For the models in this work, we experiment with both the traditional uncontextualized word embeddings `word2vec` (Mikolov et al., 2013b) (i.e., the 300 dimension version) and the recent contextualized word embeddings BERT (i.e., the uncased base model) (Devlin et al., 2019) as the pre-trained word embeddings. For BERT, we additionally evaluate the BERT-based ED models in (Wang et al., 2019) (called **DMBERT**) and (Yang et al., 2019) (called **BERT-ED**) that are the sentence-level models with the best-reported ED performance on the ACE 2005 dataset. Finally, we tune the hyperparameters for the models using the development data of the datasets in this paper.

Dataset	Training		Test		Development	
	#Pos	#Neg	#Pos	#Neg	#Pos	#Neg
CASIE	6,776	192,937	847	24,804	847	22,941
CySecED	6,382	224,684	835	29,152	797	28,384

Table 3: The size of datasets. #Pos and #Neg represent the numbers of positive and negative examples.

Results: The ED problem in this work is formulated as a word classification problem where given a sentence/document, the models need to predict the event types for its words. The set of event types includes a special type *Other* to indicate the words that are not event triggers (called the negative examples). The positive examples for ED correspond to the event trigger words. In order to evaluate the ED models on CySecED, we use 240 documents for training data, 30 other documents for test data, and the remaining 30 documents for the development data (i.e., the document split ratio of 80:10:10). In order to compare CySecED and CASIE, we also divide the documents in CASIE (Satyapanich et al., 2020) into the training, test, and development data using the 80:10:10 ratio to evaluate the ED models. We train all the ED models in this work with early stopping on the development datasets (i.e., we stop training the models once the performance on the development data decreases). Some statistics about the data splits for CySecED and CASIE are reported in Table 3 while Table 4 shows the performance of the models on the test datasets.

There are several important observations from the table. First, comparing CASIE and CySecED, we see that the performance of the current ED models on CySecED is in general much worse than those for CASIE. This indicates that CySecED is more challenging than CASIE for ED and the future work can use CySecED to evaluate the ED models for the cybersecurity domain. Also, the best performance of the models on CySecED (i.e., 68.4% with DEEB-RNN) is still far behind the human performance on this dataset (i.e., 81.0%), presenting much opportunities for the future research in this area. Second, comparing `word2vec` and BERT, we find that BERT mostly performs comparably or poorer than `word2vec` for different ED models and datasets, potentially due to the large difference between the training data for BERT and the cybersecurity domain. Third, among the sentence-level models, similar to the general domains (i.e., ACE 2005), MOGANED and BERT-ED still have

Model	`word2vec`		BERT	
	CASIE	CySecED	CASIE	CySecED
CNN	83.9	43.7	83.8	43.0
DMCNN	85.2	43.2	84.0	42.7
GCN	85.5	52.2	85.4	48.9
MOGANED	**86.0**	61.6	**86.5**	56.5
CyberLSTM	81.4	51.8	82.3	34.5
DMBERT	-	-	84.1	55.1
BERT-ED	-	-	84.7	58.1
HBTNGMA	85.9	60.9	85.0	62.4
DEEB-RNN	85.5	**68.4**	85.8	**65.5**

Table 4: The performance (F1 scores) of the models.

the best performance for the cybersecurity datasets. Also, the CyberLSTM model developed for CASIE in (Satyapanich et al., 2020) perform much worse than the state-of-the-art models for ED, showing that CyberLSTM is not sufficient to evaluate the complexity of the datasets for cybersecurity ED. Finally, we see that the document-level model (i.e., DEEB-RNN) is significantly better than sentence-lelvel models for CySecED. This is in contrast to CASIE where the document-level models are only comparable with the sentence-level models. This suggests the advantages of CySecED over CASIE that necessitate the modeling of document-level context information to achieve good performance and better reflect the challenges for cybersecurity ED in CySecED. To illustrate, we provide an example that can only be predicted with document-level information in CySecED in Appendix B. In addition, the large performance difference between the two document-level models (i.e., HBTNGMA and DEEB-RNN) highlights the importance to appropriately capture the document-context information and future research can consider this direction to develop effective models for cybersecurity ED.

6 Related Work

Prior work has applied NLP to perform several tasks for the cybersecurity domain, including privacy policy analysis (Peng et al., 2012; Pandita et al., 2013; Zhu and Dumitras, 2016), text analysis for cybersecurity with social media text (i.e., DDos attack detection, alert generation for threads and vulnerabilities using Twitter) (Mittal et al., 2016; Wang and Zhang, 2017; Sceller et al., 2017; Chambers et al., 2018; Perera et al., 2018; Alguliyev et al., 2019; Hasan et al., 2019), and report and timeline creation of cybersecurity events (Hackmageddon, 2019; PrivacyRight, 2019). However, none of these work considers the detection of event trigger words from cybersecurity articles as we do. Recently, (Lim et al., 2017) presents a dataset for general text-based malware behavior analysis that annotates 39 reports for malware actions and their attributes. This study is then extended in the SecureNLP SemEval evaluation (Phandi et al., 2018). However, different from our CySecED dataset, the annotated dataset in these work is very sparse (i.e., involving less than 5 examples for many labels), hindering the development of the deep learning models (Roy et al., 2019). Also, it does not annotate event triggers for rich event types as we do.

Finally, ED has been extensively studied in the literature (Liao and Grishman, 2010; Li et al., 2013; Nguyen and Grishman, 2015, 2016e; Chen et al., 2015; Nguyen et al., 2016g; Lu and Nguyen, 2018; Liu et al., 2016b, 2017; Chen et al., 2017; Hong et al., 2018; Lai et al., 2020b), partly due to the availability of the large evaluation datasets (i.e., the ACE and TAC KBP datasets (Walker et al., 2006; Mitamura et al., 2015) for the general domains, and the BioNLP datasets (Kim et al., 2009) for the biomedical domain). The closest works to our in the cybersecurity domain involve (Qiu et al., 2016) to extract events on Chinese news, (Khandpur et al., 2017) to perform cyberattack detection on Twitter, and (Satyapanich et al., 2019; Satyapanich et al., 2020) to present the CASIE dataset for event extraction. However, these datasets contain less event types and cannot support the document-level information for the models as CySecED. Finally, we notice some recent interests in new type extension learning, e.g., few-shot/zero-shot learning (Nguyen et al., 2016b; Huang et al., 2018; Lai and Nguyen, 2019; Lai et al., 2020a), that can be helpful to develop ED systems for cybersecurity domain.

7 Conclusion

We present a new dataset CySecED for event detection in the cybersecurity domain. Our dataset is manually annotated for 30 event types and provides sufficient data to develop deep learning models for this task. We extensively evaluate state-of-the-art models for ED on the proposed dataset, showing that the performance of these models is still much worse than the human performance. Our experiments also suggest that document-level information is necessary to perform ED for cybersecurity domain. In the future, we plan to extend our annotation to include event arguments and other properties of events.

A Event Types in CySecED

There are 30 event types annotated in the proposed CySecED dataset. Tables 5 and 6 present these event types along with their descriptions and examples. Note that for the types and descriptions in this section, we consult the cybersecurity taxonomy in (Simmons et al., 2014). Also, we show the distribution of the event types in CySecED in Figure 1.

B The Necessity of Document-level Information for ED in CySecED

In order to demonstrate the importance of the document-level information for the ED task in CySecED, consider the following document from CySecED:

"All the hackers have been charged with **conducting** *numerous Distributed Denial-of-Service (DDoS)* **attacks** *on major U.S. banks, with Firoozi separately gaining unauthorized access to a New York dam's industrial automation control (SCADA) system in August and September of 2013.*

"This unauthorized access allowed Firoozi to repeatedly obtain information regarding the status and operation of the dam, including information about the water levels, temperature, and status of the sluice gate, which is responsible for controlling water levels and flow rates," a DoJ statement reads.

Luckily, the sluice gate had already been manually disconnected for the purpose of maintenance at the time Firoozi attacked.

The hackers' work allegedly involved Botnets – networks of compromised machines – that **hit** *major American banks, including Bank of America and J.P. Morgan Chase, as well as the Nasdaq stock exchange and knocked them offline."*

There are three event trigger words of type *ATTACK.Denial of Service* (i.e, the words in bold) in this document. Among those, the first two trigger words (i.e., "*conducting*" and "*attacks*") can be easily assigned to this event type based on their local context (i.e., the direct word "*Denial-of-Service*" in the same sentence). However, the classification of the third trigger word "*hit*" to *ATTACK.Denial of Service* is non-trivial as the local context with the nearby sentences does not provide sufficient evidences to determine the correct event type. In this case, it is crucial for the annotators and models to capture the document-level information by looking back further to the beginning of the document to realize "Distributed Denial-of-Service (DDoS) attacks" as the main topic of the document. This topic information can then help to correctly predict the event type for "*hit*". Note that the word "*hit*" in this case is only correctly predicted by the document-level model **DEEB-RNN** and cannot be recognized by the other sentence-level models in this work. Overall, this example illustrates the challenge to encode the document-level information for ED in CySecED, serving as a guidance for the future research in this area.

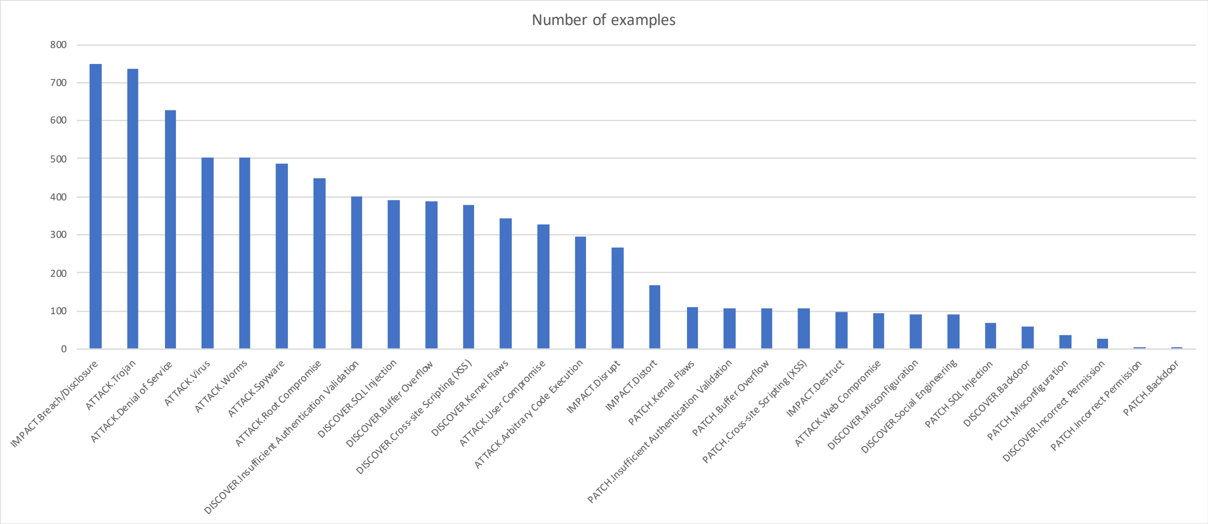

Figure 1: The distribution of the event types in CySecED.

ID	Type	Description	Example (triggers are highlighted)
	DISCOVER	A vulnerability in a software or system is detected or mentioned by some entity (i.e., hackers, engineers).	
1	DISCOVER.Misconfiguration	The discovery/mention of a configuration flaw within a particular application that enables hackers to gain access to a network or personal computer to cause a variety of attacks.	*Researchers* ***found*** *that due to lack of hostname verification, several banking applications were not checking if they connected to a trusted source.*
2	DISCOVER.Kernel Flaws	The discovery/mention of a kernel flaw within an operating system, which is the core code of an operating system, enabling hackers to gain certain privileges to exploit a vulnerability within the operating system.	*Another privilege-escalation* ***vulnerability*** *has been* ***discovered*** *in Linux kernel that dates back to 2005 and affects major distro of the Linux operating system, including Redhat, Debian, OpenSUSE, and Ubuntu.*
3	DISCOVER.Buffer Overflow	The discovery/mention of a buffer overflow where a buffer with weak or no bounds checking is populated with user supplied data. An attacker can exploit a buffer overflow vulnerability for an arbitrary code execution, often of privileges at the administrative level with the program running.	*The* ***vulnerability*** *was described as the stack buffer overflow* ***issue*** *and was* ***discovered*** *by Google's Project Zero staffer Gal Beniamini.*
4	DISCOVER.Insufficient Authentication Validation	The discovery/mention of a program failure to validate the authentication of an application and/or user sent to the program from a user. An attacker can exploit an insufficient authentication validation vulnerability and capture user credentials to impersonate a valid user, which commonly occurs within web applications.	*A critical security* ***vulnerability*** *has been* ***reported*** *in phpMyAdmin-one of the most popular applications for managing the MySQL database-which could allow remote attackers to perform dangerous database operations just by tricking administrators into clicking a link.*
5	DISCOVER.SQL Injection Flaw	The discovery/mention of injection flaws that are not properly validated and sent to an interpreter, usually due to some design flaw. An attacker can exploit this to inject arbitrary code, which commonly occurs within web applications.	*The* ***flaws****,* ***exist*** *in the Joomla version 3.2 to 3.4.4, include SQL injection* ***vulnerabilities*** *that could allow hackers to take admin privileges on most customer websites.*
6	DISCOVER.Cross-site Scripting (XSS)	The discovery/mention of XSS flaws that involve a design flaw not properly validated, allowing malicious scripts to be executed against a vulnerable application in a web browser.	*According to the in-depth technical details* ***shared*** *with The Hacker News, multiple Bigscreen* ***flaws*** *in question are persistent/stored cross-site scripting (XSS)* ***issues*** *that* ***reside*** *in the input fields where VR users are supposed to submit their username, room name, room description, room category in the Bigscreen app.*
7	DISCOVER.Backdoor	The discovery/mention of backdoor, a typically covert method of bypassing normal authentication or encryption in a computer.	*Security researchers have* ***discovered*** *a secret hard-coded* ***backdoor*** *in Western Digital's My Cloud NAS devices that could allow remote attackers to gain unrestricted root access to the device.*
8	DISCOVER.Incorrect Permission	The discovery/mention of an incorrect permission associated to a file or directory that consists of not appropriately assigning users and processes.	*The second* ***bug*** *(CVE-2018-1271)* ***resides*** *in Spring's Web model-view-controller (MVC) that allows attackers to execute directory traversal attack and access restricted directories when configured to serve static resources (e.g., CSS, JS, images) from a file system on Windows.*
9	DISCOVER.Social Engineering	The discovery/mention of a process of using social interactions to acquire information about a victim or computer system. These types of attacks provide quick alternatives in disclosing information to assist an attack that in normal circumstances may not be available.	*A critical security vulnerability has been reported in phpMyAdmin-one of the most popular applications for managing the MySQL database-which could allow remote attackers to perform dangerous database operations just by* ***tricking*** *administrators into* ***clicking*** *a link.*
	PATCH	Some entity (i.e., software companies) fixes or shows how to fix a known vulnerability.	
10	PATCH.Misconfiguration	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.Misconfiguration.	*Users are strongly recommended to* ***change*** *default credentials for their devices to* ***prevent*** *against the malware.*
11	PATCH.Kernel Flaws	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.Kernel Flaws.	*In response to the Horn's blog post, the maintainers of Ubuntu say the company would possibly* ***release*** *the* ***patches*** *for the Linux kernel flaw around October 1, 2018.*
12	PATCH.Buffer Overflow	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.Buffer Overflow.	*In the security note accompanying iOS 10.3.1, Apple describes the issue as a stack buffer overflow vulnerability, which the company* ***addressed*** *by* ***improving*** *the input validation.*
13	PATCH.Insufficient Authentication Validation	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.Insufficient Authentication Validation.	*"The* ***use*** *of authentication and authorization of messages, such as the one* ***provided*** *by Spring Security, can limit exposure to this vulnerability only to users who are allowed to use the application", the company suggests.*
14	PATCH.SQL Injection Flaw	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.SQL Injection Flaw.	*Yahoo Quickly* ***Fixes*** *SQL Injection Vulnerability Escalated to Remote Code Execution.*
15	PATCH.Cross-site Scripting (XSS)	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.Cross-site Scripting (XSS).	*The latest Webmin and Usermin* ***releases*** *also* ***address*** *a handful of cross-site scripting (XSS) vulnerabilities that were responsibly disclosed by a different security researcher who has been rewarded with a bounty.*
16	PATCH.Backdoor	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.Backdoor.	*Webmin developers have now* ***removed*** *the malicious backdoor in its software to* ***address*** *the vulnerability and* ***released*** *the clean versions, Webmin 1.930 and Usermin version 1.780.*
17	PATCH.Incorrect Permission	The mention/description of an update released by some entity to address a vulnerability of type DISCOVER.Incorrect Permission.	*It turns out that before receiving the latest* ***patch****, Guard Provider was downloading antivirus signature updates through an unsecured HTTP connection, allowing man-in-the-middle attackers sitting on open WiFi network to intercept your device's network connection and push malicious updates.*

Table 5: Event types along with their descriptions and examples in CySecED (to be continued in Table 6).

ID	Type	Description	Example (triggers are highlighted)
	ATTACK	An attacker exploits some vulnerability to impact the systems using some means. This can be a mention of an attack or the actions involved in the attack.	
18	ATTACK.User Compromise	A perpetrator gaining unauthorized use of user privileges on a host, as a user compromise.	*Remote attackers to completely **takeover** player accounts just by tricking users into clicking an unsuspectable link.*
19	ATTACK.Root Compromise	Gaining unauthorized privileges of an administrator on a particular host. This is also extended to include any elevated privileges above a normal user including administrative and/or root level privileges to a particular system.	*The flaws, exist in the Joomla version 3.2 to 3.4.4, include SQL injection vulnerabilities that could allow hackers to **take** admin privileges on most customer websites.*
20	ATTACK.Web Compromise	A website or web application using vulnerabilities to further an attack. An attack can occur through a web compromise, usually via cross-site scripting or SQL injection. Web Compromise involves the use of a malformed website or web application an attacker exploits for gain.	*Any malicious site can potentially **make** a victim's web browser **connect** to a My Cloud device on the network and **compromise** it.*
	ATTACK.Installed Malware	An attack that is launched via user-installed malware on a victim system, whether user installed or drive-by installation. Installed malware can allow an adversary to gain full control of the compromised systems leading to the exposure of sensitive information or remote control of the host. There are several subtypes for this type of attacks.	
21	ATTACK.Virus	A form of installed malware or a piece of code that will attach itself through some form of infected files, which will self-replicate upon execution of program. Viruses spread when the infected files they are attached to is transferred from one computer/device to another via the network, file sharing, or email attachments.	*The researcher demonstrated how a malicious attacker could have sent the victim's inbox to an external site, and **created** a virus that **attached** itself to all outgoing emails by secretly **adding** a malicious script to message signatures.*
22	ATTACK.Worm	A self-replicating computer program (a considerable threat to the internet today). Worms do not require human intervention to propagate as it is a self-replicating standalone program that enters a computer/device through a vulnerability in the system and takes advantage of file-transport or information-transport features throughout the network.	*Hajime botnet **works** much like Mirai by **spreading** itself via unsecured IoT devices that have open Telnet ports and uses default passwords and also uses the same list of username and password combinations that Mirai is programmed to use.*
23	ATTACK.Trojan	A harmful program that looks legitimate. Users are typically tricked into loading and executing it on their systems, allowing unauthorized backdoor access to a compromised system (a common way to introduce a victim into a multitude of attacks). Unlike viruses and worms, Trojans do not reproduce by infecting other files nor do they self-replicate. Trojans must spread through user interaction such as opening an email attachment or downloading and running a file from the Internet.	*Dubbed Trojan.Mirai.1, the new Trojan **targets** Windows computers and **scans** the user's network for compromisable Linux-based connected devices.*
24	ATTACK.Spyware	Similar to Trojans, Spyware is a type of malware programs that is covertly installed and infects its target. The difference concerns the purposes of the programs. In particular, Spyware aims to collect information from a computing system without owner's consent while Trojans can have numerous purposes and impact a system tremendously (e.g., ruining the system).	*A new variant of the X-Agent **spyware** is now **targeting** Apple macOS system that has previously been **used** in cyber **attacks** against Windows, iOS, Android, and Linux devices.*
25	ATTACK.Arbitrary Code Execution	Involves a malicious entity that gains control through some vulnerability injecting its own code to perform any operation the overall application has permission.	*Beniamini says this stack buffer overflow issue in the Broadcom firmware code could lead to remote code **execution** vulnerability, allowing an attacker in the smartphone's WiFi range to **send** and **execute** code on the device.*
26	ATTACK.Denial of Service	Denial of Service (DDoS) is an attack to deny a victim access to a particular resource or service.	*Dyn did not disclose the actual size of the **attack**, but it has been speculated that the DDoS **attack** could be much bigger than the **one** that **hit** French Internet service and hosting provider OVH that peaked at 1.1 Tbps, which is the largest DDoS **attack** known to date.*
	IMPACT	The consequence of an attack for a system.	
27	IMPACT.Distort	A distortion in information, usually when an attack has caused a modification of a file. When an attack involves distort, it is a change to data within a file, or modification of information from the victim.	*Last month, ransomware viruses hit two cities in Florida that made large ransom payments to gain back access to city files that were **encrypted** in the attacks.*
28	IMPACT.Disrupt	A disruption in services, usually from a Denial of Service. When an attack involves disrupt, it is an access change, or removal of access to victim or to information.	*The attack **prevented** prepaid customers from buying electricity units.*
29	IMPACT.Destruct	A destruction of information, usually when an attack has caused a deletion of files or removal of access. Destruct is the most malicious impact, as it involves the file deletion, or removal of information from the victim.	*All the attacker needs to do is trick the victims into clicking a specially crafted Facebook URL, as mentioned on his blog, designed to perform various actions like posting anything on their timeline, change or **delete** their profile picture, and even trick users into **deleting** their entire Facebook accounts.*
30	IMPACT.Breach/Disclosure	A disclosure of information, usually providing an attacker with a view of information they would normally not have access to and with the possibility of leading to other compromises.	*VPNFilter is a multi-stage, modular malware that can **steal** website credentials and **monitor** industrial controls or SCADA systems, such as those used in electric grids, other infrastructure and factories.*

CHARM: Inferring Personal Attributes from Conversations

`{tigunova, ayates, paramita, weikum}@mpi-inf.mpg.de`

Abstract

Personal knowledge about users' professions, hobbies, favorite food, and travel preferences, among others, is a valuable asset for individualized AI, such as recommenders or chatbots. Conversations in social media, such as Reddit, are a rich source of data for inferring personal facts. Prior work developed supervised methods to extract this knowledge, but these approaches can not generalize beyond attribute values with ample labeled training samples. This paper overcomes this limitation by devising CHARM: a zero-shot learning method that creatively leverages keyword extraction and document retrieval in order to predict attribute values that were never seen during training. Experiments with large datasets from Reddit show the viability of CHARM for open-ended attributes, such as professions and hobbies.

1 Introduction

Motivation. Personal Knowledge Bases (PKBs) capture individual user traits for customizing downstream applications like chatbots or recommender systems (Balog et al., 2019). A potentially automatic way to populate a PKB is to draw personal knowledge from the user's conversations in social media and dialogues on other platforms. These interactions are a rich source of personal attributes, such as hobbies, professions, cities visited, medical conditions (experienced by the user) and many more. Each of these would consist of key-value pairs, such as *cities visited:Paris* or *symptom:dizziness*. However, a large number of potential attributes and their respective values makes this a challenging task. In particular, there is little hope to have training data for each of these key-value pairs. Moreover, the textual cues in user conversations are often implicit and thus difficult to learn.

Example. Consider the user's utterance: *"I just visited London, which was a disaster. My hotel was a headache and I spent half the time in bed with a fever... So glad to be back home finishing the masts on my galleon."* As humans, we can infer the following attribute-value pairs: (a) *cities visited:London*, (b) *symptom:fever*, (c) *hobby:model ships*. Capturing such user traits is a daunting task, however, with both implicit and explicit signals present. We need to consider the context *"spent in bed with"*, to infer that *fever* relates to a disease (as opposed to *headache*). To predict the user's hobby *model ships*, we have to pay attention to the cues 'galleon' and 'mast'. Proper inference requires both deep language understanding and background knowledge (e.g., about ships, cities, etc.).

State of the Art and its Limitations. Explicit mentions of attribute-value pairs can be captured by pattern-based methods (e.g., Li et al. (2014); Yen et al. (2019)). Such methods are able to extract *London* from the the previous example by using the pattern *"I . . . visited* ⟨*city_name*⟩". Pattern-based approaches are limited, though, by their inability to consider implicit contexts, such as *"finishing the* ***masts*** *on my* ***galleon****"*. Question answering methods can be used to relax rigid patterns (e.g., Levy et al. (2017)), but still rely on explicit mentions of attribute values.

In this work we aim to extract attribute values leveraging both explicit and implicit cues, such as inferring *symptom:fever* and *hobby:model ships*. Additionally, we address the cases where there is a long-tailed set of values for such attributes as *hobby*. In principle, deep learning is suitable for such inference (Tigunova et al., 2019; Preoţiuc-Pietro et al., 2015; Rao et al., 2010), but it critically hinges on the availability of labeled training samples for every attribute value that the model should predict. Supervised training is suitable for a pre-specified limited-scope setting, such as learning personal interest from a fixed list of ten movie genres, but

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5391–5404,
November 16–20, 2020.

it does not work for the situation with large and open-ended sets of possible values, for which there is little hope of obtaining comprehensive training samples. Therefore, we pursue a *zero-shot learning* (Larochelle et al., 2008; Palatucci et al., 2009) approach that learns from labeled samples for a small subset of labels (i.e., attribute values in our setting) and generalizes to the full set of labels including values *unseen* at training time.

Problem Statement. For a given attribute we consider the set of *known* values V, which can be drawn from lists in dictionary-like sources like Wikipedia. At training time, our method requires samples for a small subset of values $S \subset V$. Typically, the complement $V \setminus S$ is much larger than S: $|V \setminus S| \gg |S|$. For instance, S may consist solely of the popular values *sports, travel, reading, music, games*, whereas the complement includes hundreds of long-tail values, such as *beach volleyball*, *model ships*, *brewing*, etc. At inference time we need to predict values from all of V, although most of the values are *unseen* during training.

Approach and Contributions. We present CHARM, a Conversational Hidden Attribute Retrieval Model, for inferring attribute values in a zero-shot setting. CHARM identifies cues in related to a target attribute, which it then uses to retrieve relevant texts from external document collections, indicative of different attribute values. These external documents could be gathered by simple web search. They help CHARM to link the cues in the user's utterances to the actual attribute values to predict. CHARM consists of two components: *(i)* a cue detector, which identifies attribute-relevant keywords in a user's utterances (e.g., *galleon*), and *(ii)* a value ranker, which matches these keywords against documents that indicate possible values of the attribute (e.g., *model ships*).

To evaluate our approach, we conduct experiments predicting Reddit users' professions and hobbies based on their conversational utterances. We demonstrate that CHARM performs well when inferring unseen values and performs competitively with the best-performing baselines when predicting values seen during training. CHARM can easily be extended to other attributes with long-tail values, such as *favorite cuisine*, *preferred news topics* or *medication taken*, by providing a list of known attribute values, training examples for a subset of these values and access to external documents (e.g., via a Web search engine).

The salient contributions of this paper are: *(1)* a method for inferring both seen and previously unseen (zero-shot) attribute values from a user's conversational utterances; *(2)* a comprehensive evaluation for the *profession* and *hobby* attributes over a large dataset of Reddit discussions; and *(3)* labeled data and code as resources for later research.[1] [2]

2 Related Work

User profiling from utterances. There is ample prior work on classification models to predict a user's personal traits based on hand-crafted textual features (Preoţiuc-Pietro et al., 2015; Basile et al., 2017), or with embedding-based representations (Li et al., 2016; Bayot and Gonçalves, 2018; Tigunova et al., 2019). While classification models work well for inferring demographic attributes with a small set of values such as *age*, *gender* or *occupational class* (Preoţiuc-Pietro et al., 2015; Flekova et al., 2016; Basile et al., 2017) their dependence on seeing all attribute values in (sufficiently many) labeled training samples renders supervised classifiers inappropriate for open-ended attributes such as *profession* (Tigunova et al., 2019), *hobby* (Bando et al., 2019) or *favorite food* (Zeng et al., 2019), which are often modeled as a binary multilabel task predicting the presence of each attribute value (Welch et al., 2019). Similar to our approach, some studies map user input to Wikipedia concepts (Abel et al., 2011; Krishnamurthy et al., 2014) to predict interests or locations. However, this method requires explicit mentions of the entities.

Pattern-based approaches alleviate the problem of the lack of labeled entities for long-tail classes by employing information extraction techniques to obtain personal attribute values from users' utterances, using sequence labeling methods (Jing et al., 2007; Li et al., 2014) or context classification (Yen et al., 2019). However, their coverage is limited because they require crisp and explicit statements, like *"I am a **student**"*, which are infrequent in conversations.

Our approach is designed for handling attribute values that were never seen at training time. This is known as the *zero-shot learning* problem, which has been widely studied in the field of computer vision but less explored in NLP. We employ a technique similar to Ba et al. (2015) for visual classes,

---

[1] `https://github.com/Anna146/CHARM`

[2] `https://www.mpi-inf.mpg.de/departments/databases-and-information-systems/research/pkb`

which builds image classifiers directly from encyclopedia articles without training images.

Most zero-shot studies for NLP (Wang et al., 2019) deal with machine translation, cross-lingual retrieval and entity/relation extraction (Levy et al., 2017; Pasupat and Liang, 2014), which are not suitable for our task, because they identify values that are explicitly mentioned rather than inferring them. Our task is similar to zero-shot text classification (Yazdani and Henderson, 2015; Zhang et al., 2019), where the class labels are represented as single-word embeddings. We consider a zero-shot BERT baseline (Devlin et al., 2018) that matches utterances with rich document representations.

Keyword extraction from conversational text. Notable applications of keyword extraction from conversational text include *just-in-time information retrieval* (Habibi and Popescu-Belis, 2015), with continuous monitoring of users activities (e.g., participation in meetings) and generating personalized tags for Twitter users (Wu et al., 2010) or search for relevant email attachments (Van Gysel et al., 2017). Prior work mostly pursued unsupervised approaches, e.g. *TextRank* (Mihalcea and Tarau, 2004) and *RAKE* (Rose et al., 2010), due to limited availability of training data. Exceptions use supervised learning, with feature-based classifiers (Kim and Baldwin, 2012) or neural sequence tagging models (Zhang et al., 2016).

Our neural approach lies in between, as we learn to identify salient keywords for a specific attribute (e.g., *profession*), without having training data of relevant keywords.

Information Retrieval in NLP. Most existing work leveraging Information Retrieval (IR) components to solve NLP tasks focused on Question Answering (QA) (Kratzwald and Feuerriegel, 2018; Wang et al., 2018; Guu et al., 2020) or dialogue systems (Feng et al., 2019; Luo et al., 2019), where the retrieval part is responsible for ranking the most appropriate answers or responses, given a question or chat session. As far as we know, we are the first to leverage a retrieval-based model for inferring attribute values without training samples.

3 Methodology

Overview. As illustrated in Figure 1, CHARM consists of two stages: *cue detection* and *value ranking*. As input CHARM receives a user's utterances $U = u_0..u_N$ that contain a set of terms $t_0..t_M$, for example, $U =$\{*“I stayed late at the* ***library*** *yesterday”, “**Studied** for the **exam** so I could have better **grades** than my **classmates**”*\}. In the first stage, the term scoring model assigns a score to each term in the user's utterances, yielding $l_0..l_M$. The highest scoring terms are then selected to form a query $Q = q_0..q_K$ characterizing the user's correct attribute value, e.g., $Q =$“library studied exam grades classmates” for the *profession* attribute.

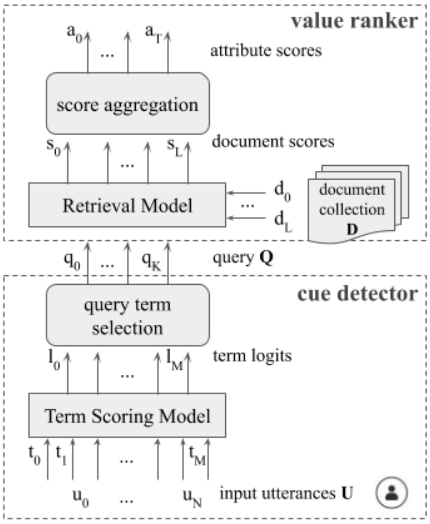

Figure 1: The pipeline of CHARM. The Term Scoring Model assigns scores $l_0..l_M$ to the terms in the input utterances $u_0..u_N$. The terms with the highest scores are passed to the Retrieval Model, which queries the document collection D. The document scores are aggregated to produce attribute value scores for predictions.

In the second stage, Q is evaluated against an external document collection $D = d_0..d_L$; each document in D is associated with possible attribute values. Documents such as *Wiki:Student* and *Wiki:Dean's List*, which are associated with the attribute value *student*, would score high with the example query. The score aggregator then ranks the attribute values based on the documents' scores $s_0..s_L$, for instance, yielding a high attribute score for *student* given our example utterances. The list of attribute values V is **known** in advance (e.g., taken from Wikipedia lists); however, potentially only a subset of values $S \subset V$ have instances **seen** during training.

3.1 Cue detection

The term scoring model δ evaluates how useful each word in a given user's utterances is for making a prediction, and assigns real-value scores $l_0...l_M$ to the terms accordingly. That is, $l_j = \delta(t_j|t_0,..t_M;W)$, where W denotes the parameters of the model. The term scores $l_0..l_M$ are then used to select the words which will form the query for the value ranking component.

The term scoring model should produce high scores for terms that are descriptive of the user and of the attribute in general, instead of a specific attribute value. This means that it should be able to exploit background knowledge and a term's context to judge its relevance to the attribute. For instance, having seen the phrase *"stayed late at the hospital"* for the *physician* at training time, at prediction time an ideal model would correctly estimate the importance of the word 'library' in the phrase *"stayed late at the library"*, even if there were no instances of *student* in the training set.

