results. On all test sets, our framework significantly outperforms other contrast models. Furthermore, we reach the following conclusions:

First, on the in-domain test sets, both *IDDA(λ=0)* and *IDDA* surpass *Single*, *Mix*, *FT*, *MFT* and *KD*, most of which are commonly used in the domain adaptation for NMT. This confirms the difficulty in completely one-pass transferring the useful out-of-domain translation knowledge to the in-domain NMT model. Moreover, the in-domain NMT model benefits from multiple-pass knowledge transfers under our framework.

Second, compared with *DC*, *DM* and *WDCD* that are proposed for multi-domain NMT, both *IDDA(λ=0)* and *IDDA* still exhibit better performance on the in-domain test sets. The underlying

Table 1: Experimental results on the Chinese-English translation task. † indicates statistically significantly better than (ρ <0.01) the result of *WDCD*.

reason is that these multi-domain models discriminate domain-specific and domain-shared information in encoder, however, their shared decoder are inadequate to effectively preserve domain-related text style and idioms. In contrast, our framework is adept at preserving these information since we construct an individual NMT model for each domain.

Third, *IDDA* achieves better performance than *IDDA(λ=0)*, demonstrating the importance of retaining previously learned translation knowledge. Surprisingly, *IDDA* significantly outperforms *IDDA(λ=0)* on out-of-domain data sets. We conjecture that during the process of knowledge distillation, by assigning non-zero probabilities to multiple words, the output distribution of teacher model is more smooth, leading to smaller variance in gradients (Hinton et al., 2015). Consequently, the out-of-domain NMT model becomes more robust by iteratively absorbing the translation knowledge from the best out-of-domain model.

Finally, note that even on the out-of-domain test sets, *IDDA* still has better performance than all listed contrast models in the subsequent experimental analyses. This result demonstrates the advantage of dual domain adaptation under our framework.

According to the reported performance of our framework shown in Table 1, we only considered *IDDA* in all subsequent experiments. Besides, we only chose *MFT*, *KD*, and *WDCD* as typical contrast models. This is because *KD* is the basic domain adaption approach of our framework, *MFT* and *WDCD* are the best domain adaptation method and multi-domain NMT model for comparison, respectively.

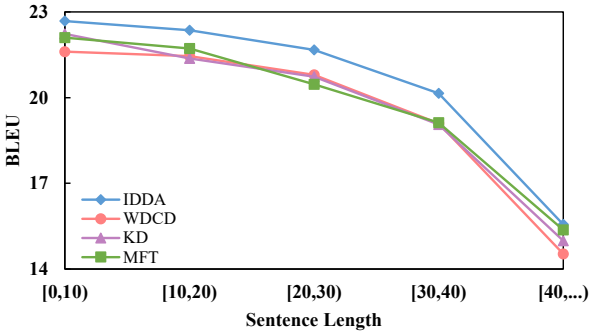

Figure 4: BLEU scores on different IWSLT test sets divided according to source sentence lengths.

4.2.3 Results on Source Sentences with Different Lengths

Following previous work (Bahdanau et al., 2015), we divided IWSLT test sets into different groups based on the lengths of source sentences and then investigated the performance of various models.

Figure 4 illustrates the results. We observe that our framework also achieves the best performance in all groups, although the performances of all models degrade with the increase of the length of source sentences.

4.2.4 Effect of Out-of-domain Corpus Size

In this group of experiments, we investigated the impacts of out-of-domain corpus size on our proposed framework. Specifically, we inspected the results of our framework using different sizes of out-of-domain corpora: 50K, 200K and 1.12M, respectively

Figure 5 shows the comparison results on the average BLEU scores of all IWSLT test sets. No matter how large out-of-domain data is used, *IDDA* always achieves better performance than

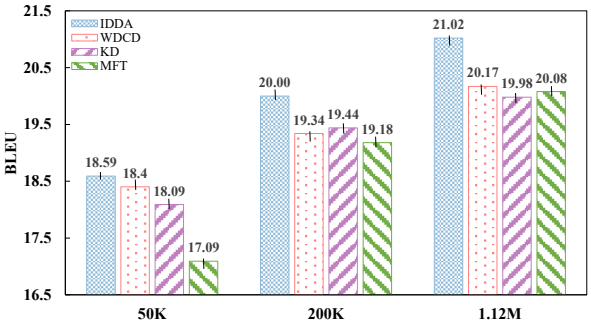

Figure 5: Experimental results with different sizes of out-of-domain corpora.

Table 2: Experimental results of comparing IDDA with its two variants.

other contrast models, demonstrating the effectiveness and generality of our framework. Specially, *IDDA* with 200K out-of-domain corpus is comparable to *KD* with 1.12M corpus. From this result, we confirm again that our framework is able to better exploit the complementary information between domains than *KD*.

4.2.5 Effects of Dual Domain Adaptation and Updating Teacher Models

Two highlights of our framework consist of the usage of bidirectional translation knowledge transfer and continuous updating teacher models θ^*_{out} and θ^*_{in} (See Line 6, 10 of Algorithm 1). To inspect their effects on our framework, we compared our framework with its two variants: (1) *IDDA-unidir*, where we only iteratively transfer out-of-domain translation knowledge to the in-domain NMT model; (2) *IDDA-fixTea*, where teacher models are fixed as the initial out-of-domain and in-domain NMT models, respectively.

The results are displayed in Table 2. We can see that our framework exhibits better performance than its two variants, which demonstrates that dual domain adaptation enables NMT models of two domains to benefit from each other, and updating teacher models is more helpful to retain useful translation knowledge.

4.2.6 Case Study

Table 3 displays the 1-best translations of a sampled test sentence generated by *MFT*, *KD*, *WDCD*, and *IDDA* at different iterations. Inspecting this

example provides the insight into the advantage of our proposed framework to some extent. Specifically, we observe that *MFT*, *KD*, *WDCD* are unable to correctly understand the meaning of "zhílì xíngzǒu de língzhǎnglèi dòngwù" and thus generate incorrect or incomplete translations, while *IDDA* successfully corrects these errors by gradually absorbing transferred translation knowledge.

4.3 Results on English-German Translation

4.3.1 Overall Performance

We first calculated the distance between the in-domain and each out-of-domain corpora: $\hat{d}_A$(*Ted Talk*, *News*) = 0.92 and $\hat{d}_A$(*Ted Talk*, *Medical*) = 1.92. Obviously, the *News* domain is more relevant to *TED Talk* domain than *Medical* domain, and thus we determined the final transfer order as $\{\theta_{\text{out}_{\text{medical}}}, \theta_{\text{out}_{\text{news}}}\}$ for this task. Then, as implemented in the previous Chinese-English experiments, we determined the optimal K=2 on the development set.

Table 4 shows experimental results. Similar to the previously reported experiment results, our framework still obtains the best performance among all models, which verifies the effectiveness of our framework on many-to-one domain adaptation for NMT.

As described above, we have two careful designs for many-to-one NMT domain adaptation: (1) We distinguish different out-of-domain corpora, and then iteratively perform bidirectional translation knowledge transfer between in-domain and each out-of-domain NMT models. (2) We determine the transfer order according to the seman-

Table 5: Experimental results of IDDA using different configurations.

tic distance between each out-of-domain and in-domain training corpora. Here, we carried out two groups of experiments to investigate their impacts on our framework. In the first group of experiments, we first combined all out-of-domain training corpora into a mixed corpus, and then applied our framework to establish the in-domain NMT model. In the second group of experiments, we employed our framework in different transfer orders to perform domain adaptation.

Table 5 shows the final experimental results, which are in line with our expectations and verify the validity of our designs.

5 Conclusion

In this paper, we have proposed an iterative dual domain adaptation framework for NMT, which continuously fully exploits the mutual complementarity between in-domain and out-domain corpora for translation knowledge transfer. Experimental results and in-depth analyses on translation tasks of two language pairs strongly demonstrate the effectiveness of our framework.

In the future, we plan to extend our framework to multi-domain NMT. Besides, how to leverage monolingual sentences of different domains to refine our proposed framework. Finally, we will apply our framework into other translation models (Bahdanau et al., 2015; Su et al., 2018; Song et al., 2019), so as to verify the generality of our framework.

Abstract

Conventional Neural Machine Translation (NMT) models benefit from the training with an additional agent, e.g., dual learning, and bidirectional decoding with one agent decoding from left to right and the other decoding in the opposite direction. In this paper, we extend the training framework to the multi-agent scenario by introducing diverse agents in an interactive updating process. At training time, each agent learns advanced knowledge from others, and they work together to improve translation quality. Experimental results on NIST Chinese-English, IWSLT 2014 German-English, WMT 2014 English-German and large-scale Chinese-English translation tasks indicate that our approach achieves absolute improvements over the strong baseline systems and shows competitive performance on all tasks.

1 Introduction

Training with more than one agents has attracted intensive research interest in recent years, for example, dual learning (He et al., 2016; Xia et al., 2017, 2018) and bidirectional decoding (Liu et al., 2016; Zhang et al., 2019b). The former method leverages the duality between the two related agents as the feedback signal to regularize training, while the latter targets the agreement between one agent decoding from left to right (L2R) while the other decoding in opposite direction (R2L). Both methods enhance the translation models by introducing a regularization term into the training objective.

The effectiveness of these two methods lies in the fact that appropriate regularization can help each agent to learn from the superior models while integrating their advantages (e.g., good translations for prefixes for L2R, and good translation quality for suffixes for R2L). As shown in the Table 1, due to the *exposure bias* problem (Ranzato et al., 2016), the agent trained to decode from left to right tends to generate better prefixes and bad suffixes, and the agent decoding in the reverse direction demonstrates the opposite preference. By introducing additional Kullback-Leibler (KL) divergences between the probability distributions defined by L2R and R2L models into the NMT training objective (Zhang et al., 2019b), it is possible for two models to learn advantages from each other.

Src	此次 豪雨 灾情 , 半数 遇难 者 遭 洪水 冲走 溺 毙 ; 其他 则 因 房屋 倒塌 或 电线 走火 触电 致死 。
Ref	In this disaster caused by torrential rains, half of the victims were carried away and drowned in the floods; the others died because their houses collapsed or from electrocution caused by short circuits.
L2R	In the torrential rain, half of the victims were washed away by floods, while others ***died of electricity caused by collapsed houses or electric wires.***
R2L	***Half of the victims were drowned by floods,*** while others were killed by collapsed houses or electrocuted by sparkling wires.

Table 1: In this sample, NMT systems with different implementations present diverse translation errors for one long sentence. The agent decoding from left to right (*L2R*) tends to generate better prefixes and bad suffixes (bold letters), and the *R2L* agent has the opposite preference.

According to the empirical achievements of previous studies on training with two agents, it is natural to consider the training with more than two agents, and to extend our study to the multi-agent scenario. However, training with more than two agents is more complex, and we face two critical

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 856–865,
Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

problems. First, when deploying the multi-agent system, should we focus on the diversity or the strength of each agent? (Wong et al., 2005; Marcolino et al., 2013) Second, learning in multi-agent scenario is *many-to-many*, as opposed to the relatively simpler *one-to-one* learning in two-agent training, and requires an effective learning strategy.

There have been many alternatives to improve the diversity of models even based on the Transformer model (Vaswani et al., 2017). For example, decoding in the opposite direction usually results in different preferences: good prefixes and bad prefixes (Zhang et al., 2019b). Rather, self-attention with relative position representations enhances the generalization to sequence lengths unseen during training (Shaw et al., 2018). Furthermore, increasing the size of layers in the encoder is expected to specialize in word sense disambiguation (Tang et al., 2018; Domhan, 2018). In this paper, we investigate the effects of two teams of multi-agents: a team of alternative agents mentioned above, and a uniform team of different initialization for the same model.

To resolve the second problem, we simplify the *many-to-many* learning to the *one-to-many* (one teacher $vs.$ many students) learning, extending ensemble knowledge distillation (Fukuda et al., 2017; Freitag et al., 2017; Liu et al., 2018; Zhu et al., 2018). During the training, each agent performs better by learning from the ensemble model (*Teacher*) of all agents integrating the knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016) into the training objective. This procedure can be viewed as the introduction of an additional regularization term into the training objective, with which each agent can learn advantages from the ensemble model gradually. With this method, each agent is optimized not only to the maximization of the likelihood of the training data, but also to the minimization of the divergence between its own model and the ensemble model.

However, the above learning strategy converges on the local optimum rapidly in our empirical studies. It seems that each agent tends to focus on learning from the ensemble model while completely ignoring its own exploration. To alleviate this problem, we train each agent to learn from the ensemble models when necessary, and to distill the knowledge based on the translation quality (BLEU score) of the ensemble model. This means we evaluate the quality of the ensemble model to see whether it is good enough to be studied. Consequently, the knowledge distillation from the ensemble model to the agent stems from the better translation generated by the ensemble model.

We evaluate our model on NIST Chinese-English Translation Task, IWSLT 2014 German-English Translation task, large-scale WMT 2014 English-German Translation task and large-scale Chinese-English Translation Task. Extensive experimental results indicate that our model significantly improves the translation quality, compared to the strong baseline systems. Moreover, our model also reports competitive performance on the German-English and English-German translation tasks, achieving 36.27 and 29.67 BLEU scores, respectively.

To the best of our knowledge, this is the first work on training NMT model with more than two agents [1]. The contributions of this paper are summarized as follows:

- We extend the study on training with two agents to the multi-agent scenario, and propose a general learning strategy to train multiple agents.
- We investigate the effects of the diversity and the strength of each agent in the multi-agent training scenario.
- We simplify complex *many-to-many* learning in multi-agent learning to *one-to-many* learning by forcing each agent learning knowledge from ensemble model as necessary.
- Extensive experiments on multiple translation tasks confirm that our model significantly improves the translation quality and reports the new state-of-the-art results on IWSLT 2014 German-English and competitive results on WMT 2014 English-German translation tasks.

2 Background

Conventional autoregressive NMT models (Bahdanau et al., 2015; Sutskever et al., 2014) decode target tokens sequentially, which indicates that the

[1] Although Wang et al. (2019) proposed a work named multi-agent dual learning contemporarily, the training in their work is conducted on the two agents with fixed parameters of other agents.

determination of the current token is conditioned by the previous generated sequence. Formally, at time step t, the generation of the current token y_t is determined by the following equation:

$$p(y_t) = p(y_t|y_{<t}, x; \theta) \quad (1)$$

where $y_{<t}$ represents the previously generated sequence, and θ are the parameters of the representation of the source sequence and the partial target sequence.

Furthermore, the usual training criterion is to minimize the negative log-likelihood for each sample from the training data,

$$\mathcal{L}_{NLL} = -\sum_{t=0}^{T}\sum_{k=1}^{|\mathcal{V}|} \mathbb{1}\{y_t = k\} \log p(y_t = k|y_{<t}, x; \theta) \quad (2)$$

where T is the length of the target sequence, $|\mathcal{V}|$ is the size of vocabulary and $\mathbb{1}\{\cdot\}$ is the indicator function. This objective can be viewed as minimizing the cross-entropy between the correct translation y^* and the model generation $p(y_t|y_{<t}, x; \theta)$.

3 Multi-agent Learning

Empirical studies indicate that one agent is trained to perform better through learning advantages from the other agent in the two-agent scenario, namely *one-to-one* learning (Figure 1.(a)). The training objective of the agent is regularized, which is to learn better models by leveraging the relationship between the two agents as feedback, i.e., duality in dual learning problem, and agreement in bidirectional decoding.

Extending the study to the multi-agent scenario is feasible and desirable, as multiple agents might supply more reliable and diverse advantages compared to the two-agents scenario. However, the agent is expected to learn advantages from each other in the multi-agent scenario, which results in a complex *many-to-many* learning problem(Figure 1.(b)).

Instead of tackling *many-to-many* learning, we force the agent to learn from a common *Teacher* by introducing ensemble knowledge distillation, thus reduce the learning to *one-to-many* (Figure 1.(c)). With this learning strategy, each agent can learn to improve the performance in an interactive updating process.

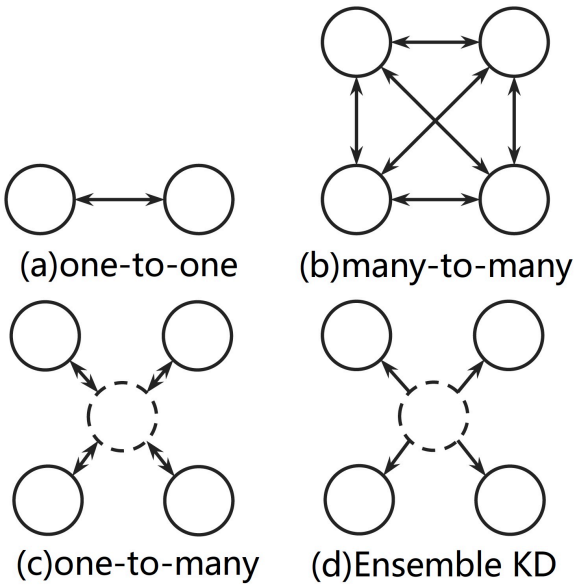

Figure 1: Illustration for different learning approaches.

As opposed to ensemble Knowledge Distillation (KD) (Figure 1.(d)), the important difference is that in the knowledge distillation of an ensemble of models, the *Teacher* network is fixed after pre-training, during the training process. While in our framework, the state of the *Teacher* network is updated at each iteration, and its performance can be further improved by the improvements of each agent explicitly, in an interactive updating process. In some ways the ensemble KD can be viewed as a particular case of our model, as we fix the update of the *Teacher* network in the training framework.

3.1 Overall Framework

For the sake of simplicity, four variant agents are referred to as $Agent1$, $Agent2$, $Agent3$ and $Agent4$. We begin by pre-training each agent independently (Figure 2.(a)), and then enhance the model in the multi-agent scenario in two steps: 1) Generating Ensemble Model (Figure 2.(b)), and 2) *One-to-Many* Learning (Figure 2.(c)). The performance of each agent is improved in an interactive updating process, through repeating the above two steps.

3.2 Generate Ensemble Model

As pointed out in the work of Liu et al. (2018), ensemble models can empirically alleviate problems existing in the standard NMT model, such as ambiguities in the training data, and discrepancy between training and testing.

According to the practical advantages of ensem-

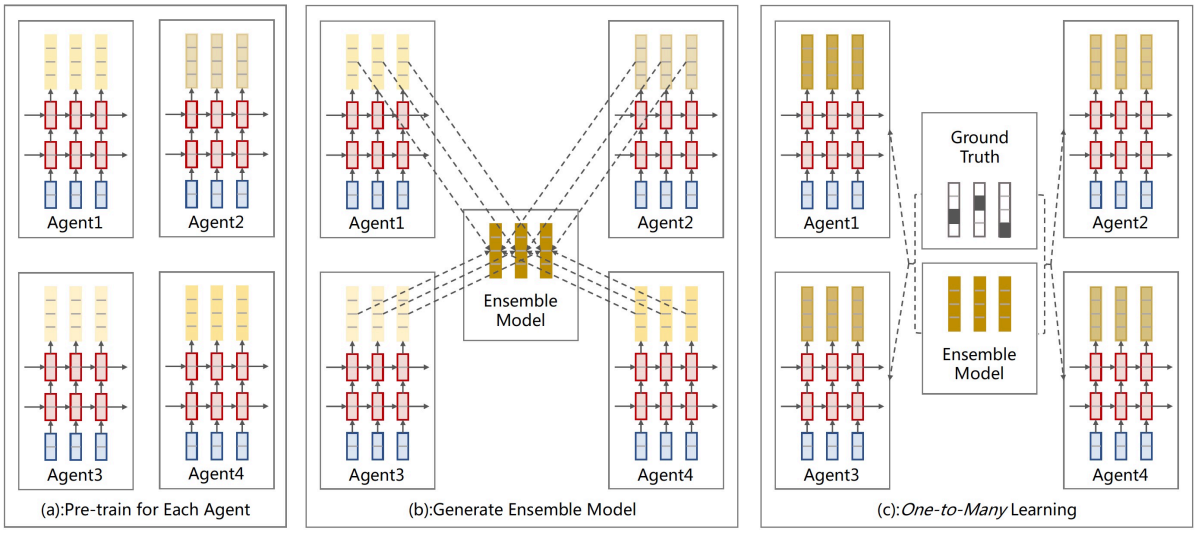

Figure 2: In this example, four agents decode the similar sentence with different model capacity. (a): At first, each agent is pre-trained to generate the translation independently. (b) The ensemble model is generated by the average prediction from each agent. (c): The *One-to-Many* learning distills the knowledge from the ensemble model to each agent as necessary. The performance of each agent is improved explicitly in an interactive updating process, through repeating the process (b) and (c).

ble models, it is relevant to force agents to learn from the ensemble model, instead of learning from each other separately. Following previous work, we develop our ensemble model by averaging the model distributions of all agents.

Formally, the model distribution of the i-th agent $agent_i$ is defined as $p(y_t^i|y_{<t}^i, x; \theta)$. Assume we have $\mathcal{N}$ agents, the model distribution of the ensemble model can be formulated as:

$$q(y_t|y_{<t}, x; \theta_t) = \frac{1}{\mathcal{N}} \sum_{i=1}^{\mathcal{N}} p(y_t^i|y_{<t}^i, x; \theta_i) \quad (3)$$

where θ_t are parameters for representing the ensemble model. Notably, we do not train it in the training process.

In the above formula, the probability $q(y_t|y_{<t}, x; \theta_t)$ is one reliable estimator of the model distribution, as the majority of the agents are likely to generate correct sequence. From this perspective, we expect that more agents will lead to better and more robust performance.

3.3 *One-to-Many* Learning

In the *one-to-many* learning framework, the ensemble model acts as the *Teacher* network, which distills knowledge to each agent iteratively.

Rather than minimizing cross-entropy with the observed data, we minimize the cross-entropy with the probability distribution from the ensemble model for each agent.

$$\mathcal{L}_{KD}^i = -\sum_{t=0}^{T}\sum_{k=1}^{|\mathcal{V}|} q(y_t = k|y_{<t}, x; \theta_t) \times \log p(y_t^i = k|y_{<t}^i, x; \theta) \quad (4)$$

With the above formula, the agent is optimized to the minimization of the model divergence between its own model and the ensemble model.

However, integrating the above regularization term into the training objective straightforwardly is problematic in practice. The agent tends to focus on learning from the ensemble model rather than exploring its own prediction to converge rapidly. Consequently, the model converges at a suboptimal point, and fails to enhance the performance by learning from each other due to the lack of evaluation of the ensemble model.

To alleviate this problem, we train each agent to learn from the ensemble model when necessary, distilling the knowledge conditioned by the translation quality of the ensemble model. We evaluate the quality of the ensemble model to see whether it is good enough to be studied. The knowledge distillation from the ensemble model to the agent comes from the better translation generated by the ensemble model. Otherwise, the agent is forced to learn its own distribution.

Let $< X_g, Y_g >$ be one sentence pair in the training corpus, the quality of the translation sequence generated by the ensemble model is mea-

sured by the BLEU score,

$$score(Y_t) = \text{BLEU}(Y_t, Y_g) \tag{5}$$

where Y_t is generated by the model distribution $q(y_t|y_{<t}, x; \theta_t)$. The quality of the translation sequence generated by each agent can also be defined using the similar metric,

$$score(Y_s^i) = \text{BLEU}(Y_s^i, Y_g) \tag{6}$$

where Y_s^i is generated by the model distribution $p(y_t^i|y_{<t}^i, x; \theta)$ of each agent.

Conditioned by the translation quality of the ensemble model, we modify the training objective for each agent as follows:

$$\mathcal{L}_{KD}^i = -\sum_{t=0}^{T}\sum_{k=1}^{|\mathcal{V}|} S \times \log p(y_t^i = k|y_{<t}^i, x; \theta) \tag{7}$$

where S is defined as:

$$S = \begin{cases} q(y_t = k|y_{<t}, x; \theta_t) & score(Y_t) > score(Y_s^i) \\ \mathbb{1}_s\{y_t^i = k\} & otherwise \end{cases} \tag{8}$$

where $\mathbb{1}_s\{\cdot\}$ is an indicator, conditioned by the existence of $y_t^i = k$ in the sequence Y_s^i.

In practice, each agent is not only optimized to maximize the likelihood of the training data, but also to minimize the model divergence between its own model and the ensemble model:

$$\mathcal{L}_a^i = \lambda_i \mathcal{L}_{NLL} + (1 - \lambda_i)\mathcal{L}_{KD}^i \tag{9}$$

where λ_i is a hyperparameter, balancing the weight of two factors.

From the perspective of learning, the agent learns to minimize the training objective by generating competitive translations, which leads to a global improvement for all agents. On the other hand, a sequence-level training objective might alleviate the *exposure bias* problem implicitly (Ranzato et al., 2016).

3.4 Joint Learning

In the work of Zhang et al. (2019b), they proposed a relatively complex joint learning framework for training two agents. In this paper, according to the previous experiments, we find that a simple multi-task learning technique without sharing any modules presents promising performance,

$$\mathcal{L}_{final} = \sum_{i=1}^{\mathcal{N}} \mathcal{L}_a^i \tag{10}$$

In Algorithm 1, we describe the overall procedure of our approach. It deserves noting that in line 3, we assume the model reads a single pair of training examples per timestep for simplistic description, while in practice the model reads a batch size of samples at each step.

Algorithm 1: Multi-agent Learning

Input: N variant agents;

15 **until** *convergence*;

4 Experiments

In this paper, we evaluate our model on four translation tasks: NIST Chinese-English Translation Task, IWSLT 2014 German-English Translation Task, WMT 2014 English-German Translation Task and large-scale Chinese-English Translation Task.

4.1 Data Preprocessing

To compare with previous studies, we conduct byte-pair encoding (Sennrich et al., 2016) for Chinese, English and German sentences, setting the

Table 2: BLEU score for the representative models in multi-agent training on NIST Chinese-English translation. $X \times Y$ stands for Y agents with the indentical model X but from different initializing seeds.

vocabulary size to 20K and 18K for Chinese-English, a joint 20K vocabulary for German-English, and a joint 32K vocabulary for English-German, respectively.

For Chinese-English task, the training data consists of about 1.5M sentence pairs extracted from LDC corpora [2]. We choose the NIST 2006 (MT06) dataset for validation, and NIST 2002-2004 (MT02-04), as well as NIST 2008 (MT08) datasets for testing. For large-scale Chinese-English task, the training data consists of about 40M sentence pairs extracted from web data.

4.2 Agent Variants

To increase the diversity of agents, we implement the following variants of the Transformer based system: *L2R*, the officially released open source toolkit for running Transformer model, *R2L*, the standard Transformer decodes in reversed direction, *Enc*, the standard Transformer with 30 layers in the encoder, and *Rel*, the reimplementation of self-attention with relative position (Shaw et al., 2018).

[2]LDC2002E18, LDC2002L27, LDC2002T01, LDC2003E07, LDC2003E14, LDC2004T07, LDC2005E83, LDC2005T06, LDC2005T10, LDC2005T34, LDC2006E24, LDC2006E26, LDC2006E34, LDC2006E86, LDC2006E92, LDC2006E93, LDC2004T08(HK News, HK Hansards)

4.3 Training Details

We implement our models using PaddlePaddle [3], an end-to-end open source deep learning platform developed by Baidu. It provides a complete suite of deep learning libraries, tools and service platforms to make the research and development of deep learning simple and reliable.

We use the hyperparameters of the *base* version for the standard Transformer model of NIST Chinese-English and IWSLT German-English translation tasks, except the smaller token size ($batch_size = 320$). For WMT English-German and large-scale Chinese-English translation tasks, we use the hyperparameters of the *big* version. As described in the previous section, we use a hyperparameter λ_i for each agent to balance the preference between learning from the observed data and the ensemble model. According to the performance of each agent after pre-training, we set this value as follows:

$$\lambda_i = 0.5 + \max(-0.5, \min(0.5, \frac{B_i - B_{avg}}{10})) \quad (11)$$

where B_i is the BLEU score obtained by the pre-training of the $i-th$ agent, and the B_{avg} is the average BLEU score of all agents.

The above formula suggests the agent learns more from the ensemble model as its performance

Task	*L2R*	*Rel*	KD-4	Dual-5	Rel-4
De-En	33.63	34.91	35.53	34.70	**36.27**

Table 3: BLEU score on IWSLT 2014 German-English translation. KD-4 stands for ensemble knowledge distillation with four agents. Dual-5 is the SOTA model from the work of Wang et al. (2019). And Rel-4 is our best model (*Rel*) training with four diverse agents.

is worse than the majority vote, rather than focusing on exploring by its own prediction.

We train our model with parallelization at data batch level. For NIST Chinese-English task, it takes about 1.5 days to train models on 8 NVIDIA P40 GPUs, 5 days for WMT English-German task, 8 hours for IWSLT German-English task and 7 days for large-scale Chinese-English task. The detailed training process is as follows, first we train each agent until BLEU doesn't improve any more and then execute Algorithm 1 for one-to-many learning which takes 30K-40K steps to converge.

4.4 Chinese-English Results

Study on different numbers of agents. We first assess the impact of diverse agents on translation quality. From Table 2, we see that the model's performance consistently improves as the number of agents increases, and we observe that 1) The four baseline systems with different implementations present diverse translation quality, in particular *Rel* with refined position encoding achieves the best performance. 2) The improvement of each agent after multi-agent learning is dependent on the performance of the co-trained agent (+0.33, +0.8, +0.63 improvements obtained by *L2R* when training with *R2L*, *Enc* and *Rel*). 3) Better results can be obtained by increasing the number of training agents (e.g., 47.3 $\rightarrow$ 47.73 $\rightarrow$ 47.95 for L2R).

From the overall results, increasing the number of agents in multi-agent learning significantly improves the performance of each agent (at most +1.39, +0.9, +1.33, +1.17 in *a*+*b*+*c*+*d*), which suggests that each agent learns advantages from the other agents, and more agents might lead to further improvement. More importantly, our improvements are obtained from the advanced training strategy without any modification in decoding stage, which indicates its practicability in deployment.

Study on uniform agents. To measure the importance of diversity in multi-agents, we conduct multiple experiments by initializing the similar model with different initialization seeds to generate multiple agents. As reported in Table 2, although the single *Rel* model achieves the best performance compared to the other three single agents, the *d* $\times$ *2* (47.44) and *d* $\times$ *3* (47.57) perform worse than the best counterparts *c*+*d* (47.79) and *a*+*c*+*d* (47.94). Moreover, when training with more than two agents, the performance of *d* $\times$ *3* (47.57) is even lower than arbitrary diverse counterparts (*a*+*b*+*c* (47.74); *a*+*b*+*d* (47.73)).

These results suggest that multi-agent learning is better conducted with diverse agents instead of the uniform agents with excellent single performance. On the other hand, in our multi-agent learning, training with more agents brings consistent improvements even when deployed by identical models from different initialization seeds.

4.5 German-English and English-German Results

We work with the IWSLT German-English translation to compare our model to the SOTA model. From Table 3, we observe that both KD-4 and Rel-4 models achieve the best result on this dataset (35.53 and 36.27), which manifests the effectiveness of using multiple agents.

Even when trained with four agents, our model outperforms the dual model trained with five agents (34.70), and reports a SOTA score on this translation task. Moreover, we argue that fine-tuning with *L2R* to obtain a better performance could further improve the performance of Rel-4, as there exists a large gap between *L2R* and *Rel*, which affects the learning efficiency.

We further investigate the performance of our

Models	AVERAGE
L2R(baseline)	33.74
L2R+R2L+Enc+Rel	**34.60**

Table 5: BLEU score for the L2R model in multi-agent training on large-scale corpus of Chinese-English translation. Because we only use L2R model in Baidu Translate, so part of results are presented.

model on the WMT English-German translation task, which achieves a competitive result of 29.67 BLEU score on newstest2014. From Table 4, we can see that another related work, multi-agent dual learning (Wang et al., 2019) achieves promising results. This confirms that training with more agents leads to better translation quality, and reveals the relevance of using multiple agents.

Although Sergey et al. (2018) reports a BLEU score of 35.0 on this dataset, they leverage refined training corpus and a large number of monolingual data. We argue that our model can bring further improvement using their back-translation technique. Moreover, the goal of this paper is introducing a general learning framework for multi-agent learning rather than exhaustively fine-tuning to report a SOTA results. We argue that the performance of our model can be further improved using an advanced single agent, such as DynamicConv (Wu et al., 2019) and Dual (Wang et al., 2019).

4.6 Large-Scale Chinese-English Results

In order to prove that multi-agent learning can yield improvement in large-scale corpus, we conducted experiments on 40M Chinese-English sentence pairs with the same data processing method as NIST. We built test sets of more than 10K sentences which cover various domains such as news, spoken language and query logs. From Table 5, we can see that multi-agent learning can increase the average baseline BLEU score of several test sets by 0.86. This technique has already been applied to Baidu Translate.

4.7 Contrastive Evaluation

In this paper, we evaluate our model on the two types of contrastive evaluation datasets: ***Lingeval97*** [4] and ***ContraWSD*** [5]. The former is utilized to measure the performance of different models on dealing with subject-verb agreement in English-German translation, while the latter evaluates the performance on word sense disambiguation in German-English translation. We suggest the readers refer to the work (Sennrich, 2017; Tang et al., 2018) for detailed descriptions of the two datasets.

Models	SVA (%)	WSD (%)
L2R	89.06	78.05
R2L	88.92	77.97
Enc	89.13	**79.07**
Rel	**89.21**	78.75
L2R+R2L	89.28	77.94
L2R+Enc	**89.42**	78.29
L2R+Rel	89.39	**78.47**
L2R+R2L+Enc	89.26	78.36
L2R+R2L+Rel	**89.58**	78.28
L2R+Enc+Rel	89.39	**78.84**
L2R+R2L+Enc+Rel	89.47	78.62

Table 6: Accuracy of subject-verb agreement (SVA) and word sense disambiguation (WSD) for different models. We report the performance of *L2R* in different models for comparison of using different agents.