BERT (Devlin et al., 2018) is well-suited for this requirement, because it is a sequential model that effectively uses word context and incorporates world knowledge.

For further description, let us suppose the cue detector picks the words $Q = q_0...q_K$ as our query terms for CHARM's value ranking stage. A typical query would consist of the terms associated with the correct attribute value (e.g., $Q =$"library studied exam grades classmates").

3.2 Value ranking

The second stage of the model consists of two steps: first, using the selected query terms to rank the documents in the external collection; and second, aggregating document scores to predict values.

Document ranking. The ranking component takes two inputs: query terms $Q = q_0...q_K$ resulting from the cue detector and an (automatically labeled) document collection $D = d_0...d_L$. The document collection could be a set of Web pages, where each page indicates a specific attribute value, $v_0...v_L$. For example, by generating a search-engine query "hobby ⟨value⟩" we can gather web pages related to specific hobbies.

The ranker $\rho(Q, d_k)$ evaluates the query Q, constructed by the cue detector, against each document d_k in the document collection to produce document relevance scores $s_0...s_L$. For the example query "library studied exam grades classmates", the document *Wiki:Dean's List* labeled with *student* will get a higher score than *Wiki:Junior doctor* (for *physician*). We consider two particular instantiations of the ranker: BM25 (Robertson et al., 1995) and KNRM (Xiong et al., 2017). BM25 is a strong unsupervised retrieval model, whereas KNRM is an efficient neural retrieval model that can consider semantic similarity via term embeddings in addition to considering exact matches of query terms.

Document score aggregation. The document scores $s_0...s_L$ obtained from the ranker are then aggregated to produce scores for each known attribute value. Depending on the document collection used, each attribute value may be represented by several documents. For example, the *student* attribute value may be associated with documents *Wiki:Dean's List*, *Wiki:Master's degree*, etc. In this case, the scores per document have to be aggregated to form the final scores $a_0...a_T$ for each attribute value in V. In our experiments, we consider the following aggregation techniques: *(i) average* (which allows multiple documents to contribute to the final ranking) and *(ii) max* (which may help when the document collection is noisy and we care only about the top-scoring document for each value). Having obtained the final attribute scores $a_0...a_T$, we sort them to get the top value as the model prediction.

3.3 Training

While predicting attribute values is not inherently a reinforcement learning problem, we utilize the REINFORCE policy gradient method (Sutton et al., 2000) to train the cue detector component because there are no labels indicating which input terms should be selected. This allows the cue detector to be trained based on the correct attribute values regardless of the non-differentiable `argmax` operation needed to identify the K top scoring terms from the scores it outputs.

When using the policy gradient method, the *state* in our system is represented by a sequence of input terms $t_0...t_M$. Each of the M input terms also represents an independent *action*. The term scoring model acts as the *policy*, which outputs the term selection probabilities based on the current state. Then a term is sampled (at training time) or the term with maximum probability is selected (at prediction time) and added to the query.

During training, we form the query sampling without replacement one word at a time. After sampling each term, we issue the current query and get intermediate feedback. The training episode ends when the query reaches its maximum length K. We define the reward r_τ for an intermediate query to be the normalized discounted cumulative gain (the nDCG ranking metric) of the correct attribute values' scores after aggregation at timestep

τ. The objective of REINFORCE is to maximize $J = \sum_{\tau=1}^{K} r_\tau * \log p_\tau$ by updating the weights of the policy network (where p_τ is the probability of selecting a term at timestep τ).

4 Dataset

Made a small test batch of apple cider using apples which I juiced. Its been fermenting for less than 2 weeks, forming a pile of dead yeast at the bottom

Figure 2: Example of an input utterance from Reddit.

The datasets used in our experiments cover two types of input: *(i)* users' utterances along with their corresponding attribute-value pairs (e.g., *hobby:brewing* from the example in Figure 2), and *(ii)* a collection of documents associated with each attribute value (e.g., documents describing *brewing* as a hobby). We consider two exemplary attributes: *profession* and *hobby*. We define lists of their attribute values based on Wikipedia lists[3].

4.1 Users' utterances

We consider publicly-available Reddit submissions and comments[4] from 2006 to 2018 as users' utterances. Given a Reddit user having a set of utterances $U = u_0..u_N$, we aim to label the user with a set of *profession* and *hobby* values, based on explicit personal assertions (e.g., *"I work as a **doctor**"*) found in the user's posts. To label the candidate users with attribute values we utilized the Snorkel framework (Ratner et al., 2017). We provide details on our data labeling using Snorkel in Appendix A.1.

For our experiments, we removed all posts containing explicit personal assertions that we used for labeling each user, because we want to test the ability of CHARM to predict attribute values based on inference, as opposed to explicit pattern extraction. The final dataset consists of 6000 users per attribute, with a maximum of 500 and an average of 23 users per attribute value. The number of attribute values for *hobby* and *profession* attributes is 149 and 71 respectively.

We evaluated the quality of Snorkel labeling on a held-out validation set, which we manually annotated. The validation set contains roughly 100 users per attribute, and was annotated with attribute values agreed by at least two out of three judges. The labeling obtained by Snorkel corresponded to 0.9 precision on the validation set. To demonstrate that Snorkel provides the same level of quality as crowdsourcing, we calculated the precision of human annotators on the same validation set by comparing the labels of each annotator against the agreement labels. The obtained precision scores were 0.91 for profession and 0.88 for hobby, demonstrating that Snorkel is a reasonable alternative.

4.2 Document collection

The scope of possible attribute values may be open-ended in nature, and thus, calls for an automatic method for collecting Web documents. In this work, we consider three different Web document collections; summary statistics on the number of documents per attribute value are provided in Table 1. Each document may be associated with multiple attribute values. To provide more diversity and comprehensiveness we augmented our pre-defined lists of known attribute values with their synonyms and hyponyms.[5]

Note that the approaches used to construct the document collections are straightforward and easily applicable for further attributes, such as favorite travel destination or favorite book genre.

Wikipedia pages (Wiki-page). To create this collection we take the lists of known attribute values and automatically retrieve a Wikipedia page corresponding to each value, which usually coincides with the article title (e.g., *Wiki:Barista*).

Wikipedia pages–extended (Wiki-category). This collection is an extension of Wiki-page that additionally includes pages found using Wikipedia categories. This allows us to include pages about concepts related to the attribute values, such as tools used for a profession and the profession's specializations. To construct Wiki-category, we identified at least one relevant category for each attribute value and included all leaf pages under the category (i.e., including no subcategories).

Web search. To create this collection we queried a Web search engine using attribute-specific patterns: *"my profession as ⟨profession value⟩"* and *"my favorite hobby is ⟨hobby value⟩"*. The collection consists of the top 100 documents returned for each value. Such patterns can be created with low effort by evaluating a few sample queries. Alternatively, patterns could be mined from a corpus or simplified to the generic form *"⟨attribute⟩ ⟨value⟩"*.

5 Experimental Setup

We evaluate the proposed method's performance in two experimental settings. First, we consider a zero-shot setting in which the attribute values in the training and test data are completely disjoint (i.e., the test set only contains *unseen* labels). This setting evaluates how well CHARM can predict attribute values that were not observed during training. Second, we consider the standard classification scenario in which all attribute values are *seen* as labels in both training and test sets.This demonstrates that CHARM's performance in a normal classification setting does not substantially degrade because of its proposed architecture.

Experimental setup details differ for these two evaluation settings, which will be discussed in the following subsections. All our models were implemented in PyTorch; technical details are in Appendix B. The code and labeled datasets will be made publicly available upon acceptance.

Training and test data. For the *unseen* experiments, we perform ten fold cross-validation with folds constructed such that each attribute value appears in only one test fold. Each of the folds contains roughly the same number of users and approximately 2-4 unique attribute values.[6] We assigned the users having multiple attribute values to a fold corresponding to one of their randomly chosen values. For the experiments with *seen* values, we randomly split the users into training and test sets in a 9:1 proportion, respectively.

Hyperparameters. BERT, the term selection component, generates a contextualized embedding for each input term, which we process with a fully connected layer to produce a term score for each word in its context. Specifically, we use the pre-trained BERT base-uncased model with 12 transformer layers. To reduce BERT's computational requirements, we discard the last 6 transformer layers (i.e., we use embeddings produced by the earliest 6 layers) after observing in pilot experiments that this outperformed a distilled BERT model. (Sanh et al., 2019)

Following prior work (Hui et al., 2018), KNRM was trained with frozen word2vec embeddings on data from the 2011-2014 TREC Web Track with the 2009-2010 years for validation. We initialize KNRM with these pre-trained weights.

During training, we sample 5 negative labels (i.e., incorrect attribute values) to be ranked when calculating the nDCG reward. For each label, we sample a subset of 15 documents to represent the label (i.e., attribute value). If the document collection has fewer than 15 documents for a label (e.g., Wiki-page), we consider all the label's available documents. When making predictions, we consider all documents and all labels (values). In both settings, we truncate documents to 800 terms when using KNRM for efficiency and use the full documents with BM25. We use ten fold cross-validation on the training data to optimize the following hyperparameters in a grid search: (*i*) document aggregation strategy (*average* vs *max*); (*ii*) length of query; and (*iii*) maximum number of epochs. Further details on the hyperparameter search are in Appendix B.

Baselines. For the *unseen* experiments, we evaluate CHARM's performance against an end-to-end BERT ranking method and against a BM25 (Robertson and Zaragoza, 2009) *ranker* combined with two state-of-the-art unsupervised keyword extraction methods: TextRank and RAKE. We additionally include a baseline giving the user's full utterances as input to BM25 (baseline: *No-keyword*).

Following related work (Nogueira and Cho, 2019; Dai and Callan, 2019), we train the BERT IR baseline using a binary cross-entropy loss to predict the relevance of each document to the user's utterances (acting as queries). We use the same pre-trained BERT model as in CHARM. To fit both utterances and documents into the input size of BERT, we split both into 256-token chunks and run BERT on their Cartesian product. To obtain the final score for each utterances-document pair we average across all chunk pairs. Given N utterances and M documents, this baseline processes $N \times M$ inputs with BERT, whereas CHARM processes N inputs with BERT and M inputs with an efficient ranking method. This makes the BERT IR baseline very computationally expensive on the Wiki-category and Web search document collec-

Table 4: CHARM$_{\text{KNRM}}$'s top 10 terms per label for *profession* attribute, compared with TextRank keywords.

tions, which contain 4,000-12,000 documents. In order to run the baseline on these collections, we sample three documents per label; even with this change, BERT IR is 60x slower than CHARM. More details on the models' running time are in Appendix B. We use the full document collection with Wiki-page.

For the *seen* experimental setup, we compare CHARM with both state-of-the-art supervised approaches for inferring attribute values and a fine-tuned supervised BERT model that performs classification using its `[CLS]` representation. The Hidden Attribute Model (HAM$_{\text{2attn}}$) (Tigunova et al., 2019) is an attention-based neural classification model for inferring users' attribute values. N-GrAM (Basile et al., 2017) is a SVM classifier with n-gram features. W2V-C (Preoţiuc-Pietro et al., 2015) is a Gaussian Process (GP) classifier with embedding clusters as features. Finally, we include a neural CNN-based model (Bayot and Gonçalves, 2018). In this setup the baseline models are single-value, therefore, we split every multi-value user into several inputs through all their attribute values.

Evaluation metrics. Given the difficulty of inferring the correct attribute values for an attribute with many possible values, ranking metrics are the most informative and have been used in prior work (Tigunova et al., 2019; Preoţiuc-Pietro et al., 2015). We consider MRR (Mean Reciprocal Rank) and nDCG (normalized Discounted Cumulative Gain). Given that MRR assumes there is only one correct attribute value for each user, we calculate MRR independently for each attribute value before averaging. We average nDCG over users.

6 Results and Discussion

6.1 Quantitative Results

***Unseen* values (zero-shot mode).** The models' performance evaluated only on values that were not observed during training is shown in Table 2. Both CHARM variants significantly outperform all unsupervised keyword-extraction baselines for both attributes on all document collections. This suggests the importance of training the cue detector to identify terms related to the attribute, instead of

	hobby					
	baking (MRR=0.46, #sample=64)		**quilting** (MRR=0.26, #sample=27)		**model aircraft** (MRR=0.11, #sample=2)	
CHARM	cake	bread	sewing	way	cat	dimensions
	food	cream	quilting	game	plane	pilots
	recipe	cooking	quilt	metal	construction	song
	cheese	pasta	fabric	design	planes	steam
	baking	cook	music	playing	energy	music
TextRank	thanks	things	thanks	today	thanks	work
	first	work	first	science	german	elyrion
	amp	food	things	kids	steam	time
	people	time	people	time	tapjoy	purchase
	recipes	second	amp	lots	motorola	air

Table 5: CHARM$_{\text{KNRM}}$'s top 10 terms per label for *hobby* attribute, compared with TextRank keywords.

the more general keywords usually given by unsupervised keyword extractors. BERT IR performs similarly to CHARM for the Wiki-page dataset, but performs significantly worse for the remaining datasets while taking approximately 60x longer than CHARM$_{\text{KNRM}}$ to perform inference.

For both attributes, CHARM$_{\text{KNRM}}$ always outperforms the BM25 variant with Wiki-category and Web search collections. This may be related to the size of document collections which allow for more variations in the vocabularies that are captured well by embeddings with KNRM. Another observation is that for CHARM$_{\text{KNRM}}$, while Web search yields the best result for *profession*, Wiki-category is the best collection for *hobby*, possibly due to the noisy hobby-related documents from web search. CHARM$_{\text{BM25}}$ on Wiki-page does not require any additional inputs and consistently performs as well as or better than the baselines across both attributes. Wiki-category performs significantly better than all baselines for both attributes, making it a reasonable choice when Wikipedia categories are available.

To demonstrate that the collections are resilient to inaccuracies in their automatic construction, we conducted an experiment where some percentage of the documents' attribute values were randomly changed. We found that randomly changing 20% of the documents' labels resulted in approximately a 15% MRR decrease for CHARM$_{\text{KNRM}}$ on Web-search and Wiki-category. The performance decrease on these collections was roughly linear. This indicates that noise in the document collection does not severely damage CHARM's performance.

Seen **values (supervised mode).** In this experiment we evaluate CHARM's performance in the fully supervised setting (i.e., all labels are seen during training). In Table 3 we observe that CHARM's performance is competitive compared to HAM$_{\text{2attn}}$ (i.e., the best-performing attribute value prediction method from prior work) and the state-of-the-art BERT model. The fully supervised BERT model consistently performs the best for both attributes, though these increases are not statistically significant over all CHARM configurations. Furthermore, BERT and HAM$_{\text{2attn}}$ are trained with full supervision in this experimental setting, whereas CHARM still uses a policy gradient. In this experiment, the Web search collection consistently performs best, suggesting that the collection's shortcomings are mitigated when all labels are observed.

6.2 Qualitative Analysis

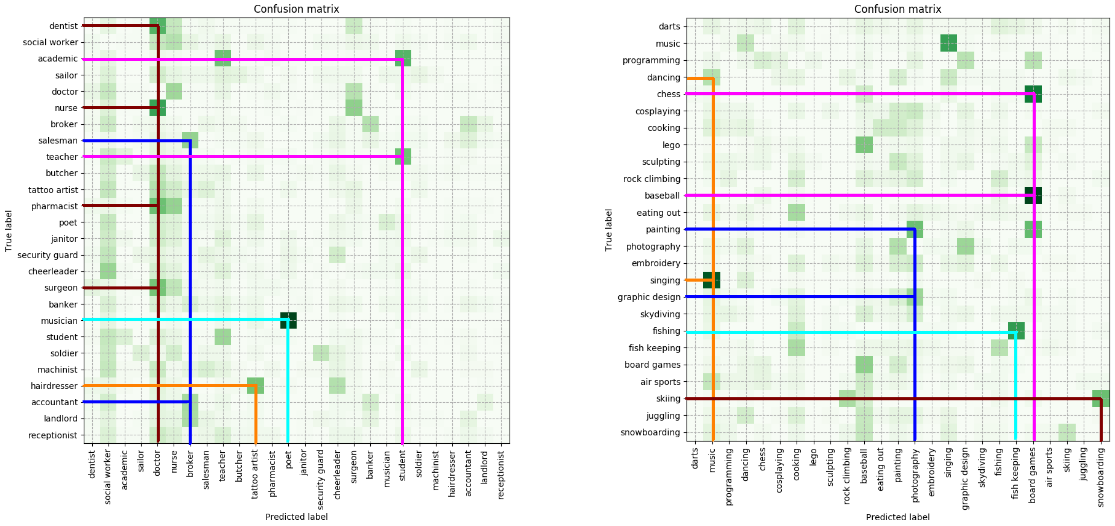
Analysis of selected terms For each attribute value, we gathered all query terms that were selected for the users predicted as having the attribute value, together with the scores given by the cue detector. We then averaged the scores for each term within an attribute value, and selected top 10 terms as the representative ones. Terms were extracted using CHARM$_{\text{KNRM}}$ with Wiki-category on *unseen* experiments. We performed the same method for TextRank keywords, because this was the best performing keyword-based baseline in the *unseen* experiments. The comparison of selected terms by CHARM vs TextRank is reported in Table 4 and Table 5 for selected attribute values of *profession* and *hobby*, respectively.

We can observe that, regardless of the small sample size for some values like *airplane pilot*, CHARM can still detect meaningful words. For *barista*, CHARM did not even consider the term 'barista', but rather focuses on words such as 'coffee' and 'starbucks'. Choosing terms like 'screenplay', 'scripts' and 'screenwriting' helps the model to distinguish *screenwriter* from other film-related professions like *director*.

Picking the terms like 'cake', 'baking' and 'bread', helps the model to distinguish between *baking* and *cooking* hobbies more effectively. Note, that even for rare unusual hobbies like *quilting*, CHARM manages to pick indicative terms. This essentially shows that the model can easily be used for large lists of attribute values, with long tail.

Finally, as opposed to CHARM, TextRank keywords rarely make sense. This suggests that unsupervised keyword detectors are not capable of producing useful attribute-value-related keywords from users' utterances.

Misclassification Study To conduct error analysis,



(a) *profession* (b) *hobby*

Figure 3: Confusion matrix for *profession* and *hobby* with CHARM$_{\text{KNRM}}$ on *unseen* experiments, with some values removed for brevity. Unseen values are aggregated across folds. Darker cells indicate more misclassifications. The lines illustrate misclassifications of interest.

profession		***hobby***	
firefighter (MRR=0.46)	**investor** (MRR=0.52)	**knitting** (MRR=0.68)	**ice hockey** (MRR=0.68)
Firefighter	Index_fund	Yarn_over	Extra_attacker
Firefighter_assist_and_search_team	Venture_capital	Brioche_knitting	Ice_hockey_rules
Calvert_County_Fire-Rescue-EMS	Treasury_management	Combined_knitting	Neutral_zone_trap
Firefighter_arson	Buy_side	Flat_knitting	Playoff_beard
Fire_captain	Sovereign_wealth_fund	Tunisian_crochet	Line_(ice_hockey)

Table 6: CHARM$_{\text{KNRM}}$'s top 5 retrieved documents per attribute value.

we plotted confusion matrices of CHARM$_{\text{KNRM}}$ on *unseen* experiments, which are shown in Figure 3a and 3b for *profession* and *hobby*, respectively.

We observe that medical professions such as *dentist, nurse, pharmacist* and *surgeon* are often confused to *doctor* in general. Professions associated with studying (*academic, teacher* and *student*), beauty (*hairdresser* and *tattoo artist*) and art (*musician* and *poet*) are often confused with each other. *Salesman* and *accountant* are confused to *broker*, because of the common financial terms used.

Hobbies associated with music (*dancing, singing* and *music*) and images (*painting*, *graphic design* and *photography*) are often mixed up. Hobbies in which the term 'game' is profusely used like *chess* and *baseball* are confused to *board games*; similarly, *fishing* and *fish keeping*, as well as *skiing* and *snowboarding* are confused due to the common lexicon used.

Analysis of top ranked documents For each attribute value, we collected all documents that were returned for a user with the given value as the ground-truth label. We then averaged the scores for each page and select the top 5 retrieved pages from Wiki-category, shown in Table 6 for selected *profession* and *hobby* attribute values.

It is interesting to observe, that in spite of the common lexicon for some similar values, the model manages to retrieve documents which are relevant to a particular value, e.g., documents for *investor* are distinct from other financial-related professions, like *broker* or *salesman*. It is also worth mentioning that the retrieved pages for *investor* and *ice hockey* are rather the pages for related lexicon (*venture capital*, *playoff beard*), which shows the power of CHARM's cue detection.

7 Conclusion

We presented the CHARM method for inferring personal traits from conversations. CHARM differs from prior work by its zero-shot ability to predict attribute values that are not present in the training samples at all. We demonstrated the viability of CHARM for inferring users' unseen attribute values by comprehensive experiments with Reddit conversations, leveraging document collections from Wikipedia and web search results for CHARM's retrieval component.

Appendices

A Data

All datasets used in the experiments are available at `https://github.com/Anna146/CHARM`. We provide IDs and texts of the posts used as training and test data for CHARM. All users are anonymized by replacing usernames with IDs. Additionally, we provide the posts containing explicit personal assertions, which have been used for ground truth labeling with the Snorkel framework.

A.1 Labeling users' utterances with Snorkel

Our data consists of submissions on Reddit, which are: *(1)* authored by users having 10-50 posts, *(2)* 10-40 words long, and *(3)* containing a personal pronoun (except for 3rd person ones. Requirements *(1)* and *(2)* were derived from observing the distributions on the full dataset. Requirement *(3)* comes from the assumption that posts containing personal pronouns are most likely to contain personal assertions. These restrictions allow us to select posts that look more similar to the real conversation (i.e., relatively short and containing references to the speakers with personal pronouns). In addition, we did not consider the following subreddit types: *(i) dating*, which may provide plenty of personal information but no real conversation to infer from, and *(ii) fantasy/video games* (for the *profession* attribute), because users may refer to gaming personalities. We took only users whose utterances contain at least one mention of attribute values, resulting in around 250K and 500K candidate users for profession and hobby, respectively.

We used the Snorkel framework (Ratner et al., 2017) that allows data labeling using weak supervision, relying on the inference that combines multiple *labeling functions*, which are manually specified and can be potentially noisy. Given a user's utterance set U, an attribute a and a possible attribute value v, Snorkel will decide on *positive/negative* label–denoting the user as having/not having personal trait $a{:}v$–or *abstain* label. We have separate labeling models for each attribute a, and defined two labeling functions which consider: *(LF1)* the existence of *attribute-specific patterns*, and *(LF2)* the weighted count of the words belonging to the *value-specific lexicon*.

LF1: Attribute-specific patterns. We compiled a list of positive and negative patterns for each attribute (see Table 7), e.g., *"my hobby is ⟨hobby-value⟩"* vs *"I hate ⟨hobby-value⟩"* as positive vs negative patterns for hobby. LF1 labels a user with a *positive/negative* label for each attribute value v if there exist at least one positive/negative pattern in the user's utterances U, and *abstain* otherwise.

LF2: Value-specific lexicon. For each attribute-value pair, we used *Empath* (Fast et al., 2016)–pre-trained on the Reddit corpus–to build a lexicon of *typical words* (e.g., 'cider' and 'yeast' for *hobby:brewing*). Given seed words, Empath builds lexical categories by means of an embedding model. As our value-specific lexicon, we took the union of Empath terms for a specific attribute value and all its synonyms; each typical word is weighted by embedding similarity to the seed words. Given a user's utterance set U and an attribute value v, LF2 yields a *positive* label if the weighted count of typical words of v is above an empirically-chosen threshold, and *abstain* otherwise.

Given a pair of user's utterance set U and a possible attribute value v, the Snorkel probabilistic labeling model utilizes our labeling functions to predict a confidence score for the *positive* label, i.e., the user is labeled with attribute value v. As our labeled dataset, we took only the user-value pairs with confidence scores above a specific threshold.

To determine the threshold of confidence scores, we manually annotated a held-out validation set containing 100 users per attribute. Given a post and a set of attribute values mentioned explicitly in the post, the annotators must identify whether the candidate user traits truly hold. For instance, from *"My dad bought me a* ***chess*** *board even though I enjoy* ***video games*** *more"*, *hobby:video games* is correct while *hobby:chess* is not applicable. The final annotation for each post consists of attribute values agreed by at least two out of three judges. The selected confidence threshold corresponds to the 0.9 precision of the model on the validation set. After thresholding, we obtained 13.5k users labeled with profession values and 11.7k users with hobby values.

Finally, for practical reasons, for each attribute we sorted the labeled users by confidence scores and cropped the set to maximum 500 users per attribute value and 6000 users in total. Note that users might have multiple values for each attribute (e.g., having *brewing* and *swimming* as hobbies); there are 605 such users for profession and 245 for hobby.

	positive	**negative**
profession	i am/i'm a(n) my profession is i work as my job is my occupation is i regret becoming a(n)	(no/not/don't within pos. patterns)
hobby	i am/i'm obsessed with i am/i'm fond of i am/i'm keen on i like i enjoy i love i play i take joy in i adore i appreciate i am/i'm fan of i am/i'm fascinated by i am/i'm interested in i fancy i am/i'm mad about i practise i am/i'm into i am/i'm sucker for my interest is my hobby is my passion is my obsession is	i hate i dislike i detest i can't stand (never/not/don't within pos. patterns)

Table 7: Positive and negative patterns used in the labeling function LF1 of the Snorkel labeling model. Each pattern must be followed by possible attribute values within a context window of 2 terms.

B Training details and hyperparameters

In our experiments we used the server with 32 cores (2x Intel Xeon Gold 6242, 16C/32T 22MB) and 2 GPU NVIDIA Corporation GV100 [Tesla V100]. On this server the running time of our models was fast, compared to the baseline BERT IR architecture as shown in Table 8. BERT IR inference is slow because for a single utterance-document pair it makes several passes through BERT for each chunk combination, which is repeated for every document. CHARM runs BERT once on each utterance only, independent of the number of documents. Using BM25 as a ranker is slower because it requires iteration through the query-document inputs to calculate term frequencies, whereas KNRM uses efficient vectorized representations of the inputs. However, it is possible to speed up BM25 inference, by providing a precomputed inverted index.

	train (10.000 instances)	**test** (100 instances)
$\text{CHARM}_{\text{KNRM}}$	31.8	1.2
$\text{CHARM}_{\text{BM25}}$	54.4	10.9
BERT IR	56.2	72.7

Table 8: Running time of the models given in minutes. The train time is a sum of the times across all training epochs, all times are averaged across folds in the unseen experiment.

The numbers of parameters in $\text{CHARM}_{\text{KNRM}}$ model are shown in Table 9. We used manual tuning to search for the hyperparameters, running about 280 search trials per attribute and collection combination. Several hyperparameters were fixed across different setups (across attributes, document collections and rankers) and some we tuned to each setup individually. The bounds for each hyperparameter and the best parameters are in Tables 11, 10. The best parameters were chosen based on the MRR score. Additionally we performed some experiments on changing the policy gradient training setup, adding discounting factor to the reward after each sampled query term and changing the reward from nDCG to MRR. We found that the results after these modifications did not significantly change.

	Number of parameters (e+3)
BERT embeddings	23,832.6
word2vec embeddings	882,366
BERT parameters	43,118.6
KNRM parameters	0.4

Table 9: Number of model parameters. $\text{CHARM}_{\text{KNRM}}$ uses all parameters mentioned in the table, while $\text{CHARM}_{\text{BM25}}$ and BERT IR use only parameters related to BERT.

Parameter	**Options**	***hobby***						***profession***					
		CHARM$_{\text{BM25}}$			CHARM$_{\text{KNRM}}$			CHARM$_{\text{BM25}}$			CHARM$_{\text{KNRM}}$

Event Detection: Gate Diversity and Syntactic Importance Scores for Graph Convolution Neural Networks

Viet Dac Lai[1]**, Tuan Ngo Nguyen**[1] **and Thien Huu Nguyen**[1,2]

Abstract

Recent studies on event detection (ED) have shown that the syntactic dependency graph can be employed in graph convolution neural networks (GCN) to achieve state-of-the-art performance. However, the computation of the hidden vectors in such graph-based models is agnostic to the trigger candidate words, potentially leaving irrelevant information for the trigger candidate for event prediction. In addition, the current models for ED fail to exploit the overall contextual importance scores of the words, which can be obtained via the dependency tree, to boost the performance. In this study, we propose a novel gating mechanism to filter noisy information in the hidden vectors of the GCN models for ED based on the information from the trigger candidate. We also introduce novel mechanisms to achieve the contextual diversity for the gates and the importance score consistency for the graphs and models in ED. The experiments show that the proposed model achieves state-of-the-art performance on two ED datasets.

1 Introduction

Event Detection (ED) is an important task in Information Extraction of Natural Language Processing. The main goal of this task is to identify event instances presented in text. Each event mention is associated with a word or a phrase, called an event trigger, which clearly expresses the event (Walker et al., 2006). The event detection task, precisely speaking, seeks to identify the event triggers and classify them into some types of interest. For instance, consider the following sentences:

(1) *They'll be* ***fired*** *on at the crossing.*

(2) *She is on her way to get* ***fired****.*

An ideal ED system should be able to recognize the two words "*fired*" in the sentences as the triggers of the event types "Attack" (for the first sentence) and "End-Position" (for the second sentence).

The dominant approaches for ED involve deep neural networks to learn effective features for the input sentences, including separate models (Chen et al., 2015) and joint inference models with event argument prediction (Nguyen and Nguyen, 2019). Among those deep neural networks, graph convolutional neural networks (GCN) (Kipf and Welling, 2017) have achieved state-of-the-art performance due to the ability to exploit the syntactic dependency graph to learn effective representations for the words (Nguyen and Grishman, 2018; Liu et al., 2018; Yan et al., 2019). However, two critical issues should be addressed to further improve the performance of such models.

First, given a sentence and a trigger candidate word, the hidden vectors induced by the current GCN models are not yet customized for the trigger candidate. As such, the trigger-agnostic representations in the GCN models might retain redundant/noisy information that is not relevant to the trigger candidate. As the trigger candidate is the focused word in the sentence, that noisy information might impair the performance of the ED models. To this end, we propose to filter the noisy information from the hidden vectors of GCNs so that only the relevant information for the trigger candidate is preserved. In particular, for each GCN layer, we introduce a gate, computed from the hidden vector of the trigger candidate, serving as the irrelevant information filter for the hidden vectors. Besides, as the hidden vectors in different layers of GCNs tend to capture the contextual information at different abstract levels, we argue that the gates for the different layers should also be regulated to exhibit such abstract representation distinction. Hence, we additionally introduce a novel regularization term for the overall loss function to achieve these distinctions for the gates.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5405–5411,
November 16–20, 2020.

Second, the current GCN models fail to consider the overall contextual importance scores of every word in the sentence. In previous GCN models, to produce the vector representation for the trigger candidate word, the GCN models mostly focus on the closest neighbors in the dependency graphs (Nguyen and Grishman, 2018; Liu et al., 2018). However, although the non-neighboring words might not directly carry useful context information for the trigger candidate word, we argue that their overall importance scores/rankings in the sentence for event prediction can still be exploited to provide useful training signals for the hidden vectors in ED. In particular, we propose to leverage the dependency tree to induce a **graph-based** importance score for every word based on its distance to the trigger candidate. Afterward, we propose to incorporate such importance scores into the ED models by encouraging them to be consistent with another set of **model-based** importance scores that are computed from the hidden vectors of the models. Based on this consistency, we expect that graph-based scores can enhance the representation learning for ED. In our experiments, we show that our method outperforms the state-of-the-art models on the benchmark datasets for ED.

2 Related Work

Prior studies on ED involve handcrafted feature engineering for statistical models (Ahn, 2006; Ji and Grishman, 2008; Hong et al., 2011; Li et al., 2013; Mitamura et al., 2015) and deep neural networks, e.g., CNN (Chen et al., 2015, 2017; Nguyen and Grishman, 2015; Nguyen et al., 2016g), RNN (Nguyen et al., 2016; Jagannatha and Yu, 2016; Feng et al., 2016), attention mechanism (Liu et al., 2017; Chen et al., 2018), contextualized embeddings (Yang et al., 2019), and adversarial training (Wang et al., 2019). The last few years witness the success of graph convolutional neural networks for ED (Nguyen and Grishman, 2018; Liu et al., 2018; Veyseh et al., 2019; Yan et al., 2019) where the dependency trees are employed to boost the performance. However, these graph-based models have not considered representation regulation for GCNs and exploiting graph-based distances as we do in this work.

3 Model

Task Description: The goal of ED consists of identifying trigger words (**trigger identification**) and classifying them for the event types of interest (**event classification**). Following the previous studies (Nguyen and Grishman, 2015), we combine these two tasks as a single multi-way classification task by introducing a *None* class, indicating non-event. Formally, given a sentence $X = [x_1, x_2, \dots, x_n]$ of n words, and an index t ($1 \leq t \leq n$) of the trigger candidate x_t, the goal is to predict the event type y^* for the candidate x_t. Our ED model consists of three modules: (1) Sentence Encoder, (2) GCN and Gate Diversity, and (3) Graph and Model Consistency.

Sentence Encoder: We employ the pre-trained BERT (Devlin et al., 2019) to encode the given sentence X. In particular, we create an input sequence of $[[CLS], x_1, \cdots, x_n, [SEP], x_t, [SEP]]$ where $[CLS]$ and $[SEP]$ are the two special tokens in BERT. The word pieces, tokenized from the words, are fed to BERT to obtain the hidden vectors of all layers. We concatenate the vectors of the top M layers to obtain the corresponding hidden vectors for each word piece, where M is a hyper-parameter. Then, we obtain the representation of the sentence $E = \{e_1, \cdots, e_n\}$ in which the vectors e_i of x_i is the average of layer-concatenated vectors of its word pieces. Finally, we feed the embedding vectors in E to a bidirectional LSTM, resulting in a sequence of hidden vectors $h^0 = \{h^0_1, \cdots, h^0_n\}$.