From Table 6, we can see that the *L2R* training with multiple agents improves the accuracy both on SVA and WSD, and we observe that: 1) The *L2R* improves its ability of SVA with the help of the other agents significantly. 2) The *Enc* presents better advantage in resolving WSD than in SVA, while *Rel* has the opposite preference. 3) Although the *R2L* presents ordinary BLEU score, it still does help the *L2R* resolve the SVA.

5 Related Work

The most related work is recently proposed by Wang et al. (2019), who introduced a multi-agent algorithm for dual learning. However, the major differences are 1) the training in their work is conducted on the two agents while fixing the parameters of other agents. 2) they use identical agent with different initialization seeds. 3) our model is simple yet effective. Actually, it is easy to incorporate additional agent trained with their dual learning strategy in our model, to further improve the performance. More importantly, both of our work and their work indicate that using more agents can improve the translation quality significantly.

Another related work is ensemble knowledge distillation (Fukuda et al., 2017; Freitag et al., 2017; Liu et al., 2018; Zhu et al., 2018), in which

[4] https://github.com/rsennrich/lingeval97

[5] https://github.com/a-rios/ContraWSD

the ensemble model of all agents is leveraged as the *Teacher* network, to distill the knowledge for the corresponding *Student* network. However, as described in the previous section, the knowledge distillation is one particular case of our model, as the performance of the *Teacher* in their model is fixed, and cannot be further improved by the learning process.

Our work is also motivated by the work of training with two agents, including dual learning (He et al., 2016; Xia et al., 2017, 2018), and bidirectional decoding (Liu et al., 2016; Zhang et al., 2018, 2019b,a). Our method can be viewed as a general learning framework to train multiple agents, which explores the relationship among all agents to enhance the performance of each agent efficiently.

6 Conclusions and Future Work

In this paper, we propose a universal yet effective learning method for training multiple agents. In particular, each agent learns advantages from the ensemble model when necessary. The knowledge distillation from the ensemble model to the agent stems the better translation generated by the ensemble model, which enables each agent to learn high-quality knowledge while retaining its own exploration.

Extensive experimental results prove that our model brings an absolute improvement over the baseline system, reporting SOTA results on IWSLT 2014 German-English and competitive results on WMT 2014 English-German translation tasks.

In the future, we will focus on training with more agents by translating apart of one sentence considering its advantage for each agent, rather than translating the whole sentence.

Abstract

We present effective pre-training strategies for neural machine translation (NMT) using parallel corpora involving a pivot language, i.e., source-pivot and pivot-target, leading to a significant improvement in source→target translation. We propose three methods to increase the relation among source, pivot, and target languages in the pre-training: 1) step-wise training of a single model for different language pairs, 2) additional adapter component to smoothly connect pre-trained encoder and decoder, and 3) cross-lingual encoder training via autoencoding of the pivot language. Our methods greatly outperform multilingual models up to +2.6% BLEU in WMT 2019 French→German and German→Czech tasks. We show that our improvements are valid also in zero-shot/zero-resource scenarios.

1 Introduction

Machine translation (MT) research is biased towards language pairs including English due to the ease of collecting parallel corpora. Translation between non-English languages, e.g., French→German, is usually done with pivoting through English, i.e., translating French (*source*) input to English (*pivot*) first with a French→English model which is later translated to German (*target*) with a English→German model (De Gispert and Marino, 2006; Utiyama and Isahara, 2007; Wu and Wang, 2007). However, pivoting requires doubled decoding time and the translation errors are propagated or expanded via the two-step process.

Therefore, it is more beneficial to build a single source→target model directly for both efficiency and adequacy. Since non-English language pairs often have little or no parallel text, common choices to avoid pivoting in NMT are generating pivot-based synthetic data (Bertoldi et al., 2008; Chen et al., 2017) or training multilingual systems (Firat et al., 2016; Johnson et al., 2017).

In this work, we present novel transfer learning techniques to effectively train a single, direct NMT model for a non-English language pair. We pre-train NMT models for source→pivot and pivot→target, which are transferred to a source→target model. To optimize the usage of given source-pivot and pivot-target parallel data for the source→target direction, we devise the following techniques to smooth the discrepancy between the pre-trained and final models:

- Step-wise pre-training with careful parameter freezing.
- Additional adapter component to familiarize the pre-trained decoder with the outputs of the pre-trained encoder.
- Cross-lingual encoder pre-training with autoencoding of the pivot language.

Our methods are evaluated in two non-English language pairs of WMT 2019 news translation tasks: high-resource (French→German) and low-resource (German→Czech). We show that NMT models pre-trained with our methods are highly effective in various data conditions, when fine-tuned for source→target with:

- Real parallel corpus
- Pivot-based synthetic parallel corpus (*zero-resource*)
- None (*zero-shot*)

For each data condition, we consistently outperform strong baselines, e.g., multilingual, pivoting, or teacher-student, showing the universal effectiveness of our transfer learning schemes.

[*] Equal contribution.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 866–876, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

The rest of the paper is organized as follows. We first review important previous works on pivot-based MT in Section 2. Our three pre-training techniques are presented in Section 3. Section 4 shows main results of our methods with a detailed description of the experimental setups. Section 5 studies variants of our methods and reports the results without source-target parallel resources or with large synthetic parallel data. Section 6 draws conclusion of this work with future research directions.

2 Related Work

In this section, we first review existing approaches to leverage a pivot language in low-resource/zero-resource MT. They can be divided into three categories:

1. **Pivot translation (pivoting).** The most naive approach is reusing (already trained) source→pivot and pivot→target models directly, decoding twice via the pivot language (Kauers et al., 2002; De Gispert and Marino, 2006). One can keep N-best hypotheses in the pivot language to reduce the prediction bias (Utiyama and Isahara, 2007) and improve the final translation by system combination (Costa-Jussà et al., 2011), which however increases the translation time even more. In multilingual NMT, Firat et al. (2016) modify the second translation step (pivot→target) to use source and pivot language sentences together as the input.
2. **Pivot-based synthetic parallel data.** We may translate the pivot side of given pivot-target parallel data using a pivot→source model (Bertoldi et al., 2008), or the other way around translating source-pivot data using a pivot→target model (De Gispert and Marino, 2006). For NMT, the former is extended by Zheng et al. (2017) to compute the expectation over synthetic source sentences. The latter is also called teacher-student approach (Chen et al., 2017), where the pivot→target model (teacher) produces target hypotheses for training the source→target model (student).
3. **Pivot-based model training.** In phrase-based MT, there have been many efforts to combine phrase/word level features of source-pivot and pivot-target into a source→target system (Utiyama and Isahara, 2007; Wu and Wang, 2007; Bakhshaei et al., 2010; Zahabi et al., 2013; Zhu et al., 2014; Miura et al., 2015). In NMT, Cheng et al. (2017) jointly train for three translation directions of source-pivot-target by sharing network components, where Ren et al. (2018) use the expectation-maximization algorithm with the target sentence as a latent variable. Lu et al. (2018) deploy intermediate recurrent layers which are common for multiple encoders and decoders, while Johnson et al. (2017) share all components of a single multilingual model. Both methods train the model for language pairs involving English but enable zero-shot translation for unseen non-English language pairs. For this, Ha et al. (2017) encode the target language as an additional embedding and filter out non-target tokens in the output. Lakew et al. (2017) combine the multilingual training with synthetic data generation to improve the zero-shot performance iteratively, where Sestorain et al. (2018) applies the NMT prediction score and a language model score to each synthetic example as gradient weights.

Our work is based on transfer learning (Zoph et al., 2016) and belongs to the third category: model training. On the contrary to the multilingual joint training, we suggest two distinct steps: pre-training (with source-pivot and pivot-target data) and fine-tuning (with source-target data). With our proposed methods, we prevent the model from losing its capacity to other languages while utilizing the information from related language pairs well, as shown in the experiments (Section 4).

Our pivot adapter (Section 3.2) shares the same motivation with the interlingua component of Lu et al. (2018), but is much compact, independent of variable input length, and easy to train offline. The adapter training algorithm is adopted from bilingual word embedding mapping (Xing et al., 2015). Our cross-lingual encoder (Section 3.3) is inspired by cross-lingual sentence embedding algorithms using NMT (Schwenk and Douze, 2017; Schwenk, 2018).

Transfer learning was first introduced to NMT by Zoph et al. (2016), where only the source language is switched before/after the transfer. Nguyen and Chiang (2017) and Kocmi and Bojar (2018) use shared subword vocabularies to work

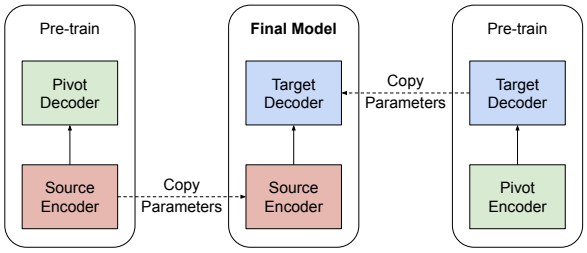

Figure 1: Plain transfer learning.

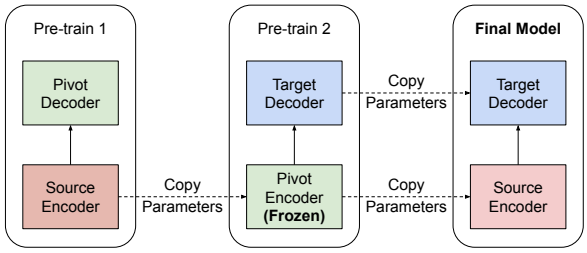

Figure 2: Step-wise pre-training.

with more languages and help target language switches. Kim et al. (2019) propose additional techniques to enable NMT transfer even without shared vocabularies. To the best of our knowledge, we are the first to propose transfer learning strategies specialized in utilizing a pivot language, transferring a source encoder and a target decoder at the same time. Also, for the first time, we present successful zero-shot translation results only with pivot-based NMT pre-training.

3 Pivot-based Transfer Learning

Our methods are based on a simple transfer learning principle for NMT, adjusted to a usual data condition for non-English language pairs: lots of source-pivot and pivot-target parallel data, little (low-resource) or no (zero-resource) source-target parallel data. Here are the core steps of the plain transfer (Figure 1):

1. Pre-train a source→pivot model with a source-pivot parallel corpus and a pivot→target model with a pivot-target parallel corpus.
2. Initialize the source→target model with the source encoder from the pre-trained source→pivot model and the target decoder from the pre-trained pivot→target model.
3. Continue the training with a source-target parallel corpus.

If we skip the last step (for zero-resource cases) and perform the source→target translation directly, it corresponds to zero-shot translation.

Thanks to the pivot language, we can pre-train a source encoder and a target decoder without changing the model architecture or training objective for NMT. On the contrary to other NMT transfer scenarios (Zoph et al., 2016; Nguyen and Chiang, 2017; Kocmi and Bojar, 2018), this principle has no language mismatch between transferor and transferee on each source/target side. Experimental results (Section 4) also show its competitiveness despite its simplicity.

Nonetheless, the main caveat of this basic pre-training is that the source encoder is trained to be used by an English decoder, while the target decoder is trained to use the outputs of an English encoder — not of a source encoder. In the following, we propose three techniques to mitigate the inconsistency of source→pivot and pivot→target pre-training stages. Note that these techniques are not exclusive and some of them can complement others for a better performance of the final model.

3.1 Step-wise Pre-training

A simple remedy to make the pre-trained encoder and decoder refer to each other is to train a single NMT model for source→pivot and pivot→target in consecutive steps (Figure 2):

1. Train a source→pivot model with a source-pivot parallel corpus.
2. Continue the training with a pivot-target parallel corpus, while freezing the encoder parameters of 1.

In the second step, a target decoder is trained to use the outputs of the pre-trained source encoder as its input. Freezing the pre-trained encoder ensures that, even after the second step, the encoder is still modeling the source language although we train the NMT model for pivot→target. Without the freezing, the encoder completely adapts to the pivot language input and is likely to forget source language sentences.

We build a joint vocabulary of the source and pivot languages so that the encoder effectively represents both languages. The frozen encoder is pre-trained for the source language in the first step, but also able to encode a pivot language sentence in a similar representation space. It is more effective for linguistically similar languages where

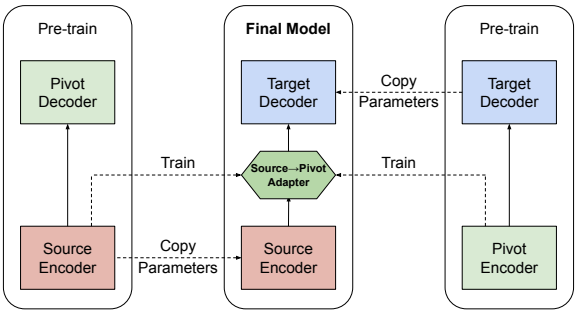

Figure 3: Pivot adapter.

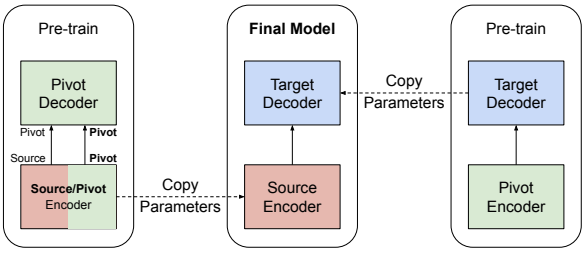

Figure 4: Cross-lingual encoder.

many tokens are common for both languages in the joint vocabulary.

3.2 Pivot Adapter

Instead of the step-wise pre-training, we can also postprocess the network to enhance the connection between the source encoder and the target decoder which are pre-trained individually. Our idea is that, after the pre-training steps, we adapt the source encoder outputs to the pivot encoder outputs to which the target decoder is more familiar (Figure 3). We learn a linear mapping between the two representation spaces with a small source-pivot parallel corpus:

1. Encode the source sentences with the source encoder of the pre-trained source→pivot model.
2. Encode the pivot sentences with the pivot encoder of the pre-trained pivot→target model.
3. Apply a pooling to each sentence of 1 and 2, extracting representation vectors for each sentence pair: $(\mathbf{s}, \mathbf{p})$.
4. Train a mapping $\mathbf{M} \in \mathbb{R}^{d \times d}$ to minimize the distance between the pooled representations $\mathbf{s} \in \mathbb{R}^{d \times 1}$ and $\mathbf{p} \in \mathbb{R}^{d \times 1}$, where the source representation is first fed to the mapping:

$$\hat{\mathbf{M}} = \operatorname*{argmin}_{\mathbf{M}} \sum_{\mathbf{s},\mathbf{p}} \|\mathbf{M}\mathbf{s} - \mathbf{p}\|^2 \qquad (1)$$

where d is the hidden layer size of the encoders. Introducing matrix notations $\mathbf{S} \in \mathbb{R}^{d \times n}$ and $\mathbf{P} \in \mathbb{R}^{d \times n}$, which concatenate the pooled representations of all n sentences for each side in the source-pivot corpus, we rewrite Equation 1 as:

$$\hat{\mathbf{M}} = \operatorname*{argmin}_{\mathbf{M}} \|\mathbf{M}\mathbf{S} - \mathbf{P}\|^2 \qquad (2)$$

which can be easily computed by the singular value decomposition (SVD) for a closed-form solution, if we put an orthogonality constraint on $\mathbf{M}$ (Xing et al., 2015). The resulting optimization is also called Procrustes problem.

The learned mapping is multiplied to encoder outputs of all positions in the final source→target tuning step. With this mapping, the source encoder emits sentence representations that lie in a similar space of the pivot encoder. Since the target decoder is pre-trained for pivot→target and accustomed to receive the pivot encoder outputs, it should process the mapped encoder outputs better than the original source encoder outputs.

3.3 Cross-lingual Encoder

As a third technique, we modify the source→pivot pre-training procedure to force the encoder to have cross-linguality over source and pivot languages; modeling source and pivot sentences in the same mathematical space. We achieve this by an additional autoencoding objective from a pivot sentence to the same pivot sentence (Figure 4).

The encoder is fed with sentences of both source and pivot languages, which are processed by a shared decoder that outputs only the pivot language. In this way, the encoder is learned to produce representations in a shared space regardless of the input language, since they are used in the same decoder. This cross-lingual space facilitates smoother learning of the final source→target model, because the decoder is pre-trained to translate the pivot language.

The same input/output in autoencoding encourages, however, merely copying the input; it is said to be not proper for learning complex structure of the data domain (Vincent et al., 2008). Denoising autoencoder addresses this by corrupting the input sentences by artificial noises (Hill et al., 2016). Learning to reconstruct clean sentences, it encodes linguistic structures of natural language sentences, e.g., word order, better than copying. Here are the

noise types we use (Edunov et al., 2018):

- Drop tokens randomly with a probability p_{del}
- Replace tokens with a <BLANK> token randomly with a probability p_{rep}
- Permute the token positions randomly so that the difference between an original index and its new index is less than or equal to d_{per}

We set $p_{\text{del}} = 0.1$, $p_{\text{rep}} = 0.1$, and $d_{\text{per}} = 3$ in our experiments.