GCN and Gate Diversity: To apply the GCN model, we first build the sentence graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ for X based on its dependency tree, where $\mathcal{V}, \mathcal{E}$ are the sets of nodes and edges, respectively. $\mathcal{V}$ has n nodes, corresponding to the n words X. Each edge (x_i, x_j) in $\mathcal{E}$ amounts to a directed edge from the head x_i to the dependent x_j in the dependency tree. Following (Marcheggiani and Titov, 2017), we also include the opposite edges of the dependency edges and the self-loops in $\mathcal{E}$ to improve the information flow in the graph.

Our GCN module contains L stacked GCN layers (Kipf and Welling, 2017), operating over the sequence of hidden vectors h^0. The hidden vector h^l_i ($1 \leq i \leq n, 1 \leq l \leq L$) of the word x_i at the l-th layer is computed by averaging the hidden vectors of neighboring nodes of x_i at the $(l-1)$-th layer. Formally, h^l_i is computed as follow:

$$h^l_i = \text{ReLU}\left(W^l \sum_{(x_i,x_j)\in\mathcal{E}} \frac{h^{l-1}_j}{|\{x_j\}|}\right) \quad (1)$$

where W^l is a learnable weight of the GCN layer.

The major issue of the current GCN for ED is that its hidden vectors h_i^l are induced without special awareness of the trigger candidate x_t. This might result in irrelevant information (for the trigger word candidate) in the hidden vectors of GCNs for ED, thus hindering further performance improvement. To address this problem, we propose to filter that unrelated information by introducing a gate for each GCN layer. The vector g^l for the gate at the l-th layer is computed from the embedding vector e_t of the trigger candidate: $g^l = \sigma(W_g^l e_t)$ where W_g^l are learnable parameters for the l-th layer. Then, we apply these gates over the hidden vectors of the corresponding layer via the element-wise product, resulting in the filtered vectors: $m_i^l = g^l \circ h_i^l$.

As each layer in the GCN module has access to a particular degree of neighbors, the contextual information captured in these layers is expectedly distinctive. Besides, the gates for these layers control which information is passed through, therefore, they should also demonstrate a certain degree of contextual diversity. To this end, we propose to encourage the distinction among the outcomes of these gates once they are applied to the hidden vectors in the same layers. Particularly, starting with the hidden vectors h^l of of the l-layer, we apply the gates g^k (for all $(1 \leq k \leq L)$) to the vectors in h^l, which results in a sequence of filtered vectors $\bar{m}_i^{k,l} = g^k \circ h_i^l$. Afterward, we aggregate the filtered vectors obtained by the same gates using max-pooling: $\bar{m}^{k,l} = \text{max\_pool}(\bar{m}_1^{k,l}, \cdots, \bar{m}_n^{k,l})$. To encourage the gate diversity, we enforce vector separation between $\bar{m}^{l,l}$ with all the other aggregated vectors from the same layer l (i.e., $\bar{m}^{k,l}$ for $k \neq l$). As such, we introduce the following cosine-based regularization term $\mathcal{L}_{GD}$ (for Gate Diversity) into the overall loss function:

$$\mathcal{L}_{GD} = \frac{1}{L(L-1)} \sum_{l=1}^{L} \sum_{k=l+1}^{L} \text{cosine}(\bar{m}^{l,l}, \bar{m}^{l,k}) \quad (2)$$

Note that the rationale for applying the gates g^k to the hidden vectors h^l for the gate diversity is to ground the control information in the gates to the contextual information of the sentence in the hidden vectors to facilitate meaningful context-based comparison for representation learning in ED.

Graph and Model Consistency: As stated above, we seek to supervise the model using the knowledge from the dependency graph. Inspired by the contextual importance of the neighboring words for the event prediction of the trigger candidate x_t, we compute the **graph-based importance scores** $P = p_1, \cdots, p_n$ in which p_i is the negative distance from the word x_i to the trigger candidate.

In contrast, the model-based importance scores for each word x_i is computed based on the hidden vectors of the models. In particular, we first form an overall feature vector V_t that is used to predict the event type for x_t via:

$$V_t = [e_t, m_t^L, \text{max\_pool}(m_1^L, \cdots, m_n^L)]$$

In this work, we argue that the hidden vector of an important word in the sentence for ED should carry more useful information to predict the event type for x_t. Therefore, we consider a word x_i as more important for the prediction of the trigger candidate x_t if its representation m_i^L is more similar to the vector V_t. We estimate the **model-based important scores** for every word x_i with respect to the candidate x_t as follow:

$$q_i = \sigma(W^v V_t) \cdot \sigma(W^m m_i^L) \quad (3)$$

where W^v and W^m are trainable parameters.

Afterward, we normalize the scores P and $Q = q_1, \ldots, q_n$ using the softmax function. Finally, we minimize the KL divergence between the graph-based important scores P and the model-based importance scores Q by injecting a regularization term $\mathcal{L}_{ISC}$ (for the graph-model Importance Score Consistency) into the overall loss function:

$$\mathcal{L}_{ISC}(P, Q) = -\sum_{i=1}^{n} p_i \frac{p_i}{q_i} \quad (4)$$

To predict the event type, we feed V_t into a fully connected network with softmax function in the end to estimate the probability distribution $P(\hat{y}|X, t)$. To train the model, we use the negative log-likelihood as the classification loss $\mathcal{L}_{CE} = -\log P(y^*|X, t)$. Finally, we minimize the following combined loss function to train the proposed model:

$$\mathcal{L} = \mathcal{L}_{CE} + \alpha \mathcal{L}_{GD} + \beta \mathcal{L}_{ISC} \quad (5)$$

where α and β are trade-off coefficients.

4 Experiments

Datasets: We evaluate our proposed model (called GatedGCN) on two ED datasets, i.e., ACE-2005 and Litbank. **ACE-2005** is a widely used benchmark dataset for ED, which consists of 33 event types. In contrast, **Litbank** is a newly published dataset in the literature domain, annotating words with two labels *event* and *none-event* (Sims et al., 2019). Hence, on Litbank, we essentially solve trigger identification with a binary classification problem for the words.

As the sizes of the ED dataset are generally small, the pre-processing procedures (e.g., tokenization, sentence splitting, dependency parsing, and selection of negative examples) might have a significant effect on the models' performance. For instance, the current best performance for ED on ACE-2005 is reported by (Yang et al., 2019) (i.e., 80.7% F1 score on the test set). However, once we re-implement this model and apply it to the data version pre-processed and provided by the prior work (Nguyen and Grishman, 2015, 2018), we are only able to achieve an F1 score of 76.2% on the test set. As the models share the way to split the data, we attribute such a huge performance gap to the difference in data pre-processing that highlights the need to use the same pre-processed data to measure the performance of the ED models. Consequently, in this work, we employ the exact data version that has been pre-processed and released by the early work on ED for ACE-2005 in (Nguyen and Grishman, 2015, 2018) and for Litbank in (Sims et al., 2019).

The hyper-parameters for the models in this work are tuned on the development datasets, leading to the following selected values: one layer for the BiLSTM model with 128 hidden units in the layers, $L = 2$ for the number of the GCN layers with 128 dimensions for the hidden vectors, 128 hidden units for the layers of all the feed-forward networks in this work, and $5e$-5 for the learning rate of the Adam optimizer. These values apply for both the ACE-2005 and Litbank datasets. For the trade-off coefficients α and β in the overall loss function, we use $\alpha = 0.1$ and $\beta = 0.2$ for the ACE dataset while $\alpha = 0.3$ and $\beta = 0.2$ are employed for Litbank. Finally, we use the case $\text{BERT}_{\text{base}}$ version of BERT and freeze its parameters during training in this work. To obtain the BERT representations of the word pieces, we use $M = 12$ for ACE-2005 and $M = 4$ for Litbank (Sims et al., 2019).

Results: We compare our model with two classes of baselines on ACE-2005. The first class includes the models with non-contextualized embedding, i.e., **CNN**: a CNN model (Nguyen and Grishman, 2015), **NCNN**: non-consecutive CNN model: (Nguyen and Grishman, 2016), and **GCN-ED**: a GCN model (Nguyen and Grishman, 2018). Note that these baselines use the same pre-processed data like ours. The second class of baselines concern the models with the contextualized embeddings, i.e., **DMBERT**: a model with dynamic pooling (Wang et al., 2019) and **BERT+MLP**: a MLP model with BERT (Yang et al., 2019). These models currently have the best-reported performance for ED on ACE-2005. Note that as these works employ different pre-processed versions of ACE-2005, we re-implement the models and tune them on our dataset version for a fair comparison. For Litbank, we use the following baselines reported in the original paper (Sims et al., 2019): **BiLSTM**: a BiLSTM model with `word2vec`, **BERT+BiLSTM**: a BiLSTM model with BERT, and **DMBERT** (Wang et al., 2019).

Model	**P**	**R**	**F**
CNN	71.8	66.4	69.0
NCNN	-	-	71.3
GCN-ED	77.9	68.8	73.1
DMBERT	79.1	71.3	74.9
BERT+MLP	77.8	74.6	76.2
GatedGCN (Ours)	78.8	76.3	**77.6**

Table 1: Performance on the ACE-2005 test set.

Table 1 presents the performance of the models on the ACE-2005 test set. This table shows that GatedGCN outperforms all the baselines with a significant improvement of 1.4% F1-score over the second-best model BERT+MLP. In addition, Table 2 shows the performance of the models on the Litbank test set. As can be seen, the proposed model is better than all the baseline models with 0.6% F1-score improvement over the state-of-the-art model BERT+BiLSTM. These improvements are significant on both datasets ($p < 0.05$), demonstrating the effectiveness of GatedGCN for ED.

Ablation Study: The proposed model involves three major components: (1) the **Gates** to filter irrelevant information, (2) the Gate **Diversity** to encourage contextual distinction for the gates, and (3) the **Consistency** between graph and model-based importance scores. Table 3 reports the ablation study on the ACE-2005 development set when the components are incrementally removed from the full model (note that eliminating **Gate** also removes **Diversity** at the same time). As can be seen,

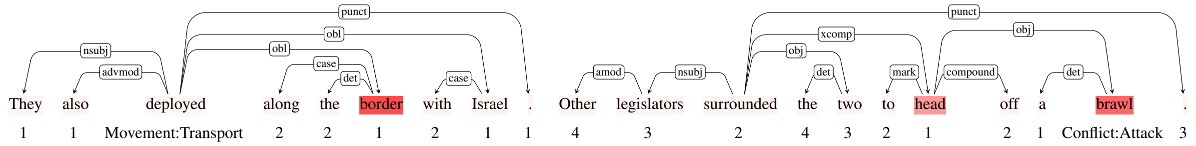

Figure 1: Visualization of the model-based importance scores computed by the proposed model for several GatedGCN-successful examples. The words with bolder colors have larger importance scores in this case. Note that the golden event types "*Movement:Transport*" and "*Conflict:Attack*" are written under the trigger words in the sentences. Also, below each word in the sentences, we indicate the number of the words along the path from that word to the trigger word (i.e., the distances used in the graph-based importance scores).

Model	**P**	**R**	**F**
BiLSTM	70.4	60.7	65.2
+ document context	74.2	58.8	65.6
+ sentence CNN	71.6	56.4	63.1
+ subword CNN	69.2	64.8	66.9
DMBERT	65.0	76.7	70.4
BERT+BiLSTM	75.5	72.3	73.9
GatedGCN (Ours)	69.9	79.8	**74.5**

Table 2: Performance on the Litbank test set.

Model	**P**	**R**	**F**
GatedGCN (full)	76.7	70.5	**73.4**
-Diversity	78.5	67.0	72.3
-Consistency	80.5	64.7	71.7
-Diversity -Consistency	79.0	63.0	70.1
-Gates	77.8	65.3	71.3
-Gates -Consistency	83.0	62.5	71.0

Table 3: Ablation study on the ACE-2005 dev set.

excluding any component results in significant performance reduction, clearly testifying to the benefits of the three components in the proposed model for ED.

Importance Score Visualization: In order to further demonstrate the operation of the proposed model GatedGCN for ED, we analyze the model-based importance scores for the words in test set sentences of ACE-2005 that can be correctly predicted by GatedGCN, but leads to incorrect predictions for the ablated model "-Gate-Consistency" in Table 3 (called the GatedGCN-successful examples). In particular, Figure 1 illustrates the model-based importance scores for the words in the sentences of several GatedGCN-successful examples. Among others, we find that although the trigger words are directly connected to several words (including the irrelevant ones) in these sentences, the **Gates**, **Diversity**, and **Consistency** components in GatedGCN help to better highlight the most informative words among those neighboring words by assigning them larger importance scores. This enables the representation aggregation mechanism in GCN to learn better hidden vectors, leading to improved performance for ED in this case.

5 Conclusion

We demonstrate how gating mechanisms, gate diversity, and graph structure can be used to integrating syntactic information and improve the hidden vectors for ED models. The proposed model achieves state-of-the-art performance on two ED datasets. In the future, we plan to apply the proposed model for the related tasks and other settings of ED, including new type extension (Nguyen et al., 2016b; Lai and Nguyen, 2019), and few-shot learning (Lai et al., 2020a,b).

Abstract

In this paper, we propose a neural architecture and a set of training methods for ordering events by predicting temporal relations. Our proposed models receive a pair of events within a span of text as input and they identify temporal relations (*Before*, *After*, *Equal*, *Vague*) between them. Given that a key challenge with this task is the scarcity of annotated data, our models rely on either pretrained representations (i.e. RoBERTa, BERT or ELMo), transfer and multi-task learning (by leveraging complementary datasets), and self-training techniques. Experiments on the MATRES dataset of English documents establish a new state-of-the-art on this task.

1 Introduction

The task of temporal ordering of events involves predicting the temporal relation between a pair of input events in a span of text (Figure 1). This task is challenging as it requires deep understanding of temporal aspects of language and the amount of annotated data is scarce.

> Albright **(e1, came)** to the State Department to **(e2, offer)** condolences.

Figure 1: Example from the MATRES dataset. The relation between **(e1, came)** and **(e2, offer)** is *Before*. Note that for the same span there may be other relation pairs.

The MATRES dataset (Ning et al., 2018) has become a de facto standard for temporal ordering of events.[1] It contains 13,577 pairs of events annotated with a temporal relation (*Before*, *After*, *Equal*, *Vague*) within 256 **English** documents (and 20 more for evaluation) from TimeBank[2] (Pustejovsky et al., 2003), AQUAINT[3] (Graff, 2002) and Platinum (UzZaman et al., 2013).

In this paper, we present a set of neural architectures for temporal ordering of events. Our main model (Section 2) is similar to the temporal ordering models designed by Goyal and Durrett (2019), Liu et al. (2019a) and Ning et al. (2019).

Our main contributions are: (1) a neural architecture that can flexibly adapt different encoders and pretrained word embedders to form a contextual pairwise argument representation. Given the scarcity of training data, (2) we explore the application of an existing framework for Scheduled Multitask-Learning (henceforth SMTL) (Kiperwasser and Ballesteros, 2018) by leveraging complementary (temporal and non temporal) information to our models; this imitates pretraining and finetuning. This consumes timex information in a different way than Goyal and Durrett (2019). (3) A self-training method that incorporates the predictions of our model and learns from them; we test it jointly with the SMTL method.

Our baseline model that uses RoBERTa (Liu et al., 2019b) already surpasses the state-of-the-art by 2 F1 points. Applying SMTL techniques affords further improvements with at least one of our auxiliary tasks. Finally, our self-training experiments, explored via SMTL as well, establishes yet another state-of-the-art yielding a total improvement of almost 4 F1 points over results from past work.

2 Our Baseline Model

Our pairwise temporal ordering model receives as input a sequence $X_{[0,n)}$ of n tokens

November 16–20, 2020.

(or subword units for BERT-like models) i.e. $\{x_0, x_1, ..., x_{n-1}\}$, representing the input text. A subsequence $span_i$ is defined by $start_i$, $end_i \in [0, n)$. Subsequences $span_1$ and $span_2$ represent the input pair of argument events $e1$ and $e2$ respectively. The goal of the model is to predict the temporal relation between $e1$ and $e2$.

First, the model embeds the input sequence into a vector representation using either static wang2vec representations (Ling et al., 2015), or contextualized representations from ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), or RoBERTa (Liu et al., 2019b). These embedded sequences are then optionally encoded with either LSTMs or Transformers. When BERT or RoBERTa is used to embed the input, we do not use any sequence encoders. The final sequence representation $H_{[0,n)}$ comprises of individual token representations i.e. $\{h_0, h_1, ..., h_{n-1}\}$.

While the goal is to predict the temporal relation between $span_1$ and $span_2$, the context around these two spans also has linguistic signals that connect the two arguments. To use this contextual information, we extract five constituent subsequences from the sequence representation $H_{[0,n)}$: (1) S_1, the subsequence before $span_1$ i.e., $H_{[0,start_1)}$, (2) S_2, the subsequence corresponding to $span_1$ i.e., $H_{[start_1,end_1)}$, (3) S_3, the subsequence between $span_1$ and $span_2$ i.e, $H_{[end_1,start_2)}$, (4) S_4, the subsequence corresponding to $span_2$ i.e., $H_{[start_2,end_2)}$ and (5) S_5, the subsequence after $span_2$, i.e. $H_{[end_2,n)}$. Each of these subsequences S_i has a variable number of tokens which are pooled to yield a fixed size representation s_i:

$$s_i = pool(S_i) \;\; \forall i \in \{1, ..., 5\} \tag{1}$$

where *pool* is the result of concatenating the output of an attention mechanism (we use the *word attention* pooling method (Yang et al., 2016) for all tokens in a given span) and mean pooling.

The final contextual pair representation c is formed by concatenating[4] the five span representations s_i with a sequence representation r. For models with BERT and RoBERTa, r is the CLS and <s> token representation respectively while for other models $r = pool(H_{[0,n)})$.

$$c = s_1 \odot s_2 \odot s_3 \odot s_4 \odot s_5 \odot r \tag{2}$$

This final contextual pair representation c is then projected with a fully connected layer followed by a softmax function to get a distribution over the output classes. The entire model is trained end-to-end using the cross entropy loss.

3 Multi-task Learning

While the model described in the previous section can be directly trained using labeled training data, the amount of annotated training data for this task (in the MATRES dataset) is limited. We enrich our model with useful information from other complementary tasks via SMTL.

3.1 Method

We adapt the framework of Kiperwasser and Ballesteros (2018), where three **schedulers** are used. They follow either a constant, sigmoid or exponential curve $p(t)$, where $p(t)$ is the probability of picking a batch from the main task, t is the amount of data visited so far throughout the training process and α is a hyperparameter. The constant scheduler splits the batches randomly; at any time step, the model will be trained with sentences belonging to either the main task or the auxiliary task ($p^{const}(t) = \alpha, 0 \leq \alpha \leq 1$) . The sigmoid scheduler allows the model to visit batches from both the auxiliary task and the main task at the beginning while the latest updates are always with batches consisting of batches from the main task ($p^{sig}(t) = \frac{1}{1+e^{-\alpha t}}$). The exponential scheduler starts by visiting only the batches from the auxiliary task while the latest updates are always from the main task ($p^{exp}(t) = 1 - e^{-\alpha t}$).

Following past work, we prepend a trained task vector to the encoder to help the model to differentiate between the main and the auxiliary tasks (Ammar et al., 2016; Johnson et al., 2017; Kiperwasser and Ballesteros, 2018, *inter alia*).

3.2 Auxiliary Datasets

We use three different **auxiliary datasets** in our SMTL setup. The first two have a different taxonomy and label set than MATRES, but have gold annotations. The last one is a silver dataset with predicted labels and same taxonomy as MATRES.

Our first dataset is the **ACE relation extraction task**.[5] We hypothesize that this task can add knowledge of different domains and of the concept of linking two spans in text given a taxonomy

Robert F. Angelo, who **(event, left)** Phoenix at **(timex, the beginning of October)**.

Figure 2: Example of an event-timex annotation from the Timex annotations. The relation between **(event, left)** and **(timex, the beginning of October)** is *Is_included*.

of relations. While this is not directly related to events and our farthest task in terms of similarity, the pairwise span classification is the reason we include this.

We also use a closer and complementary temporal annotation dataset, i.e. the **Timebank and Aquaint annotations involving timex relations** (timex-event, event-timex, timex-timex) (Ning et al., 2018; Goyal and Durrett, 2019).[6] We expect the model to greatly benefit from being exposed to the timex relations in an MTL framework by learning about temporality in general and by adding specificity of the event-event temporal relations from the MATRES annotations. Figure 2 shows an example of the data annotated with an event-timex relation.

We use self-training (Scudder, 1965) to generate our third dataset: **a silver dataset**. This requires an unlabeled text, a tagger to extract events from this text, and a classifier to predict temporal relations for pairs of extracted events. As our unlabeled text, we use 6,000 random documents from the CNN / Daily Mail dataset which is a collection of news articles collected between 2007 and 2015 (Hermann et al., 2015). We picked 85K segments of text within these documents that contain between 10 and 40 tokens after tokenization. We train a RoBERTa-based named entity tagger and use it to tag events in these segments.[7] This results in about 65K events. We consider all 285K pairs of events that lie within a segment as candidates for temporal ordering. Finally, we use our baseline RoBERTa temporal model to classify the temporal relation between these candidate pairs and use the top $\frac{2}{3}^{rd}$ most confident classifications based on softmax scores to get about 190K instances of silver relations.

4 Experiments and Results

The MATRES dataset is our primary dataset for training and validation. As in previous work, we use TimeBank and AQUAINT (256 articles) for training, 25 articles of which are selected at random for validation and Platinum (20 articles) as a held-out test set (Ning et al., 2018; Goyal and Durrett, 2019; Ning et al., 2019). Articles from TimeBank and AQUAINT at full length are about 400 tokens long on average. We believe that the document in its entirety is not required to infer the temporality between a given pair of events. Moreover, BERT style models are also often pre-trained for shorter inputs than this. For these reasons, we truncate our input text to a window of sentences[8] starting with one sentence before the first event argument up to and including one sentence after the second event argument.

We use one set of hyperparameters for all LSTM models and another set for all the Transformer models (both with and without ELMo embedder).[9] BERT and/or RoBERTa are loaded as a replacement of the Transformer parameters and they are therefore used both as embedders and encoders. We run our SMTL and self training experiments with our best baseline model on the development data: the RoBERTa model.

For the SMTL experiments, we explore the α hyperparameter, and we pick the one that produces the highest scores in our development data.

Finally, we picked our best SMTL model on the development data (see Table, this is the constant scheduler with silver data) parameters and continue training on the gold data only; we reduce the learning rate to 10^{-6}. This is because the model trained in the first step is already in a good state and we want to avoid distorting it with aggressive updates.

We compare our results (Table 1) with other top performing systems. First, we observe that among models without contextualized representations, the LSTM encoder is 2.5 F1 points better than the Transformer encoder. We observe that replacing static word representations with ELMo representations leads to significantly worse F1 with

---

[6] `http://www.timeml.org/publications/timeMLdocs/timeml_1.2.1.html`.

[7] The tagger is simply a dense layer on top of RoBERTa representation. We evaluate the tagger by using it to tag events in the MATRES validation set. The tagger reaches a F1 score of 89.5 on the MATRES development set.

[8] We use spacy (Honnibal and Montani, 2017) for sentence segmentation of the articles

[9] LSTM models use 2 hidden layers with 256 hidden units each, and a batch size of 64. Transformer models use 1 hidden layer with 128 hidden units, and a batch size of 24. All models are trained using Adam (Kingma and Ba, 2014) with a learning rate of 10^{-5} on an NVIDIA V100 16GB GPU.

Experiment	**Acc**	**F1**

Ning et al. (2019)	71.7	76.7

Table 1: Results, including comparison with the best systems on the MATRES test set (Platinum). Results highlighted in bold are the best in each metric. We report average (and standard deviation) of accuracy and F1 over 5 runs with different random seeds. Given that it does not carry temporal information, we treat the relation VAGUE as a *no relation* for the F1 results as in Ning et al. (2019). For the SMTL experiments, the selected α value is shown between parentheses.

the LSTM encoder, but marginally improves upon the F1 of the Transformer encoder. We attribute this difference to the non-complementary nature of LSTM and ELMo representations, as ELMo is also LSTM-based, and thus the ELMo+LSTM combination might need more training data in order to extract meaningful signals.

Importantly, however, our base model that uses pretrained RoBERTa surpasses the previous state-of-the-art (Ning et al., 2019) which uses BERT. Our BERT models yield very similar results to them. The main differences are that they do not finetune BERT along with the updates to the model, while we do and also, we model the context around the argument spans explicitly as part of S_1, S_3 and S_5. The reason why RoBERTa is better than BERT in this case is likely due to the fact that it has been trained longer, over more data, and over longer sequences. This matters because our temporal ordering model usually takes into account a long span in which both events occur.

The SMTL experiments show that the auxiliary task with timex annotations provides non-negligible improvements of almost 1 F1 point on top of our RoBERTa model. Learning from the timex annotations makes our model more aware of time relations and thus, better at ordering events in time. The sigmoid and exponent schedulers perform better than the constant scheduler, suggesting that the model needs to first learn about temporality, and then learn to be more specialized on predicting temporal ordering relations later. We believe this timex multi-tasking setup to be an implicit yet effective way to teach our model about timexes in general without timex embeddings used in (Goyal and Durrett, 2019). When we use the ACE relation extraction dataset as an auxiliary task, none of the schedulers produce improvements while the sigmoid and exponent scheduler fare significantly worse. This result suggests that if the tasks differ too much, SMTL might not be a helpful strategy.

The self-training experiments (including SMTL with silver data) show that the silver data helps to reach better performance with constant being the best scheduler. Furthermore, fine-tuning of the best model (according to development set score, which in this case it is the same as test set score) on the gold data gives us another boost in performance establishing a new state of the art in the task that is 2.7 F1 points better than our RoBERTa baseline, and almost 4 points better than the previous published results.

5 Conclusions and Future Work

This paper presents neural architectures for ordering events in time. It establishes a new state-of-the-art on the task through pretraining, leveraging complementary tasks through SMTL and self-training techniques.

For the future, instead of using the RoBERTa baseline model for the self-training experiments, we could run several iterations by retraining on the data produced by our best self-trained model(s); this could be a good avenue for further improvements. In addition we plan to extend our work by moving to other languages beyond English (we currently have not tried this due to lack of data) using cross-lingual models, (Subburathinam et al., 2019), applying other architectures like CNNs (Nguyen and Grishman, 2015), incorporating tree structure in our models (Miwa and Bansal, 2016) and/or by handling jointly performing event recognition and temporal ordering (Li and Ji, 2014; Katiyar and Cardie, 2017).

Abstract

It has recently been observed that neural language models trained on unstructured text can implicitly store and retrieve knowledge using natural language queries. In this short paper, we measure the practical utility of this approach by fine-tuning pre-trained models to answer questions *without access to any external context or knowledge*. We show that this approach scales with model size and performs competitively with open-domain systems that explicitly retrieve answers from an external knowledge source when answering questions. To facilitate reproducibility and future work, we release our code and trained models.[1]

1 Introduction

Big, deep neural language models that have been pre-trained on unlabeled text have proven to be extremely performant when fine-tuned on downstream Natural Language Processing (NLP) tasks (Devlin et al., 2018; Yang et al., 2019; Liu et al., 2019; Lan et al., 2019; Raffel et al., 2019). Interestingly, it has also recently been observed that these models can internalize a sort of implicit "knowledge base" after pre-training (Petroni et al., 2019; Jiang et al., 2019; Talmor et al., 2019). This behavior is potentially useful because 1) the knowledge is built up by pre-training on unstructured and unlabeled text data, which is freely available in huge quantities on the Internet (Raffel et al., 2019; Wenzek et al., 2019), and 2) it is possible to retrieve information using informal natural language queries since these pre-trained language models excel when fine-tuned on natural language understanding tasks.

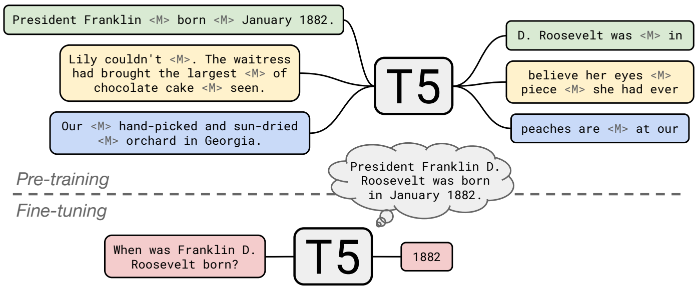

Figure 1: T5 is pre-trained to fill in dropped-out spans of text (denoted by `<M>`) from documents in a large, unstructured text corpus. We fine-tune T5 to answer questions without inputting any additional information or context. This forces T5 to answer questions based on "knowledge" that it internalized during pre-training.

Past work investigating "language models as knowledge bases" has typically tried to understand the scope of the information stored in the model using synthetic tasks that are similar to the pre-training objective (Petroni et al., 2019; Jiang et al., 2019) and/or measure reasoning capabilities (Talmor et al., 2019). In this work, we take a different approach by evaluating the capability of language models on the practical task of open-domain question answering – specifically, we fine-tune the model to answer questions *without access to any external knowledge or context*. To do so, the model must parse a natural language query and "look up information" stored in its parameters.

Most past work on question answering either explicitly feeds pertinent information to the model alongside the question (for example, an article that contains the answer (Rajpurkar et al., 2016; Zhang et al., 2018; Khashabi et al., 2018; Clark et al., 2019)) or allows the model to retrieve information from an external knowledge source (Berant et al., 2013; Chen et al., 2017). By feeding the model the input question alone, we can determine how much knowledge it has stored in its param-

---

[*] Equal contribution. Noam suggested trying T5 on open-domain QA and coded and ran initial experiments on TriviaQA showing improved performance with model size. Adam wrote the code and ran most experiments. Colin set the research scope, wrote the paper, and ran a few experiments.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5418–5426,
November 16–20, 2020.

eters while measuring its performance on a useful real-world problem. We refer to this task as "closed-book question answering".

A separate question we address in this work is whether models with more parameters end up storing more information. It has been shown that transfer learning performance on many downstream tasks tends to improve as the model size and amount of unsupervised pre-training increases (Radford et al., 2019; Liu et al., 2019; Raffel et al., 2019). In this work, we leverage the pre-trained "T5" models released by Raffel et al. (2019), the largest of which has around 11 billion parameters. By measuring knowledge retrieval capabilities on models of various sizes – including models that have an order of magnitude more parameters than considered in past work – we can explore how well our approach scales.

2 Background

Question Answering The task of training a model to either select or output the correct answer to a given question is referred to as "question answering". The most popular variant of this task feeds the model some "context" containing the answer (for example, a paragraph from an encyclopedia article) alongside the question (Rajpurkar et al., 2016; Zhang et al., 2018; Khashabi et al., 2018; Clark et al., 2019). Models can be trained either to indicate the span of the context that contains the answer or output the text of the answer itself. Since this format can be seen as reading some text and answering a question about it, it has been referred to as "reading comprehension".

A more difficult variant is "open-domain question answering" (Prager, 2006), where the model can be asked arbitrary context-independent questions (e.g. well-known facts or historical details). It is typically assumed that the model can access an external collection of knowledge when answering questions (e.g. a structured knowledge base or unstructured text corpus), but the model is not given any information about where in the collection the answer appears. The reading comprehension task can be considered a simplified version of open-domain question answering where the model is provided with the oracle context to answer a given question. As an analogy, the open-domain question answering system acts as if it is taking an **open-book** exam where it can find and use information in an external source of knowledge.[2]

In this work, we consider open-domain question answering with the additional constraint that the model is *not* allowed to access any external knowledge whatsoever when answering questions. Instead, the model itself must be pre-trained to store knowledge in its parameters before being fine-tuned to answer questions. In one view, this can be seen as an alternative way to approach open-domain question answering where instead of learning to access external knowledge the model needs to have "memorized" it in order to answer questions; in another view, this constraint creates a third and potentially more ambitious variant of the question answering task. A model that answers questions in this way is metaphorically similar to a student taking a **closed-book** exam, where the student must study and memorize all pertinent information before taking the test.

Transfer Learning with Language Models In the past few years, it has become increasingly common to pre-train a language model using an unsupervised objective on a large, unstructured text corpus before fine-tuning it on a downstream task of interest (Dai and Le, 2015; Howard and Ruder, 2018; Radford et al., 2018). The popularity of this form of "transfer learning" is attributable to its empirical success on many NLP tasks (Peters et al., 2018; Devlin et al., 2018; Yang et al., 2019; Lan et al., 2019; Raffel et al., 2019). Loosely speaking, the pre-training step may provide the model with some generally-useful awareness of meaning, syntax, and "world knowledge". In question answering in particular, most state-of-the-art systems use some form of transfer learning.

Currently, the most popular model architectures used in transfer learning for NLP are Transformer-based (Vaswani et al., 2017) "encoder-only" models like BERT (Devlin et al., 2018). These models can produce a single prediction for each input token and have been applied to reading comprehension-style question answering by predicting which tokens of the context contain the answer. Encoder-only models are not applicable to closed-book question answering because no context is provided to extract the answer span from. An alternative to encoder-only models, recently advocated by Raffel et al. (2019), is to treat ev-

---

[2] While our definition of open-book is the same as in the OpenBookQA dataset introduced by Mihaylov et al. (2018), we do not directly address multi-hop inference in this work.

ery NLP task as a text-to-text problem using an encoder-decoder Transformer. When this framework is applied to question answering, the model is trained to generate the literal text of the answer in a free-form fashion. Despite the potential difficulty of generating rather than extracting the answer, Raffel et al. (2019) demonstrated state-of-the-art results on the SQuAD (Rajpurkar et al., 2016), MultiRC (Khashabi et al., 2018), BoolQ (Clark et al., 2019), and ReCoRD (Zhang et al., 2018) reading comprehension tasks.

The text-to-text framework is directly applicable to closed-book question answering since the model can be trained to generate an answer with or without any additional information in its input. Crucially, fine-tuning a text-to-text model to answer questions without any context requires that the model retrieve information from its parameters that it learned during pre-training. Radford et al. (2019) considered a similar task to evaluate the zero-shot question answering capabilities of a language model. The concurrent "RELIC" and "EAE" models of Ling et al. (2020) and Févry et al. (2020) learn representations for an explicitly predefined set of entities and are evaluated on the same closed-book variant of TriviaQA that we consider. Relatedly, Petroni et al. (2019) show that it is possible to manually convert some questions to a fill-in-the-blank format amenable to an encoder-only model (e.g. "Who developed the theory of relativity?" gets mapped to "The theory of relativity was developed by ____").

3 Experiments

Datasets We consider the following open-domain question answering datasets: *Natural Questions* (Kwiatkowski et al., 2019), a dataset of questions from web queries, each accompanied by a Wikipedia article containing the answer; *WebQuestions* (Berant et al., 2013), comprising questions from web queries matched to corresponding entries in FreeBase (Bollacker et al., 2008); and *TriviaQA* (Joshi et al., 2017), a collection of questions from quiz league websites where each question is accompanied by pages from web and Wikipedia searches that may contain the answer. In this work, we only make use of the questions from each dataset – *we completely ignore the matching documents supplied for each question*.

For WebQuestions and TriviaQA we follow the standard evaluation procedures where each predicted answer is compared to the ground-truth after both are lowercased and stripped of articles, punctuation, and duplicate whitespace (Rajpurkar et al., 2016). For Natural Questions, we evaluate using both 1) the standard "open-domain" version as used e.g. by (Lee et al., 2019; Min et al., 2019b,a; Asai et al., 2019) where the model is only required to produce a single normalized answer and 2) the standard multi-answer variant used with reading comprehension systems (Kwiatkowski et al., 2019). We review the details of Natural Questions evaluation in appendix A.

Note that Natural Questions and TriviaQA have private test sets, so standard practice on their open-domain variants is to report performance on the development sets. However, we also include our results on the official TriviaQA test set by fine-tuning on the unfiltered training set and submitting our test set predictions to the leaderboard for the Wikipedia domain. We urge future work to adopt this approach to help ensure the validity of results and avoid potentially overfitting to a public set.

Training We leverage the pre-trained models provided by Raffel et al. (2019), referred to as the "Text-to-Text Transfer Transformer" (T5). The original T5 models were pre-trained on a multi-task mixture including an unsupervised "span corruption" task on the C4 dataset as well as supervised translation, summarization, classification, and reading comprehension tasks. Note that none of the reading comprehension datasets used for pre-training T5 overlap with the question answering datasets that we consider in this paper. In order to measure how performance scales with model size, we perform experiments with the Base (220 million parameters), Large (770 million), 3B (3 billion), and 11B (11 billion) variants of T5. Given that the T5 models were pre-trained on a multitask mixture including question answering, we also report performance using the "T5.1.1" checkpoints, which were pre-trained on unlabeled data only.[3]

For fine-tuning the T5 checkpoints, we follow the procedure used in Raffel et al. (2019) without any additional hyperparameter tuning: We use the AdaFactor optimizer (Shazeer and Stern, 2018) with a constant learning rate of 0.001, 10% dropout rate, and a batch size of 196,608 tokens. We halve the batch and double the dropout rate for WebQuestions due to its small size. For the T5.1.1 checkpoints, we follow the same procedure

---

[3] `https://goo.gle/t5-checkpoints`

but with a dropout rate of 5% for all three datasets.

For evaluation, we follow the procedure used in Lee et al. (2019): for each dataset, we hold out 10% of the training set as a validation split, fine-tune a model from the remaining 90% of examples, and select the best-performing checkpoint for final evaluation on the test set. While we chose to train for 20,000 steps, our validation accuracy typically plateaued after only a few hundred steps and showed no signs of overfitting.

We decode the model's predictions by choosing the most likely token at each timestep. To map question answering tasks to the text-to-text format, we simply feed the question with a task-specific prefix into the model as input and train it to predict the literal answer text as output.

Salient Span Masking Recently, Guu et al. (2020) found that a "salient span masking" (SSM) pre-training objective produced substantially better results in open-domain question answering. This approach first uses BERT (Devlin et al., 2018) to mine sentences that contain salient spans (named entities and dates) from Wikipedia. The question answering model is then pre-trained to reconstruct masked-out spans from these sentences, which Guu et al. (2020) hypothesize helps the model "focus on problems that require world knowledge". We experimented with using the same SSM data and objective to continue pre-training the T5 checkpoints for 100,000 additional steps before fine-tuning for question answering.

Results Our results on the open-domain Natural Questions, WebQuestions, and TriviaQA tasks are shown in table 1. Notably, performance on each dataset improves as the model size increases, with either T5-11B or the comparably-sized T5.1.1-XXL (pre-trained only on unlabeled data) performing best in every case. Further, we find that using Guu et al. (2020)'s SSM pre-training produces a substantial boost in performance. T5.1.1-XXL with SSM ultimately achieves state-of-the-art on WebQuestions and our largest models beat most other methods on Natural Questions and TriviaQA. Importantly, all previous methods except Ling et al. (2020) and Févry et al. (2020) operate in the "open-book" setting by explicitly retrieving and using information from an external knowledge source. While our largest models are computationally intensive, we note that most open-domain question answering systems must first do an expensive lookup step over the entire knowledge corpus and then attend to a long document to extract an answer. Our approach omits both of these steps, which ultimately saves a large amount of computation and memory.

Table 1: Scores achieved by fine-tuning T5 on the open-domain Natural Questions (NQ), WebQuestions (WQ), and TriviaQA (TQA) tasks.

	NQ	WQ	TQA	
			dev	test
Chen et al. (2017)	–	20.7	–	–
Lee et al. (2019)	33.3	36.4	47.1	–
Min et al. (2019a)	28.1	–	50.9	–
Min et al. (2019b)	31.8	31.6	55.4	–
Asai et al. (2019)	32.6	–	–	–
Ling et al. (2020)	–	–	35.7	–
Guu et al. (2020)	40.4	40.7	–	–
Févry et al. (2020)	–	–	43.2	53.4
Karpukhin et al. (2020)	**41.5**	42.4	**57.9**	–
T5-Base	25.9	27.9	23.8	29.1
T5-Large	28.5	30.6	28.7	35.9
T5-3B	30.4	33.6	35.1	43.4
T5-11B	32.6	37.2	42.3	50.1
T5-11B + SSM	34.8	40.8	51.0	60.5
T5.1.1-Base	25.7	28.2	24.2	30.6
T5.1.1-Large	27.3	29.5	28.5	37.2
T5.1.1-XL	29.5	32.4	36.0	45.1
T5.1.1-XXL	32.8	35.6	42.9	52.5
T5.1.1-XXL + SSM	35.2	**42.8**	51.9	**61.6**

Having established that our approach is competitive on open-domain question answering, we now evaluate it on the standard (and more difficult) multi-answer variant of Natural Questions. Virtually all models used on this task are reading comprehension systems that select the correct answer from an oracle context. After fine-tuning, T5-11B + SSM achieves a recall of 36.2 on the validation set, which lags behind the state-of-the-art score of 51.9 from Pan et al. (2019)[4] but outperforms the best baseline published alongside the dataset (recall of 33.2 (Kwiatkowski et al., 2019)). This shows that T5 can effectively answer questions with multiple answers. We discuss additional experiments and negative results in appendix B.

Human Evaluation The benchmarks we used and the "exact match" score assume that the model directly extracts answers from an external knowledge source. In contrast, our model generates answers in a free-form fashion. We hypothesize that this results in many false negatives when an-

---

[4] Validation set recall scores from Pan et al. (2019) were reported in private correspondence with the authors.

Table 2: A breakdown of the 150 hand-evaluated examples from Natural Questions where the T5 predictions were labelled as incorrect by the automatic procedure. We found only 62% of these to be true positives.

		Example		
Category	Percentage	Question	Target(s)	T5 Prediction
True Negative	62.0%	what does the ghost of christmas present sprinkle from his torch	little warmth, warmth	confetti
Phrasing Mismatch	13.3%	who plays red on orange is new black	kate mulgrew	katherine kiernan maria mulgrew
Incomplete Annotation	13.3%	where does the us launch space shuttles from	florida	kennedy lc39b
Unanswerable	11.3%	who is the secretary of state for northern ireland	karen bradley	james brokenshire

swers do not exactly match the ground-truth context intended for each question. We therefore manually inspected 150 examples from the Natural Questions validation set where our model's prediction was counted as incorrect in hopes of identifying "false negatives" according to the exact match metric. We found that false negatives fell into three broad categories: First, answers with meaning-preserving differences in phrasing (e.g. "April 15" vs. "April 15th"); second, questions that were missing all possible correct answers (e.g. "where does the us launch space shuttles from" was annotated with the single ground-truth answer "florida", despite many possible correct answers such as "Kennedy Space Center", "Merritt Island", "Cape Canaveral", etc.); and finally, some questions were unanswerable without knowing the exact time or article they referred to (e.g. "what is the latest version of microsoft office 2010" depends on when the question is being asked). We provide examples of each of these false negative types in table 2. We note that open-book question answering systems could also be impacted to a lesser extent by these issues (e.g. if they select a slightly different answer span from the annotated one or retrieve a non-golden document that contains a different correct answer).

Of the 150 examples inspected, we found that 20 were marked as incorrect due to differences in phrasing, another 20 were not annotated with all correct answers, and 17 were unanswerable without appropriate context. Removing unanswerable questions from the validation set and recomputing our model's accuracy based on this false-negative rate produces a score of 57.8. This suggests that the performance of closed-book question answering systems (in terms of how often it correctly answers questions) is substantially underestimated by the evaluation procedure used in these benchmarks. For full transparency, we publicly release the results of our human evaluation and include an appropriate reference when we determined that a predicted answer was missing from ground-truth.[5]

4 Conclusion

In this short paper, we have shown that large language models pre-trained on unstructured text can attain competitive results on open-domain question answering benchmarks without any access to external knowledge. This suggests a fundamentally different approach to designing question answering systems, motivating many threads for future work: First, we obtained state-of-the-art results only with the largest models which had around 11 billion parameters. This model size can be prohibitively expensive in resource-constrained settings, prompting future work on more efficient language models. Second, "open-book" models typically provide some indication of what information they accessed when answering a question. This can provide a useful form of interpretability. In contrast, our model distributes knowledge in its parameters in an inexplicable way and hallucinates realistic-looking answers when it is unsure. Third, the maximum-likelihood objective used to train our model provides no guarantees as to whether a model will learn a fact or not. This makes it difficult to ensure that the model obtains specific knowledge over the course of pre-training and prevents us from explicitly updating or removing knowledge from a pre-trained model. Finally, the tasks we used in this paper mainly measure "trivia"-style knowledge. We are therefore interested in measuring performance on question answering tasks that require reasoning capabilities such as DROP (Dua et al., 2019).

A Metrics for Natural Questions

Compared to WebQuestions and TriviaQA, Natural Questions is distributed with a much richer set of annotations: Each question can be annotated either as unanswerable (given the oracle context), with a short answer, or with a yes/no answer; questions in the validation set can be annotated more than once; and some questions have multiple answers (e.g. "Who are the members of the Beatles?" has four answers). We consider two variants of Natural Questions. In both cases, we omit the "unanswerable" label and long answers, which are nearly impossible to predict without the oracle context.

The first variant is the standard "open-domain" version as used e.g. by (Lee et al., 2019; Min et al., 2019b,a; Asai et al., 2019), where 1) the model is only ever trained to output a single answer; 2) if a question has multiple answers, it is only trained to predict the first answer; 3) any questions with answers longer than five tokens are ignored; 4) answers are normalized before being compared (in the same manner as is typically done for WebQuestions and SQuAD); and 5) a predicted answer is considered correct if it matches any of the answers provided by any of the annotators (e.g. "Ringo Starr" would be considered a correct answer to "Who are the members of the Beatles?").

The second variant closely matches the official evaluation procedure used by the Natural Questions leaderboard, where our model is trained to predict all ground-truth answers and is only considered correct if it predicts *all* answers for any one of the annotators. As in the official evaluation, we consider questions with fewer than two non-null annotations unanswerable (given the context), but because we cannot predict unanswerability without the context, we only report the recall score. Further, because our model does not have access to the oracle context, we also normalize predicted and ground-truth answers when comparing them. The use of multiple possible answers also required minor modification of our text-to-text format. In this case, we trained the model to output each answer delimited by the text "answer:" (for example, "answer: John Lennon answer: Ringo Starr answer: George Harrison answer: Paul McCartney"). We then split out each answer from the model's predictions as a postprocessing step before evaluating it against the set of answers provided by each annotation.

B Other Things We Tried

In the course of undertaking this study, we tried various ideas that ultimately did not improve performance. We briefly discuss them here.

Continued Pre-Training on Wikipedia The T5 checkpoints we used were primarily pre-trained on C4, a large and diverse dataset of unstructured web content. We were interested to see whether we could improve performance by doing further pre-training on data that was better tailored to the tasks we considered. Since both Natural Questions and TriviaQA source their answers from Wikipedia articles, we experimented with further pre-training on text data from English Wikipedia with the same unsupervised objective ("span corruption") as was used by T5. We found that this additional "in-domain" pre-training had virtually no effect on performance. This may be because C4 already contains many articles from Wikipedia and the T5 checkpoints were pre-trained long enough to see plenty of this content.

Pre-Training From Scratch On Wikipedia Since *all* of the answers to the questions in Natural Questions appeared in Wikipedia, we carried out an additional experiment where we pre-trained T5 from scratch only on data from Wikipedia. We pre-trained on up to 1 trillion tokens (the same amount the T5 checkpoints were pre-trained on) with the span corruption objective and measured fine-tuned performance after various amounts of pre-training. Unfortunately, this resulted in dramatically worse performance regardless of the amount of pre-training. We suspect that this is because Wikipedia is too small and results in detrimental overfitting.

Span-Corruption Pre-Training on Wikipedia Sentences with Salient Spans As described previously, we observed significant performance gains with additional pre-training using "salient span masking" (SSM) on the Wikipedia sentence dataset from Guu et al. (2020) but not when using the standard "span corruption" (SC) from Raffel et al. (2019) on longer Wikipedia articles. While SC masks random spans of the input by dropping 15% of its tokens (sampled each epoch) and replacing each consecutive span of dropped tokens with a unique sentinel, SSM specifically masks out one named entity or date in the input sentence.

We were interested in determining whether the

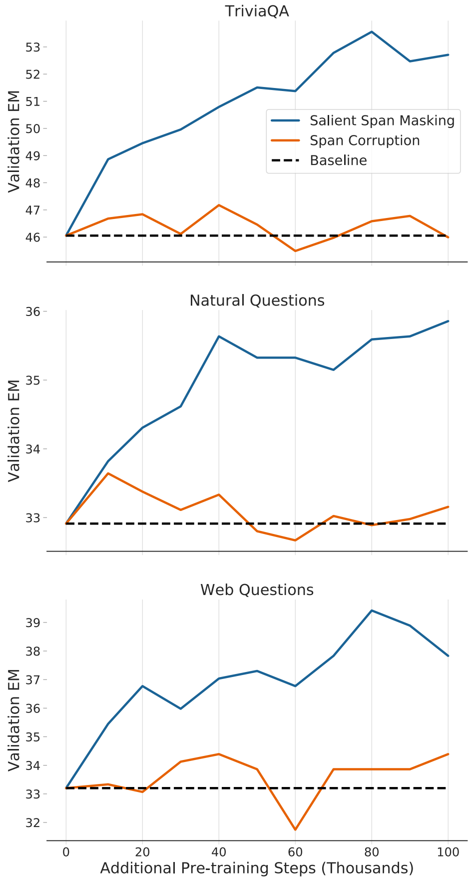

Figure 2: Comparing additional pre-training using either salient span masking (SSM) or span corruption (SC). We further pre-trained T5.1.1-XXL on the Wikipedia sentence dataset from Guu et al. (2020) with each objective, fine-tuning on a mixture of our three closed-book QA tasks every 10,000 steps. For each fine-tuning run, we report the maximum exact match score achieved on the validation set over 10,000 steps of fine-tuning.

gains achieved were attributable to the use of a more task-specific dataset (pre-split into sentences that are known to contain at least one entity) or if the SSM objective itself was critical. As illustrated in fig. 2, the SSM objective is clearly an important ingredient in the improved performance; we saw no significant improvement versus the baseline T5 model when using SC.

Fine-Tuning On All Question Answering Tasks The text-to-text framework used by T5 makes it simple to train multitask models simply by supplying a different task-specific prefix for each task and concatenating all of the constituent datasets. Since all of the question answering tasks we consider in this study follow the same basic structure, we were hopeful that training on a multitask mixture of Natural Questions, WebQuestions, and TriviaQA would improve performance due to the additional supervised data. While multitask training improved performance on the Natural Questions by 0.5, it produced slightly worse results on the other tasks.

Randomly Sampling Answers For Natural Questions In the open-domain variant of Natural Questions, the model is only trained to generate a single answer at a time. For the results presented in the main text, when a question was annotated with multiple answers, we simply trained the model on the first annotated answer. We also experimented with sampling a random answer from the set of possible answers for pre-training and found that it did not affect performance.

EXAMS: A Multi-Subject High School Examinations Dataset for Cross-Lingual and Multilingual Question Answering

Abstract

We propose $E\chi\alpha\mu s$ – a new benchmark dataset for cross-lingual and multilingual question answering for high school examinations. We collected more than 24,000 high-quality high school exam questions in 16 languages, covering 8 language families and 24 school subjects from Natural Sciences and Social Sciences, among others.

$E\chi\alpha\mu s$ offers a fine-grained evaluation framework across multiple languages and subjects, which allows precise analysis and comparison of various models. We perform various experiments with existing top-performing multilingual pre-trained models and we show that $E\chi\alpha\mu s$ offers multiple challenges that require multilingual knowledge and reasoning in multiple domains. We hope that $E\chi\alpha\mu s$ will enable researchers to explore challenging reasoning and knowledge transfer methods and pre-trained models for school question answering in various languages which was not possible before. The data, code, pre-trained models, and evaluation are available at `http://github.com/mhardalov/exams-qa`.

1 Introduction

Research on science question answering has attracted a lot of attention in recent years (Clark, 2015; Schoenick et al., 2017; Clark et al., 2019). Such questions are challenging as they require domain and common sense knowledge (Clark et al., 2018), as well as complex reasoning and different forms of inference over a variety of knowledge sources (Khashabi et al., 2016, 2018). Indeed, a combination of these was required to achieve noticeable performance gains (Clark et al., 2016). This inevitably made research in school-level science Question Answering (QA) hard for languages other than English due to the scarceness of resources (Clark et al., 2014; Khot et al., 2017, 2018; Bhakthavatsalam et al., 2020).

Figure 1: Properties and examples from $E\chi\alpha\mu s$.

There has been a recent mini-revolution in QA, as well as in the field of Natural Language Processing (NLP) in general, due to the invention of the Transformer (Vaswani et al., 2017), and the subsequent rise of large-scale pre-trained models (Peters et al., 2018; Radford et al., 2018, 2019; Devlin et al., 2019; Lan et al., 2020; Yang et al., 2019; Liu et al., 2019c; Raffel et al., 2020). Nowadays, fine-tuning such models on task-specific data has become an essential element of any top-scoring QA system. Yet, for science QA, training on datasets from a different domain (Sun et al., 2019; Khashabi et al., 2020) and carefully selected background knowledge (Banerjee et al., 2019; Ni et al., 2019) could improve such models further.

The success of large-scale pre-trained models and the development of their multilingual versions (Devlin et al., 2019; Conneau et al., 2020) gives hopes for supposedly better performance in multilingual question answering. Therefore, several new datasets have been released for multilingual reading comprehension and open-domain question answering in the Wikipedia domain (Liu et al., 2019a; Lewis et al., 2020; Artetxe et al., 2020; Clark et al., 2020).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5427–5444,
November 16–20, 2020.

Here, we present $E\chi\alpha\mu s$, a new dataset and benchmark for multilingual and cross-lingual evaluation of models and methods for answering diverse school science questions (see Figure 1).

Our contributions are as follows:

- We advance the task of science Question Answering (QA) with multilingual and cross-lingual evaluations.
- We collect a new challenging dataset $E\chi\alpha\mu s$ from multilingual high school examinations, which offers several advantages over existing datasets: (*i*) it covers various domains, (*ii*) it is nearly three times larger than pre-existing Science QA datasets, (*iii*) it extends multilingual QA tasks to more languages, (*iv*) the questions are written by experts, rather than translated or crowdsourced, (*v*) the questions are harder since they are from matriculation exams rather than 4-8th grade.
- We use fine-grained evaluation – per subject and per language – which yields more precise comparison between models.
- We perform extensive experiments and analysis using top-performing multilingual models (mBERT, XLM-R), and we show that $E\chi\alpha\mu s$ offers several challenges that such models would need to overcome in the future, including multi-lingual and cross-lingual knowledge retrieval, aggregation, and reasoning, among others.

We release our code, pre-trained models and data for research purposes.[1]

2 Related Work

Science QA The work in Science Question Answering emerged in recent years with the development of several challenging datasets. The most notable is ARC (Clark et al., 2018), which is a QA reasoning challenge that contains both *Easy* and *Challenge* questions from 4th to 8th grade examinations in the *Natural Science* domain. As in $E\chi\alpha\mu s$, the questions in ARC are created by experts, albeit our dataset covers a wide variety of high school (8th-12th grade) subjects including but not limited to, Natural Sciences, Social Sciences, Applied Studies, Arts, Religion, etc. (see Section 3.2 for details). We provide definitions of the less known subjects in $E\chi\alpha\mu s$ in Appendix B.1.

The early versions of ARC (Clark, 2015; Schoenick et al., 2017) inspired several crowdsourced datasets: Welbl et al. (2017) proposed a scalable approach for crowdsourcing science questions given a set of basic supporting science facts. Dalvi et al. (2019) focused on specific phenomena including understanding science procedural texts, Mihaylov et al. (2018) and Khot et al. (2020) studied multi-step reasoning, given a set of science facts and commonsense knowledge, Tafjord et al. (2019), and Mitra et al. (2019) worked on reasoning about qualitative relationships, and declarative texts, among others. Unlike these English-only datasets, $E\chi\alpha\mu s$ offers questions in 16 languages. Moreover, it contains questions about multiple subjects, which are presumably harder as they were extracted mostly from matriculation examinations (8-12th grade). Finally, $E\chi\alpha\mu s$ contains over 24,000 questions, which is more than three times as many as in ARC.

Multilingual and Cross-lingual QA Recently, several QA datasets have been created that cover languages other than English, but still focusing on one such language. Gupta et al. (2018) proposed a parallel QA task for English and Hindi, Liu et al. (2019b) collected a bilingual cloze-style dataset in Chinese and English. Jing et al. (2019) crowdsourced parallel paragraphs from novels in Chinese and English. A few datasets investigated multiple-choice school QA (Hardalov et al., 2019; Van Nguyena et al., 2020), albeit in a limited domain, and for lower school grades (1st-5th). Other efforts focused on building bi-lingual datasets that are similar in spirit to SQuAD (Rajpurkar et al., 2016) – extractive reading comprehension over open-domain articles. Such datasets are collected by crowdsourcing questions, following a procedure similar to (Rajpurkar et al., 2016), in Russian (Efimov et al., 2020), Korean (Lim et al., 2019), French (d'Hoffschmidt et al., 2020), or by translating existing English QA pairs to Spanish (Carrino et al., 2020).

Recently, some multilingual datasets, were released to the public. MLQA (Lewis et al., 2020), and XQuAD (Artetxe et al., 2020) use translations by professionals and extend the monolingual SQuAD (Rajpurkar et al., 2016) to 7 and 11 languages, respectively, thus forming cross-lingual evaluation benchmarks. Clark et al. (2020) collected an entirely new dataset (TyDi QA) of questions in 11 typologically diverse languages.

---

Table 1: Statistics about $E\chi\alpha\mu s$. The average length of the question (*Question Len*) and the choices (*sChoice Len*) are measured in number of tokens, and the vocabulary size (*Vocab*) is measured in number of words.

The task was to ask a question, and then the shortest span answering it from a list of paragraphs was selected. As these datasets are complementary, rather than making each other obsolete, hereby the recently released XTREME (Hu et al., 2020) benchmark combined them in a joint task. $E\chi\alpha\mu s$ differs from the aforementioned multilingual benchmarks in several aspects. First, we extend the multilingual QA efforts to a different, more challenging domain (Clark et al., 2018). Second, our datasets support more languages. Next, the questions in $E\chi\alpha\mu s$ are written by educational experts rather than non-expert annotators, making the evaluation results comparable to a top-performing student. Finally, our fine-grained evaluation for different subjects, languages, and combinations thereof allows for in-depth analysis and comparison.

3 $E\chi\alpha\mu s$ Dataset

We introduce $E\chi\alpha\mu s$, a new benchmark dataset for multilingual and cross-lingual question answering from high school examinations. In this section, we present the properties of the dataset, and we give details about the process of data collection, preparation and normalization, as well as information about the data splits, and the parallel questions.

3.1 Dataset Statistics

We collected $E\chi\alpha\mu s$ from official state exams prepared by the ministries of education of various countries. These exams are taken by students graduating from high school, and often require knowledge learned through the entire course.

Table 2: Parallel questions for different language pairs.

The questions cover a large variety of subjects and material based on the country's education system. Moreover, we do not focus only on major school subjects such as Biology, Chemistry, Geography, History, and Physics, but we also cover highly-specialized ones such as Agriculture, Geology, Informatics, as well as some applied and profiled studies. These characteristics make the questions in the dataset of very high variety, and not easily solvable, due to the need for highly specialized knowledge. Next, we discuss the cross-lingual and the multilingual properties of our dataset.

Parallel Questions Some countries allow students to take official examinations in several languages. Such parallel examinations also exist in our dataset. In particular, there are 9,857 parallel question pairs spread across seven languages as shown in Table 2. The parallel pairs are coming from Croatia (Croatian, Serbian, Italian, Hungarian), Hungary (Hungarian, German, French, Spanish, Croatian, Serbian, Italian), and North Macedonia (Macedonian, Albanian, Turkish).

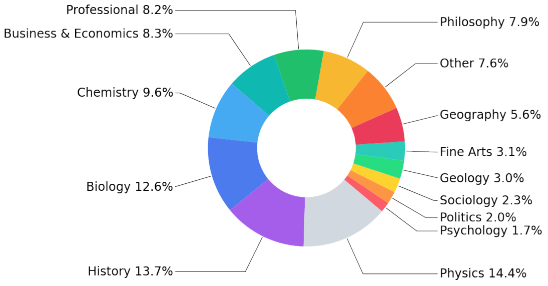

Figure 2: Relative sizes of the subjects. Those that cover less than 1.5% of the examples are in *Other*.

Multilinguality Our dataset includes a total of 24,143 questions in 16 languages from eight language families. Each question is a 3-way to 5-way (3.96 on average) multiple-choice question with a single correct answer. Table 1 shows a breakdown for each language, where the number of subjects, questions, and the vocabulary size are shown as absolute numbers, while the question length, the choice length, and the number of choices are averaged. All statistics about the questions and the answer options are measured in terms of words. We see that we have a rich vocabulary with almost 160,000 unique words. Interestingly, there are ∼9,500 shared words between at least one pair of languages in our dataset, excluding numbers and punctuation. As expected, the overlapping words are mostly between closely related languages (bg-mk, bg-sr, es-it, es-pt, hr-sr, mk-sr). Other common shared words are subject-specific words such as person names (e.g., *Abraham*, *Karl*, *Ivan*), chemical compounds (e.g., *NaOH*, *HCl*), units (e.g., *m/s*, *g/mol*), etc. Then, there are cognates with the exact same spelling (homographs) even between unrelated languages, mostly words of Latin or Greek origin, e.g., *temperatura* (temperature) and *forma* (form). Finally, there are also *false friends*, whose meaning differs across languages, e.g., *para* can mean *for* (es/pt) vs. *money* (mk/tr/sq) vs. *couple* (pl); similarly, *ser* can mean *be* (es/pt) vs. *cheese* (pl) vs. *after* (vi).

3.2 Subjects and Categories

Each education system has its own specifics, resulting in some differences in curricula, topics, and even naming of the subjects. That being said, the original, non-normalized categories in our dataset are more than 40 for exams from just a few countries. Given the sparse nature of the subjects, we use a two-level taxonomy in order to categorize them into logically connected groups. The lower-level is a subject, and the higher level is a major group. We normalized the subject using a two-step algorithm: first, we put each subject (with its original naming) in a separate category, then, if the subject was general enough, e.g., Biology, History, etc., or there were no similar ones, we retained the category; otherwise, we merged all similar subjects together in a unifying category, e.g., Economics Basics, and Economics & Marketing. We repeated the aforementioned steps until there were no suitable merge candidates. As a result, we ended up with a total of 24 subjects (see Appendix B for more details), which we further grouped into three major categories, based on the main branches of science: **Natural Science** – *"the study of natural phenomena"*, **Social Sciences** – *"the study of human behavior and societies"*, **Other** – *Applied Studies, Arts, Religion, etc.* (see Figure 1). [2]

The distribution of the major categories is *Natural Sciences* (40.0%) and *Social Sciences* (44.0%) and 16.0% for *Others* (these are the actual numbers, not approximate). The remaining questions are labeled as *Other* as they are not suitable for the two main categories. Figure 2 presents the relative sizes of the subjects in the dataset.

3.3 Collection and Preparation

Here, we describe the process of collecting and preparing the data, as it is not trivial and it could be applied to other languages and examinations. First, we identified potential online sources of publicly available school exams starting from the *Matriculation Examination* page in Wikipedia.[3]

For all languages in our dataset, the first step in the process of data collection was to download the PDF files per year, per subject, and per language (when parallel languages were available in the same source). We converted the PDF files to text and we used only those that were well-formatted and followed the document structure.

Then, we used Regular Expressions (RegEx) to parse the questions, their corresponding choices and the correct answer choice. In order to ensure that all our questions are answerable using textual input only, we removed questions that contained visual information. We did that using a manually curated list of words such as *map*, *table*, *picture*, *graph*, etc., in the corresponding language.

Table 3: Number of examples in the data splits based on the experimental setup.

Next, we performed data cleaning to ensure the quality of the generated dataset, by manually reviewing each question and its choices and ensuring that all options, text, and symbols (e.g., $\mu, \rightarrow, \alpha, \leftarrow$) were displayed correctly. As a result, we filtered out about 17% of the questions (the percentage varies based on the source, the language, and the subject). Finally, in order to remove frequency bias such as "most answers are B)", we shuffled each question's choices.

3.4 Data Splits

In our experiments, we aim at evaluating the multilingual and the cross-lingual question answering capabilities of different models. Therefore, we split the data in order to support both evaluation strategies: *Multilingual* and *Cross-lingual*.

Multilingual In this setup, we want to train and to evaluate a given model with multiple languages, and thus we need multilingual *training*, *validation* and *test* sets. In order to ensure that we include as many of the languages as possible, we first split the questions independently for each language L into Train$_L$, Dev$_L$, Test$_L$ with 37.5%, 12.5%, 50% of the examples, respectively.[4] We then unite all language-specific subsets into the multilingual sets Train$_{Mul}$, Dev$_{Mul}$, Test$_{Mul}$, and we used them for training, development, and testing.

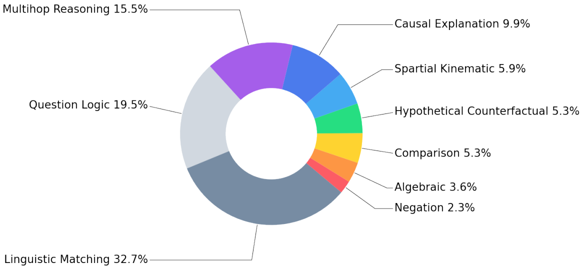

Figure 3: Relative sizes of reasoning types in $E\chi\alpha\mu s$.

Since we have parallel data for several languages (discussed in Section 3.1), in this setup, we ensure that the same parallel questions are only found in either training, development or testing, so that we do not leak the answer from training via some other language. In order to do that, we sample the questions with the assumptions and the ratios mentioned above, stratified per subject in the given language. The number of examples per language and the total number of multilingual sets are shown in the first three columns of Table 3.[5]

Cross-Lingual In this setting, we want to explore the capability of a model to transfer its knowledge from a single source language L_{src} to a new unseen target language L_{tgt}. In order to ensure that we have a larger training set, we train the model on 80% of L_{src}, we validate on 20% of the same language, and we test on a subset of L_{tgt}.[6] The last three columns of Table 3 show the number of examples used for training and validation with the corresponding language.

3.5 Reasoning and Knowledge Types

In order to give a better understanding of the reasoning, and the knowledge types in $E\chi\alpha\mu s$, we sampled and annotated 250 questions, all of which are from the multilingual Dev. For each question, we provided English translations as not all annotators were native speakers of the questions' language. We followed the procedure and re-used the annotation types presented in earlier work (Clark et al., 2018; Boratko et al., 2018). However, as they were designed mainly for Nature Science questions, we extended them with two new annotation types: *"Domain Facts and Knowledge"* and *"Negation"* (see Appendix C for examples).

---

[4] For languages with fewer than 900 examples, we only have Test$_L$.

[5] Sometimes, grouping parallel questions in the same split slightly violates the splitting ratios.

[6] To ensure that the cross-lingual evaluation is comparable to the multilingual one, we use the same subset of questions from language L_{tgt} that are used in Test$_{Mul}$

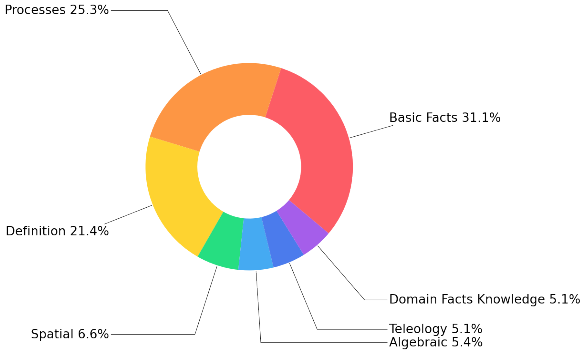

Figure 4: Relative size of the $E\chi\alpha\mu s$ knowledge types.