The key idea of all three methods is to build a closer connection between the pre-trained encoder and decoder via a pivot language. The difference is in when we do this job: Cross-lingual encoder (Section 3.3) changes the encoder pre-training stage (source→pivot), while step-wise pre-training (Section 3.1) modifies decoder pre-training stage (pivot→target). Pivot adapter (Section 3.2) is applied after all pre-training steps.

4 Main Results

We evaluate the proposed transfer learning techniques in two non-English language pairs of WMT 2019 news translation tasks[1]: French→German and German→Czech.

Data We used the News Commentary v14 parallel corpus and newstest2008-2010 test sets as the source-target training data for both tasks. The newstest sets were oversampled four times. The German→Czech task was originally limited to unsupervised learning (using only monolingual corpora) in WMT 2019, but we relaxed this constraint by the available parallel data. We used newstest2011 as a validation set and newstest2012/newstest2013 as the test sets.

Both language pairs have much abundant parallel data in source-pivot and pivot-target with English as the pivot language. Detailed corpus statistics are given in Table 1.

Preprocessing We used the Moses[2] tokenizer and applied true-casing on all corpora. For all transfer learning setups, we learned byte pair encoding (BPE) (Sennrich et al., 2016) for each language individually with 32k merge operations, except for cross-lingual encoder training with joint BPE only over source and pivot languages. This is for modularity of pre-trained models: for example, a French→English model trained with joint French/English/German BPE could be transferred smoothly to a French→German model, but would not be optimal for a transfer to e.g., a French→Korean model. Once we pre-train an NMT model with separate BPE vocabularies, we can reuse it for various final language pairs without wasting unused portion of subword vocabularies (e.g., German-specific tokens in building a French→Korean model).

On the contrary, baselines used joint BPE over all languages with also 32k merges.

Usage	Data	Sentences	Words (Source)
Pre-train	fr-en	35M	950M
	en-de	9.1M	170M
Fine-tune	fr-de	270k	6.9M
Pre-train	de-en	9.1M	181M
	en-cs	49M	658M
Fine-tune	de-cs	230k	5.1M

Table 1: Parallel training data statistics.

Model and Training The 6-layer base Transformer architecture (Vaswani et al., 2017) was used for all of our experiments. Batch size was set to 4,096 tokens. Each checkpoint amounts to 10k updates for pre-training and 20k updates for fine-tuning.

Each model was optimized with Adam (Kingma and Ba, 2014) with an initial learning rate of 0.0001, which was multiplied by 0.7 whenever perplexity on the validation set was not improved for three checkpoints. When it was not improved for eight checkpoints, we stopped the training. The NMT model training and transfer were done with the OpenNMT toolkit (Klein et al., 2017).

Pivot adapter was trained using the MUSE toolkit (Conneau et al., 2018), which was originally developed for bilingual word embeddings but we adjusted for matching sentence representations.

Baselines We thoroughly compare our approaches to the following baselines:

1. *Direct source→target*: A standard NMT model trained on given source→target paral-

Table 2: Main results fine-tuned with source-target parallel data.

lel data.

2. *Multilingual*: A single, shared NMT model for multiple translation directions (Johnson et al., 2017).
    - *Many-to-many*: Trained for all possible directions among source, target, and pivot languages.
    - *Many-to-one*: Trained for only the directions *to* target language, i.e., source→target and pivot→target, which tends to work better than many-to-many systems (Aharoni et al., 2019).

In Table 2, we report principal results after fine-tuning the pre-trained models using source-target parallel data.

As for baselines, multilingual models are better than a direct NMT model. The many-to-many models surpass the many-to-one models; since both tasks are in a low-resource setup, the model gains a lot from related language pairs even if the target languages do not match.

Plain transfer of pre-trained encoder/decoder without additional techniques (Figure 1) shows a nice improvement over the direct baseline: up to +2.7% BLEU for French→German and +5.2% BLEU for German→Czech. Pivot adapter provides an additional boost of maximum +0.7% BLEU or -0.7% TER.

Cross-lingual encoder pre-training is proved to be not effective in the plain transfer setup. It shows no improvements over plain transfer in French→German, and 0.4% BLEU worse performance in German→Czech. We conjecture that the cross-lingual encoder needs a lot more data to be fine-tuned for another decoder, where the encoder capacity is basically divided into two languages at the beginning of the fine-tuning. On the other hand, the pivot adapter directly improves the connection to an individually pre-trained decoder, which works nicely with small fine-tuning data.

Pivot adapter gives an additional improvement on top of the cross-lingual encoder; up to +0.4% BLEU in French→German and +0.6% BLEU in German→Czech. In this case, we extract source and pivot sentence representations from the same shared encoder for training the adapter.

Step-wise pre-training gives a big improvement up to +1.2% BLEU or -1.6% TER against plain transfer in French→German. It shows the best performance in both tasks when combined with the cross-lingual encoder: up to +1.2% BLEU in French→German and +2.6% BLEU in German→Czech, compared to the multilingual baseline. Step-wise pre-training prevents the cross-lingual encoder from degeneration, since the pivot→target pre-training (Step 2 in Section 3.1) also learns the encoder-decoder connection with a large amount of data — in addition to the source→target tuning step afterwards.

Note that the pivot adapter, which inserts an extra layer between the encoder and decoder, is not appropriate after the step-wise pre-training; the decoder is already trained to correlate well with the pre-trained encoder. We experimented with the pivot adapter on top of step-wise pre-trained models — with or without cross-lingual encoder — but obtained detrimental results.

Compared to pivot translation (Table 5), our

best results are also clearly better in French →German and comparable in German→Czech.

5 Analysis

In this section, we conduct ablation studies on the variants of our methods and see how they perform in different data conditions.

5.1 Pivot Adapter

Adapter Training	newstest2013 BLEU [%]	TER [%]
None	18.2	70.7
Max-pooled	18.4	70.5
Average-pooled	**18.7**	**70.3**
Plain transfer	18.0	70.9

Table 3: Pivot adapter variations (German→Czech). All results are tuned with source-target parallel data.

Firstly, we compare variants of the pivot adapter (Section 3.2) in Table 3. The row "None" shows that a randomly initialized linear layer already guides the pre-trained encoder/decoder to harmonize with each other. Of course, when we train the adapter to map source encoder outputs to pivot encoder outputs, the performance gets better. For compressing encoder outputs over positions, average-pooling is better than max-pooling. We observed the same trend in the other test set and in French→German.

We also tested nonlinear pivot adapter, e.g., a 2-layer feedforward network with ReLU activations, but the performance was not better than just a linear adapter.

5.2 Cross-lingual Encoder

Trained on	Input	newstest2013 BLEU [%]	TER [%]
Monolingual	Clean	15.7	77.7
	Noisy	17.5	73.6
Pivot side of parallel	Clean	15.9	77.3
	Noisy	**18.0**	**72.7**

Table 4: Cross-lingual encoder variations (French→ German). All results are in the zero-shot setting with step-wise pre-training.

Table 4 verifies that the noisy input in autoencoding is indeed beneficial to our cross-lingual encoder. It improves the final translation performance by maximum +2.1% BLEU, compared to using the copying autoencoding objective.

As the training data for autoencoding, we also compare between purely monolingual data and the pivot side of the source-pivot parallel data. By the latter, one can expect a stronger signal for a joint encoder representation space, since two different inputs (in source/pivot languages) are used to produce the exactly same output sentence (in pivot language). The results also tell that there are slight but consistent improvements by using the pivot part of the parallel data.

Again, we performed these comparisons in the other test set and German→Czech, observing the same tendency in results.

5.3 Zero-resource/Zero-shot Scenarios

If we do not have an access to any source-target parallel data (*zero-resource*), non-English language pairs have two options for still building a working NMT system, given source-English and target-English parallel data:

- *Zero-shot*: Perform source→target translation using models which have not seen any source-target parallel sentences, e.g., multilingual models or pivoting (Section 2.1).
- *Pivot-based synthetic data*: Generate synthetic source-target parallel data using source↔English and target↔English models (Section 2.2). Use this data to train a model for source→target.

Table 5 shows how our pre-trained models perform in zero-resource scenarios with the two options. Note that, unlike Table 2, the multilingual baselines exclude source→target and target→source directions. First of all, plain transfer, where the encoder and the decoder are pre-trained separately, is poor in zero-shot scenarios. It simply fails to connect different representation spaces of the pre-trained encoder and decoder. In our experiments, neither pivot adapter nor cross-lingual encoder could enhance the zero-shot translation of plain transfer.

Step-wise pre-training solves this problem by changing the decoder pre-training to familiarize itself with representations from an already pre-trained encoder. It achieves zero-shot performance of 11.5% BLEU in French→German and 6.5% BLEU in German→Czech (newstest2013), while

	French→German				German→Czech			
	newstest2012		newstest2013		newstest2012		newstest2013	
	BLEU [%]	TER [%]	BLEU [%]	TER [%]	BLEU [%]	TER [%]	BLEU [%]	TER [%]
Multilingual many-to-many	14.1	79.1	14.6	79.1	5.9	-	6.3	99.8
Pivot translation	16.6	72.4	17.9	72.5	16.4	74.5	**19.5**	**70.1**
Teacher-student	18.7	70.3	20.7	69.5	16.0	75.0	18.5	70.9
Plain transfer	0.1	-	0.2	-	0.1	-	0.1	-
Step-wise pre-training	11.0	81.6	11.5	82.5	6.0	92.1	6.5	87.8
+ Cross-lingual encoder	17.3	72.1	18.0	72.7	14.1	76.8	16.5	73.5
+ Teacher-student	**19.3**	**69.7**	**20.9**	**69.3**	**16.5**	**74.6**	19.1	70.2

Table 5: Zero-resource results. Except those with the teacher-student, the results are all in the zero-shot setting, i.e., the model is not trained on any source-target parallel data. '-' indicates a TER score over 100%.

showing comparable or better fine-tuned performance against plain transfer (see also Table 2).

With the pre-trained cross-lingual encoder, the zero-shot performance of step-wise pre-training is superior to that of pivot translation in French→German with only a single model. It is worse than pivot translation in German→Czech. We think that the data size of pivot-target is critical in pivot translation; relatively huge data for English→Czech make the pivot translation stronger. Note again that, nevertheless, pivoting (second row) is very poor in efficiency since it performs decoding twice with the individual models.

For the second option (pivot-based synthetic data), we compare our methods against the sentence-level beam search version of the teacher-student framework (Chen et al., 2017), with which we generated 10M synthetic parallel sentence pairs. We also tried other variants of Chen et al. (2017), e.g., N-best hypotheses with weights, but there were no consistent improvements.

Due to enormous bilingual signals, the model trained with the teacher-student synthetic data outperforms pivot translation. If tuned with the same synthetic data, our pre-trained model performs even better (last row), achieving the best zero-resource results on three of the four test sets.

We also evaluate our best German→Czech zero-resource model on newstest2019 and compare it with the participants of the WMT 2019 unsupervised news translation task. Ours yield 17.2% BLEU, which is much better than the best single unsupervised system of the winner of the task (15.5%) (Marie et al., 2019). We argue that, if one has enough source-English and English-target parallel data for a non-English language pair, it is more encouraged to adopt pivot-based transfer learning than unsupervised MT — even if there is no source-target parallel data. In this case, unsupervised MT unnecessarily restricts the data condition to using only monolingual data and its high computational cost does not pay off; simple pivot-based pre-training steps are more efficient and effective.

5.4 Large-scale Results

We also study the effect of pivot-based transfer learning in more data-rich scenarios: 1) with large synthetic source-target data (German→Czech), and 2) with larger real source-target data in combination with the synthetic data (French→German). We generated synthetic parallel data using pivot-based back-translation (Bertoldi et al., 2008): 5M sentence pairs for German→Czech and 9.1M sentence pairs for French→German. For the second scenario, we also prepared 2.3M more lines of French→German real parallel data from Europarl v7 and Common Crawl corpora.

Table 6 shows our transfer learning results fine-tuned with a combination of given parallel data and generated synthetic parallel data. The real source-target parallel data are oversampled to make the ratio of real and synthetic data to be 1:2. As expected, the direct source→target model can be improved considerably by training with large synthetic data.

Plain pivot-based transfer outperforms the synthetic data baseline by up to +1.9% BLEU or -3.3% TER. However, the pivot adapter or cross-lingual encoder gives marginal or inconsistent improvements over the plain transfer. We suppose that the entire model can be tuned sufficiently well without

	French→German				German→Czech

Table 6: Results fine-tuned with a combination of source-target parallel data and large synthetic data. French→German task used larger real parallel data than Table 2.

additional adapter layers or a well-curated training process, once we have a large source-target parallel corpus for fine-tuning.

6 Conclusion

In this paper, we propose three effective techniques for transfer learning using pivot-based parallel data. The principle is to pre-train NMT models with source-pivot and pivot-target parallel data and transfer the source encoder and the target decoder. To resolve the input/output discrepancy of the pre-trained encoder and decoder, we 1) consecutively pre-train the model for source→pivot and pivot→target, 2) append an additional layer after the source encoder which adapts the encoder output to the pivot language space, or 3) train a cross-lingual encoder over source and pivot languages.

Our methods are suitable for most of the non-English language pairs with lots of parallel data involving English. Experiments in WMT 2019 French→German and German→Czech tasks show that our methods significantly improve the final source→target translation performance, outperforming multilingual models by up to +2.6% BLEU. The methods are applicable also to zero-resource language pairs, showing a strong performance in the zero-shot setting or with pivot-based synthetic data. We claim that our methods expand the advances in NMT to many more non-English language pairs that are not yet studied well.

Future work will be zero-shot translation without step-wise pre-training, i.e., combining individually pre-trained encoders and decoders freely for a fast development of NMT systems for a new non-English language pair.

Abstract

Modern sentence-level NMT systems often produce plausible translations of isolated sentences. However, when put in context, these translations may end up being inconsistent with each other. We propose a monolingual DocRepair model to correct inconsistencies between sentence-level translations. DocRepair performs automatic post-editing on a sequence of sentence-level translations, refining translations of sentences in context of each other. For training, the DocRepair model requires only monolingual document-level data in the target language. It is trained as a monolingual sequence-to-sequence model that maps inconsistent groups of sentences into consistent ones. The consistent groups come from the original training data; the inconsistent groups are obtained by sampling round-trip translations for each isolated sentence. We show that this approach successfully imitates inconsistencies we aim to fix: using contrastive evaluation, we show large improvements in the translation of several contextual phenomena in an English→Russian translation task, as well as improvements in the BLEU score. We also conduct a human evaluation and show a strong preference of the annotators to corrected translations over the baseline ones. Moreover, we analyze which discourse phenomena are hard to capture using monolingual data only.[1]

1 Introduction

Machine translation has made remarkable progress, and studies claiming it to reach a human parity are starting to appear (Hassan et al., 2018). However, when evaluating translations of the whole documents rather than isolated sentences, human raters show a stronger preference for human over machine translation (Läubli et al., 2018). These findings emphasize the need to shift towards context-aware machine translation both from modeling and evaluation perspective.

Most previous work on context-aware NMT assumed that either all the bilingual data is available at the document level (Jean et al., 2017; Wang et al., 2017; Tiedemann and Scherrer, 2017; Bawden et al., 2018; Voita et al., 2018; Maruf and Haffari, 2018; Agrawal et al., 2018; Kuang et al., 2018; Miculicich et al., 2018) or at least its fraction (Voita et al., 2019). But in practical scenarios, document-level parallel data is often scarce, which is one of the challenges when building a context-aware system.

We introduce an approach to context-aware machine translation using only monolingual document-level data. In our setting, a separate monolingual sequence-to-sequence model (DocRepair) is used to correct sentence-level translations of adjacent sentences. The key idea is to use monolingual data to imitate typical inconsistencies between context-agnostic translations of isolated sentences. The DocRepair model is trained to map inconsistent groups of sentences into consistent ones. The consistent groups come from the original training data; the inconsistent groups are obtained by sampling round-trip translations for each isolated sentence.

To validate the performance of our model, we use three kinds of evaluation: the BLEU score, contrastive evaluation of translation of several discourse phenomena (Voita et al., 2019), and human evaluation. We show strong improvements for all metrics.

We analyze which discourse phenomena are hard to capture using monolingual data only. Using contrastive test sets for targeted evaluation of several contextual phenomena, we compare the performance of the models trained on round-trip

[1]The code and data sets (including round-trip translations) are available at https://github.com/lena-voita/good-translation-wrong-in-context.

Proceedings of the 2019 Conference on Empirical Methods in Natural Language Processing and the 9th International Joint Conference on Natural Language Processing, pages 877–886, Hong Kong, China, November 3–7, 2019. ©2019 Association for Computational Linguistics

translations and genuine document-level parallel data. Among the four phenomena in the test sets we use (deixis, lexical cohesion, VP ellipsis and ellipsis which affects NP inflection) we find VP ellipsis to be the hardest phenomenon to be captured using round-trip translations.