The relative sizes of the knowledge and the reasoning types are shown in Figures 3 and 4. Here, we must note that the sizes are approximate rather than exact, since the annotations are subjective and the distribution may vary.

4 Baseline Models

We divide our baselines into the following two categories: (*i*) models without additional training, and (*ii*) fine-tuned models. The first group contains common baselines, i.e., random guessing and information retrieval solver (Clark et al., 2016). In addition, we evaluate the knowledge contained in the pre-trained language model, i.e., mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), and we use it as an answering mechanism. The second group of baselines compare the learning ability of state-of-the-art multilingual models on the task of multiple-choice question answering. Since we have multi-choice questions, we adopt accuracy as an evaluation measure, as this is standard for this setup.

4.1 No Additional Training

Information Retrieval (IR) This IR baseline is from Clark et al. (2016), and it ranks the possible options o for each question q based on the relevance score returned by a search engine[7]. In particular, for each option o_i, we form a query by appending the option's text to the question's $(q + o_i)$, and we send this concatenation to the search engine. We then sum the returned scores for the top-10 hits, and we predict the choice with the highest score to be the correct answer. More detailed discussion can be found in Appendix D.

Pre-trained Model as a Knowledge Base (KB) As we start to understand pre-trained BERT-like models better(Petroni et al., 2019; Rogers et al., 2020), we observe some interesting phenomena. Here, we evaluate the knowledge contained in the model by leveraging the standard masking mechanism used in pre-training. We tokenize each question-option pair into subwords, and then we replace all the pieces from the option with the special [MASK] token. Following the notation from Devlin et al. (2019), the input sequence can be written as follows:

[CLS] [Q_1] . . . [Q_N] [M_O_1] . . . [M_O_M] [SEP],

where Q is the question, and M_O is the masked option. Following the notation above, we obtain a score for each option in the question based on the normalized log-probability for the entire masked sequence. (see Eq. 1).

$$score(O_i) = \frac{1}{|O_i|} \sum_{t \in O_i} \log P_{MLM}(t|Q) \qquad (1)$$

We could probably obtain better results for that evaluation if we form the question-option pairs as a single statement, e.g., "What is the purpose of *something*? [SEP] [M_O] → The purpose of *something* is [M_O]."

4.2 Fine-Tuned Models

We are interested in evaluating the ability of pre-trained models to transfer science-based knowledge across languages when fine-tuned.

In order to evaluate the QA capability of these models, we follow the established approach in this setting (Devlin et al., 2019; Liu et al., 2019c; Sun et al., 2019), and we fine-tune them to predict the correct answer in a multi-choice setting, given a selected context. This setup feeds the pre-trained model with a text, tokenized using the corresponding tokenizer for the model in the format:

[CLS] C [SEP] Q + O [SEP],

where C, Q and O are the tokenized *knowledge context* (see Appendix D), the *question*, and the *option*, respectively. Each question-option pair (Q+O) is evaluated, and the one with the highest confidence of being an answer is selected.

In our experiments, we used the Transformers library (Wolf et al., 2019). We experimented with the best-performing multilingual models: the Multilingual version of BERT, or mBERT Devlin et al. (2019), and the recently proposed XLM-RoBERTa, or XLM-R (Conneau et al., 2020).

---

[7] We build and use a separate index for each language using ElasticSearch.

Table 4: Overall per-language evaluation. The first three columns show the results on ARC Easy (E), ARC Challenge (C), and Regents 12 LivEnv (en). The following columns show the per-language and the overall results (the last column All) for all languages. *All* is the score averaged over all $E\chi\alpha\mu s$ questions.

Multilingual BERT (Devlin et al., 2019) is a fundamental multilingual model trained on 104 languages with a vocabulary of 110K word-pieces, with a total of 172M parameters (12 layers, 768 hidden states, 12 heads).

XLM-RoBERTa (Conneau et al., 2020) is a recent multilingual model based on RoBERTa (Liu et al., 2019c). It is trained on 100 languages, with a larger vocabulary of 250K sentence pieces. It comes in two sizes: *XLM-R*$_{Base}$ (270M parameters, same architecture as mBERT, except vocab size), and *XLM-R* (550M parameters, 24 layers, 1,024 hidden states, 16 heads). For completeness, we include both in our experiments.

We fine-tuned the aforementioned models following the standard procedure for multiple-choice comprehension tasks, as described in (Devlin et al., 2019) and (Liu et al., 2019c), using the Transformers library (Wolf et al., 2019). The training details can be found in Appendix A.

5 Experiments and Results

In this section, we evaluate the performance of the baseline models described in Section 4 on the $E\chi\alpha\mu s$ dataset. In Table 4, we show the overall per-language performance of the evaluated models. The first group shows simple baselines: random guessing and IR over Wikipedia articles. IR is better than random guessing, but it is clear that most questions require reasoning beyond simple word matching. In the last group, we evaluate the knowledge contained in the models before and after the QA fine-tuning. First, we evaluate XLM-R as a knowledge base, and then we use the *Full* model but with the question–option pair only.

5.1 Multilingual Evaluation

The next two groups show (*i*) how continuous fine-tuning of XLM-R on multi-choice machine reading comprehension and multi-choice science QA helps, and (*ii*) how the different models (XLM-R, XLM-R$_{\text{Base}}$, and mBERT) compare. We follow a standard training scheme for such tasks: first we fine-tune on RACE (Lai et al., 2017) (∼85k EN questions over documents), then on the AI2 English science datasets (we call them SciENs for shorter), including ∼9k EN questions with provided relevant contexts[8], and, finally, on our multilingual training set (see Section 3.4) with retrieved relevant contexts from Wikipedia (see Appendix D), which is our desired multilingual evaluation setting and we call it *Full*. We can also see that training on the SciENs, which has mostly primary school questions from Natural Sciences, only yields +0.5% improvement on $E\chi\alpha\mu s$. Nevertheless, we see a 2.4% improvement with multilingual fine-tuning on $E\chi\alpha\mu s$ and +0.5% for English. In the third group, we compare the results from mBERT, XLM-R$_{\text{Base}}$, and XLM-R after fine-tuning. Increasing the capacity of the model yields improvements: XLM-R scores 7.4% higher on $E\chi\alpha\mu s$, and more than 14% on English datasets, compared to its base version (XLM-R$_{\text{Base}}$). However, mBERT and XLM-R$_{\text{Base}}$ have close performance, with mBERT having a small advantage in the multilingual setting.

Finally, we fine-tuned mBERT on $E\chi\alpha\mu s$ only. As expected, the performance drops by 3% absolute compared to the *Full* setup.

Table 5: Cross-lingual zero-shot performance on $E\chi\alpha\mu s$. The first three columns show the performance on the test set of the AI2 science datasets (English), followed by per-language evaluation. The underlined values mark languages that have parallel data with the source language, and the ones with an asterisk* are from the same family.

5.2 Knowledge Evaluation

The last two rows of Table 4 evaluate the knowledge in the best model, namely XLM-R. With *XLM-R as KB* (see Section 4.1) we see small improvement over the random baseline: +5% ARC Easy, 2% on R12, and just +1% on $E\chi\alpha\mu s$ and ARC Challenge. Furthermore, we evaluate the knowledge contained in the model after the *Full* fine-tuning by excluding the relevant knowledge context (*ctx*). This is better than the *XLM-R as KB*, but it still achieves inferior overall results, which shows that the stored knowledge is not enough, and that we need to explicitly obtain additional knowledge from an external source.

5.3 Cross-lingual Evaluation

Table 5 shows the results from the cross-lingual zero-shot transfer compared to the English-only baseline en_{all}, from XLM-R fine-tuned on SciEN. The languages are ordered by family, and then alphabetically. We further fine-tune on a single source language and we test on all other languages using the splits described in Subsection 3.4. The results show that the additional fine-tuning on a single language is mostly positive. This is notable when fine-tuning on a language with similar linguistic characteristics to the target language, e.g., Balto-Slavic: bg-sr, hr-mk, pl-mk, sr-bg.

We also see gains when the source language contains more questions from largely represented and harder subjects. Examples of such are the experiments showing the positive effects of training on Vietnamese and Macedonian as source languages; they both contain such subjects: Biology, History, Chemistry, Physics, and Geography.

This is an indication that the knowledge from the same or from related subjects in a non-related language is preferred over knowledge from non-related subjects from a related language. For the same reasons, Portuguese and Polish show negative effects of fine-tuning on some of the target languages. They contain mostly niche subjects such as Professional, Philosophy, Economics, Geology. We see a noticeable drop in accuracy for Portuguese almost everywhere, but it has positive effect on languages that contain similar subjects (Biology, Economics) or are from the same language family such as Spanish and Italian (for Portuguese). We see the opposite in the Lithuanian-Polish pair, languages from the same family (but different subjects) have negative, or no effect on each other. Finally, we analyze the results from language pairs containing parallel examples (the underlined values). Such pairs show consistent improvement (+5 to +10), which suggests that the model learns to align the parallel knowledge from the source language to the target language. However, we also must note that the effect is strongly dependent on the size of the overlapping sets.

5.4 Per-subject Fine-grained Evaluation

Fine-grained evaluation (Mihaylov and Frank, 2019; Xu et al., 2020) allows an in-depth analysis of the question answering models. One of the nice features of $E\chi\alpha\mu s$ is that it supports subject-related fine-grained evaluation. On Figure 5, the results are shown by subject group and per-subject for Natural Science.[9]

Figure 5: Fine-grained evaluation by language and school subjects.

We can see that the Natural Science questions are the most challenging ones, which is mostly due to Chemistry and Physics. Those questions require very complex reasoning and knowledge such as understanding physical models, processes and causes, comparisons, algebraic skills and multi-hop reasoning (see Section 3.5). These skills are currently beyond the capabilities of the current QA models, and pose interesting challenges for future work (Welbl et al., 2018; Yang et al., 2018; Saxton et al., 2019; Lample and Charton, 2020). Informatics is another challenging subject, as it requires understanding programming code and positional numerical systems among others.

6 Discussion

Our results show that initial fine-tuning on a large monolingual out-of-domain multi-choice machine reading comprehension dataset (RACE (Lai et al., 2017)) performs much better than *no training* baselines for answering multilingual $E\chi\alpha\mu s$ questions. Moreover, additional training on English science QA in lower school levels has no significant effect on the overall accuracy. These results suggest that further investigation of fine-tuning with other multilingual datasets (Gupta et al., 2018; Lewis et al., 2020; Clark et al., 2020; Efimov et al., 2020; d'Hoffschmidt et al., 2020; Artetxe et al., 2020; Longpre et al., 2020) is needed in order to understand the domain transfer benefits to science QA in $E\chi\alpha\mu s$, even if they are not in a multi-choice setting (Khashabi et al., 2020). Using *domain-adaptive* and *task-adaptive pre-training* (Gururangan et al., 2020) to the multilingual science QA might offer further potential benefits.

Moreover, we need a better knowledge context for a given question–choice pair (the last row in Table 4). Knowing that the context retrieved from the noisy Wikipedia corpus is relevant for answering $E\chi\alpha\mu s$ questions, suggests that we need a better multilingual science corpus, similar to Clark et al. (2018); Pan et al. (2019); Bhakthavatsalam et al. (2020). We further need better multilingual knowledge selection and ranking (Banerjee et al., 2019). Finally, our cross-lingual experiments show that we can align the knowledge between languages from parallel examples, which poses a new question: *Is it only due to keyword matching or could the model align full sentences?*

7 Conclusion and Future Work

We presented $E\chi\alpha\mu s$, a new challenging cross-lingual and multilingual benchmark for science QA in 16 languages and 24 subjects from high school examinations.

We further proposed new fine-grained evaluation that allows precise comparison across different languages and school subjects. We performed various experiments and analysis with pre-trained multilingual models (XLM-R, mBERT), and we demonstrated that there is a need for better reasoning and knowledge transfer in order to solve some of the questions from $E\chi\alpha\mu s$. We hope that our publicly available data and code will enable work on multilingual models that can reason about question answering in the challenging science domain.

In future work, we plan to extend the dataset with more questions, more subjects, and more languages. We further plan to develop new models to address the specific challenges we identified.

Acknowledgments

We thank the anonymous reviewers for their helpful questions and comments. We thank the AI2 Aristo Team for providing the data splits used for pre-training on SciEN datasets.

This research is partially supported by Project UNITe BG05M2OP001-1.001-0004 funded by the OP "Science and Education for Smart Growth" and co-funded by the EU through the ESI Funds.

A Fine-Tuning and Hyper-parameters

In this work, we are interested in the cross-lingual transferability of multilingual models such as mBERT (Devlin et al., 2019) and XLM-RoBERTa (Conneau et al., 2020), each of which comes pre-trained on more than 100 languages. We evaluated the QA capabilities of these models, following the established protocol (Devlin et al., 2019; Liu et al., 2019c; Sun et al., 2019), namely we fine-tuned them to predict the correct answer in a multi-choice setting, given a selected context. The aforementioned setup feeds the pre-trained model with a text, processed using the model's tokenizer in the following format:

[CLS] C [SEP] Q + O [SEP]

where C, Q and O are the tokenized *knowledge* ***C****ontext* (see Appendix D), ***Q****uestion*, and ***O****ption*, respectively.

We used the Transformers library (Wolf et al., 2019). We fine-tuned mBERT, XLM-R, and XLM-R_{Base} in three steps. We first fine-tuned the models with RACE (Lai et al., 2017), a multiple-choice reading comprehension dataset with around 85k questions for training. Then, we trained on the combination of ARC (Clark et al., 2018), OpenBookQA (Mihaylov et al., 2018), and Regents Living Environments, as in the *AristoRoBERTaV7* ARC Challenge leaderboard entry[10]; we refer to these datasets as *SciENs* (**Sci**ence **E**nglish dataset**s**). We used the resulting pre-trained models as base models for our *Multilingual* and *Cross-lingual* evaluations (Section 5 in the paper). For the multilingual evaluation, we continued training the model, previously fine-tuned on the SciENs datasets, with our multilingual Train_{Mul} set, validating on Dev_{Mul} and testing on Test_{Mul}. For our cross-lingual evaluation, we continued training the SciENs model on separate languages, as described in Section 5.3.

In Table 6, we show the values of the hyper-parameters for each fine-tuning step and corresponding model. Note that these hyper-parameters were **not** obtained with an exhaustive search, and thus a better setting might exist for each model and dataset. Initially, we used the hyper-parameters for *AristoRoBERTaV7* ARC Leaderboard submission for English-only RoBERTa (Liu et al., 2019c): epochs = 4, learning rate = 1e-5.

With these parameters alone, the models did not perform well, and thus we added a warmup of 0.1 and a weight decay of 0.06, which stabilized the training. In all experiments, we used the Adam optimizer with β_1=0.9, β_2=0.999, and ϵ=1e-08.

We further performed manual tuning of the hyper-parameters: we experimented with variations thereof, depending on the performance on the corresponding development sets, and we ended up with the values in Table 6. Moreover, we adjusted the batch size and the accumulation steps depending on the availability of the GPUs on our cluster: Nvidia GTX 1080 Ti (Pascal, 11GB memory) or Nvidia Quadro RTX 6000 (24GB). For each examined setting, we trained for up-to 6 epochs, evaluating the model on the corresponding development set every 100 to 1000 update steps, depending on the dataset size and the effective batch size. For the final evaluations, we chose the model with the highest accuracy score on the corresponding development set.

Fine-tuning XLM-R (550M parameters) on Nvidia Quadro RTX 6000 (24GB) with the given hyper-parameters took around three hours per epoch when fine-tuned on RACE ($\sim$85k examples), 30 minutes per epoch when fine-tuned on SciENs ($\sim$9k examples), and 30 minutes on $E\chi\alpha\mu s$ on Train_{Mul} ($\sim$8k examples). Fine-tuning XLM-R_{Base} (270M parameters) and mBERT (172M parameters) on Nvidia GTX 1080 Ti (Pascal, 11GB memory) with the given hyper-parameters took roughly 2 to 2.5 hours per epoch when fine-tuned on RACE ($\sim$85k examples), 30 to 35 minutes per epoch when fine-tuned on SciENs ($\sim$9k examples), and additional 30 minutes on the $E\chi\alpha\mu s$ Train_{Mul} ($\sim$8k examples).

B Subject Analysis

The *Natural Science* group contains five subjects. The corresponding question length is 16.4 characters and 3.9 answers on average. Some of the subjects are well-known and widely studied, such as *Physics, Biology* and *Chemistry*. They appear in at least 10 out of the 16 languages, covering 7 out of 8 language families. However, *Geology* is less common and is present for only 4 languages. Finally, *Science* is an isolated subject for Arabic. This group contributes a total of 9,962 questions in the entire dataset, as shown in Table 7. The major groups in the table are divided with a horizontal line for convenience.

for each source language (Step 3 - Cross-lingual)						
mBERT XLM-R XLM-R$_{\text{Base}}$	2	8	320	0.00001	0.2	0.06

Table 6: The hyper-parameter values we used for fine-tuning.

The second subject group covers *Social Sciences*. *Geography, History, Philosophy, Psychology* and *Ethics* are more common, and thus are included in seven languages on average (see Table 7). The subject group's average question length is 18.5 characters. The only sizeable deviation being for Citizenship, as most of the questions in this subject explain some social situation in detail.

The last and smallest of the three subject groups is *Others*. It combines subjects that cannot be categorized as exactly science-related (either social or natural). Those subjects are often specific for a particular country or culture and are fairly diverse. As expected, they are present for less languages (just two).

B.1 Subject Definitions

Next, we give a brief description of the less commonly known subjects included in our dataset.

Agriculture covers questions about soil farming and preservation, small animals breeding and their general health care, and vehicle maintenance and repair.

Business & Economics is a term used to combine five similar subjects related to business and economics. The questions in these subjects cover theoretical questions on economics basis, marketing questions, business questions with elements of accountancy, finances, and organizational studies.

Citizenship is a specific subject from the Vietnamese school system, which tries to inform and give better perspective on different social situations, to educate students in how to perform better, and to be a more aware member of the society by analyzing different norms and personal morality.

Fine Arts contains analytical and historical questions about different forms of art such as movies, music, art, etc.

Forestry studies the craft of managing, using, conserving, and repairing forests, woodlands, and associated resources around them such as water sources and soil.

Geology is the study of the Earth, with the general exclusion of present-day life, flow within the ocean, and the atmosphere. Questions from this subject cover branches of Geology such as Economical Geology, Marine Geology, Geomorphology, and Geophysics.

Informatics consists of questions about basic hardware knowledge and software management as well as basics of different positional numeral systems (e.g., binary and hexadecimal).

Islamic Studies refers to the academic studies of Islam, Quran excerpts, and Muslim morality. This a subject studied in the Qatari educational system during both middle and high school.

Table 7: Per-subject statistics. The grade is High (H), and Middle (M). The average length of the question (*Q Len*) and the choices (*Ch Len*) are measured in number of tokens, and the vocabulary size (*Vocab*) is shown in number of words.

Landscaping teaches about modifying the visible features of an area of land, trees and park decorations. It also contains questions about plants and soils.

Politics covers Croatia's political system, historical questions about the country's development, as well as different regulations and laws, international relations and contracts.

Professional subject is present in the Polish school system and covers knowledge on specific professions such as flight attendant, babysitter, care taker, office worker in terms of profession's regulations, rules and established norms, etc.

Religion subject covers Christianity studies such as Bible knowledge, related traditions, e.g., baptism, marriage, etc.

Tourism covers hospitality management, as well as basis of business and traditions in Hungary and its neighbouring countries.

Science which is used in the Arabic school system throughout middle and high grade studies combines general science questions from Biology, Chemistry, Physics Geology and their branches such as as Biophysics, Astrophysics, and Biochemistry.

Social subject, similarly to Science, combines questions from political, cultural, historical and geographical studies.

Sociology is the study of society, patterns of social relationships, social interaction, and culture that surrounds our everyday life.

Table 8: Description of the per-language indices used as a source of background knowledge in our experiments.

C Reasoning and Knowledge Types

For our reasoning and knowledge type annotations, we followed the procedure and re-used the annotation types presented in (Clark et al., 2018; Boratko et al., 2018). However, as they were designed mainly for Natural Science questions, we had to extend them with two new types:

Domain Facts and Knowledge (Knowledge) This skill requires specific expertise in properties and facts in a given domain, e.g., physical properties, characteristics of a chemical element.

Example from Philosophy (*Portugal*):

> *Which of the following is an example of a priori knowledge?*
> A) I know my name.
> B) I know how old I am.
> C) *I know that no brother is an only child.* ✓
> D) I know some parents are not married.

Negation (Reasoning) is a direct statement of negation, and it is often combined with other reasoning types such as linguistic matching.

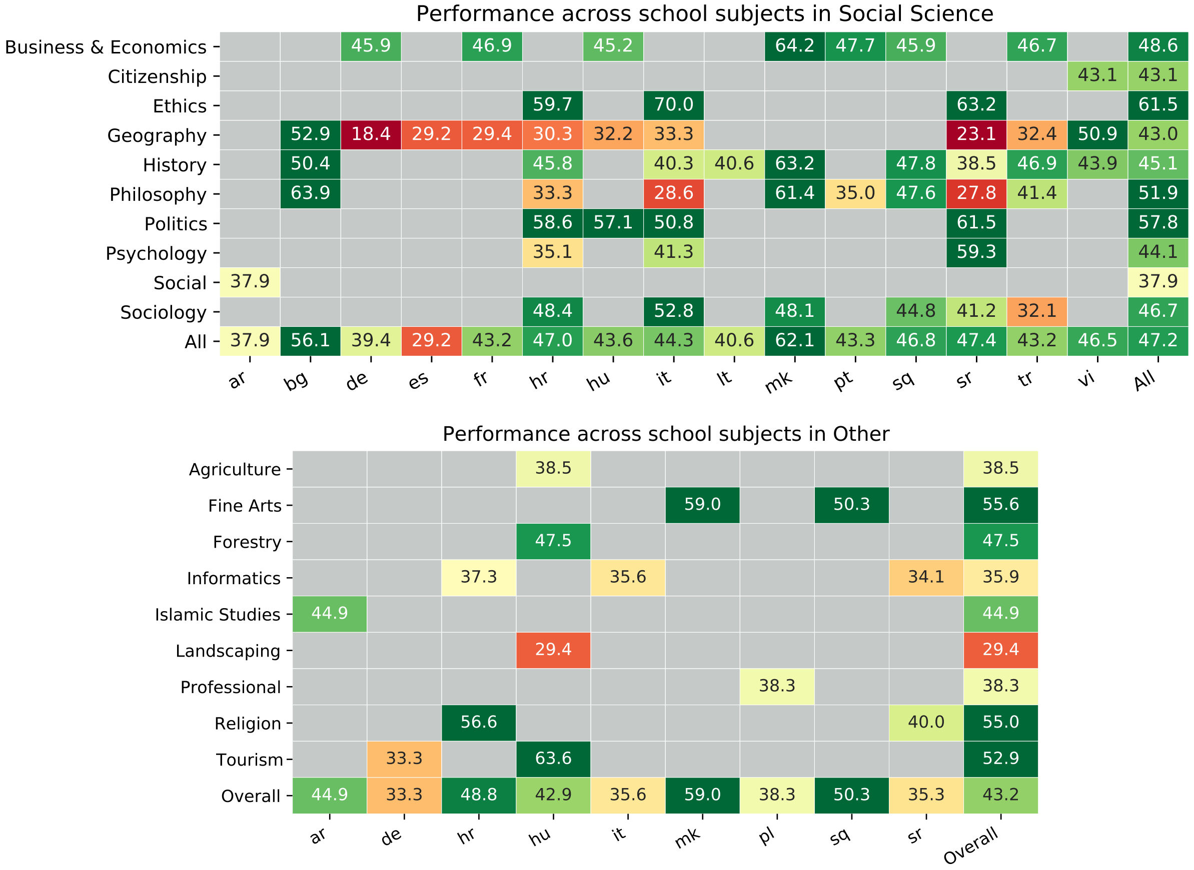
Example from Fine Arts (*North Macedonia*):

> *Which of the following works of art does* ***not*** *belong to the fine arts?*
> A) Graphics.
> B) *Poem.* ✓
> C) Design.
> D) Sculpture.

D Background Knowledge Corpus

Students need good textbooks to study before they can pass an exam, and the same holds for a good machine reading model. However, finding the information needed to answer a question, especially for questions in such a narrow domain as the subjects studied in high schools, usually requires a collection of specialized texts. The ARC Corpus (Clark et al., 2018) is an example of such a collection. It is built by querying a major search engine, and around 100 hand-written templates for 80 science topics covered by US elementary and middle schools. Albeit effective, this strategy relies on crafting templates for all language–subject pairs, making the task time-consuming if applied to multiple languages and subjects.

In our work, we used articles from Wikipedia to build a background knowledge corpus for each language. In particular, we parsed the text from the entire Wikipage, removing non-textual content, e.g., HTML tags, tables, etc. Following the common strategy used to solve similar tasks in English (Clark et al., 2018; Mihaylov et al., 2018), we split each document into sentences and we indexed them using an inverted index. In order to reduce the search space, and to mitigate the effect of known linguistic phenomena within the same language family, e.g., homonyms, partially shared alphabet, etc., we created a separate index for each language.



Performance across school subjects in Social Science

Figure 6: Fine-grained evaluation by language and school subjects in *Social Science* and *Other*.

Table 8 describes the main characteristics of the indices created for each language from its Wikipedia dump.[11] We compared the size of our index to the one from ARC (Clark et al., 2018). The number of articles for each language is taken from Wikipedia's official statistics [12]. We also marked the language analysis applied on the index. Some of the languages in $E\chi\alpha\mu s$ are low-resource ones, especially the ones from the Balto-Slavic family, which is also clear from their Wikipedia sizes. In the table, we see that half of the languages have under one million articles, and Albanian even falls under 100K. Moreover, even more languages are comparable with the number of sentences in the ARC Corpus, which is also built from science books. Finally, some of the languages (Serbian, Croatian, Macedonian, and Albanian) are not processed with any language-specific ElasticSearch analyzers.

E Fine-Grained Evaluation

Figure 6 shows fine-grained evaluation for two subject groups: *Social Science* and *Others*. We can see that these subjects are less challenging than Natural Science. One reason is that many of the subjects in these two groups such as Business & Economics, Geography, and History can be answered using knowledge that is easily accessible in sources such as Wikipedia (e.g., "*Who was the first prime minister of Poland after 1990?*"), i.e., without the need for complex reasoning or calculations, which are often needed in order to answer questions in subjects such as Physics and Chemistry. Nevertheless, while seeing scores as high as 60% for some subjects and languages, the current multilingual QA models are still far from perfect, which leaves a lot of room for improvement.

Abstract

We propose an end-to-end approach for synthetic QA data generation. Our model comprises a single transformer-based encoder-decoder network that is trained end-to-end to generate both answers and questions. In a nutshell, we feed a passage to the encoder and ask the decoder to generate a question and an answer token-by-token. The likelihood produced in the generation process is used as a filtering score, which avoids the need for a separate filtering model. Our generator is trained by fine-tuning a pretrained LM using maximum likelihood estimation. The experimental results indicate significant improvements in the domain adaptation of QA models outperforming current state-of-the-art methods.

1 Introduction

Improving question answering (QA) systems through automatically generated synthetic data is a long standing research goal (Mitkov and Ha, 2003; Rus et al., 2010). Although many past works have proposed different strategies for question generation, they have limited or no success in improving the downstream QA task (Du et al., 2017; Sun et al., 2018; Song et al., 2018; Klein and Nabi, 2019; Wang et al., 2020; Ma et al., 2020; Chen et al., 2020; Tuan et al., 2019).

Some recent approaches for synthetic QA data generation based on large pretrained language models (LM) have started to demonstrate success in improving the downstream Reading Comprehension (RC) task with automatically generated data (Alberti et al., 2019; Puri et al., 2020). However, these approaches typically consist of multi-stage systems that use three modules: span/answer detector, question generator and question filtering. Given an input passage, the *span detector* is responsible for extracting spans that will serve as answers for which questions will be generated. This module normally combines a pretrained QA model with handcrafted heuristics. The *question generator* is a large LM fine-tuned for the task of conditional generation of questions given passage and answer. The *question filtering* comprises another RC model that is used to score and filter the generated QA pairs. Each module of this synthetic data generation pipeline is trained/tuned separately and errors from one stage can propagate to the next stages. Additionally, each module is expensive to be computed because all use large transformer networks (Vaswani et al., 2017).

In this work, we propose an end-to-end approach for synthetic QA data generation. Our model comprises a single transformer-based encoder-decoder network that is trained end-to-end to generate both the answer and the question. In a nutshell, we feed a passage to the encoder and ask the decoder to generate the question and the answer token-by-token. The likelihood produced in the generation process is used as a filtering score, which avoids the need of a separate filtering model. Our generator is trained by fine-tuning a pretrained LM using maximum likelihood estimation (MLE). We use BART (Lewis et al., 2019) as the pretrained LM in our experiments.

We perform experiments with three different variations of our synthetic QA data generator: (1) *AQGen*, which generates first the answer then the question; (2) *QAGen*, which generates first the question then the answer; (3) *QAGen Two-step (2S)*, which generates first the question, concatenates it to the passage, then generates the answer in a second pass through the same encoder-decoder.

We focus our empirical evaluation on the task of data augmentation for domain adaptation of reading comprehension (RC) models trained on

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5445–5460,
November 16–20, 2020.

SQuAD 1.1 dataset. We assess the effectiveness of our QA data generators for domain adaptation of four different target domain datasets: Natural Questions (NQ), BioASQ, NewsQA and DuoRC. We compare our results with recent work on domain adaptation for QA as well as with a three-stage synthetic data generator. QAGen performs better than AQGen and the baselines for all datasets, while QAGen2S provides the best results overall because it allows bidirectional attention between passage and question. For NQ dataset, QAGen2S improves the SQuAD baseline by more than 8 points in EM and more than 7 points in F1. For NewsQA and BioASQ the gains in EM are also above 4 points. Additionally, we also demonstrate that synthetically generated data by QAGen2S can improve the in-domain performance of both small and large RC models, leading to F1/EM improvements of 1/0.5 and 3.1/2.2 on `RoBERTa-large` and `bert-base-uncased` trained RC models on SQuAD dev.

The main contributions of this work can be summarized as follows: (1) we propose the first effective end-to-end approach for synthetic QA data generation; (2) our approach solves an important issue in previous methods for QA data generation: the detection of good spans. We show that span detection can be effectively solved as a generation task, just like question generation; (3) as it uses a single end-to-end model, our data generation pipeline is simpler, faster and more efficient; (4) we perform comprehensive experiments that demonstrate the effectiveness of our proposed approach for domain adaptation of QA systems.

2 End-to-End Model for Question and Answer Generation and Filtering

We model the problem of synthetic QA data generation as a conditional language modeling task. More specifically, we use an encoder-decoder (enc-dec) conditional LM as described in what follows.

2.1 Enc-Dec Conditional Language Models

Language modeling consists of learning the probability distribution $p(x)$ over variable-length token sequences $x = (x_1, x_2, ..., x_{|x|})$, where the tokens come from a fixed size vocabulary V. The training of LMs typically involves solving the task of predicting the next token based on past tokens. The distribution $p(x)$ can be represented by the conditional probability of the next token given the previous ones (Bengio et al., 2003):

$$p(x) = \prod_{i=1}^{|x|} p(x_i|x_{<i}) \tag{1}$$

In the case of conditional LMs, the generation is conditioned on an additional context c:

$$p(x|c) = \prod_{i=1}^{|x|} p(x_i|x_{<i}, c) \tag{2}$$

Transformer-based encoder-decoder conditional LMs (Lewis et al., 2019; Raffel et al., 2019) use bidirectional self-attention in the encoding step to create vector representations of the tokens in the context c. The decoding step generates the tokens of the sequence x in an auto-regressive manner, while performing self-attention on previously generated tokens of x and all the representations output by the encoder for c.

2.2 Question-Answer Generation

In the case of end-to-end synthetic data generation for QA, we need to model the joint conditional distribution $p(a, q|c)$, where the input context c is a passage, q is a question and a is the correct answer, which is a span in c. Our approach to model $p(a, q|c)$ involves fine-tuning a pretrained Enc-Dec conditional LM using a training set $D = \{(c^1, q^1, a^1), (c^2, q^2, a^2), ..., (c^{|D|}, q^{|D|}, a^{|D|})\}$. We train the Enc-Dec with parameters θ through maximum likelihood estimation (MLE) by minimizing the negative log-likelihood over D:

$$\mathcal{L}(D) = -\sum_{i=1}^{|D|} \log p_\theta(a^i, q^i|c^i) \tag{3}$$

We can have different variations of the generator depending on how we place the items in the output sequence: answer-question or question-answer. This difference in the ordering is crucial because it defines which part is conditioned on the other. Based on this observation, we propose three variations of our generative model:

AQGen: this model generates answer and question jointly given the input context: $(q, a) \sim p(a, q|c)$. During sampling, the answer tokens are generated, which are followed by question tokens. This makes the generation of the question conditioned on both input context (through attention on the encoder) and answer (through self-attention in the decoder). Fig. 1 depicts this model.

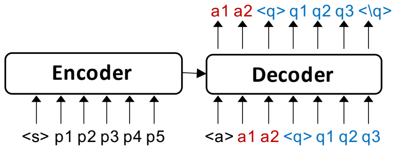

Figure 1: AQGen Model: given an input passage the model generates an answer followed by a question.

QAGen: this model generates question and answer jointly given the input passage: $(q, a) \sim p(a, q|c)$. During sampling, the question tokens are generated, which are followed by answer tokens. This makes the generation of the answer conditioned on both input context (through attention on the encoder) and question (through self-attention in the decoder). Fig. 2 depicts this model.