Our key contributions are as follows:

- we introduce the first approach to context-aware machine translation using only monolingual document-level data;
- our approach shows substantial improvements in translation quality as measured by BLEU, targeted contrastive evaluation of several discourse phenomena and human evaluation;
- we show which discourse phenomena are hard to capture using monolingual data only.

2 Our Approach: Document-level Repair

We propose a monolingual DocRepair model to correct inconsistencies between sentence-level translations of a context-agnostic MT system. It does not use any states of a trained MT model whose outputs it corrects and therefore can in principle be trained to correct translations from any black-box MT system.

The DocRepair model requires only monolingual document-level data in the target language. It is a monolingual sequence-to-sequence model that maps inconsistent groups of sentences into consistent ones. Consistent groups come from monolingual document-level data. To obtain inconsistent groups, each sentence in a group is replaced with its round-trip translation produced in isolation from context. More formally, forming a training minibatch for the DocRepair model involves the following steps (see also Figure 1):

1. sample several groups of sentences from the monolingual data;
2. for each sentence in a group, (i) translate it using a target-to-source MT model, (ii) sample a translation of this back-translated sentence in the source language using a source-to-target MT model;
3. using these round-trip translations of isolated sentences, form an inconsistent version of the initial groups;

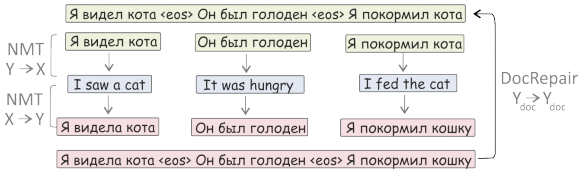

Figure 1: Training procedure of DocRepair. First, round-trip translations of individual sentences are produced to form an inconsistent text fragment (in the example, both genders of the speaker and the cat became inconsistent). Then, a repair model is trained to produce an original text from the inconsistent one.

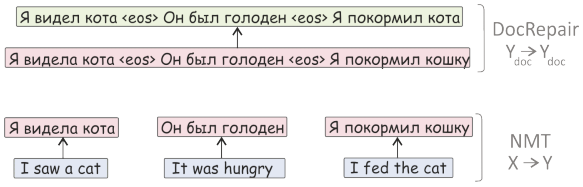

Figure 2: The process of producing document-level translations at test time is two-step: (1) sentences are translated independently using a sentence-level model, (2) DocRepair model corrects translation of the resulting text fragment.

4. use inconsistent groups as input for the DocRepair model, consistent ones as output.

At test time, the process of getting document-level translations is two-step (Figure 2):

1. produce translations of isolated sentences using a context-agnostic MT model;
2. apply the DocRepair model to a sequence of context-agnostic translations to correct inconsistencies between translations.

In the scope of the current work, the DocRepair model is the standard sequence-to-sequence Transformer. Sentences in a group are concatenated using a reserved token-separator between sentences.[2] The Transformer is trained to correct these long inconsistent pseudo-sentences into consistent ones. The token-separator is then removed from corrected translations.

3 Evaluation of Contextual Phenomena

We use contrastive test sets for evaluation of discourse phenomena for English-Russian by Voita et al. (2019). These test sets allow for testing different kinds of phenomena which, as we show, can

[2] In preliminary experiments, we observed that this performs better than concatenating sentences without a separator.

	total	distance 1	2	3
deixis	3000	1000	1000	1000
lex. cohesion	2000	855	630	515
ellipsis (infl.)	500			
ellipsis (VP)	500			

Table 1: Size of test sets: total number of test instances and with regard to the distance between sentences requiring consistency (in the number of sentences). For ellipsis, the two sets correspond to whether a model has to predict correct NP inflection, or correct verb sense (VP ellipsis).

be captured from monolingual data with varying success. In this section, we provide test sets statistics and briefly describe the tested phenomena. For more details, the reader is referred to Voita et al. (2019).

3.1 Test sets

There are four test sets in the suite. Each test set contains contrastive examples. It is specifically designed to test the ability of a system to adapt to contextual information and handle the phenomenon under consideration. Each test instance consists of a true example (a sequence of sentences and their reference translation from the data) and several contrastive translations which differ from the true one only in one specific aspect. All contrastive translations are correct and plausible translations at the sentence level, and only context reveals the inconsistencies between them. The system is asked to score each candidate translation, and we compute the system accuracy as the proportion of times the true translation is preferred to the contrastive ones. Test set statistics are shown in Table 1. The suites for deixis and lexical cohesion are split into development and test sets, with 500 examples from each used for validation purposes and the rest for testing. Convergence of both consistency scores on these development sets and BLEU score on a general development set are used as early stopping criteria in models training. For ellipsis, there is no dedicated development set, so we evaluate on all the ellipsis data and do not use it for development.

3.2 Phenomena overview

Deixis Deictic words or phrases, are referential expressions whose denotation depends on context. This includes personal deixis ("I", "you"), place deixis ("here", "there"), and discourse deixis, where parts of the discourse are referenced ("that's a good question"). The test set examples are all related to person deixis, specifically the T-V distinction between informal and formal you (Latin "tu" and "vos") in the Russian translations, and test for consistency in this respect.

Ellipsis Ellipsis is the omission from a clause of one or more words that are nevertheless understood in the context of the remaining elements. In machine translation, elliptical constructions in the source language pose a problem in two situations. First, if the target language does not allow the same types of ellipsis, requiring the elided material to be predicted from context. Second, if the elided material affects the syntax of the sentence. For example, in Russian the grammatical function of a noun phrase, and thus its inflection, may depend on the elided verb, or, conversely, the verb inflection may depend on the elided subject.

There are two different test sets for ellipsis. One contains examples where a morphological form of a noun group in the last sentence can not be understood without context beyond the sentence level ("ellipsis (infl.)" in Table 1). Another includes cases of verb phrase ellipsis in English, which does not exist in Russian, thus requires predicting the verb when translating into Russian ("ellipsis (VP)" in Table 1).

Lexical cohesion The test set focuses on reiteration of named entities. Where several translations of a named entity are possible, a model has to prefer consistent translations over inconsistent ones.

4 Experimental Setup

4.1 Data preprocessing

We use the publicly available OpenSubtitles2018 corpus (Lison et al., 2018) for English and Russian. For a fair comparison with previous work, we train the baseline MT system on the data released by Voita et al. (2019). Namely, our MT system is trained on 6m instances. These are sentence pairs with a relative time overlap of subtitle frames between source and target language subtitles of at least 0.9.

We gathered 30m groups of 4 consecutive sentences as our monolingual data. We used only documents not containing groups of sentences from general development and test sets as well as from contrastive test sets. The main results we report

are for the model trained on all 30m fragments.

We use the tokenization provided by the corpus and use `multi-bleu.perl`[3] on lowercased data to compute BLEU score. We use beam search with a beam of 4.

Sentences were encoded using byte-pair encoding (Sennrich et al., 2016b), with source and target vocabularies of about 32000 tokens. Translation pairs were batched together by approximate sequence length. Each training batch contained a set of translation pairs containing approximately 15000[4] source tokens. It has been shown that Transformer's performance depends heavily on batch size (Popel and Bojar, 2018), and we chose a large batch size to ensure the best performance. In training context-aware models, for early stopping we use both convergence in BLEU score on the general development set and scores on the consistency development sets. After training, we average the 5 latest checkpoints.

4.2 Models

The baseline model, the model used for back-translation, and the DocRepair model are all *Transformer base* models (Vaswani et al., 2017). More precisely, the number of layers is $N = 6$ with $h = 8$ parallel attention layers, or heads. The dimensionality of input and output is $d_{model} = 512$, and the inner-layer of a feed-forward networks has dimensionality $d_{ff} = 2048$. We use regularization as described in Vaswani et al. (2017).

As a second baseline, we use the two-pass CADec model (Voita et al., 2019). The first pass produces sentence-level translations. The second pass takes both the first-pass translation and representations of the context sentences as input and returns contextualized translations. CADec requires document-level parallel training data, while DocRepair only needs monolingual training data.

4.3 Generating round-trip translations

On the selected 6m instances we train sentence-level translation models in both directions. To create training data for DocRepair, we proceed as follows. The Russian monolingual data is first translated into English, using the Russian→English model and beam search with beam size of 4. Then, we use the English→Russian model to sample translations with temperature of 0.5. For each sentence, we precompute 20 sampled translations and randomly choose one of them when forming a training minibatch for DocRepair. Also, in training, we replace each token in the input with a random one with the probability of 10%.

[3] https://github.com/moses-smt/mosesdecoder/tree/master/scripts/generic

[4] This can be reached by using several of GPUs or by accumulating the gradients for several batches and then making an update.

model	BLEU
baseline	33.91
CADec	33.86
sentence-level repair	34.12
DocRepair	**34.60**

Table 2: BLEU scores. For CADec, the original implementation was used.

4.4 Optimizer

As in Vaswani et al. (2017), we use the Adam optimizer (Kingma and Ba, 2015), the parameters are $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\varepsilon = 10^9$. We vary the learning rate over the course of training using the formula:

$$l_{rate} = scale \cdot \min(step_num^{0.5}, step_num \cdot warmup_steps^{1.5}),$$

where $warmup_steps = 16000$ and $scale = 4$.

5 Results

5.1 General results

The BLEU scores are provided in Table 2 (we evaluate translations of 4-sentence fragments). To see which part of the improvement is due to fixing agreement between sentences rather than simply sentence-level post-editing, we train the same repair model at the sentence level. Each sentence in a group is now corrected separately, then they are put back together in a group. One can see that most of the improvement comes from accounting for extra-sentential dependencies. DocRepair outperforms the baseline and CADec by 0.7 BLEU, and its sentence-level repair version by 0.5 BLEU.

5.2 Consistency results

Scores on the phenomena test sets are provided in Table 3. For deixis, lexical cohesion and ellipsis (infl.) we see substantial improvements over both the baseline and CADec. The largest improvement over CADec (22.5 percentage points)

model	deixis	lex. c	ell. infl.	ell. VP
baseline	50.0	45.9	53.0	28.4
CADec	81.6	58.1	72.2	**80.0**
DocRepair	**91.8**	**80.6**	**86.4**	75.2
	+10.2	+22.5	+14.4	-4.8

Table 3: Results on contrastive test sets for specific contextual phenomena (deixis, lexical consistency, ellipsis (inflection), and VP ellipsis).

(a) **EN** No one believed me. But she did.

RU Мне никто не верил. Но она сказала.

(b)**RU** Никто мне не верил. Но она верила.

EN No one believed me. But she believed.

RU Мне никто не верил. Но она поверила.

Figure 3: (a) Example of a discrepancy caused by VP ellipsis: correct meaning is "believe", but MT produces сказала ("say"). (b) Example of producing round-trip translations. From top to bottom: target, first translation, round-trip translation. When translating from Russian, main verbs are unlikely to be translated into auxiliary ones in English, and VP ellipsis is not present.

is for lexical cohesion. However, there is a drop of almost 5 percentage points for VP ellipsis. We hypothesize that this is because it is hard to learn to correct inconsistencies in translations caused by VP ellipsis relying on monolingual data alone. Figure 3(a) shows an example of inconsistency caused by VP ellipsis in English. There is no VP ellipsis in Russian, and when translating auxiliary "did" the model has to guess the main verb. Figure 3(b) shows steps of generating round-trip translations for the target side of the previous example. When translating from Russian, main verbs are unlikely to be translated as the auxiliary "do" in English, and hence the VP ellipsis is rarely present on the English side. This implies the model trained using the round-trip translations will not be exposed to many VP ellipsis examples in training. We discuss this further in Section 6.2.

Table 4 provides scores for deixis and lexical cohesion separately for different distances between sentences requiring consistency. It can be seen, that the performance of DocRepair degrades less than that of CADec when the distance between sentences requiring consistency gets larger.

		distance		
	total	1	2	3
deixis

all	equal	better	worse
700	367	242	90
100%	52%	35%	13%

Table 5: Human evaluation results, comparing DocRepair with baseline.

5.3 Human evaluation

We conduct a human evaluation on random 700 examples from our general test set. We picked only examples where a DocRepair translation is not a full copy of the baseline one.[5]

The annotators were provided an original group of sentences in English and two translations: baseline context-agnostic one and the one corrected by the DocRepair model. Translations were presented in random order with no indication which model they came from. The task is to pick one of the three options: (1) the first translation is better, (2) the second translation is better, (3) the translations are of equal quality. The annotators were asked to avoid the third answer if they are able to give preference to one of the translations. No other guidelines were given.

The results are provided in Table 5. In about 52% of the cases annotators marked translations as having equal quality. Among the cases where one of the translations was marked better than the other, the DocRepair translation was marked better in 73% of the cases. This shows a strong preference of the annotators for corrected translations over the baseline ones.

[5] As we further discuss in Section 7, DocRepair does not change the base translation at all in about 20% of the cases.

	BLEU	deixis	lex. c.	ellipsis
2.5m	34.15	89.2	75.5	81.8 / 71.6
5m	34.44	90.3	77.7	83.6 / 74.0
30m	**34.60**	**91.8**	**80.6**	**86.4 / 75.2**

6 Varying Training Data

In this section, we discuss the influence of the training data chosen for document-level models. In all experiments, we used the DocRepair model.

6.1 The amount of training data

Table 6 provides BLEU and consistency scores for the DocRepair model trained on different amount of data. We see that even when using a dataset of moderate size (e.g., 5m fragments) we can achieve performance comparable to the model trained on a large amount of data (30m fragments). Moreover, we notice that deixis scores are less sensitive to the amount of training data than lexical cohesion and ellipsis scores. The reason might be that, as we observed in our previous work (Voita et al., 2019), inconsistencies in translations due to the presence of deictic words and phrases are more frequent in this dataset than other types of inconsistencies. Also, as we show in Section 7, this is the phenomenon the model learns faster in training.

6.2 One-way vs round-trip translations

In this section, we discuss the limitations of using only monolingual data to model inconsistencies between sentence-level translations. In Section 5.2 we observed a drop in performance on VP ellipsis for DocRepair compared to CADec, which was trained on parallel data. We hypothesized that this is due to the differences between one-way and round-trip translations, and now we test this hypothesis. To do so, we fix the dataset and vary the way in which the input for DocRepair is generated: round-trip or one-way translations. The latter assumes that document-level data is parallel, and translations are sampled from the source side of the sentences in a group rather than from their back-translations. For parallel data, we take 1.5m parallel instances which were used for CADec training and add 1m instances from our monolingual data. For segments in the parallel part, we either sample translations from the source side or use round-trip translations. The results are provided in Table 7.

The model trained on one-way translations is slightly better than the one trained on round-trip translations. As expected, VP ellipsis is the hardest phenomena to be captured using round-trip translations, and the DocRepair model trained on one-way translated data gains 6% accuracy on this test set. This shows that the DocRepair model benefits from having access to non-synthetic English data. This results in exposing DocRepair at training time to Russian translations which suffer from the same inconsistencies as the ones it will have to correct at test time.

6.3 Filtering: monolingual (no filtering) or parallel

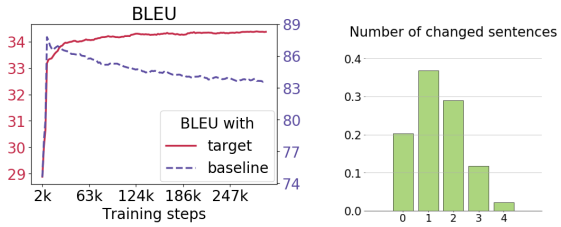
Note that the scores of the DocRepair model trained on 2.5m instances randomly chosen from monolingual data (Table 6) are different from the ones for the model trained on 2.5m instances combined from parallel and monolingual data (Table 7). For convenience, we show these two in Table 8.

The domain, the dataset these two data samples were gathered from, and the way we generated training data for DocRepair (round-trip translations) are all the same. The only difference lies in how the data was filtered. For parallel data, as in the previous work (Voita et al., 2018), we picked only sentence pairs with large relative time overlap of subtitle frames between source-language and target-language subtitles. This is necessary to

ensure the quality of translation data: one needs groups of consecutive sentences in the target language where every sentence has a reliable translation.

Table 8 shows that the quality of the model trained on data which came from the parallel part is worse than the one trained on monolingual data. This indicates that requiring each sentence in a group to have a reliable translation changes the distribution of the data, which might be not beneficial for translation quality and provides extra motivation for using monolingual data.

7 Learning Dynamics



Let us now look into how the process of DocRepair training progresses. Figure 4a shows how the BLEU scores with the reference translation and with the baseline context-agnostic translation (i.e. the input for the DocRepair model) are changing during training. First, the model quickly learns to copy baseline translations: the BLEU score with the baseline is very high. Then it gradually learns to change them, which leads to an improvement in BLEU with the reference translation and a drop in BLEU with the baseline. Importantly, the model is reluctant to make changes: the BLEU score between translations of the converged model and the baseline is 82.5. We count the number of changed sentences in every 4-sentence fragment in the test set and plot the histogram in Figure 4b. In over than 20% of the cases the model has not changed base translations at all. In almost 40%, it modified only one sentence and left the remaining 3 sentences unchanged. The model changed more than half sentences in a group in only 14% of the cases. Several examples of the DocRepair translations are shown in Figure 6.

Figure 5 shows how consistency scores are changing in training.[6] For deixis, the model achieves the final quality quite quickly; for the rest, it needs a large number of training steps to converge.

8 Related Work

Our work is most closely related to two lines of research: automatic post-editing (APE) and document-level machine translation.

[6]Deixis and lexical cohesion scores are evaluated on the development sets which were used in training for the stopping criteria. Ellipsis test sets were not used at training time; the scores are shown here only for visualization purposes.

8.1 Automatic post-editing

Our model can be regarded as an automatic post-editing system – a system designed to fix systematic MT errors that is decoupled from the main MT system. Automatic post-editing has a long history, including rule-based (Knight and Chander, 1994), statistical (Simard et al., 2007) and neural approaches (Junczys-Dowmunt and Grundkiewicz, 2016; Pal et al., 2016; Freitag et al., 2019).

In terms of architectures, modern approaches use neural sequence-to-sequence models, either multi-source architectures that consider both the original source and the baseline translation (Junczys-Dowmunt and Grundkiewicz, 2016; Pal et al., 2016), or monolingual repair systems, as in Freitag et al. (2019), which is concurrent work to ours. True post-editing datasets are typically small and expensive to create (Specia et al., 2017), hence synthetic training data has been created that uses original monolingual data as output for the sequence-to-sequence model, paired with an automatic back-translation (Sennrich et al., 2016a) and/or round-trip translation as its input(s) (Junczys-Dowmunt and Grundkiewicz, 2016; Fre-

Figure 6: Examples of the DocRepair translations. First is the baseline translation, then – corrected by the DocRepair. The differences between translations are underlined. (a) corrected wrong translation of "it": violated gender agreement with the antecedent. (b) corrected wrong gender (marked on a verb): from the third sentence it's clear that the speaker in the second one is feminine (Rayna), but the baseline translation was masculine. (c) corrected wrong morphological form of the pronoun, which was not understood with the elided verb in the third sentence.

itag et al., 2019).

While previous work on automatic post-editing operated on the sentence level, the main novelty of this work is that our DocRepair model operates on groups of sentences and is thus able to fix consistency errors caused by the context-agnostic baseline MT system. We consider this strategy of sentence-level baseline translation and context-aware monolingual repair attractive when parallel document-level data is scarce.

For training, the DocRepair model only requires monolingual document-level data. While we create synthetic training data via round-trip translation similarly to earlier work (Junczys-Dowmunt and Grundkiewicz, 2016; Freitag et al., 2019), note that we purposefully use sentence-level MT systems for this to create the types of consistency errors that we aim to fix with the context-aware DocRepair model. Not all types of consistency errors that we want to fix emerge from a round-trip translation, so access to parallel document-level data can be useful (Section 6.2).

8.2 Document-level NMT

Neural models of MT that go beyond the sentence-level are an active research area (Jean et al., 2017; Wang et al., 2017; Tiedemann and Scherrer, 2017; Bawden et al., 2018; Voita et al., 2018; Maruf and Haffari, 2018; Agrawal et al., 2018; Miculicich et al., 2018; Kuang et al., 2018; Voita et al., 2019). Typically, the main MT system is modified to take additional context as its input. One limitation of these approaches is that they assume that parallel document-level training data is available.

Closest to our work are two-pass models for document-level NMT (Xiong et al., 2019; Voita et al., 2019), where a second, context-aware model takes the translation and hidden representations of the sentence-level first-pass model as its input. The second-pass model can in principle be trained on a subset of the parallel training data (Voita et al., 2019), somewhat relaxing the assumption that all training data is at the document level.

Our work is different from this previous work in two main respects. Firstly, we show that consistency can be improved with only monolingual document-level training data. Secondly, the

DocRepair model is decoupled from the first-pass MT system, which improves its portability.

9 Conclusions

We introduce the first approach to context-aware machine translation using only monolingual document-level data. We propose a monolingual DocRepair model to correct inconsistencies between sentence-level translations. The model performs automatic post-editing on a sequence of sentence-level translations, refining translations of sentences in context of each other. Our approach results in substantial improvements in translation quality as measured by BLEU, targeted contrastive evaluation of several discourse phenomena and human evaluation. Moreover, we perform error analysis and detect which discourse phenomena are hard to capture using only monolingual document-level data. While in the current work we used text fragments of 4 sentences, in future work we would like to consider longer contexts.

Abstract

Current state-of-the-art neural machine translation (NMT) uses a deep multi-head self-attention network with no explicit phrase information. However, prior work on statistical machine translation has shown that extending the basic translation unit from words to phrases has produced substantial improvements, suggesting the possibility of improving NMT performance from explicit modeling of phrases. In this work, we present *multi-granularity self-attention* (MG-SA): a neural network that combines multi-head self-attention and phrase modeling. Specifically, we train several attention heads to attend to phrases in either n-gram or syntactic formalism. Moreover, we exploit interactions among phrases to enhance the strength of structure modeling – a commonly-cited weakness of self-attention. Experimental results on WMT14 English-to-German and NIST Chinese-to-English translation tasks show the proposed approach consistently improves performance. Targeted linguistic analysis reveals that MG-SA indeed captures useful phrase information at various levels of granularities.

1 Introduction

Recently, TRANSFORMER (Vaswani et al., 2017), implemented as deep multi-head self-attention networks (SANs), has become the state-of-the-art neural machine translation (NMT) model in recent years. The popularity of SANs lies in its high parallelization in computation, and flexibility in modeling dependencies regardless of distance by explicitly attending to all the signals.

More recently, an in-depth study (Raganato and Tiedemann, 2018) reveals that SANs generally focus on disperse words and ignore continuous phrase patterns, which have proven essential in both statistical machine translation (SMT, Koehn et al., 2003; Chiang, 2005; Liu et al., 2006) and NMT (Eriguchi et al., 2016; Wang et al., 2017; Yang et al., 2018; Zhao et al., 2018).

To alleviate this problem, in this work we propose *multi-granularity self-attention* (MG-SA), which offers SANs the ability to model phrases and meanwhile maintain their simplicity and flexibility. The starting point for our approach is an observation: the power of multiple heads in SANs is not fully exploited. For example, Li et al. (2018) show that different attention heads generally attend to the same positions, and Voita et al. (2019) reveal that only specialized attention heads do the heavy lifting while the rest can be pruned. Accordingly, we spare several attention heads for modeling phrase patterns for SANs.

Specifically, we use two representative types of phrases that are widely-used in SMT models: *n-gram phrases* (Koehn et al., 2003) to use surface of adjacent words, and *syntactic phrases* (Liu et al., 2006) induced from syntactic trees to represent well-formed structural information. We first partition the input sentence into phrase fragments at different levels of granularity. For example, we can split a sentence into 2-grams or 3-grams. Then, we assign an attention head to attend over phrase fragments at each granularity. In this way, MG-SANs provide a lightweight strategy to explicitly model phrase structures. Furthermore, we also model the interactions among phrases to enhance structure modeling, which is one commonly-cited weakness of SANs (Tran et al., 2018; Hao et al., 2019b).

We evaluate the proposed model on two widely-used translation tasks: WMT14 English-to-German and NIST Chinese-to-English. Experimental results demonstrate that our approach consistently improves translation performance over strong TRANSFORMER baseline model (Vaswani et al., 2017) across language pairs, while

speeds marginally decrease. Analysis on multi-granularity label prediction tasks reveals that MG-SA indeed captures and stores the information of different granularity phrases as expected.

2 Background

Multi-Head Self-attention Instead of performing a single attention, Multi-Head Self-attention Networks (MH-SA), which are the defaults setting in TRANSFORMER (Vaswani et al., 2017), project the queries, keys and values into multiple subspaces and performs attention on the projected queries, keys and values in each subspace. In the standard MH-SA, it jointly attends to information from different representation subspaces at different positions. Specifically, MH-SA transform input layer $\mathbf{H} = h_1, ..., h_n \in \mathbb{R}^{n \times d}$ into h-th subspace with different linear projections:

$$\mathbf{Q}^h, \mathbf{K}^h, \mathbf{V}^h = \mathbf{H}\mathbf{W}_Q^h, \mathbf{H}\mathbf{W}_K^h, \mathbf{H}\mathbf{W}_V^h, \quad (1)$$

where $\{\mathbf{Q}^h, \mathbf{K}^h, \mathbf{V}^h\} \in \mathbb{R}^{n \times d_h}$ are respectively the query, key, and value representations of the h-th head, $\{\mathbf{W}_Q^h, \mathbf{W}_K^h, \mathbf{W}_V^h \in \mathbb{R}^{d \times d_h}\}$ denote parameter matrices associated with the h-th head, d and d_h represent the dimensionality of the model and h-th head subspace. Moreover, N attention functions are applied to generate the output states $\{\mathbf{O}^1, ..., \mathbf{O}^N\}$ in parallel, among them:

$$\mathbf{O}^h = \text{ATT}(\mathbf{Q}^h, \mathbf{K}^h)\ \mathbf{V}^h. \quad (2)$$

Finally, the output states are concatenated to produce the final state. Here ATT denotes attention models, which can be implemented as either additive attention or dot-product attention. In this work, we use dot-product attention which is efficient and effective compared with its additive counterpart (Vaswani et al., 2017):

$$\text{ATT}(\mathbf{Q}^h, \mathbf{K}^h) = softmax(\frac{\mathbf{Q}^h \mathbf{K}^{h^T}}{\sqrt{d_h}}), \quad (3)$$

where $\sqrt{d_h}$ is the scaling factor.

Motivation We demonstrate our motivation from two aspects. On the one hand, the conventional MH-SA model the individual word dependencies, in such scenario the query directly attends all words in memory without considering the latent structure of the input sentence. We argue that self-attention can be further improved by taking phrase pattern into account. On the other hand, recent study (Vaswani et al., 2017) implicitly hint that attention heads are underutilized as increasing number of heads from 4 to 8 or even 16 can hardly improve the translation performance. Several attention heads can be further exploited under specific guidance to improve the performance (Strubell et al., 2018). We expect the inductive bias for multi-granularity phrase can further improve the performance of SANs and meanwhile maintain its simplicity and flexibility.

3 Multi-Granularity Self-Attention

We first introduce the framework of the proposed MG-SA. Then we describe the approaches of generating multi-granularity representation on a certain granularity representation. Finally, we introduce the training objective of our model with auxiliary supervision.

3.1 Framework

The proposed MG-SA aims at improving the capability of MH-SA by modeling both word and phrase. We introduce various phrase granularity over the conventional word-level memory to generate phrase level memory.

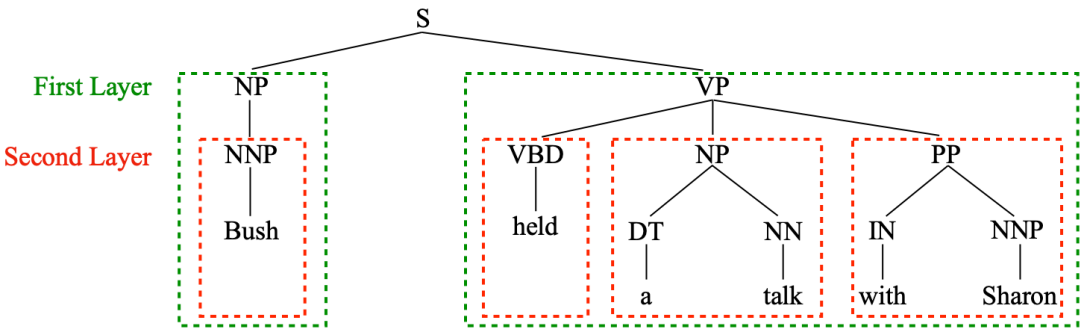
Specifically, we first transform the input layer $\mathbf{H}$ to a phrase level memory by function F_h in certain attention head:

$$\mathbf{H}_g = F_h(\mathbf{H}), \quad (4)$$

where $\mathbf{H}_g$ is the generated phrase level memory, h denotes the h-th head which is used to generate a certain granularity of phrase memory, and F_h is a representation function with its own trainable parameters. The details for F_h will be described in Section 3.2.

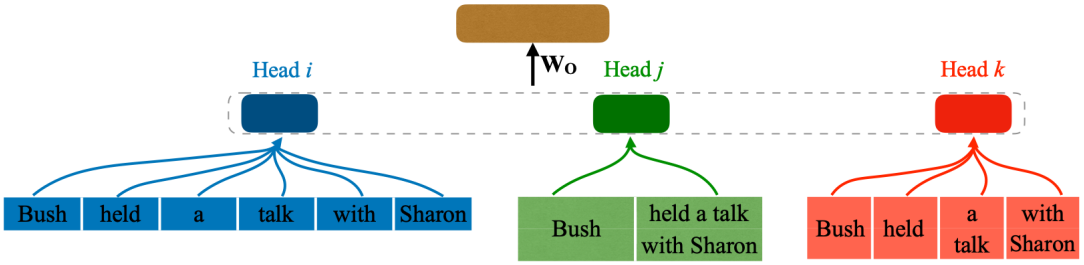
Then we perform attention on phrase level memory $\mathbf{H}^g$:

$$\mathbf{Q}^h, \mathbf{K}^h, \mathbf{V}^h = \mathbf{H}\mathbf{W}_Q^h, \mathbf{H}_g\mathbf{W}_K^h, \mathbf{H}_g\mathbf{W}_V^h \quad (5)$$



$$\mathbf{O}^h = \text{ATT}(\mathbf{Q}^h, \mathbf{K}^h)\ \mathbf{V}^h, \quad (6)$$

where $\mathbf{Q}^h \in \mathbb{R}^{n \times d_h}, \mathbf{K}^h \in \mathbb{R}^{p \times d_h}, \mathbf{V}^h \in \mathbb{R}^{p \times d_h}$, the p means the length of the key and value vectors which is decided by the granularity of phrase.



Based on the single head self-attention, the final output of MG-SA can be expressed as follows:

$$\text{MG-SA}(\mathbf{H}) = [\mathbf{O}^1, ..., \mathbf{O}^N], \quad (7)$$

where N denotes the number of heads. One head conducts either conventional word level attention or a certain granularity of phrase attention.

(a) Syntactic phrase partition

(b) *Multi-Granularity Self-Attention* on syntactic phrase partition

Figure 1: Illustration of the proposed MG-SA model for syntactic phrase partition. In this example, we partition the sentence with top two layers in the constituent parse tree and obtain the syntactic phrase partitions ("Bush", "held a talk with Sharon"), ("Bush", "held", "a talk", "with Sharon"). Under the syntactic partition, multi-head attention in MG-SA attends the phrase memory (heads j and k) as well as the conventional word memory (head i). The approach of phrase memory representation is described in Section 3.2. Best viewed in colour.

3.2 Multi-Granularity Representation

As seen in Figure 1, multi-granularity phrases are simultaneously modeled by different heads. To obtain the multi-granularity phrase representation, we first introduce phrase partition and composition strategies. Then, we describe phrase tag supervision and phrase interaction to further enhance the structure modeling on phrase representation.

Phrase Partition Partially inspired by Shen et al. (2018), we split the entire sequence into N-grams without overlaps. Such N-gram phrases are expressed as structurally adjacent and continuous items in the sequence. Formally, let $\mathbf{x} = (x_1, ..., x_T)$ be a sequence, the phrases sequence of $\mathbf{x}$ can be denoted as is $P_\mathbf{x} = (p_1, ..., p_M), M = T/n$, where $p_m = (x_{n\times(m-1)}, ..., x_{n\times m}), 1 \leq m \leq M$, and n denotes the length of the phrase which is a hyper-parameter. Padding is applied to the last phrase if necessary.

In addition, syntactic information has proven helpful in both SMT and NMT. We further introduce a syntactic phrase partition to represent well-formed structural information. Syntactic phrases organize words into nested constituents by using constituent parse tree. To obtain phrases in the view syntax, we break down the nodes at top K layers in the parse tree to capture top K levels of granularity for phrases, as illustrated in Figure 1 (a). Formally, one phrase in a certain layer of the parse tree can be defined as $p_m = (x^1, ..., x^l)$, l is the length of the phrase which is decided by the parse tree. The phrase sequence of the given input $\mathbf{x}$ is $P_\mathbf{x} = (p_1, ..., p_M)$, M is the number of phrase in the sequence.