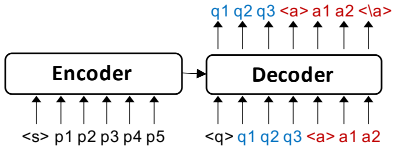

Figure 2: QAGen Model: given an input passage the model generates a question followed by an answer.

QAGen Two-Step (2S): this model performs question generation and answer generation in two separate passes over the Enc-Dec LM. First, the question is generated given the input context $q \sim p(q|c)$, (Step 1). Next, the question is concatenated with the input context and the resulting sequence is given as input to the Enc-Dec, which finally generates the answer $a \sim p(a|q, c)$, (Step 2). QAGen 2S sampling approach is illustrates in Fig. 3. This model uses a single Enc-Dec LM that is trained with samples of both $p(q|c)$ and $p(a|q, c)$. We use control codes $<q>$ and $<a>$ to inform the decoder whether to generate a question or an answer, respectively.

2.3 Decoding

A natural choice for decoding with conditional neural LMs is beam search. However, our preliminary experiments with beam search showed a lack of diversity and a high repetition of generated question-answer pairs. Generating diverse question-answer pairs is crucial to the performance of downstream RC models. Particularly, diversity of answer spans ensures that various parts of the passage are used, and different question types are generated. We use a variant of nucleus sampling (Holtzman et al., 2019), where we pick top k tokens, and within top k, we pick tokens that comprise top 95% probability mass. We set k to 20 in our experiments. We refer to this setting as *Topk+Nucleus*. This decoding was used in QAGen, AQGen, and question sampling step in QAGen2S. The answer generation of QAGen2S was performed by greedy decoding. We discard generated (q, a) pairs whose answers do not occur in the input passage, as non-extractive QA is outside the scope of this work. We observed between 10% to 15% of samples being dropped because of this issue.

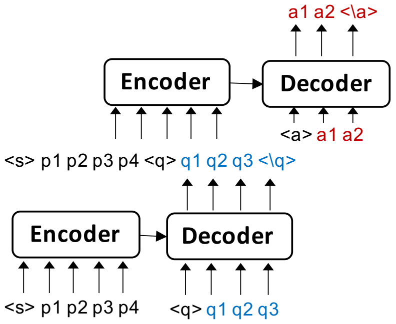

Figure 3: QAGen Two-Step: given an input passage the model first generates a question (Step 1). Next, the question is concatenated with the passage and both are given to the encoder-decoder that generates the answer (Step 2).

2.4 Filtering

Recent work have used the *round-trip filtering* method (Alberti et al., 2019; Puri et al., 2020) to prune the synthetic QA set and improve data quality. This method consists of two steps: (1) using an RC model to provide answers to the generated questions; (2) dropping the QA pairs for which the answer of the RC model does not match the span detected answer. While round-trip filtering has shown to be effective, it is not the most efficient approach because it involves the application of an RC system over the whole set of generated data. Additionally, there might exist cases that are difficult for the filtering model, but in fact are of high quality.

We propose using the likelihood of the generated question-answers as a measure to perform filtering and address the efficiency issue, as it avoids the use of an RC model for filtering. We argue that such a likelihood score, albeit noisy, is an indicator of whether a generated question-answer is high quality for training a downstream RC model. We refer to this approach as *LM filtering*. Essentially, given an input passage, we sample n different QA pairs, rank them according to decreasing order of

PubMed

Lymph node status has major prognostic importance in colorectal cancer and greater precision in the diagnosis of lymph node metastases should provide better prognostic and therapeutic guidance. **Keratin 20** (K20) gene expression has been used as a marker of lymph node metastases, but the evidence for this remains circumstantial. This study has therefore sought to determine K20 specificity and to correlate K20 expression with mutant K-RAS expression, in order to provide direct evidence that K20 expression in lymph nodes of colorectal cancer patients genuinely reflects metastatic disease. Specificity of K20 expression was established against a range of tissue types and 289 lymph nodes from 41 non-cancer control patients. K20 expression was restricted to **gastrointestinal epithelia** and was only present in one of the 289 control lymph nodes, giving a calculated specificity of 97.6 % (95% confidence limits: **87.1-99.9**%)...

Q: *What is K20 expression found to be restricted to?*	A: *gastrointestinal epithelia*
Q: *What was the 95% confidence range of the mutation analysis?*	A: *87.1-99.9%*
Q: *What is the name of the gene that can be used as a marker of metastatic disease?*	A: *Keratin 20*

Clark Russell, a prominent writer, concludes that he will visit the south in the capacity of a farm hand and thus secure atmosphere for a new story. He learns that laborers are needed on a certain farm and as he journeys into the country he rescues a young woman whose horse is running away. When Clark applies for work he is treated lightly by **Bud**, the foreman, until the owner of the farm arrives with his daughter, Anna, who recognizes her hero of the afternoon. A few days later at the dinner table Clark defends Polly, a maid, when she is annoyed by Bud and after the hands departed for the fields the two men settle their score in a fight, the bully receiving a severe lesson. Polly overhears Bud declaring that he will be revenged but she is unable to warn Clark. Later in the day **the bully** tries to force Clark into the hopper of the threshing machine but Anna sees the struggle from a distance and stops the engine...

Q: *What is the name of the foreman at the farm?*	A: *Bud*
Q: *Who saves Anna?*	A: *Clark Russell*
Q: *Who tries to force Clark into a hopper of the threshing machine?*	A: *the bully*

Table 1: Samples of generated question-answer pairs using QAGen2S model for four target domains. The generated answers are shown in **bold**. The paragraphs are truncated from their original sizes due to space limitations.

LM score and pick the top m samples. This is similar to the *sample-and-rerank* approach suggested by Holtzman et al. (2019) and Adiwardana et al. (2020). Formally, for QAGen and QAGen2S, we use the score:

$$\text{LM score} = \sum_{i=1}^{N_a} \log p(a^i|c, q)$$

And for AQGen :

$$\text{LM score} = \sum_{i=1}^{N_a} \log p(a^i|c) + \sum_{i=1}^{N_q} \log p(q^i|c, a)$$

Where N_q and N_a indicate the lengths of generated question and answer, respectively. We use answer-only scores for QAGen and QAGen2S because question quality would have a dominant effect on LM scores since questions are usually longer than answers. Additionally, using answer-only scores when conditioned on the generated question is more suitable for the RC tasks because it better mimics the score of a downstream RC model, which is answer centric. With AQGen, we use both answer and question LM scores, as answer generation is not conditioned on the question. We use likelihood summation instead of averaging because experiments showed that the former works slightly better. Further details included in Appendix B.3. We speculate this is due to average pooling encouraging longer question-answers, which could be of lower quality than shorter question-answer pairs.

3 Related Work

Question generation (QG) has been extensively studied from the early heuristic-based methods (Mitkov and Ha, 2003; Rus et al., 2010) to the recent neural-base approaches. However, most work (Du et al., 2017; Sun et al., 2018; Zhao et al., 2018; Kumar et al., 2019; Wang et al., 2020; Ma et al., 2020; Tuan et al., 2019; Chen et al., 2020) only takes QG as a stand-alone task, and evaluates the quality of generated questions with either automatic metrics such as BLEU, or human evaluation. Tang et al. (2017), Duan et al. (2017) and Sachan and Xing (2018) verified that generated questions can improve the downstream answer sentence selection tasks. Song et al. (2018) and Klein and Nabi (2019) leveraged QG to augment the training set for machine reading comprehend tasks. However, they only got improvement when only a small amount of human labeled data is available. Recently, with the help of large pre-trained language models, Alberti et al. (2019) and Puri et al. (2020) have been able to improve the performance of RC models using generated questions. However, they need two extra BERT models to identify high-quality answer spans, and filter out low-quality question-answer pairs. Lee et al. (2020) follow a similar approach while using InfoMax Hierarchical Conditional VAEs. Nishida et al. (2019) showed improvements by fine-tuning the language model on the target domains.

4 Experimental Setup and Results

4.1 Datasets

We used **SQuAD 1.1** dataset (Rajpurkar et al., 2016) to train the generative models as well as in-domain supervised data for the downstream RC task in this work. We used the default train and dev splits, which contain 87,599 and 10,570 (q, a) pairs, respectively.

Similar to (Nishida et al., 2019), we selected the following four datasets as target domains:

Natural Questions (Kwiatkowski et al., 2019), which consist of Google search questions and the annotated answers from Wikipedia. We used MRQA Shared Task (Fisch et al., 2019) preprocessed training and dev sets, which consist of 104,071 and 12,836 (q, a) pairs, respectively. The training set passages were used as the unlabeled target domain corpus, while the evaluations were performed on the dev set.

NewsQA (Hermann et al., 2015), which consists of question and answer pairs from CNN news articles. We used the dev set from the MRQA Shared Task, which removes unanswerable questions and those without annotator agreement. We prefer this version as we focus only on the generation of answerable questions. The dev set consists of 4,212 (q, a) pairs. Passages from CNN/Daily Mail corpus of Hermann et al. (2015) are used as unlabeled target domain corpus.

BioASQ (Tsatsaronis et al., 2015): we employed MRQA shared task version of BioASQ, which consists of a dev set with 1,504 samples. We collected PubMed abstracts to use as target domain unlabeled passages.

DuoRC (Saha et al., 2018) contains question-answer pairs from movie plots which are extracted from both Wikipedia and IMDB. ParaphraseRC task of DuoRC dataset was used in our evaluations, consisting of 13,111 pairs. We crawled IMDB movie plots to use as the unlabeled target domain corpus.

4.2 Experimental Setup

We used Pytorch (Paszke et al., 2019) and Transformers (Wolf et al., 2019) to develop the models and perform experiments. Generative models are trained on SQuAD 1.1 for 5 epochs, and the best model is selected based on the cross entropy loss on the SQuAD dev set. AdamW (Loshchilov and Hutter, 2017) optimizer with learning rate of 3×10^{-5} is employed.

For RC model training, we use `bert-base-uncased` model (Devlin et al., 2018). AdamW optimizer is used with learning rate of 3×10^{-5} and batch size 24 for 2 epochs without linear warmup. We set maximum sequence length 384 with document stride 128. SQuAD 1.1 dev set is used to select the best model during training. As a baseline for QA data generation, we implemented a three-stage pipeline similar to the state-of-the-art approach of Puri et al. (2020). We call this baseline ***QGen***, which generates a question given a passage and extracted span, $q \sim p(q|a, c)$. The span detection module consists of `bert-base-uncased` fine-tuned on SQuAD 1.1 passage and spans, where the start and end classification heads are trained to perform span detection. For QGen, we experimented with sampling top 5 spans and generating two questions per each, as suggested by (Puri et al., 2020), as well as sampling top 10 spans and generating one question per each. Our results showed the latter outperforming the former. Henceforth, we used this configuration in our evaluations.

We trained QGen models on both BART-Large and GPT2-Medium (Radford et al., 2019), which have an equivalent number of parameters, 406M (BART) vs 350M (GPT2), and evaluated BLEU score of the generated question w.r.t. the ground truth question on the SQuAD dev set. BART and GPT2 achieved 21.29 and 18.31 BLEU, respectively. We believe the bi-directional encoding in BART is superior to uni-directional encoding in GPT2. Hence, we used BART for the rest of the experiments.

4.3 Synthetic Data Generation

For each of the unlabeled target domain corpora, we randomly selected 100,000 passages to perform synthetic data generation. Passages shorter than 100 tokens were discarded. Selected ones were truncated to maximum length of 550 tokens. We removed the passages that existed in the dev sets.

Question-answer generation with AQGen, QAGen, and QAGen2S is performed using Topk+Nucleus, as discussed in Sec. 2.3. For each passage, 10 samples are generated. Unless otherwise mentioned, LM filtering is applied by sorting the 10 samples of each passage according to LM scores as detailed in Sec. 2.4, and the top 5 samples are selected. The number of synthetically generated pairs is between 860k to 890k without filtering and 480k to 500k after LM filtering. Tab. 1 shows generated question-answer pairs from four target domain (see Appendix for more examples). We can observe that the generative model is able to generate question answer pairs even from raw HTML input that corresponds to a table. The rendered table can be seen in Tab. 12 (Appendix C.3). Considering the fact that the training data of the generative model does not include any HTML input, this further demonstrates the robustness and efficacy of our proposed approach.

4.4 Domain Adaptation Results

Tab. 2 shows the results of domain adaptation experiments. Each experiment was performed by training the RC model on the synthetic data generated on the target domain corpus. We refer to the dataset to which the downstream model is being adapted as the target domain. Source domain indicates the supervised training dataset (SQuAD).

We also performed experiments by using both Synthetic + SQuAD1.1 data. Our QAGen and QAGen2S models outperform by wide margins the baseline models trained on SQuAD 1.1 only, as well as unsupervised domain adaptation approaches (UDA) suggested by Nishida et al. (2019) and Lee et al. (2020). Additionally, QAGen and QAGen2S significantly outperforms QGen, our implementation of the three-stage pipeline of Puri et al. (2020).

Even though our SQuAD 1.1 baselines are generally higher than both Nishida et al. (2019) and Lee et al. (2020), our best model achieves more point-wise improvements in all of the target domain datasets, except with BioASQ, where Nishida et al. (2019) observe 4.3 points in EM versus 4 points with ours, and 4.2 points in F1 versus 2.2 with ours.

Comparing LM and round-trip filtering when applied to the best performing model, QAGen2S, we can observe that the LM filtering approach (Sec. 2.4) is more effective than round-trip filtering in BioASQ and DuoRC target domains. It barely underperforms ($\sim$ 1 point) in F1 and EM in the other two domains. This demonstrates the efficacy of the suggested filtering approach, which also simplifies the question-answer generation pipeline.

The highest (EM/F1) domain adaptation gains seen with BioASQ (4/2.2) and DuoRC (1.2/1.1) are smaller than those with Natural Questions (8.5/7.5) and NewsQA (5.5/4.5). We postulate this is due to two reasons: Firstly, both BioASQ and DuoRC domains are more dissimilar to the source domain, SQuAD, compared to NewsQA and Natural Questions; Secondly, BioASQ and DuoRC are more difficult datasets. Comparing our results with supervised target domain training of DuoRC, we observe that with using only synthetic data outperforms the DuoRC training set, which consists of 39144 pairs. While our domain adaptation methods show substantial gains with NewsQA and Natural Questions domain, there is still room for improvements to match the performance of supervised target domain training (last row in Tab. 2).

While results in Tab. 2 suggest that generating synthetic QA data from target domain text leads to significant gains on the target domain dev set, one can argue whether it is essential to generate synthetic data from the corpus matching the target dev set's domain to achieve good performance. Hence, we performed cross-domain experiments to check this argument. Tab. 3 shows the performance

on every target domain dev set of RC models fine-tuned on synthetic data of different target domain corpora. We can see that diagonal elements, which have same domain of dev set and target corpus, show either the best performance (underlined results) or are within a narrow margin of top EM/F1 scores. Therefore, the most effective strategy is achieved when the passages used in the generation of synthetic samples are from the same domain as the target, which is expected in a domain adaptation method. Additionally, we trained an RC model with the synthetic data from all the four domains (last two rows in Tab. 3). This produced our best F1 results for all datasets, indicating that mixing synthetic data from different domains is beneficial for the QA task. Tab. 3 also shows EM/F1 scores of the cross-domain RC models on SQuAD 1.1 dev set. We can see that using synthetic data from any of the four domains significantly improved the performance for SQuAD. In particular, when training the RC model with data from all domains + SQuAD training data (last row), there is a large gain in both EM (3.8) and F1 (2.7).

4.5 Comparison of AQGen, QAGen and QAGen2S models

Comparing our proposed LM filtering-based models in Tab. 2, we propose the following explanations: (1) QAGen2S and QAGen outperform AQGen because generating answers conditioned on the question results in better spans, which is crucial in the training of the downstream RC task. Generated answer spans not conditioned on questions could include spurious tokens, or be a partial span. (2) QAGen2S outperforms QAGen because including the generated question in the bidirectional encoder allows cross attention between the passage and generated question, which results in even more accurate answer generation. Comparing the performance when only synthetic question-answer pairs are employed versus adding SQuAD training pairs, we can observe that the addition of labeled data results in marginal gains. This becomes even more evident for the best performing data generators. In fact, in some cases, adding SQuAD data degrades EM, such as QAGen2S + LM filtering with Natural

Model	Beam Search N=5		Topk+Nucleus N=5		Topk+Nucleus N=10		Topk+Nucleus N=20	
	EM	F1	EM	F1	EM	F1	EM	F1
Synthetic	49.73	63.19	52.20	66.19	52.64	65.56	51.08	63.50
Synthetic + SQuAD	49.95	64.08	49.68	64.47	52.03	65.70	51.87	64.82

Table 4: Beam search vs. Topk+Nucleus sampling with various sample sizes per passage. NQ is used as target domain and QAGen2S with LM filtering is used as generator. For N $>$ 5, top 5 samples per passage were selected according to LM scores.

Questions and NewsQA.

4.6 Ablation Studies

Sampling Design Choices

Tab. 4 shows a comparison between beam search and Topk+Nucleus sampling with different number of samples (5, 10, and 20). The results indicate that beam search underperforms Topk+Nucleus. We attribute this to the lack of diversity in the generated samples using beam search. We observed that beam search tends to select fewer distinct spans, compared to Topk+Nucleus, and generates minor variations of the same question. Appendix C.1 examines this issue.

When training the RC model we only used the top 5 samples based on LM score per each passage. We can observe that sampling 10 pairs per document leads to the best EM/F1 on the target domain. By sampling many QA pairs per passage, we increase the chance of generating good samples. However, if we sample too many qa pairs the top ranked ones might be too similar. Therefore, we used sample size of 10 in this work since a higher sample size incurs higher computation cost while not showing improvements.

LM Filtering

We argue that using LM filtering, as discussed in section 2.4, results in improvements in the target domain downstream RC models by enhancing the quality of the generated (q, a) pairs. Results in Tab. 5 indicate that in the majority of the experiments using LM filtering leads to improved F1/EM metrics. AQGen benefits the most from LM filtering as it generates data with lower quality than the other two models. Tables 10 and 12 in the Appendix show examples of QA pairs and their LM scores.

Fig. 4 shows experimental results when varying the number of (q, a) pairs selected from the 10 pairs sampled per each passage. We chose the value of 5 as this configuration outperforms other values overall. A high value is more likely to allow undesired pairs, while a low value might discard plenty of high quality samples.

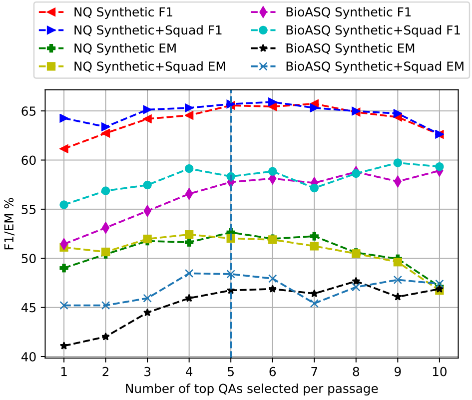

Figure 4: Effect of number of QAs selected per passage in LM filtering. QAGen2S model is used for generation. The likelihood score of the generated answer is used to sort the generated question answer pairs decreasingly.

Correlation between LM and F1 Scores

In this work, we proposed using the LM score of the generated samples as a surrogate to round-trip filtering. We postulate that the LM score correlates with the F1 score used in round-trip filtering. To more thoroughly examine this, we devised an experiment where we sorted the generated samples by their answer LM scores, divided them into contiguous buckets each with 200 samples, and calculated the average F1 score of the samples in each bucket. Fig. 5 shows the results of this experiment. As we can see, there exists a strong correlation between the two scores.

While the correlation looks promising, a challenge with using the LM score is that it is relatively noisy. For example, to use the LM score to get only samples whose F1 scores are 1, a very high threshold needs to be set, forcing the vast majority of samples to be dropped. Future work can explore how to reduce this noise.

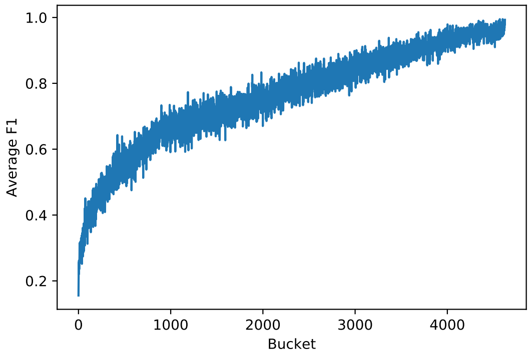

Figure 5: Average F1 score of sorted items based on LM scores. Samples were generated using QAGen2S on Natural Questions passages.

Impact of Synthetic Dataset Size

In Fig. 6, we present plots that correlate synthetic dataset size (in # of passages) and RC model performance (EM/F1). We can see that with increasing the number of generated (q, a) pairs (5 pairs per passage), RC model performance improves. Such correlation is more evident when not using the SQuAD training data. This is expected as with added supervised training samples, there would be less need for a large number of synthetic samples.

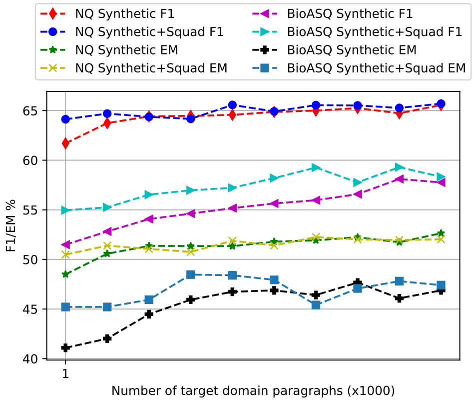

Figure 6: The effect of number of target domain passages on the RC task with synthetically generated QA pairs. QAGen2S is employed to generate questions on NQ and PubMed.

4.7 Experiments with Large QA Models

The downstream RC models presented in previous sections were based on fine-tuning `BERT-base` model, which has 110 million parameters. In this section, we assess the efficacy of our proposed domain adaptation approach on a higher capacity transformer as the RC model. For these experiments, we chose pretrained `RoBERTa-large` (Liu et al., 2019) model from transformers library (Wolf et al., 2019), which has 355 million parameters. Tab. 6 displays the domain adaptation results on the NQ domain using QAGen2S generated samples. It also includes performance on the source domain dev set. Although the SQuAD 1.1 baselines (first row), is significantly higher than those with `BERT-base` in Tab. 2, EM/F1 gains of 5.8/3.4 are achieved on the target domain. 1/0.5 gains in EM/F1 are observed in SQuAD 1.1 dev set. These results demonstrate that our proposed end-to-end synthetic data generation approach is capable of achieving substantial gains even on state-of-the-art RC baselines such as `RoBERTa-large`.

Model	**FT Data**	**SQuAD 1.1** EM	F1	**NQ** EM	F1
SQuAD1.1 (SQ)	SQ	86.43	93.18	50.57	67.09

	+ SQ	**87.46**	**93.67**	**56.35**	**70.47**

Table 6: Source and target domain performance with RoBERTa-large as downstream RC model.

5 Conclusions

We presented a novel end-to-end approach to generate question-answer pairs by using a single transformer-based model. Our experiments showed that by proper decoding, significant improvements in domain adaptation of RC models can be achieved. We concluded that using LM filtering improves the quality of synthetic question-answer pairs; however, there is still a gap with round-trip filtering with some of the target domains. Improving LM-score-based filtering is a future direction of our work.

While we were able to generate diverse, high quality and challenging synthetic samples on the target domains, the types of the questions produced still were limited to those of SQuAD, since the generative models were trained on SQuAD. It would be interesting to explore how one can adapt the generative models to the type of target domain questions.

A Additional Details Regarding the Datasets Used

SQuAD 1.1 dataset is used to train the generative models as well as in-domain supervised data for the downstream RC task. We use the default train and dev splits, which contain 87,599 and 10,570 (q, a) pairs, respectively. SQuAD 1.1 questions exhibit high lexical overlap with answers, since annotators were presented with passages and extracted answers when creating questions.

Natural Questions dataset consists of Google search questions, the Wikipedia pages from top 5 search results, and the corresponding annotated answers. This dataset and SQuAD are both derived from Wikipedia pages, however, questions from Natural Questions have considerably less ngram overlap with annotated answers compared to those from SQuAD. Also different from SQuAD, Natural Questions dataset contains passages with HTML tables and tags. We use MRQA Shared Task preprocessed training and dev sets, which consist of 104,071 and 12,836 (q, a) pairs, respectively. We utilize training set passages as the target domain (unlabeled) corpus, while preforming evaluations on the dev set.

NewsQA consists of question and answer pairs from CNN news articles. We use the dev set from the MRQA Shared Task, which removes unanswerable questions and those without annotator agreement. We believe this version better suits our work, as we focus only on generation of answerable questions. The train and dev sets consists of 74,160 and 4,212 samples, respectively. Passages from CNN/Daily Mail corpus are used as target domain passages.

BioASQ challenge is a competition on semantic indexing and question answering tasks based on annotated PubMed documents. As with the previous dataset, we employ MRQA shared task version of BioASQ, which consists of a dev set with 1,504 pairs. We collected PubMed abstracts to use as target domain passages. Being from Biomedical domain, BioASQ makes a clear domain shift from other datasets.

DuoRC contains question answer pairs from movie plots which are extracted from both Wikipedia and IMDB. This dataset has been developed to have question and answer pairs with minimal lexical overlap, which makes it more challenging. ParaphraseRC task of DuoRC dataset is used in our evaluations. Training and dev sets include 39,144 and 13,111 pairs, respectively. We crawled IMDB movie plots to use as the target domain unlabeled corpus. The dataset has been developed by selecting the same movie plot from both sources, and generating question from one source and selecting the answer from the other. This approach has resulted in question and answer pairs with minimal lexical overlap.

All of the validation sets of the aforementioned out-of-domain tasks are identical to those used by Nishida et al., except DuoRC, where we use MRQA shared task formatted DuoRC dev set.

B Additional Ablation Studies

B.1 Performance on SQuAD 1.1 with Different Filtering Approaches

While the performance of the RC models on the target domains is important, weak performance on the source domain could inhibit the use of our proposed methods in applications that require strong performance in both source and target domains. Tab. 7 shows EM/F1 scores of the `bert-base-uncased` RC models trained with synthetic data generated from the IMDB corpus on SQuAD 1.1 dev set. We can observe that adding synthetic samples to the SQuAD training set always improves the performance on the dev set compared to using the SQuAD training set only. In fact, with QAGen2S, impressive 3.1(EM)/2.2(F1) gains are achieved. Synthetic only samples from the same model outperform the SQuAD baseline. Similar to previous domain adaptation results, we observe that QAGen2S outperforms QAGen, and QAGen exceeds AQGen.

B.2 Comparison of Using Filtering vs. No Filtering

Tab. 8 presents comprehensive results of using LM filtering over all the of the target domains. We can observe that the arguments made in Sec. 4.7 hold for NewsQA and DuoRC as well.

B.3 Impact of Language Model Score Pooling

To aggregate the LM scores of a given question-answer pair, one can use either sum or average of the token scores, as defined in Sec. 2.4. We experimented with both options and summarized the results in Tab. 9 for QAGen and AQGen models. We can observe that using summation generally outperforms averaging. We speculate this is because average pooling encourages longer question-

Model	fine-tune Data	None		LM		Rountrip

Table 8: Comparison of using LM filtering versus no filtering. **Bold** values indicate best performance on each target domain for each model (per rows separated by sold lines).

answer pairs, which are more likely to consist of incorrect samples. By using summation, shorter question-answer pairs would be more likely to be selected during LM filtering.

C Examples of Generated Samples

C.1 Illustration of Answer LM Score

Tab. 10 presents unfiltered question-answer pairs and associated answer LM scores generated from a randomly selected Natural Questions corpus using the QAGen2S model. As can be seen from Topk+Nucleus decoded samples, the last two generated samples are incorrect and would be filtered out using the LM filtering approach that is used in this work. The last sample, which consists of an answer that is entirely irrelevant to its question, has a considerably lower answer LM score than the rest of the samples.

With beam search, due to the high number of repetitions, the scores are close. While beam search generates samples with high likelihood, due to the lack of diversity, as evident here, the performance of the trained RC models on such synthetic samples underperforms those of Topk+Nucleus.

C.2 Comparison of Generated Samples by AQGen, QAGen and QAGen2S

Tab. 11 presents unfiltered question-answers pairs generated using each of our proposed models on a randomly selected passage from CNN/Daily Mail corpus. We can observe that generated samples using AQGen have lower quality than the other two models. Also, the selected spans are repetitive. Only 3 out of the 6 properly generated samples are correct question-answer pairs. Comparing QAGen and QAGen2S samples, we can observe that QAGen2S generates more diverse and longer answer spans. In this example, we can see that more repeated spans are generated by QAGen than QAGen2S.

While the Topk+Nucleus sampling approach improves the diversity of generated question-answer pairs, we can still see repetitions and incorrect pairs. We believe using the LM score filtering, the vast majority of incorrect pairs are discarded. However, this also means there is room for improving the generative models.

C.3 Question Answers from Table

The Natural Questions dataset includes HTML formatted passages. We noticed that some of them

Model	LM Pooling	fine-tune Data	NQ		NewsQA		BioASQ		DuoRC

are web tables. Tab. 12 illustrates one such example. The content under ***Passage*** is the input string, as seen by the generative models, and ***Rendered Passage*** indicates how the table appears in a browser. We experimented with using **QGen** model on this passage, and noticed that the span detection model was not capable of distinguishing between textual content and HTML tags properly, resulting in selecting spans that included HTML tags. However, the samples generated by the joint span and question generation model, QAGen2S in this example, show surprisingly high-quality spans and questions. Only one sample is not correct (*What team is Tampa Bay's home arena?*). We believe this is because when the span generation is conditioned on the generated question, the likelihood of spans that include spurious tokens, HMTL tags in this example, diminishes sharply. This opens the door to the possibility of using our proposed models in structured corpora without any extra effort.

D Training and Platform Details

All of the experiments in this work were performed on Amazon EC2 instances. We employed p3.8xlarge, p3.16xlarge, and p3dn.24xlarge GPU instances. In the training of the generative models, warmup was set to 10% of total training steps. We used a batch size of 24. Each epoch took 2 to 3 hours on 3 GPUs. We observed that usually, the best model is achieved within the first two epochs.

The RC models with Synthetic+SQuAD samples were trained by combining synthetic samples and SQuAD training set and randomly shuffling them. Each epoch of training took 2 to 12 hours, depending on the average length of target domain passages on 1 GPU.

All of the hyperparameters of both generative and RC downstream models were fixed. We only performed hyperparameter tuning on those mentioned in the paper.

Passage: (CNN) – Fifteen people have now died after consuming **cantaloupe** contaminated with the listeria monocytogenes bacteria, the Centers for Disease Control and Prevention said **Friday**. At least **84** people in 19 states have become ill with the bacteria, the agency said. And the **number of illnesses** could still grow, added the CDC, citing **reporting lags and how the disease can develop slowly in some people**. On Tuesday, the CDC was reporting 13 deaths and 72 illnesses in what was already then the deadliest food-borne illness outbreak in the United States since **1998**. Five people have died in New Mexico from eating the tainted cantaloupes, the CDC said. **Three** people died in Colorado, **two** in Texas and one each in Kansas, Maryland, Missouri, Nebraska and Oklahoma. Illnesses have also been reported in Alabama, Arkansas, California, Illinois, Indiana, Montana, North Dakota, Virginia, West Virginia, Wisconsin and Wyoming. What you need to know about Listeria. **Most of those who fell ill are more than 60 years old**, the CDC said. Doctors also are closely monitoring the pregnancies of two women who ate contaminated cantaloupe, with the agency noting that **listeriosis** can cause miscarriages and stillbirths. Older adults and people with compromised immune systems are also especially susceptible. Public health investigators have traced the source of the bacteria to a farm in **Granada, Colorado**. Food Poisoning 101. The grower, **Jensen Farms**, issued a recall for its Rocky Ford-brand cantaloupes on September 14. By now, the cantaloupes should all be off store shelves, the CDC said. The agency warned that people should not eat Rocky Ford cantaloupes, even if they have eaten part of one and have not yet fallen ill. It also said that consumers **should be wary of eating any cantaloupes if they don't know where they came from**. How to keep your food safe.

Abstract

Transfer learning techniques are particularly useful in NLP tasks where a sizable amount of high-quality annotated data is difficult to obtain. Current approaches directly adapt a pre-trained language model (LM) on in-domain text before fine-tuning to downstream tasks. We show that extending the vocabulary of the LM with domain-specific terms leads to further gains. To a bigger effect, we utilize structure in the unlabeled data to create auxiliary synthetic tasks, which helps the LM transfer to downstream tasks. We apply these approaches incrementally on a pre-trained Roberta-large LM and show considerable performance gain on three tasks in the IT domain: Extractive Reading Comprehension, Document Ranking and Duplicate Question Detection.

1 Introduction

Pre-trained language models (Radford et al., 2019; Devlin et al., 2019; Liu et al., 2019) have pushed performance in many natural language processing tasks to new heights. The process of model construction has effectively been reduced to extending the pre-trained LM architecture with simpler task-specific layers, while fine-tuning on labeled target data. In cases where the target task has limited labeled data, prior work has also employed transfer learning by pre-training on a source dataset with abundant labeled data before fine-tuning on the target task dataset (Min et al., 2017; Chung et al., 2018; Wiese et al., 2017). However, directly fine-tuning to a task in a new domain may not be optimal when the domain is distant in content and terminology from the pre-training corpora.

To address this language mismatch problem, recent work (Alsentzer et al., 2019; Lee et al., 2019; Beltagy et al., 2019; Gururangan et al., 2020) has adapted pre-trained LMs to specific domains by continuing to train the same LM on target domain text. Similar approaches are also used in multilingual adaptation, where the representations learned from multilingual pre-training are further optimized for a particular target language (Liu et al., 2020; Bapna and Firat, 2019). However, many specialized domains contain their own specific terms that are not part of the pre-trained LM vocabulary. Furthermore, in many such domains, large enough corpora may not be available to support LM training from scratch. To resolve this out-of-vocabulary issue, in this work, we *extend* the open-domain vocabulary with in-domain terms while adapting the LM, and show that it helps improve performance on downstream tasks.