Composition Strategies Given phrase sequence $P_\mathbf{x} = (p_1, ..., p_M)$ of input sequence, to capture local structure and context dependency inside each phrase and further generate phrase representation Q_M, we adopt phrase composition function to each phrase in the phrase sequence:

$$g_m = \text{COM}(p_m), \tag{8}$$

where COM is the composition function with shared parameters to all phrases, $g_m \in \mathbb{R}^{1\times d_h}$ is the phrase representation after composition. There general choices of composition function are Convolution Neural Networks (CNNs), Recurrent Neural Networks (RNNs) and Self-attention Net-

works (SANs). For CNNs we only apply the Max-pooling layer. For RNNs, we use the last hidden state of Long Short-term Memory Networks (LSTM) as phrase representation. For SANs, we use max pooling vector of the phrase to serve as the query for extracting inside phrase features to generate phrase representation. Then the phrase level memory of the input sequence can be denoted as $\mathbf{G_x} = (g_1, ..., g_M)$.

Phrase Tag Supervision Recent study shows auxiliary supervision on heads of SANs can further improve semantic role labeling performance (Strubell et al., 2018). In this work, we leverage tag information as the auxiliary supervision on syntactic phrase representation. We argue that the proposed framework provide a natural way to incorporate syntactic tag signal of phrase representation. In detail, given phrase level memory $\mathbf{G_x} = (g_1, ..., g_M)$ after phrase composition, we predict the phrase tag of each phrase representation. We extract the node of each phrase in the constituent parsing tree to generate the phrase tag sequence $\mathbf{T_x} = (t_1, ..., t_M)$. t_i denotes the tag for each phrase. For example, "NP" is the tag of the phrase "a talk" in second layer of parse tree, as shown in Figure 1 (a). We use the phrase representation to compute the probability of phrase tags:

$$p_{\theta_i} = softmax(W_t g_i + b_t), i = 1, ..., M, \quad (9)$$

where W_t and b_t are parameters of tag generator. Formally, the phrase tag loss can be written as:

$$\mathcal{L}_{tag} = -\sum_{i=1}^{M} t_i \log p_{\theta_i}(t_i). \quad (10)$$

The loss is equivalent to maximizing the conditional probability of tag sequence $\mathbf{T_x}$ given phrase representation $\mathbf{G_x}$.

Phrase Interaction We introduce phrase interaction approach to better model dependencies between phrase representation. Since recurrence has proven important for capturing structure information (Tran et al., 2018; Hao et al., 2019b), we propose to introduce recurrence to interact phrases and further model latent structure among phrases. Specifically, we apply the recurrence function $\text{REC}(\cdot)$ on the output of phrase composition $\mathbf{G_x} = (g_1, ..., g_M)$ in order to model the latent structure of the phrase sequence.

$$\mathbf{H}_g = \text{REC}(\mathbf{G_x}), \quad (11)$$

where $\mathbf{H}_g$ is the final phrase level memory for the input layer $\mathbf{H}$. One general choice for $\text{REC}(\cdot)$ is Long Short-term Memory Networks (LSTM). Recently, Shen et al. (2018) introduce a new syntax-oriented inductive bias, namely ordered neurons, which enables LSTM models to perform tree-like composition without breaking its sequential form, and propose an advanced LSTM variant – *Ordered Neurons* LSTM (ON-LSTM). Hao et al. (2019a) demonstrate the effectiveness of ON-LSTM on modeling structure in NMT. Accordingly, we further use ON-LSTM for $\text{REC}(\cdot)$, and expect ON-LSTM can capture the latent structure under such syntax-oriented inductive bias between phrases.

Finally, the representation function F_h in Equation 4 of the framework can be summarized by the following components: 1). Phrase partition. 2). Phrase composition. 3). Phrase interaction.

3.3 Training

The training loss for a single training instance $\mathbf{x} = (x_1, ..., x_T), \mathbf{y} = (y_1, ..., y_L)$ is defined as a weighted sum of the negative conditional log likelihood and the phrase tag loss. The total loss function can be written as:

$$\mathcal{L} = -\sum_{i=1}^{L} y_i log P_\omega(y_i) + \lambda \mathcal{L}_{tag}, \quad (12)$$

where λ is the coefficient to balance two loss functions and $\mathcal{L}_{tag}$ follows Equation 10. The hyperparameter λ is empirically set to 0.001 in this work.

4 Experiments

In this section, we conduct experiments and make analysis to answer the following three questions:

Q1. Does the integration of the proposed MG-SA into the state-of-the-art TRANSFORMER improve the translation quality in terms of the BLEU score?

Q2. Does the proposed MG-SA promote the generation of the target phrases?

Q3. Does MG-SA capture more phrase information at the various granularity levels?

In Section 4.1, we demonstrate that integrating the proposed MG-SA into the TRANSFORMER consistently improves the translation quality on both WMT14 English⇒German and

NIST Chinese⇒English (Q1). Further analysis reveals that our approach has stronger ability of capturing the phrase information and promoting the generation of the target phrases (Q2).

In Section 4.2, we conduct experiments on the multi-granularity label prediction tasks (Shi et al., 2016), and investigate the representations of NMT encoders trained on both translation data and the training data of the label prediction tasks. Experimental results show that the proposed MG-SA indeed captures useful phrase information at various levels of granularities in both scenarios (Q3).

4.1 Machine Translation

Implementation Detail We conduct the experiments on the WMT14 English-to-German (En⇒De) and NIST Chinese-to-English (Zh⇒En) translation tasks.

For En⇒De, the training dataset consists of 4.56M sentence pairs. We use the newstest2013 and newstest2014 as development set and test set respectively. For Zh⇒En, the training dataset consists of about 1.25M sentence pairs. We used NIST MT02 dataset as development set, and MT 03-06 datasets as test sets. Byte pair encoding (BPE) toolkit[1] (Sennrich et al., 2016) is used with 32K merge operations. We used case-sensitive NIST BLEU score (Papineni et al., 2002) as the evaluation metric, and bootstrap resampling (Koehn et al., 2003) for statistical significance test. We use the Stanford parser (Klein and Manning, 2003) to parse the sentences and obtain the relevant tags.

We test both *Base* and *Big* models, which differ at hidden size (512 vs. 1024), filter size (2048 vs. 4096) and the number of attention heads (8 vs. 16). All models are trained on eight NVIDIA Tesla P40 GPUs where each is allocated with a batch size of 4096 tokens. We implement the proposed approaches on top of TRANSFORMER (Vaswani et al., 2017) – a state-of-the-art SANs-based model on machine translation, and followed the setting in previous work (Vaswani et al., 2017) to train the models.

We incorporate the proposed model into the encoder. In each of our model variant, we maintain a quarter of heads for vanilla word level self-attention. For N-gram phrase models, we arrange the rest 3 quarters of heads for 2-gram, 3-gram and 4-gram respectively. For syntactic based models, we use the top 3 levels of granularity for phrases generated from constituent parse tree, each granularity of phrase modeled in a quarter of heads. There are many possible ways to implement the general idea of MG-SA. The aim of this paper is not to explore this whole space but simply to show that some fairly straightforward implementations work well.

Phrase Modeling	# Para.	Speed	BLEU
n/a	88.0M	1.28	27.31
MAX-POOLING	88.0M	1.27	27.56
SANs	90.4M	1.26	**27.69**
LSTM	96.1M	1.14	27.58

Table 1: Evaluation of various phrase composition strategies under N-gram phrase partition. "# Para" denotes the trainable parameter size of each model (M=million), "Speed" denotes the training speed (steps/second).

Encoder Layers	# Para.	Speed	BLEU
$[1-6]$	90.4M	1.26	27.69
$[1-3]$	89.2M	1.27	27.74
$[1]$	88.4M	1.28	**27.83**

Table 2: Evaluation of different layers in the encoder, which are implemented as self-attention with SANs phrase composition under N-gram partition. "1" denotes the bottom layer.

Table 1, 2 and 3 show the results on WMT14 English⇒German translation task with TRANSFORMER-BASE. These results show the evaluation on the impact of different components.

Phrase Composition We investigate the effect of different phrase composition strategies with N-gram phrase partition. As seen in Table 1, all proposed phrase composition methods consistently outperform TRANSFORMER-BASE baseline, validating the importance of introducing multi-granularity phrase in TRANSFORMER. Compared with other two models, SANs achieve best performance with its strong representational powers inside the phrase, while only marginally increase the parameters and decrease the speed. We use SANs phrase composition strategy as the default setting in subsequent experiments.

Encoder Layers Recent works (Shi et al., 2016; Peters et al., 2018) show that different layers in encoder tend to capture different syntax and semantic features. Hence, there may have different needs

#	Model Architecture	# Para.	Speed	BLEU	Δ
1	TRANSFORMER-BASE	88.0M	1.28	27.31	-
2	+ N-gram Phrase	88.4M	1.28	27.83	+0.52
3	+ Syntactic Phrase	88.4M	1.24	28.01	+0.70
4	+ Syntactic Phrase + $\mathcal{L}_{tag}$	88.4M	1.23	28.07	+0.76
5	+ LSTM Interaction	89.5M	1.20	28.14	+0.83
6	+ ON-LSTM Interaction	89.9M	1.19	**28.28**	+0.97

Table 3: Evaluation of phrase partition, tag supervision and interaction strategies.

for modeling phrase structure in each layer. In this experiment, we investigate the question of which layers should be applied with MG-SA. We apply MG-SA on different combination of layers. As shown in Table 2, reducing the applied layers from high-level to low-level consistently increase translation quality in terms of BLEU score as well as the training speed. The results reveal that the bottom layer in encoder, which is directly taking word embedding as input, benefits more from modeling phrase structure. This phenomena verifies it is unnecessary to apply the phrase structure modeling to all layers. Accordingly, we only apply MG-SA in the bottom layer in the following experiments.

Phrase Partition and Tag Supervision As seen in Table 3, syntactic phrase partition (Row 3) improves the model performance over the N-gram phrase partition (Row 2), showing that the syntactic phrase benefits to translation quality. In addition, incorporating tag loss (Row 4) in training stage can further boost the translation performance. This indicates the auxiliary syntax objective is necessary, which is consistent with the results in other NLP task (Strubell et al., 2018). We use syntactic phrase partition with tag supervision as the default setting for subsequent experiments unless otherwise stated.

Phrase Interaction As observed in Table 3, phrase interaction (Row 5-6) consistently improves performance of translation, proving the effectiveness and necessity of enhancing phrase level dependencies on phrase representation. ON-LSTM based interaction (Row 6) outperforms its LSTM counterpart (Row 5). We attribute the improvement of ON-LSTM to the stronger ability to perform syntax-oriented dependencies on phrase representation. We apply ON-LSTM as the default setting for phrase interaction.

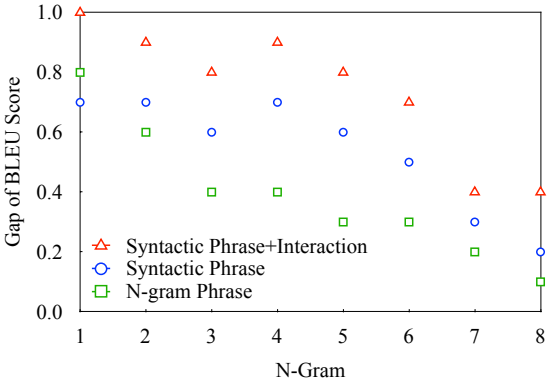

Figure 2: Performance improvement according to N-gram. Y-axis denotes the gap of BLEU score between our models and the baseline.

Main Results Table 4 lists the results on WMT14 En⇒De and NIST Zh⇒En translation tasks. Our baseline models, outperform the reported results on the same data (Vaswani et al., 2017; Zhang et al., 2019), which we believe make the evaluation convincing. As seen, in terms of BLEU score, the proposed MG-SA consistently improves translation performance across language pairs, which demonstrates the effectiveness and universality of the proposed approach.

Phrasal Pattern Evaluation As aforementioned, the proposed MG-SA aims to simultaneously model different granularities of phrases with different heads in SANs. To investigate whether the proposed MG-SA improves the generation of phrases in the output, we calculate the improvement of the proposed models over multiple N-grams, as shown in Figure 2. The results are reported on En⇒De validation set with TRANSFORMER-BASE.

Clearly, the proposed models consistently outperform the baseline model on all N-grams, indicating that the proposed MG-SA has stronger ability of capturing the phrase information and pro-

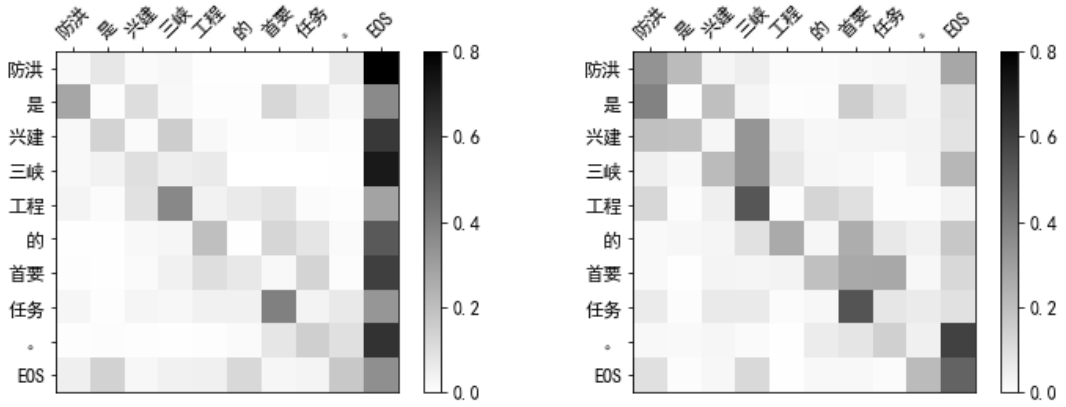
moting the generation of the target phrases. Concerning the variations of proposed models, two syntactic phrase models outperforms the N-gram phrase model on larger phrases (i.e. 4-8 grams). We attribute this to the fact that more syntactic information is beneficial for the translation performance. This is also consistent with the strengths of phrase-based and syntax-based SMT models.

Visualization of Attention In order to evaluate whether the proposed model is able to capture phrase patterns or not, we visualize the attention layers in the encoder [2]. As shown in Fig. 3, the vanilla model prefers to pay attention to the previous and next word and the end of the sentence, which is consistent with previous findings in Raganato and Tiedemann (2018). The proposed MG-SA successfully focuses on the phrases: 1) "三峡 工程", the 4th and the 5th rows in Fig. 3(b), its English translation is 'the Three Gorges Project'; 2) "首要 任务", the 7th and 8th rows in Fig. 3(b), its English translation is 'top priority'. By visualizing the attention distributions, we believe the proposed MG-SA can capture phrase patterns to improve the translation performance.

4.2 Multi-Granularity Phrases Evaluation



In this section, we conduct multi-granularity label prediction tasks to the proposed models in terms of whether the proposed model is effective as expected to capture different levels of granularity phrase information of sentences. We analyze the impact of multi-granularity self-attention based on two sets of experiments. The first set of experiments are probing the pre-trained NMT encoders, which aims to evaluate the linguistics knowledge embedded in the NMT encoder output in the machine translation section. Furthermore, to test the ability of the MG-SA itself, we conduct the second set of experiments, which are on the same tasks using encoder models trained from scratch.

Tasks Shi et al. (2016) propose 5 tasks to predict various granularity syntactic labels of from sentence to word in order to investigate whether an encoder can learn syntax information. These labels are: "Voice": active or passive, "Tense": past or non-past of main-clause verb, "TSS": top-level syntactic sequence of constituent tree, and two word-level syntactic label tasks, "SPC": the smallest phrase constituent that above each word, "POS": Part-of-Speech tags for each words. The tasks for predicting larger labels require models to capture and record larger granularity of phrase information of sentences (Shi et al., 2016). We conduct these tasks to study whether the proposed MG-SA benefits the multi-granularity phrase modeling to produce more useful and informative representation.

Data and Models We extracted the sentences from the Toronto Book Corpus (Zhu et al., 2015).We sample and pre-process 120k sentences for each task following Conneau et al. (2018). By instruction of Shi et al. (2016), we label these sentences for each task. The train/valid/test dataset ratios are set to 10/1/1.

For pre-trained NMT encoders, we use the pre-trained encoders of model variations in Table 3 followed by a MLP classifier, which are used to

[2]Since the attention weights of MG-SA cannot be visualized at word level, we visualize the attention weights in the subsequent layer after MH-SA and MG-SA.

(a) Vanilla Multi-Head Self-Attention

(b) Multi-Granularity Self-Attention

Figure 3: Visualization of attention examples of the same input sentence: (a) and (b) are produced by the vanilla multi-head self-attention and the proposed MG-SA models, respectively. Each row is the attention distribution over all the source tokens. The attention layer has 16 attention heads, and the attention weights in each row are the average of all the heads.

#	Model	Label Granularity: Large → Small					
		Voice	Tense	TSS	SPC	POS	Avg

7	Syntactic Phrase	84.70	87.52	97.42	96.95	96.24	92.57
8	Syntactic Phrase + Interaction	86.45	87.65	99.07	96.99	96.40	93.31

Table 5: Accuracies on multi-granularity label prediction tasks. "Pre-Trained NMT Encoder" denotes using the pre-trained NMT encoders of model variations in Table 3. "Train From Scratch" denotes using three encoder layers with proposed MG-SA variants, which are trained from scratch. For syntactic phrase based models, we only apply syntactic boundary of phrases and do not use any tag supervision for fair comparison.

carry out probing tasks.

For models trained from scratch, each of our model consists of 3 encoding layers followed by a MLP classifier. For each encoding layer, we employ a multi-head self-attention block and a feed-forward block as in TRANSFORMER, which have shown significant performance on several NLP tasks (Devlin et al., 2019). The difference between the compared models merely lies in the self-attention mechanism: "BASE" denotes standard MH-SA, "N-Gram Phrase" and "Syntactic Phrase" are the proposed MG-SA under N-gram phrase and syntactic phrase partition, and "Syntactic Phrase + Interaction" denotes MG-SA with phrase interaction by using ON-LSTM. We use same assignments of heads for multi-granularity phrases as machine translation task for all model variants.

Results Analysis Table 5 lists the prediction accuracies of five syntactic labels on test. Several observations can be made here. 1). Comparing the two set of experiments, the experimental results from models trained from scratch consistently outperform the results from NMT encoder probing on all tasks. 2). The models with syntactic information (Rows 3-4, 7-8) significantly perform better than those models without incorporating syntactic information (Rows 1-2, 5-6). 3). For NMT prob-

ing, the proposed models outperform the baseline model especially on relative small granularity of phrases information, such as 'SPC' and 'POS' tasks. 4). If trained from scratch, the proposed models achieve more improvements on predicting larger granularities of labels, such as 'TSS', 'Tense' and 'Voice' tasks, which require models to record larger phrase of sentences (Shi et al., 2016). The results show that the applicability of the proposed MG-SA is not limited to machine translation, but also on monolingual tasks.

5 Related Works

Phrase Modeling for NMT Several works have proven that the introduction of phrase modeling in NMT can obtain promising improvement on translation quality. Tree-based encoders, which explicitly take the constituent tree (Eriguchi et al., 2016) or dependency tree (Bastings et al., 2017) into consideration, are proposed to produce tree-based phrase representations. The difference of our work from these studies is that they adopt the RNN-based encoder to form the tree-based encoder while we explicitly introduce the phrase structure into the the state-of-the-art multi-layer multi-head SANs-based encoder, which we believe is more challenging.

Another thread of work is to implicitly promote the generation of phrase-aware representation, such as the integration of external phrase boundary (Wang et al., 2017; Nguyen and Joty, 2018; Li et al., 2019b), prior attention bias (Yang et al., 2018, 2019; Guo et al., 2019). Our work differs at that we explicitly model phrase patterns at different granularities, which is then attended by different attention heads.

Multi Granularity Representation Multi-granularity representation, which is proposed to make full use of subunit composition at different levels of granularity, has been explored in various NLP tasks, such as paraphrase identification (Yin and Schütze, 2015), Chinese word embedding learning (Yin et al., 2016), universal sentence encoding (Wu et al., 2018) and machine translation (Nguyen and Joty, 2018; Li et al., 2019b). The major difference between our work and Nguyen and Joty (2018); Li et al. (2019b) lies in that we successfully introduce syntactic information into our multi-granularity representation. Furthermore, it is not well measured how much phrase information are stored in multi-granularity representation. We conduct the multi-granularity label prediction tasks and empirically verify that the phrase information is embedded in the multi-granularity representation.

Multi-Head Attention Multi-head attention mechanism has shown its effectiveness in machine translation (Vaswani et al., 2017) and generative dialog (Tao et al., 2018) systems. Recent studies shows that the modeling ability of multi-head attention has not been completely developed. Several specific guidance cues of different heads without breaking the vanilla multi-head attention mechanism can further boost the performance, e.g., disagreement regularization (Li et al., 2018; Tao et al., 2018), information aggregation (Li et al., 2019a), and functional specialization (Fan et al., 2019) on attention heads, the combination of multi-head attention with multi-task learning (Strubell et al., 2018). Our work demonstrates that multi-head attention also benefits from the integration of the phrase information.

6 Conclusion

In this paper, we propose multi-granularity self-attention model, a novel attention mechanism to simultaneously attend different granularity phrase. We study effective phrase representation for N-gram phrase and syntactic phrase, and find that a syntactic phrase based mechanism obtains the best result due to effectively incorporating rich syntactic information. To evaluate the effectiveness of the proposed model, we conduct experiments on widely-used WMT14 En⇒De and NIST Zh⇒En datasets. Experimental results on two language pairs show that the proposed model achieve significant improvements over the baseline TRANSFORMER. Targeted multi-granularity phrases evaluation shows that our model indeed capture useful phrase information.

As our approach is not limited to specific tasks, it is interesting to validate the proposed model in other tasks, such as reading comprehension, language inference, and sentence classification.

Abstract

The general trend in NLP is towards increasing model capacity and performance via deeper neural networks. However, simply stacking more layers of the popular Transformer architecture for machine translation results in poor convergence and high computational overhead. Our empirical analysis suggests that convergence is poor due to *gradient vanishing* caused by the interaction between residual connections and layer normalization. We propose depth-scaled initialization (DS-Init), which decreases parameter variance at the initialization stage, and reduces output variance of residual connections so as to ease gradient back-propagation through normalization layers. To address computational cost, we propose a merged attention sublayer (MAtt) which combines a simplified average-based self-attention sublayer and the encoder-decoder attention sublayer on the decoder side. Results on WMT and IWSLT translation tasks with five translation directions show that deep Transformers with DS-Init and MAtt can substantially outperform their base counterpart in terms of BLEU (+1.1 BLEU on average for 12-layer models), while matching the decoding speed of the baseline model thanks to the efficiency improvements of MAtt.[1]

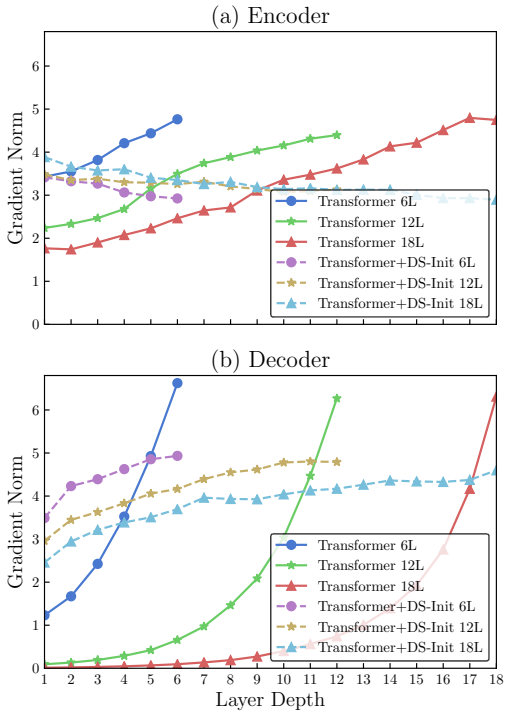

Figure 1: Gradient norm (y-axis) of each encoder layer (top) and decoder layer (bottom) in Transformer with respect to layer depth (x-axis). Gradients are estimated with ∼3k target tokens at the beginning of training. "*DS-Init*": the proposed depth-scaled initialization. "*6L*": 6 layers. Solid lines indicate the vanilla Transformer, and dashed lines denote our proposed method. During back-propagation, gradients in Transformer gradually vanish from high layers to low layers.

1 Introduction

The capability of deep neural models of handling complex dependencies has benefited various artificial intelligence tasks, such as image recognition where test error was reduced by scaling VGG nets (Simonyan and Zisserman, 2015) up to hundreds of convolutional layers (He et al., 2015). In NLP, deep self-attention networks have enabled large-scale pretrained language models such as BERT (Devlin et al., 2019) and GPT (Radford et al., 2018) to boost state-of-the-art (SOTA) performance on downstream applications. By contrast, though neural machine translation (NMT) gained encouraging improvement when shifting from a shallow architecture (Bahdanau et al., 2015) to deeper ones (Zhou et al., 2016; Wu et al., 2016; Zhang et al., 2018; Chen et al., 2018), the Transformer (Vaswani et al., 2017), a currently SOTA architecture, achieves best results with merely 6 encoder and decoder layers, and no gains were reported by Vaswani et al. (2017) from

further increasing its depth on standard datasets.

We start by analysing why the Transformer does not scale well to larger model depth. We find that the architecture suffers from gradient vanishing as shown in Figure 1, leading to poor convergence. An in-depth analysis reveals that the Transformer is not norm-preserving due to the involvement of and the interaction between residual connection (RC) (He et al., 2015) and layer normalization (LN) (Ba et al., 2016).

To address this issue, we propose depth-scaled initialization (DS-Init) to improve norm preservation. We ascribe the gradient vanishing to the large output variance of RC and resort to strategies that could reduce it without model structure adjustment. Concretely, DS-Init scales down the variance of parameters in the l-th layer with a discount factor of $\frac{1}{\sqrt{l}}$ at the initialization stage alone, where l denotes the layer depth starting from 1. The intuition is that parameters with small variance in upper layers would narrow the output variance of corresponding RCs, improving norm preservation as shown by the dashed lines in Figure 1. In this way, DS-Init enables the convergence of deep Transformer models to satisfactory local optima.

Another bottleneck for deep Transformers is the increase in computational cost for both training and decoding. To combat this, we propose a merged attention network (MAtt). MAtt simplifies the decoder by replacing the separate self-attention and encoder-decoder attention sublayers with a new sublayer that combines an efficient variant of average-based self-attention (AAN) (Zhang et al., 2018) and the encoder-decoder attention. We simplify the AAN by reducing the number of linear transformations, reducing both the number of model parameters and computational cost. The merged sublayer benefits from parallel calculation of (average-based) self-attention and encoder-decoder attention, and reduces the depth of each decoder block.

We conduct extensive experiments on WMT and IWSLT translation tasks, covering five translation tasks with varying data conditions and translation directions. Our results show that deep Transformers with DS-Init and MAtt can substantially outperform their base counterpart in terms of BLEU (+1.1 BLEU on average for 12-layer models), while matching the decoding speed of the baseline model thanks to the efficiency improvements of MAtt.

Our contributions are summarized as follows:

- We analyze the vanishing gradient issue in the Transformer, and identify the interaction of residual connections and layer normalization as its source.
- To address this problem, we introduce depth-scaled initialization (DS-Init).
- To reduce the computational cost of training deep Transformers, we introduce a merged attention model (MAtt). MAtt combines a simplified average-attention model and the encoder-decoder attention into a single sublayer, allowing for parallel computation.
- We conduct extensive experiments and verify that deep Transformers with DS-Init and MAtt improve translation quality while preserving decoding efficiency.

2 Related Work

Our work aims at improving translation quality by increasing model depth. Compared with the single-layer NMT system (Bahdanau et al., 2015), deep NMT models are typically more capable of handling complex language variations and translation relationships via stacking multiple encoder and decoder layers (Zhou et al., 2016; Wu et al., 2016; Britz et al., 2017; Chen et al., 2018), and/or multiple attention layers (Zhang et al., 2018). One common problem for the training of deep neural models are vanishing or exploding gradients. Existing methods mainly focus on developing novel network architectures so as to stabilize gradient back-propagation, such as the fast-forward connection (Zhou et al., 2016), the linear associative unit (Wang et al., 2017), or gated recurrent network variants (Hochreiter and Schmidhuber, 1997; Gers and Schmidhuber, 2001; Cho et al., 2014; Di Gangi and Federico, 2018). In contrast to the above recurrent network based NMT models, recent work focuses on feed-forward alternatives with more smooth gradient flow, such as convolutional networks (Gehring et al., 2017) and self-attention networks (Vaswani et al., 2017).

The Transformer represents the current SOTA in NMT. It heavily relies on the combination of residual connections (He et al., 2015) and layer normalization (Ba et al., 2016) for convergence. Nevertheless, simply extending this model with more layers results in gradient vanishing due to the interaction of RC and LN (see Section 4). Recent work has proposed methods to train deeper

Transformer models, including a rescheduling of RC and LN (Vaswani et al., 2018), the transparent attention model (Bapna et al., 2018) and the stochastic residual connection (Pham et al., 2019). In contrast to these work, we identify the large output variance of RC as the source of gradient vanishing, and employ scaled initialization to mitigate it without any structure adjustment. The effect of careful initialization on boosting convergence was also investigated and verified in previous work (Zhang et al., 2019; Child et al., 2019; Devlin et al., 2019; Radford et al., 2018).

The merged attention network falls into the category of simplifying the Transformer so as to shorten training and/or decoding time. Methods to improve the Transformer's running efficiency range from algorithmic improvements (Junczys-Dowmunt et al., 2018), non-autoregressive translation (Gu et al., 2018; Ghazvininejad et al., 2019) to decoding dependency reduction such as average attention network (Zhang et al., 2018) and blockwise parallel decoding (Stern et al., 2018). Our MAtt builds upon the AAN model, further simplifying the model by reducing the number of linear transformations, and combining it with the encoder-decoder attention. In work concurrent to ours, So et al. (2019) propose the evolved Transformer which, based on automatic architecture search, also discovered a parallel structure of self-attention and encoder-decoder attention.

3 Background: Transformer

Given a source sequence $\mathbf{X} = \{x_1, x_2, \ldots, x_n\} \in \mathbb{R}^{n \times d}$, the Transformer predicts a target sequence $\mathbf{Y} = \{y_1, y_2, \ldots, y_m\}$ under the encoder-decoder framework. Both the encoder and the decoder in the Transformer are composed of attention networks, functioning as follows:

$$\begin{aligned} \textsc{Att}(\mathbf{Z}_x, \mathbf{Z}_y) &= \left[\text{softmax}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}})\mathbf{V}\right]\mathbf{W}_o \\ \mathbf{Q}, \mathbf{K}, \mathbf{V} &= \mathbf{Z}_x\mathbf{W}_q, \mathbf{Z}_y\mathbf{W}_k, \mathbf{Z}_y\mathbf{W}_v, \end{aligned} \quad (1)$$

where $\mathbf{Z}_x \in \mathbb{R}^{I \times d}$ and $\mathbf{Z}_y \in \mathbb{R}^{J \times d}$ are input sequence representations of length I and J respectively, $\mathbf{W}_* \in \mathbb{R}^{d \times d}$ denote weight parameters. The attention network can be further enhanced with multi-head attention (Vaswani et al., 2017).

Formally, the encoder stacks L identical layers, each including a self-attention sublayer (Eq. 2) and a point-wise feed-forward sublayer (Eq. 3):

$$\bar{\mathbf{H}}^l = \textsc{Ln}\left(\textsc{Rc}\left(\mathbf{H}^{l-1}, \textsc{Att}(\mathbf{H}^{l-1}, \mathbf{H}^{l-1})\right)\right) \quad (2)$$

$$\mathbf{H}^l = \textsc{Ln}\left(\textsc{Rc}\left(\bar{\mathbf{H}}^l, \textsc{Ffn}(\bar{\mathbf{H}}^l)\right)\right). \quad (3)$$

$\mathbf{H}^l \in \mathbb{R}^{n \times d}$ denotes the sequence representation of the l-th encoder layer. Input to the first layer $\mathbf{H}^0$ is the element-wise addition of the source word embedding $\mathbf{X}$ and the corresponding positional encoding. $\textsc{Ffn}(\cdot)$ is a two-layer feed-forward network with a large intermediate representation and ReLU activation function. Each encoder sublayer is wrapped with a residual connection (Eq. 4), followed by layer normalization (Eq. 5):

$$\textsc{Rc}(\mathbf{z}, \mathbf{z}') = \mathbf{z} + \mathbf{z}', \quad (4)$$

$$\textsc{Ln}(\mathbf{z}) = \frac{\mathbf{z} - \mu}{\sigma} \odot \mathbf{g} + \mathbf{b}, \quad (5)$$

where $\mathbf{z}$ and $\mathbf{z}'$ are input vectors, and $\odot$ indicates element-wise multiplication. μ and σ denote the mean and standard deviation statistics of vector $\mathbf{z}$. The normalized $\mathbf{z}$ is then re-scaled and re-centered by trainable parameters $\mathbf{g}$ and $\mathbf{b}$ individually.

The decoder also consists of L identical layers, each of them extends the encoder sublayers with an encoder-decoder attention sublayer (Eq. 7) to capture translation alignment from target words to relevant source words:

$$\tilde{\mathbf{S}}^l = \textsc{Ln}\left(\textsc{Rc}\left(\mathbf{S}^{l-1}, \textsc{Att}(\mathbf{S}^{l-1}, \mathbf{S}^{l-1})\right)\right) \quad (6)$$

$$\bar{\mathbf{S}}^l = \textsc{Ln}\left(\textsc{Rc}\left(\tilde{\mathbf{S}}^l, \textsc{Att}(\tilde{\mathbf{S}}^l, \mathbf{H}^L)\right)\right) \quad (7)$$

$$\mathbf{S}^l = \textsc{Ln}\left(\textsc{Rc}\left(\bar{\mathbf{S}}^l, \textsc{Ffn}(\bar{\mathbf{S}}^l)\right)\right). \quad (8)$$