While language modeling can help the model better encode the domain language, it might not be sufficient to gain the domain knowledge necessary for the downstream task. We remark, however, that such unlabeled data in many domains can have implicit structure which can be taken advantage of. For example, in the IT domain, technical documents are often created using predefined templates, and support forums have data in the form of questions and accepted answers. In this work, we propose to make use of the structure in such unlabeled domain data to create synthetic data that can provide additional domain knowledge to the model. Augmenting training data with generated synthetic examples has been found to be effective in improving performance on low-resource tasks. Golub et al. (2017), Yang et al. (2017), Lewis et al. (2019) and Dhingra et al. (2018) develop approaches to generate natural questions that can aid downstream question answering tasks. However, when it is not possible to obtain synthetic data that exactly fits the target task description, we show that creating auxiliary tasks from such unlabeled data can be

November 16–20, 2020.

useful to the downstream task in a transfer learning setting.

For preliminary experiments in this short paper, we select the IT domain, partly because of the impact such domain adaptation approaches can have in the technical support industry. The main contributions of this paper are as follows: **(1)** We show that it is beneficial to extend the vocabulary of a pre-trained language model while adapting it to the target domain. **(2)** We propose to use the inherent structure in unlabeled data to formulate synthetic tasks that can transfer to downstream tasks in a low-resource setting. **(3)** In our experiments, we show considerable improvements in performance over directly fine-tuning an underlying RoBERTa-large LM (Liu et al., 2019) on multiple tasks in the IT domain: extractive reading comprehension (RC), document ranking (DR) and duplicate question detection (DQD).[1]

2 Datasets

We use two publicly available IT domain datasets. Table 1 shows their size statistics.

Dataset	Train	Dev	Test	Unlabeled
TechQA	600	310	490	306M
AskUbuntu	12,724	200	200	126M

Table 1: Size statistics for two IT domain datasets. Train/Dev/Test: # examples, Unlabeled: # tokens.

TechQA (Castelli et al., 2019) is an extractive reading comprehension (Rajpurkar et al., 2016) dataset developed from real user questions in the customer support domain. Each question is accompanied by 50 documents, at most one of which has the answer. A companion collection of 801K unlabeled Technotes is provided to support LM training. In addition to the primary reading comprehension task (TechQA-RC), we also evaluate on a new document ranking task (TechQA-DR). Given the question, the task is to find the document that contains the answer.

AskUbuntu[2] (Lei et al., 2016) is a dataset containing user-marked pairs of similar questions from Stack Exchange[3], which was developed for a duplicate question detection task (AskUbuntu-DQD). A static offline dump of AskUbuntu, which is organized as a set of forum posts[4], is also available and can be used for LM training.

3 Vocabulary Extension for LM Adaptation

Texts in specialized fields including technical support in the IT domain may contain numerous technical terms which are not found in open domain corpora and are therefore not well captured by the vocabulary of out-of-the-box LMs. These terms are often over-segmented into small pieces (sub-word tokens) by the segmenter rules, which are learned from the statistics of open domain language.

As an example, the token out-of-vocabulary (OOV) rate of the standard RoBERTa vocabulary in the TechQA Technotes data is 19.8% and the BPE/TOK ratio is 1.32. Contrast this with the analogous figures for 1M randomly selected Wikipedia sentences, where the OOV rate is only 8.1% and the BPE/TOK ratio is 1.12. While transformer-based pre-trained language models (Devlin et al., 2019; Liu et al., 2019) yield better representations of previously unseen tokens than traditional n-gram models, over-segmentation can still cause degradation in downstream task performance.

We address this challenge by augmenting the vocabulary of the pre-trained LM with frequent in-domain words. Specifically, the most frequent OOV tokens after tokenization are recorded and used to bypass the BPE segmentation stage. This prevents the segmenter from splitting these terms into smaller pieces. New entries in the LM vocabulary and corresponding word embeddings are created for these tokens. In our experiments, the number of such protected tokens is decided using an empirical criterion: we require that 95% of the in-domain data be covered by the extended vocabulary. We add 10k new items to the vocabulary for the Technotes corpus and 5k for the AskUbuntu corpus. The variation in coverage due to different numbers of new vocabulary entries is shown in the appendix. The pre-trained LM is then adapted to the domain-specific corpus via masked LM (MLM) training. The embeddings of the new vocabulary are randomly initialized and then learned during the MLM training. The embeddings of existing vocabulary are also fine-tuned in this phase.

4 Task-Specific Synthetic Pre-training

While in-domain LM pre-training reveals novel linguistic patterns in target domain text, in many domains including technical documents, structure present in unlabeled text can contain useful information closer to actual end tasks. In this section, we propose to utilize such structure in unlabeled data to create auxiliary pre-training tasks and associated synthetic training data, which in turn can help target tasks via transfer learning.

TechQA. The TechQA dataset release contains a companion Technotes collection with 801K human written documents with titled sections. We observe that certain sections in these documents (e.g., *Abstract*, *Error Description* and *Question*) correspond to a problem description, while others (e.g., *Cause* and *Resolving the Problem*) describe the solution[5]. We create an auxiliary reading comprehension (RC) task from these documents. Specifically, if a document contains both problem and solution sections, a synthetic example is created where the problem description section is the query, the solution section is the target answer, and the entire document excluding the query section is the context. Additionally, ten other documents are sampled from the Technotes corpus as negatives to simulate *unanswerable* examples. This auxiliary task trains an intermediate RC model which predicts the start and end positions of the solution section as the answer given the document and the problem description. While our main goal here is to generate long-answer examples common in TechQA, the general idea of utilizing the document structure can be applicable in other scenarios including in scientific domains like Bio/Medical (G. Tsatsaronis, G. Balikas, P. Malakasiotis, et al., 2015; Lee et al., 2019) where structured text is relatively common.

AskUbuntu. The AskUbuntu dataset contains a web dump of forum posts, each containing a question and multiple answers, with one answer possibly labeled by users as "Accepted". Motivated by (Qiu and Huang, 2015; Lei et al., 2016; Rücklé et al., 2019), we create an auxiliary answer selection task from this structure. Each instance in the synthetic data for this task contains a question, its accepted answer as the positive class, and an answer randomly sampled from other question posts as the negative class. An intermediate classification model is learned from these annotations, whose weights are used to initialize the target duplicate question detection (DQD) model. Even though this auxiliary task adopts a different question-answer classification objective than the DQD task's objective of question-question classification, our experimental results show that the former still serves a good initialization for the latter.

5 Experiments

5.1 Setup

Our experiments build on top of the RoBERTa-large LM. We adopt the standard methodology of using the pre-trained LM as the encoder and processing the contextualized representations it produces using task-specific layers. For the TechQA-RC task, we follow (Devlin et al., 2019) and predict the start and end position of the answer span with two separate classifiers, trained using cross entropy loss. For the TechQA-DR and AskUbuntu-DQD tasks, we follow (Adhikari et al., 2019) and classify the [CLS] token representation at the final layer with a binary classifier trained using the binary cross entropy loss; during inference, we rank the documents or questions according to their classification score. For all the tasks, during finetuning, we train the entire model end-to-end. We refer the reader to the appendix for details on hyperparameter values for all the experiments.

For the TechQA-RC task, we report both the main metric, F1, and the ancillary F1 for answerable questions, HA_F1, to capture the effects of our approach both on the end-to-end pipeline (F1) and on the answer extraction component (HA_F1). For TechQA-DR, models are evaluated by Match@1 and Match@5. For AskUbuntu-DQD, we report MAP, MRR, Precision@1 and Precision@5 following (Lei et al., 2016).

5.2 Synthetic Pre-training Corpus and Labeled Data Augmentation

Using the method described in section 4, we use the 801K Technotes to construct a synthetic corpus for the TechQA tasks. The synthetic data contains 115K positive examples, each of which has 10 randomly selected documents as negatives. For the AskUbuntu-DQD, a 210K-example synthetic corpus is constructed from the web dump data, with a positive:negative example ratio of 1:1.

Since TechQA is a very-low resource dataset

Table 3: Experimental results on TechQA-DR task. Each row with a + adds a step to the previous row. M@1 is short for Match@1 and M@5 for Match@5. Numbers in parentheses show standard deviation.

with only 600 training examples, we additionally apply data augmentation techniques to increase the size of the training set. We use simple data perturbation strategies, such as adding examples with only parts of the original query, randomly dropping words in query and passage, duplicating positive examples, removing stop words, dropping document title in the input sequence etc., to increase the size of the training set by 10 times. This augmented training set is only used under the data augmentation setting while fine-tuning on the TechQA tasks.

5.3 Results and Analysis

For each of our approaches, we show performance of the model when fine-tuned on the downstream tasks in TechQA and AskUbuntu datasets. All the numbers reported are averages over 5 seeds, unless otherwise stated. Standard deviation numbers are shown in parentheses.

TechQA-RC Table 2 describes the performance on the RC task in the TechQA dataset. The BERT baseline numbers are from (Castelli et al., 2019). Here, model performance is compared on the dev set and we report the blind test set numbers[6] for our single-best baseline and final models.

Adapting the LM without extending the vocabulary yields just 0.2 points over the RoBERTa-large baseline. Augmenting the vocabulary by 10k word pieces improves the HA_F1 score by 1.7 points. Furthermore, our RC-style synthetic pre-training yields a considerable improvement of 2.8 points on HA_F1 and 0.5 points on F1. Finally, data augmentation further boosts performance by about a point on both HA_F1 and F1, suggesting that data augmentation via simple perturbations can be effective in a very-low resource setting.

TechQA-DR Table 3 shows results from our experiments on the auxillary document ranking task over the TechQA dataset [7]. We use BM25 (Robertson and Zaragoza, 2009) as our IR baseline. We see that the RoBERTa models substantially outperform the IR system. Although vocabulary expansion only helps by 0.3 points in Match@1, we see considerable improvements in performance from our other approaches. The "RC Pre-training" entry shows a Match@1 improvement of 2.9 points over the language modelling. This demonstrates the effectiveness of pre-training on an ancillary task in a

transfer-learning setting for the document ranking task. We further see an improvement of 1.3 points from data augmentation.

AskUbuntu-DQD Table 4 shows results for the DQD task on the AskUbuntu dataset. We see that our methods give incremental improvements in performance. Our final model is considerably better than the RoBERTa-large baseline on all four metrics. We see the biggest gain in performance from the synthetic pre-training task demonstrating its relevance to the DQD task. For this dataset, we didn't explore data augmentation strategies because it had a considerable number of training instances (see Table 1) compared to the TechQA dataset.

6 Conclusion

In this work, we show that it is beneficial to extend the vocabulary of the LM while fine-tuning it on the target domain language. We show that extending the pre-training with task-specific synthetic data is an effective domain adaptation strategy. We empirically demonstrate that structure in the unsupervised domain data can be used to formulate auxillary pre-training tasks that can help downstream low-resource tasks like question answering and document ranking. In our preliminary experiments, we empirically show considerable improvements in performance over a standard RoBERTa-large LM on multiple tasks. In future work, we aim to extend our approach to more domains and explore more generalizable approaches for unsupervised domain adaptation.

A Appendix

A.1 Implementation Details

In our experiments, we used the Fairseq toolkit (Ott et al., 2019) for language modelling and the Transformers library (Wolf et al., 2019) for downstream tasks. For all of our target models, when fine-tuning on the downstream task, we choose the hyperparameters by grid search and pick the best models on the dev set according to the evaluation metrics for the corresponding task. For TechQA-RC task, we pick the best model according to (HA_F1 + F1) and for TechQA-DR, we choose based on Match@1. For the AskUbuntu-DQD, we pick the best model based on MAP. The best hyperparamters for each of the tasks are shown in the Tables 5 to 8 below:

Hyperparameter	Setting
WARMUP UPDATES	10000
PEAK LR	0.00015
TOKENS PER SAMPLE	512
MAX POSITIONS	512
MAX SENTENCES	8
UPDATE FREQ	64
OPTIMIZER	adam
DROPOUT	0.1
ATTENTION DROPOUT	0.1
WEIGHT DECAY	0.01
MAX Epochs	5
CRITERION	mask-whole-words

Abstract

Textbook Question Answering is a complex task in the intersection of Machine Comprehension and Visual Question Answering that requires reasoning with multimodal information from text and diagrams. For the first time, this paper taps on the potential of transformer language models and bottom-up and top-down attention to tackle the language and visual understanding challenges this task entails. Rather than training a language-visual transformer from scratch we rely on pre-trained transformers, fine-tuning and ensembling. We add bottom-up and top-down attention to identify regions of interest corresponding to diagram constituents and their relationships, improving the selection of relevant visual information for each question and answer options. Our system ISAAQ reports unprecedented success in all TQA question types, with accuracies of 81.36%, 71.11% and 55.12% on true/false, text-only and diagram multiple choice questions. ISAAQ also demonstrates its broad applicability, obtaining state-of-the-art results in other demanding datasets.

1 Introduction

Within NLP, machine understanding of textbooks is one of the grand AI challenges. As originally put by (Reddy, 1988): ”Reading a chapter in a college freshman text (say physics or accounting) and answering the questions at the end of the chapter is a hard (AI) problem that requires advances in vision, language, problem-solving, and learning theory.”. Towards such goals, the Textbook Question Answering (TQA) dataset presented in (Kembhavi et al., 2017) offers an excellent testbed. Drawn from middle school science curricula, it describes fairly complex phenomena through a combination of text and diagrams. Answering questions may therefore involve text, diagrams or both, and require information from multiple sentences and/or diagrams in long textbook lessons.

Another characteristic of the TQA dataset that makes it rather unique and challenging is that questions often involve reasoning beyond methods based on co-occurrence analysis or simple look-up. TQA requires parsing information from different sentences, dealing with qualitative and quantitative information (*high frequency* vs. *20,000Hz*), and relating text or visual information with the question. Solving the TQA task also requires dealing with language about negation, conjunction, polarity or commonsense. On the visual side, TQA is rich with diagrams that describe potentially complex concepts, such as photosynthesis, the trophic chain, and the cycle of water, which are hard to represent as a single natural image. Quite on the contrary, diagrams contain simpler constituents and relationships between them, whose semantics needs to be captured in order to answer the questions.

Despite recent work, overall progress in the TQA dataset has been rather limited until now, suggesting that language and diagram understanding challenges like the ones above-mentioned are still far from solved. In this paper we address such limitations by building on the success of two recent developments in natural language processing and vision-and-language reasoning: large-scale, pre-trained language models and bottom-up and top-down (BUTD) attention. We demonstrate that, compared to previous approaches, transformer-based language models like BERT and RoBERTa can significantly contribute to increase the language understanding and reasoning capabilities required to answer TQA questions. We also show that BUTD attention, originally proposed for tasks like image captioning and visual question answering with natural images, can be effectively adapted to propose regions of interest in the diagram that are relevant for the question in hand, enabling the identification of diagram constituents and their relationships. The main contributions of this paper are the following:

- For the first time, we apply transformers to

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5469–5479,
November 16–20, 2020.

language understanding in TQA, which involves fine-tuning of pre-trained transformers and ensembling.

- Based on BUTD attention we detect diagram constituents and their relationships, and link them to the question, its relevant background and answer options.
- We study the language and visual understanding capabilities of our approach, including several ablations, and demonstrate its robustness and broader applicability.
- We present ISAAQ (Intelligent System for Automatically Answering Textbook Questions), which implements our approach.

The remainder of the paper is structured as follows. Section 2 describes related work. Section 3 introduces the notation that will be used throughout the paper. We present our method in section 4, including an overview of the overall model, its main building blocks (background information retrievers, solvers, ensemble), and their interplay. We focus on each TQA question type, i.e. true/false and text and diagram multiple-choice (MC) questions, as sub-tasks of the main TQA task and propose specific solvers for each case, based on pre-trained transformers, fine-tuning and BUTD attention. In section 5, we present our experimental results, including an ablation study focused on understanding the specific contribution of each solver and their components. We also analyze the robustness of our model, its ability to generalize to other datasets, and its reasoning abilities. Finally, section 6 illustrates the impact of the different techniques used in ISAAQ to address diagram MC questions in TQA.

2 Related work

In (Kembhavi et al., 2016) several TQA baselines were proposed that were based on Machine Comprehension (MC) models like BiDAF (Seo et al., 2017) and MemoryNet (Weston et al., 2014), as well as Visual Question Answering (VQA) (Antol et al., 2015) and diagram parsing algorithms like DsDP-net (Kembhavi et al., 2016). Their results were rather modest (50.4, 32.9, and 31.3 in true/false, text and diagram MC questions), suggesting that existing MC/VQA methods would not suffice for the TQA dataset. Indeed, diagram questions entail greater complexity than dealing with natural images, as shown in (Gomez-Perez and Ortega, 2019), where we beat the TQA baselines using visual and language information extracted from the correspondence between figures and captions in scientific literature enriched with lexico-semantic information from a knowledge graph (Denaux and Gomez-Perez, 2019). By contrast, (Li et al., 2018) focused on finding contradictions between the candidate answers and their corresponding context while (Kim et al., 2019) applied graph convolutional networks on text and diagrams to represent relevant question background information as a unified graph.

The field of NLP has advanced substantially with the advent of large-scale language models such as ELMo (Peters et al., 2018), ULMFit (Howard and Ruder, 2018), GPT (Radford et al., 2018), BERT (Devlin et al., 2018), and RoBERTa (Liu et al., 2019). Using large amounts of text, e.g. BERT was trained on Wikipedia plus the Google Book Corpus of 10,000 books (Zhu et al., 2015), they are trained to learn various language prediction tasks such as guessing a missing word or the next sentence. Language models and particularly transformers have been used in question answering, as illustrated by the success of the Aristo system (Clark et al., 2019) in standard science tests. Transformers have also proved their worth as soft reasoners (Clark et al., 2020), exhibiting capabilities for natural language inference. Furthermore, whilst learning linguistic information, transformers have shown to capture semantic knowledge and general understanding of the world from the training text (Petroni et al., 2019), including a notion of commonsense that can be useful in question answering. Our approach is the first to leverage the language understanding and reasoning capabilities of existing transformer language models for TQA.

Focused on natural images, some vision-and-language reasoning systems are also adopting transformer architectures at their backbone. VL-BERT (Su et al., 2019) and LXMERT (Tan and Bansal, 2019) pre-train large-scale transformers that capture both visual concepts and language semantics, as well as cross-modal information. Pre-training is done via several tasks, like masked language modeling, masked object prediction, cross-modality matching, and image question answering, on large-scale text and visual datasets, like Conceptual Captions (Sharma et al., 2018), Google Book corpus, MS COCO (Lin et al., 2014) or Visual Genome (Krishna et al., 2017), requiring considerable compute. By contrast, our approach is much more frugal. We fine-tune pre-trained existing transformers like BERT and RoBERTa and count on a much more limited variety of datasets focused on diagrams, like AI2D (Kembhavi et al., 2016). Like LXMERT, we extend region-of-interest (RoI) features with object positional embeddings. Finally, we apply bottom-up and top-down attention (Anderson et al., 2018) to focus on the most relevant diagram regions for each question.

3 Preliminaries and notation

3.1 The TQA dataset

The TQA dataset (Kembhavi et al., 2017) comprises 1,076 lessons from Life Science, Earth Science and Physical Science textbooks, with 78,338 sentences and 3,455 diagrams, distributed in 5,400 true/false questions, 8,293 text MC, and 12,567 diagram MC questions. The dataset is split in training, validation and test sets (table 3), which are disjoint at the lesson level. Thus, our model will often need to answer questions it was not trained for, which entails additional challenges to generalize beyond the training set (section 5). TQA questions are long compared to VQA, with a mode of 8 vs. 5 words per question. Almost 85% of the questions are *what*, *how* or *which* wh- questions. Another 10% is formulated assertively, bringing additional language understanding complexity. Most (80%) text MC questions can be answered with information from one or several sentences in a paragraph. The rest may require multiple paragraphs and lessons as well as external knowledge. Over 40% diagram MC questions require complex diagram parsing, only 2% can be answered with an OCR.

3.2 Notation

We divide the TQA task in three sub-tasks, one per question type. The solvers addressing each sub-task are denoted as TF_m (true/false questions), TMC_m (text MC) and DMC_m (diagram MC). Suffix m indicates the method used for background retrieval.

$\forall l \in L$, let ls_i be each sentence in lesson l, where L is the set of lessons in the dataset. We apply BERT-style transformers (Devlin et al., 2018) to MC questions, treating the task as multiple choice classification. Given a question $q \in l$ with answer options a_i and background knowledge K, we pass the following sequence s to the transformer:

$$seq(K, QA_i) = [CLS]K[SEP]QA_i[SEP] \quad (1)$$

with $QA_i = [q, a_i]$. Similarly, for true/false questions we explore the relation between a question q and a sentence ls. Overloading the previous method, s is obtained as:

$$seq(q, ls) = [CLS]q[SEP]ls[SEP] \quad (2)$$

A transformer T will produce one vector for each token in s, including $[CLS]$, whose vector we denote as $T_{[CLS]}(s)$, which we use as a pooled representation of the whole sequence.

4 Proposed Method

Figure 1 shows our two-stage process to answer text and diagram MC questions. First, for each question we propose different retrievers to extract relevant language and visual background knowledge from the textbook. Note that we consider both approaches based on conventional information retrieval techniques and approaches that leverage transformers pre-trained on specific tasks.

During training, the retrieved background is provided along with the question and candidate answers to our solvers. Also during execution, providing the potential to "read" such knowledge and apply it to the question. We ensemble different solvers resulting from fine-tuning one or several transformers on a multiple choice classification task, which can be combined with others based e.g. on information retrieval.

For text and diagram MC questions, each transformer-based solver results from training the MCC task on the text passages produced by one of the text retrieval methods. Since each text retriever produces a different but complementary dataset of background text passages, the resulting solvers also complement each other, motivating their combination as an ensemble. In addition, for the visual part we apply BUTD attention as shown in figure 2. For true/false questions we follow an analogous two-stage process, in this case fine-tuning our transformers on a text entailment task.

4.1 Background knowledge retrieval

Information retrieval techniques to obtain background information from the text are usually keyword-based and potentially oblivious of the different artifacts of language, such as morphological variations, conjugations, terms that may be semantically related to the question, synonyms, hypernyms or multi-word expressions, which are particularly frequent in the domains of the TQA dataset. To address such shortcomings, we extend classic information retrieval approaches with pre-trained

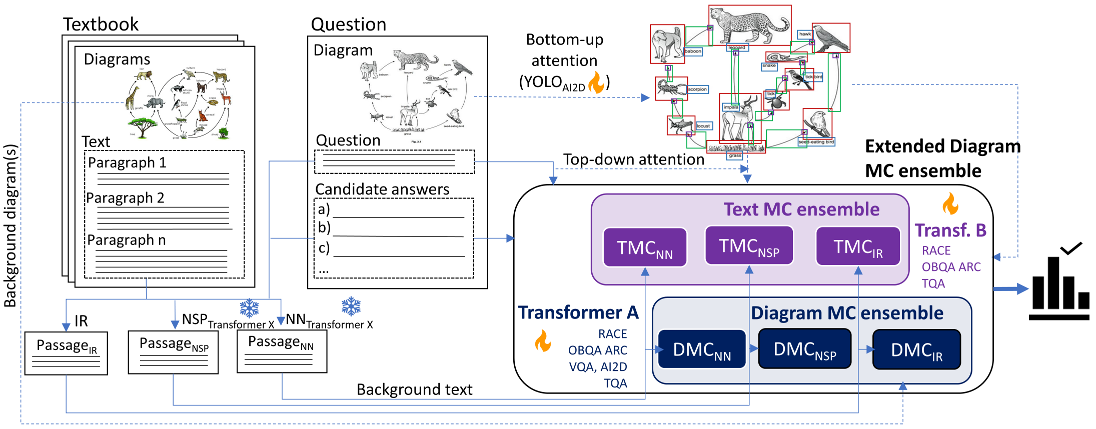

Figure 1: Overview of the proposed TQA model for text and diagram MC. Left: background retrieval stage. Right: Text and Diagram MC solvers are trained using transformers and BUTD. Flames indicate the underlying transformer is fine-tuned for the task at hand. Ice denotes the opposite. Dashed lines only apply for diagram MC.

models that leverage the language understanding capabilities of transformer language models. This results in three text background retrievers:

Information Retrieval (IR) The IR method searches the whole TQA dataset to see if question q along with an answer option is explicitly stated in the corpus. For each answer option a_i, we concatenate q and a_i and run the query against a search engine like ElasticSearch. Based on the search engine score, we take the top n sentences ($n = 10$) resulting from the query, where each sentence has at least one overlapping, non-stop word with a_i. This ensures that all sentences have some relevance to both q and a_i, while maximizing recall. Then, we concatenate the selected sentences following their ranking to compose a text passage with the desired background knowledge.

Next Sentence Prediction (NSP). We implement this retriever by treating the task as next sentence prediction using a transformer T with frozen weights. For each triple (q, a_i, ls_j) we produce a sequence $s_{ij} = seq([q, a_i], ls_j)$, where q is a question, a_i one of its possible answers, and ls_j a sentence in lesson l. We pass it to T and take the probability that ls_j can be semantically derived from the statement that a_i is the answer of q, with label `isNext`. Then, we rank the sentences based on such value, take the top n sentences, and return the passage resulting from their concatenation.

Nearest Neighbors (NN). For each question and candidate answer pair q, a_i and sentence ls_j in lesson l, we obtain their vector representations $C_i = T_{[CLS]}([q, a_i])$ and $C_j = T_{[CLS]}(ls_j)$. We calculate the cosine similarity between them, take the top n sentences based on their similarity score, and concatenate them as a single paragraph.

Diagram retrieval. In addition to text, we also retrieve background diagrams. To this purpose, we pass the question and lesson diagrams through a ResNet-101 network pre-trained on ImageNet (Deng et al., 2009). We calculate the cosine similarity between the resulting features and select the lesson diagram closest to the question diagram.

4.2 Solvers

The ISAAQ solvers result from the combination of three main components: i) the specific models used to address each TQA question type as a particular sub-task within the overall model, ii) the underlying transformer language model, and iii) the background information associated to each question used to train the solver. Here we focus on the first of such components for the different types of questions in the TQA dataset: true/false, text, and diagram MC questions.

True/False Questions. We address true/false questions as an entailment task, where question q corresponds to the hypothesis and the premise is a sentence ls_i, with $q, ls_i \in$ lesson l. Such task is modeled as sequence classification, using a pre-trained transformer T. For each ls_i, sequence $s_i = seq(q, ls_i)$ is passed to the sequence classification model, obtaining a $2-d$ logit vector. The answer, with possible labels `true` or `false`, is computed as the output of a binary classifier, trained by minimizing the negative log-likelihood of the correct answer produced by a softmax layer.

Text MC Questions. This solver aims to select the answer to question q amongst several answer options a_i, where the retrieved background knowledge for q and a_i is a passage p. To this purpose we use a pre-trained transformer T to implement a multiple choice classification model. For each a_i, we pass the input sequence $s_i = seq(p, [q, a_i])$ and obtain and $N-d$ logit vector, with N the number of answer options. The answer to q is the output of a multi-class classifier, also trained by minimizing the negative log-likelihood of the correct answer.

Diagram MC Questions

Since diagram questions involve both text and diagrams, we need to address both branches in our model and merge them in order to answer the question based on both text and visual information (see figure 2). To encode the text part, we follow the same approach as with text MC questions. For the visual part, instead of using the feature map of the diagram produced by a convolutional neural network, we apply BUTD attention (Anderson et al., 2018) to take the features of the regions of interest (RoI) detected bottom-up in the diagram and then apply top-down attention on the question.

Each RoI $r_j \in \{r_1 \dots r_m\}$ is represented by two vectors: a visual feature vector f_j with dimensionality $d_f = 1000$ and a positional vector p_j with dimensionality d_p containing 4 bounding box coordinates. In contrast to directly using the feature vector f_j as in (Anderson et al., 2018) and in line with other work like (Tan and Bansal, 2019), we learn an embedding v_j of dimensionality $d_v = 1024$:

$$\begin{aligned} \hat{f_j} &= LayerNorm(W_F, f_j + b_f) \\ \hat{p_j} &= LayerNorm(W_P, p_j + b_P) \\ v_j &= (\hat{f_j} + \hat{p_j})/2 \end{aligned} \tag{3}$$

To extract RoIs and their positional information we fine-tune YOLO (Redmon et al., 2015) on AI2D (Kembhavi et al., 2016), a dataset with TQA-style diagrams annotated with position and region type. The visual features v_j of each RoI detected bottom-up by YOLO are also made to attend top-down to the representation of question q, its background knowledge p and answer options a_i, produced by a transformer language model T (figure 2). $\forall a_i$ we provide T with input $s_i = seq(p, [q, a_i])$ and obtain $C_i = T_{[CLS]}(s) \in \mathbb{R}^H$, a pooled representation of s_i. We generate an unnormalized top-down attention weight a_{ij} for each m diagram RoI feature vector v_j as:

$$a_{ij} = w_a^T g_a([v_j, C_i]) \tag{4}$$

where $w_a \in \mathbb{R}^H$ is a learned vector. We implement the learned non-linear transformation g as a gated hyperbolic tangent activation (Dauphin et al., 2017). The normalized attention weight and attended image feature $\hat{v_i}$ for each option a_i are:

$$\begin{aligned} \alpha_{ij} &= softmax(a_{ij}) \\ \hat{v_i} &= \sum_{j=1}^{m} \alpha_{ij} v_j \end{aligned} \tag{5}$$

The distribution $\hat{y}$ over the possible outputs is:

$$\hat{y} = softmax(UW_u) \tag{6}$$

where $U \in \mathbb{R}^{NxH}$ is a matrix of u_i vectors, with N the number of answer options a_i, and $W_u \in \mathbb{R}^H$ a learned parameter vector. Each vector u_i is a joint representation of the question and the diagram for answer option a_i, where $u_i = C_i \circ \hat{v_i}$.

4.3 Ensemble

The choice of a specific background retriever may have a significant impact in the overall performance of each solver after training. Transformer-based background retrieval methods have deeper language understanding capabilities than those based on classic information retrieval approaches. However, they are also more computationally demanding. This has implications in terms of the textbook range that each retriever can reasonably cover. To address such trade-off we use information retrieval methods to extract background sentences from the whole textbook, knowing they may not be as accurate, while transformer-based methods focus on the lesson of the question to be answered, which potentially contains more relevant information.

We train our solvers using variations of the background knowledge provided by the different retrieval methods. Then, for each question type, we combine the resulting solvers in a single ensemble. Our ensemble algorithm is based on the two-step approach proposed in (Clark et al., 2019) to produce a combined score in $[0, 1]$. In the first step, each solver s is calibrated by learning a logistic regression classifier from each answer option to a correct/incorrect label. Like (Clark et al., 2019), we also calibrate on the training set. The features for answer option a_i include the raw score s_i and its value across all question options, normalized with a softmax. This step returns a calibrated score per solver s and option a_i. The second step uses the calibrated scores as the input to another logistic regression classifier whose output is the ensemble score for each a_i.

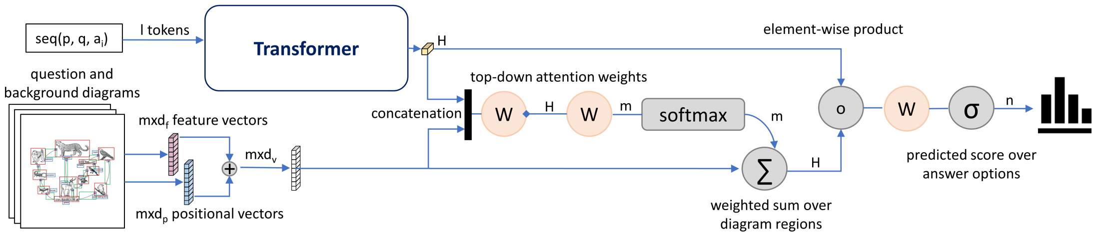

Figure 2: Overview of solver architecture for diagram questions, including BUTD attention.

5 Experiments and Results

5.1 Experimental settings

Our approach is rather frugal in terms of hardware. All training and evaluation has been done on a single server with 32GB of RAM, 1TB SSD and a single GPU GeForce RTX 2080 Ti. ISAAQ solvers have been implemented[1] using the Transformers library[2] and RoBERTa large. We apply Pareto to select maximum input sequences of 64 tokens for true/false questions and 180 for text and diagram MC. For text background retrieval we use a pre-trained BERT-base model. We train each TQA sub-task during 4 epochs and pick the epoch with the best accuracy. We take Adam (Kingma and Ba, 2014) with linearly-decayed learning-rate and warm-up as in (Devlin et al., 2018) and empirically select peak learning rates in the range $[1e^{-6}, 5e^{-5}]$, with $1e^{-5}$ for true/false and text MC questions and $1e^{-6}$ for diagram MC. Similarly, we choose a dropout value of 0.1 at the exit of the transformer. Training time per epoch is 1' for true/false questions, 30' for text MC, and 60' for diagram MC.

For diagram encoding, we pass each RoI to a pre-trained ResNet-101 (He et al., 2016) backbone. We have experimented with other visual models like VGG (Simonyan and Zisserman, 2015) with similar results. Unlike (Tan and Bansal, 2019) and (Anderson et al., 2018), who used Faster R-CNN (Ren et al., 2017) on natural images, we choose YOLO to extract RoIs from TQA diagrams. After fine-tuning on AI2D, YOLO outperformed Faster R-CNN with a test set accuracy of 81.2% vs 79.22%. Both results suggest around 20% margin for additional improvement in RoI selection. We apply Pareto to fix the maximum number of regions to 32 and fine-tune YOLO on AI2D with standard parameters[3] for 242 epochs and initial learning rate $1e^{-4}$.

5.2 Language and visual pre-training

We pre-train our text MC question solvers on several datasets (table 3), including some not specific of science. The resulting fine-tuned transformer is also used to train the true/false solvers. We follow common practice in multi-step fine-tuning, with some variations in the usual order based on dataset size. First, we fine-tune on the training set of RACE (Sun et al., 2019), a challenging set of English comprehension MC exams given in Chinese middle and high schools. Then we continue with the training sets of a collection of scientific MC question datasets: ARC (Clark et al., 2018), both Easy and Challenge, and OpenBookQA (Mihaylov et al., 2018). Finally, we fine-tune the result of the previous step on the TQA training set for text and diagram MC. Peak learning rates are $1e^{-6}$ for the first fine-tuning step and $1e^{-5}$ for the second.

We pre-train our diagram MC question solvers on the training sets of VQA abstract scenes and VQA, the latter being the largest visual resource available with support for MC questions and diagram-style images. The size of such datasets is still far from natural image datasets like Visual Genome or MS COCO. Also, note that AI2D is annotated for generic diagram constituents (blob, arrow, arrow head, text), i.e. it does not observe semantic visual categories like cloud, tree or mammal. Nor does AI2D annotate parts of diagram blobs, like the different layers of Earth or the organelles in a cell, which suggests further room for improvement. We train on VQA and AI2D with learning rate $1e^{-6}$ for 4 and 12 epochs, respectively.

5.3 Main results

Table 2 shows the results (% accuracies) obtained by ISAAQ in true/false, text and diagram MC. Figure 3 shows the ratio of correct vs. incorrectly answered questions per question type and subject matter. Results are very similar across all domains, with a slight preference for Physical sciences.

Since most previous approaches did not report

AI2D	7,824	906	978	9,708
TQA	15,154	5,309	5,797	26,260

Table 1: Dataset partition sizes (#questions).

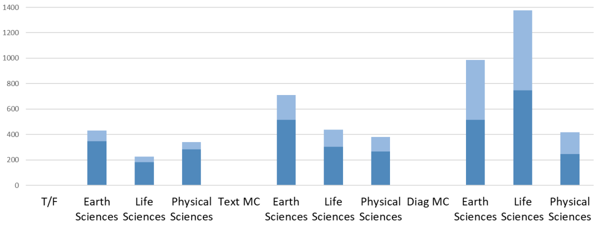

Figure 3: ISAAQ hits (darker) vs. misses (lighter).

on the test set, here we focus on validation. ISAAQ outperforms all other systems in all question types, establishing by a large margin a new SotA in TQA. We include a baseline using RoBERTa and a VQA model which, unlike ISAAQ, does not apply e.g. fine-tuning on related datasets or ensembling. This baseline outperforms all previous approaches, illustrating the benefits of applying transformers to this problem. However, ISAAQ clearly beats it in all question types, particularly in diagram MC, with a 14% improvement that demonstrates how ISAAQ successfully incorporates visual information into the transformer. On the other hand, our results also confirm the complexity of diagram MC compared to the other question types, suggesting future work in language-visual understanding. Finally, ISAAQ also obtains excellent results in all the datasets used for pre-training (table 3), confirming that our approach is robust and generalizes well.

To obtain a deeper understanding of ISAAQ's reasoning ability we focus on ARC-Challenge, which only contains questions that neither retrieval nor co-occurrence methods can answer correctly. We run ISAAQ on a sample of 203 text MC questions manually annotated by (Boratko et al., 2018) against 7 knowledge and 9 reasoning types. Since these questions were extracted from the ARC-Challenge training set, for this experiment we previously removed them from the pre-training of our model. Figure 4 shows how the results we obtain for each reasoning type are in general in line with our overall results in the ARC-Challenge test set (60.34%). We also notice an interesting spike in analogical reasoning, featured in (Kembhavi et al., 2017) as a key reasoning type in TQA, with 90% accuracy. This is consistent with the findings reported by (Clark et al., 2019, 2020) on the reasoning ability of transformer language models.

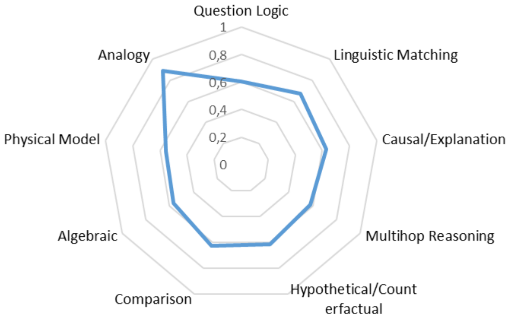

Figure 4: ISAAQ performance per reasoning type.

5.4 Ablation study

We drill down on the results reported in table 2 in order to understand the contribution of each solver to the ISAAQ ensemble, both in the validation and test sets. Tables 4, 5, and 6 show the individual results of such solvers for true/false, text, and diagram MC questions. For each sub-task, the differences between solvers result mainly from the background information used for training, which was produced by different retrievers (section 4.1).

In addition to RoBERTa large we experimented with BERT large, adding 3 more solvers to the true/false and MC ensembles. However, the added gain was extremely limited. Replacing BERT with RoBERTa large without pre-training on the datasets shown in table 3 had similar effect. Thus, we opted for the 3-way ensembles shown in the tables.

Tables 5 and 6 show how the solvers based on transformers clearly outperform an information retrieval baseline (IR), which is itself already on par with the former TQA SotA (Kim et al., 2019) for text MC questions and clearly better for diagram MC. Each of the true/false, text MC, and diagram MC solvers perform similarly in their respective question type sub-tasks. They are also complementary: in average, 33.41% of the questions answered incorrectly by one of the solvers is correctly addressed by another. Such complementarity brings an extra performance boost by combining the different solvers in each sub-task as an ensemble.

While the results obtained for text MC questions

Model		Text T/F	Text MC	Text All	Diagram MC	All

Table 3: ISAAQ vs. SotA in pre-training datasets (test).

Dataset	TF$_{\text{IR}}$	TF$_{\text{NSP}}$	TF$_{\text{NN}}$	**ISAAQ**
validation	78.26	76.25	79.16	81.36
test	77.74	74.89	75.44	78.83

Table 4: Results of each of our solvers and the overall ISAAQ model for TQA true/false questions.

do not seem to depend on the specific split, for true/false and diagram MC questions we obtain clearly better results in the validation set compared to the test set. This emphasizes the heterogeneity of the TQA splits and how challenging it is to produce a model that generalizes well across them.

Looking at the incremental analysis of our diagram MC model in table 7, visual information only enters into play once pre-training on VQA and AI2D is added, outperforming the text baseline. Additional background diagrams adds a little in test. BUTD attention does improve considerably in both validation and test, but not much more than using just bottom-up (BU) attention. The final ISAAQ model is a 6-way ensemble that combines the transformer-based solvers for text MC (table 5) and diagram MC (table 6) and uses VQA+AI2D pre-training and BUTD. These results indicate interesting challenges yet to be addressed.

Dataset	IR	TMC$_{\text{IR}}$	TMC$_{\text{NSP}}$	TMC$_{\text{NN}}$	**ISAAQ**

Table 7: ISAAQ ablations for diagram MC.

6 Qualitative study

Table 8 illustrates the impact of the different levels of attention on the question diagram, previously quantified in table 7. The first column shows question and answer options, while the second adds the question diagram. Third column illustrates the RoIs extracted through BU attention and the fourth adds attention heatmaps using BUTD. While BU assigns equal attention to all RoIs, BUTD also attends to the text of the question and each possible answer. For all the example questions, only the model with BUTD produces the correct answer.

Some observations follow. RoI detection (column three) fails to detect inner shapes in nested diagrams, e.g. state of matter, question four. The intensity of BUTD attention (column four) is rather low, with maximum values between 0.08 and 0.2 in

Question	Diagram	Diagram MC+BU	Diagram MC+BUTD
Which of the following layers comprises mineral particles? a) bedrock b) subsoil c) surface layers d) **topsoil** ✓			Which phase is shown in the picture below? a) **mitosis** ✓ b) prophase c) interphase d) mitotic			Which lamps would turn on if switch is connected? a) **b** ✓ b) a c) a, b, c d) c			In which state does the substance hold shape? a) **solid** ✓ b) liquid c) gas d) none			
Table 8: Study of the attention on question diagrams (red stands for higher attention). Samples from validation set.

a 0 to 1 scale, suggesting an opportunity to improve the cross-modal aspects of our model. When the text of the correct answer (*topsoil*, *solid*) appears explicitly in the diagram, its RoI is generally more attended than the rest. Other times, the RoI labeled by such text (*switch*) is the warmest. ISAAQ seems to attend to aspects of the diagrams that are key to answer correctly, suggesting both language and visual understanding: the two cells resulting from the original one through mitosis, the circuit segment where a lamp flashes upon switch actuation or the properties of the state in which a substance holds shape. Other examples seem to indicate some ability to deal with counting and spatial reasoning. All will deserve further investigation in future work.

7 Conclusion

This paper reports on ISAAQ, the first system to achieve accuracies above 80%, 70% and 55% on TQA true/false, text and diagram MC questions. ISAAQ demonstrates that it is possible to master the grand AI challenge of machine textbook understanding based on modern methods for language and visual understanding, with modest infrastructure requirements. Key to this success are transformers, BUTD attention, pre-training on related datasets, and the selection of complementary background information to train and ensemble different solvers. Our approach allowed overcoming critical challenges like the complexity and relatively small size of the TQA dataset or the scarcity of large diagram datasets. Still, further research is necessary to keep pushing the boundaries of textbook understanding, e.g. by charting and expanding the reasoning skills of transformers, making model outcomes more interpretable by humans, and further exploiting diagrams. Additional effort will also be needed in activities like the development of large diagram datasets, including the semantic annotation of diagram constituents and connectors, and annotating diagram questions with the reasoning and knowledge types required to answer them.

Abstract

Subjectivity is the expression of internal opinions or beliefs which cannot be objectively observed or verified, and has been shown to be important for sentiment analysis and word-sense disambiguation. Furthermore, subjectivity is an important aspect of user-generated data. In spite of this, subjectivity has not been investigated in contexts where such data is widespread, such as in question answering (QA). We develop a new dataset which allows us to investigate this relationship. We find that subjectivity is an important feature in the case of QA, albeit with more intricate interactions between subjectivity and QA performance than found in previous work on sentiment analysis. For instance, a subjective question may or may not be associated with a subjective answer. We release an English QA dataset (SubjQA) based on customer reviews, containing subjectivity annotations for questions and answer spans across 6 domains.

1 Introduction

Subjectivity is ubiquitous in our use of language (Banfield, 1982; Quirk et al., 1985; Wiebe et al., 1999; Benamara et al., 2017), and is therefore an important aspect to consider in Natural Language Processing (NLP). For example, subjectivity can be associated with different senses of the same word. BOILING is objective in the context of *hot water*, but subjective in the context of a person *boiling with anger* (Wiebe and Mihalcea, 2006). The same applies to sentences in discourse contexts (Pang and Lee, 2004). While early work has shown subjectivity to be an important feature for low-level tasks such as word-sense disambiguation and sentiment analysis, subjectivity in NLP has not been explored in many contexts where it is prevalent.

In recent years, there has been renewed interest in areas of NLP for which subjectivity is important, and a specific topic of interest is question answering (QA). This includes work on aspect extraction (Poria et al., 2016), opinion mining (Sun et al., 2017) and community QA (Gupta et al., 2019). Many QA systems are based on representation learning architectures (e.g. Devlin et al. (2018); Radford et al. (2018)) that are typically trained on factual, encyclopedic knowledge such as Wikipedia or books. It is unclear if these architectures can handle subjective statements such as those that appear in reviews.

The interactions between QA and subjectivity are even more relevant today as users' natural search criteria in many domains, including products and services, have become increasingly subjective. According to McAuley and Yang (2016a), around 20% of product queries were labeled as being 'subjective' by workers. Their questions can often be answered by online customer reviews, which tend to be highly subjective as well. Although QA over customer reviews has gained traction recently with the availability of new datasets and architectures (Grail and Perez, 2018; Gupta et al., 2019; Fan et al., 2019; Xu et al., 2019b; Li et al., 2019), these are agnostic with respect to how subjectivity is expressed in the questions and the reviews. Furthermore, the datasets are either very small (< 2000 questions) or have target-specific question types (e.g., yes-no). Most QA datasets and systems focus on answering questions over factual data such as Wikipedia articles and News (Joshi et al., 2017; Trischler et al., 2017; Rajpurkar et al., 2018; Abdou et al., 2019; Reddy et al., 2019). In this work, on the other hand, we focus on QA over subjective data from reviews on product and service websites.

In this work, we investigate the relation between subjectivity and question answering (QA) in the context of customer reviews. As no such QA

November 16–20, 2020.

dataset exists, we construct SubjQA.[1] In order to capture subjectivity, our data collection method builds on recent developments in opinion extraction and matrix factorisation, instead of relying on linguistic similarity between questions and reviews (Gupta et al., 2019). SubjQA includes over 10,000 English examples spanning 6 domains that cover both products and services. We find a large percentage of subjective questions and answers in SubjQA, as 73% of the questions are subjective and 74% of the answers are subjective. Experiments show that existing QA systems trained to find factual answers struggle with subjective questions and reviews. For instance, fine-tuning BERT (Devlin et al., 2018), a state-of-the-art QA model, yields 92.9% F_1 on SQuAD (Rajpurkar et al., 2016), but only achieves a mean score of 74.1% F_1 across the domains in SubjQA.

To demonstrate the importance of subjectivity in QA, we develop a subjectivity-aware QA model that extends an existing QA model in a multi-task learning paradigm. It is trained to predict the subjectivity label and answer span simultaneously, and does not require subjectivity labels at test time. This QA model achieves 76.3% F_1 on an average over different domains of SubjQA.

Contributions (i) We release a challenging QA dataset with subjectivity labels for questions and answers, spanning 6 domains; (ii) We investigate the relationship between subjectivity and QA; (iii) We develop a subjectivity-aware QA model; (iv) We verify the findings of previous work on subjectivity, using recent NLP architectures.

2 Subjectivity

Written text, as an expression of language, contains information on several linguistic levels, many of which have been thoroughly explored in NLP.[2] For instance, both the semantic content of text and the (surface) forms of words and sentences, as expressed through syntax and morphology, have been at the core of the field for decades. However, another level of information can be found when trying to observe or encode the so-called *private states* of the writer (Quirk et al., 1985). Examples of private states include the opinions and beliefs of a writer, and can concretely be said to not be available for verification or objective observation. It is this type of state which is referred to as *subjectivity* (Banfield, 1982; Banea et al., 2011).

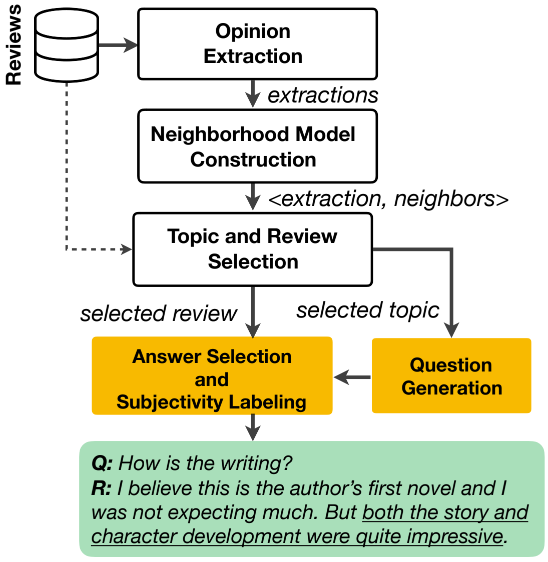

Figure 1: Our data collection pipeline

Whereas subjectivity has been investigated in isolation, it can be argued that subjectivity is only meaningful given sufficient context. Regardless, much previous work has focused on annotating words (Heise, 2001), word senses (Durkin and Manning, 1989; Wiebe and Mihalcea, 2006; Akkaya et al., 2009), or sentences (Pang and Lee, 2004), with notable exceptions such as Wiebe et al. (2005); Banea et al. (2010), who investigate subjectivity in phrases in the context of a text or conversation. There is limited work that studies subjectivity using architectures that allow for contexts to be incorporated efficiently (Vaswani et al., 2017).

As subjectivity relies heavily on context, and we have access to methods which can encode such context, what then of access to data which encodes subjectivity? We argue that in order to fully investigate research questions dealing with subjectivity in contexts, a large-scale dataset is needed. We choose to frame this as a QA dataset, as it not only offers the potential to investigate interactions in a single contiguous document, but also allows interactions *between* contexts, where parts may be subjective and other parts may be objective. Concretely, one might seek to investigate the interactions between an objective question and a subjective answer, or vice-versa.

---

[1] SubjQA is available at `https://github.com/megagonlabs/SubjQA`

[2] Subjectivity is not restricted to written texts, although we focus on this modality here.

3 Data Collection

We found two limitations of existing datasets and collection strategies that motivated us to create a new QA dataset to understand subjectivity in QA. First, data collection methods (Gupta et al., 2019; Xu et al., 2019b) often rely on the linguistic similarity between the questions and the reviews (e.g. information retrieval). However, subjective questions may not always use the same words or phrases as the review. Consider the examples below. The answer span '*vegan dishes*' is similar to the question Q_1. The answer to the more subjective question Q_2, however, is linguistically quite different.

Example 1 Q_1: Is the restaurant vegan friendly?
Review: [...] many **vegan dishes** on its menu.

Q_2: Does the restaurant have a romantic vibe?
Review: Amazing selection of wines, **perfect for a date night**.

Secondly, existing review-based datasets are small and not very diverse in terms of question topics and types (Xu et al., 2019a; Gupta et al., 2019). We, therefore, consider reviews about both products and services from 6 different domains, namely TripAdvisor, Restaurants, Movies, Books, Electronics and Grocery. We use the data of Wang et al. (2010) for TripAdvisor, and Yelp[3] data for Restaurants. We use the subsets for which an open-source opinion extractor was available (Li et al., 2019). We use the data of McAuley and Yang (2016b) that contains reviews from product pages of Amazon.com spanning multiple categories. We target categories that had more opinion expressions than others, determined by an opinion extractor.

Figure 1 depicts our data collection pipeline which builds upon recent developments in opinion extraction and matrix factorization. An opinion extractor is crucial to identify subjective or opinionated expressions, which other IR-based methods cannot. On the other hand, matrix factorization helps identify which of these expressions are related based on their co-occurrence in the review corpora, instead of their linguistic similarities. Relying on opinions instead of factual information to construct the dataset makes it inherently subjective. Furthermore, pairing questions and reviews based on related opinion expressions provides us some control over the diversity in the dataset. To the best of our knowledge, we are the first to explore such a method to construct a subjective QA dataset.

Given a review corpus, we extract opinions about various aspects of the items being reviewed (*Opinion Extraction*). Consider the following review snippets and extractions.

Example 2 Review: [...] character development was quite impressive.
e_1:‹'*impressive*', '*character development*'›

Review: 3 stars for good power and good writing.
e_2:‹'*good*', '*writing*'›

In the next (*Neighborhood Model Construction*) step, we characterize the items being reviewed and their subjective extractions using latent features between two items. In particular, we use matrix factorization techniques (Riedel et al., 2013) to construct a neighborhood model N via a set of weights $w_{e,e'}$, where each corresponds to a directed association strength between extraction e and e'. For instance, e_1 and e_2 in Example 2 could have a similarity score 0.93. This neighborhood model forms the core of data collection. We select a subset of extractions from N as *topics* (*Topic Selection*) and ask crowd workers to translate them to natural language questions (*Question Generation*). For each topic, a subset of its neighbors from N and reviews which mention them are selected (*Review Selection*). In this manner, question-review pairs are generated based on the neighborhood model.

Finally, we present each question-review pair to crowdworkers who highlight an answer span in the review. Additionally, they provide subjectivity scores for both the questions and the answer span.

3.1 Opinion Extraction

An opinion extractor processes all reviews and finds extractions ‹X,Y› where X represents an opinion expressed on aspect Y. Table 1 shows sample extractions from different domains. We use OpineDB (Li et al., 2019), a state-of-the-art opinion extractor, for restaurants and hotels. For other domains where OpineDB was not available, we use the syntactic extraction patterns of Abbasi Moghaddam (2013).

3.2 Neighborhood Model Construction

We rely on matrix factorization to learn dense representations for items and extractions, and identify similar extractions. Such a method has been shown to be effective in building knowledge bases (Bhutani et al., 2020). As depicted in Figure 2, we organize the extractions into a matrix M where each row i corresponds to an item being

---

Domain	Opinion Span	Aspect Span
Restaurants	huge	lineup
Hospitality	no free	wifi
Books	hilarious	book
Movies	not believable	characters
Electronics	impressive	sound
Grocery	high	sodium level

Table 1: Example extractions from different domains

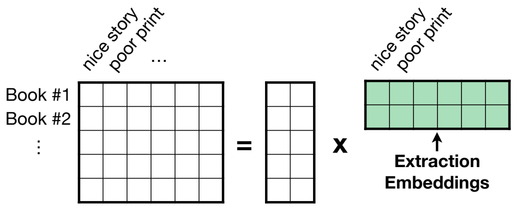

Figure 2: Learning representations of extractions via non-negative matrix factorization

reviewed and each column j corresponds to an extraction. The value M_{ij} denotes the frequency of extraction e_j in reviews of item x_i. Given M and a latent feature model F, we obtain extraction embeddings using non-negative matrix factorization. Concretely, each value M_{ij} is obtained from the dot product of two extractions of size K^F:

$$M_{ij}^F = \sum_{k}^{K^F} x_{i,k} e_{j,k}. \tag{1}$$

For each extraction, we find its *neighbors* based on the cosine similarity of their embeddings.[4]

3.3 Topic and Review Selection

We next identify a subset of extractions to be used as *topics* for the questions. In order to maximize the diversity and difficulty in the dataset, we use the following criteria developed iteratively based on manual inspection followed by user experiments.

1. **Cosine Similarity:** We prune neighbors of an extraction which have low cosine similarity (< 0.8). Irrelevant neighbors can lead to noisy topic-review pairs which would be marked *non-answerable* by the annotators.
2. **Semantic Similarity:** We prune neighbors that are linguistically similar (> 0.975 similarity)[5] as they yield easy topic-review pairs.
3. **Diversity**: To promote diversity in topics and reviews, we select extractions which have many ($>$ 5) neighbors.
4. **Frequency**: To ensure selected topics are also popular, we select a topic if: a) its frequency is higher than the median frequency of all extractions, and b) it has at least one neighbor that is more frequent than the topic itself.

We pair each topic with reviews that mention one of its neighbors. The key benefit of a factorization-based method is that it is not only based on linguistic similarity, and forces a QA system to understand subjectivity in questions and reviews.

3.4 Question Generation

Each selected topic is presented to a human annotator together with a review that mentions that topic. We ask the annotator to write a question about the topic that can be answered by the review. For example, ‹‘*good*’, ‘*writing*’› could be translated to “Is the writing any good?" or “How is the writing?".

3.5 Answer-Span and Subjectivity Labeling

Lastly, we present each question and its corresponding review to human annotators (crowdworkers), who provides a subjectivity score to the question on a 1 to 5 scale based on whether it seeks an opinion (e.g., “How good is this book?") or factual information (e.g., “is this a hard-cover?"). Additionally, we ask them to highlight the shortest answer span in the review or mark the question as unanswerable. They also provide subjectivity scores for the answer spans. We provide details of our neighborhood model construction and crowdsourcing experiments in the Appendix.

4 Dataset Analysis

In this section, we analyze the questions and answers to understand the properties of our SUBJQA dataset. We present the dataset statistics in Section 4.1. We then analyze the diversity and difficulty of the questions. We also discuss the distributions of subjectivity and answerability in our dataset. Additionally, we manually inspect 100 randomly chosen questions from the development set in Section 4.3 to understand the challenges posed by subjectivity of the questions and/or the answers.

4.1 Data Statistics

Table 2 summarizes the number of examples we collected for different domains. To generate the train, development, and test splits, we partition the topics into training (80%), dev (10%) and test (10%) sets. We partition the questions and reviews based on the partitioning of the topics.

---

[4] Details about hyper-parameters are included in the Appendix.

Domain	Train	Dev	Test	Total
TripAdvisor	1165	230	512	1686
Restaurants	1400	267	266	1683
Movies	1369	261	291	1677
Books	1314	256	345	1668
Electronics	1295	255	358	1659
Grocery	1124	218	591	1725

Table 2: No. of examples in each domain split.

Domain	Review len	Q len	A len	% answerable
TripAdvisor	187.25	5.66	6.71	78.17
Restaurants	185.40	5.44	6.67	60.72
Movies	331.56	5.59	7.32	55.69
Books	285.47	5.78	7.78	52.99
Electronics	249.44	5.56	6.98	58.89
Grocery	164.75	5.44	7.25	64.69

Table 3: Domain statistics. Len denotes n tokens.

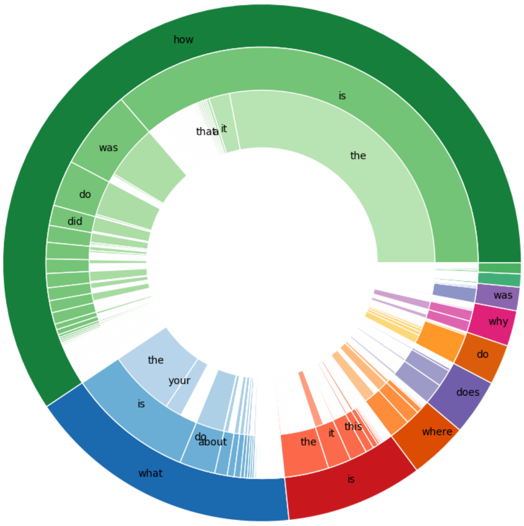

Figure 3: The distribution of prefixes of questions. The outermost ring shows unigram prefixes (e.g., 57.9% questions start with *how*). The middle and innermost rings correspond to bigrams and trigrams, respectively.

4.2 Difficulty and Diversity of Questions

Table 3 shows that reviews in different domains tend to vary in length. Answer spans tend to be 6-7 tokens long, compared to 2-3 tokens in SQuAD.

Table 4 shows the number of distinct questions and topics in each domain. On average we collected 1500 questions covering 225 aspects. We also automatically categorize the boolean questions based on a lexicon of question prefixes. Unlike other review-based QA datasets (Gupta et al., 2019), SUBJQA contains more diverse questions, the majority of which are not yes/no questions. The questions in SUBJQA are also linguistically varied, as indicated by the trigram prefixes of the questions (Figure 3). Most of the frequent trigram prefixes in SUBJQA (e.g., *how is the*, *how was the*, *how do you*) are almost missing in SQuAD and Gupta et al. (2019). The diversity of questions in SUBJQA demonstrate challenges unique to the dataset.

4.3 Data Quality Assessment

We randomly sample 100 answerable questions to manually categorize them according to their reasoning types. Table 5 shows the distribution of the reasoning types and representative examples. As expected, since a large fraction of the questions are subjective, they cannot be simply answered using a keyword-search over the reviews or by paraphrasing the input question. Answering such questions requires a much deeper understanding of the reviews. Since the labels are crowdsourced, a small fraction of the answer spans are noisy.

Domain	# questions	# aspects	% boolean Q
TripAdvisor	1411	171	16.13
Restaurants	1553	238	17.29
Movies	1556	228	15.56
Books	1517	231	16.90
Electronics	1535	314	14.94
Grocery	1333	163	14.78

Table 4: Diversity of questions and topics

We also categorized the answers based on answer-types. We observed that 64% of the answer spans were independent clauses (e.g., *the staff was very helpful and friendly*), 25% were noun phrases (e.g., *great bed*) and 11% were incomplete clauses/spans (e.g., *so much action*). This supports our argument that subjective questions often cannot be answered simply by an adjective or noun phrase.

We rely on an automatically constructed opinion KB and collect labels for answer spans and subjectivity for all the question-review pairs. As crowdworkers would label any spurious question-review pair as 'unanswerable', this might increase the number of negative examples in the dataset. However, such examples are both much more difficult and more valuable than randomly paired questions and reviews. We found that the KBs used in our dataset collection achieved 35-50% mean precision on various domains. We also found that approximately 48% of a random set of 50 question-review pairs from SubjQA were marked unanswerable because of the unrelated opinion pairs in the KB.

Reasoning	**Percent.**	**Example**
Lexical	18%	Q: How small was the hotel bathroom? R: ...**Bathroom on the small** side with older fixtures...
Paraphrase	28%	Q: How amazing was the end? R: ...The **ending was absolutely awesome**, it makes the experience not so ...
Indirect	43%	Q: How was the plot of the movie? R: ...simply because there's so much going on, **so much action**, so many complex ..
N/A	11%	Q: How do you like the episode? R: **For a show that I think was broadcast in HighDef**, it seems impossible that the...

Table 5: Types of reasoning required for the various domains. N/A indicates noisy or incorrect spans.

4.4 Answerability and Subjectivity

The dataset construction relies on a neighborhood model generated automatically using factorization. It captures co-occurrence signals instead of linguistic signals. Consequently, the dataset generated is not guaranteed to only contain answerable questions. As expected, about 65% of the questions in the dataset are answerable from the reviews (see Table 7). However, unlike Gupta et al. (2019), we do not predict answerability using a classifier. The answerability labels are provided by the crowdworkers instead, and are therefore more reliable.

Table 7 shows the subjectivity distribution in questions and answer spans across different domains. A vast majority of the questions we collected are subjective, which is not surprising since we selected topics from opinion extractions. A large fraction of the subjective questions (∼70%) were also answerable from their reviews.

We also compare the subjectivity of questions with the subjectivity of answers. As can be seen in Table 6, the subjectivity of an answer is strongly correlated with the subjectivity of the question. Subjective questions often have answers that are also subjective. Similarly, factual questions, with few exceptions, have factual answers. This indicates that a QA system must understand how subjectivity is expressed in a question to correctly find its answer. Most domains have 75% subjective questions on average. However, the BERT-QA model fine-tuned on each domain achieves 80% F1 on subjective questions in movies and books, but only achieves 67-73% F1 on subjective questions in grocery and electronics. Future QA systems for user-generated content, such as for customer support, should therefore model subjectivity explicitly.

	subj. Q	**fact. Q**
subj. A	79.8%	1.31%
fact. A	1.29%	17.58%

Electronics	69.80	65.37	69.98
Grocery	73.21	70.22	73.15

Table 7: Statistics on subjective Q, answerability, and subjective A per domain in SubjQA.

4.5 Comparison with other datasets

Although this is not the first work to design a review-based QA dataset, no prior QA dataset targets the understanding of subjectivity in reviews. AmazonQA (Gupta et al., 2019) is one of the largest review-based QA dataset, but differs from SubjQA in three core ways: i) they lack subjectivity labels; ii) they are constructed using retrieval methods; and iii) they do not highlight answer spans in the reviews and instead provide an answerability label for the question given a set of reviews. These differences make it difficult for a fair comparison with their dataset. Some of the distinguishing characteristics of the two datasets include: (a) AmazonQA reports 61% of the questions are answerable with 72% precision (based on a classifier). In comparison, 65% of the questions in SubjQA are answerable (based on human labels); (b) We provide opinion annotations and subjectivity labels for the questions, making it easier for researchers to target specific opinions and subjective text; and (c) 58% of questions in SubjQA start with 'how'. In comparison, most of the question prefixes (e.g., 'will

	IMDB	SUBJQA
Word-based (TEXTBLOB)	61.90	57.50
BERT fine-tuned	88.20	62.77

Table 8: Subjectivity prediction accuracies on IMDB data (Pang and Lee, 2004) and our dataset (SUBJQA).

this work', 'does it come with' etc.) in AmazonQA indicate product queries rather than opinion-based queries.

5 Subjectivity Modelling

We now turn to experiments on subjectivity, first investigating claims made by previous work, and whether they still hold when using recently developed architectures, before investigating how to model subjectivity in QA.

5.1 Subjectivity in Sentiment Analysis

Pang and Lee (2004) have shown that subjectivity is an important feature for sentiment analysis. Sorting sentences by their estimated subjectivity scores, and only using the top n such sentences, allows for a more efficient and better-performing sentiment analysis system, than when considering both subjective and objective sentences equally. We first investigate whether the same findings hold true when subjectivity is estimated using transformer-based architectures.[6] We predict the subjectivity of a sentence by passing its representation through a feed-forward neural network. We compare this with using subjectivity scores of TEXTBLOB[7], a sentiment lexicon-based method, as a baseline.

We evaluate this setup on subjectivity data from Pang and Lee (2004)[8] and the subjectivity labels made available in SUBJQA. Unsurprisingly, a contextually-aware classifier vastly outperforms a word-based classifier, highlighting the importance of context in subjectivity analysis (see Table 8). Interestingly, however, predicting subjectivity in SUBJQA is more challenging than in IMDB - we hypothesise that this is because SUBJQA spans multiple domains.

We further investigate if our subjectivity classifier is beneficial for sentiment analysis. We replicate Pang and Lee (2004), and perform sentiment analysis using the top N subjective and objective sentences based on our system. Figure 4 shows that giving a contextually-aware sentiment analysis model access to N subjective sentences improves performance, as compared to using all sentences, or using N objective sentences.

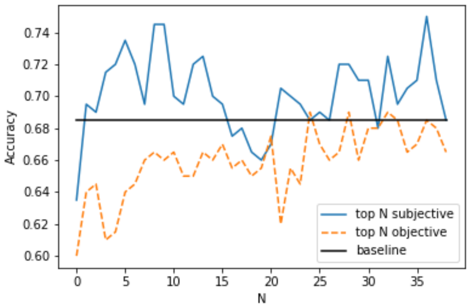

Figure 4: Sentiment Analysis accuracy using top N subj. sentences (blue), top N fact. sentences (orange dashed), compared to the all sentences baseline (black).

5.2 Subjectivity-Aware QA Model

Given the importance of subjectivity in other NLP tasks, we investigate whether it is also an important feature for QA in SUBJQA, with a relatively simple model. We approach this by implementing a subjectivity-aware QA model, as an extension of our baseline models FastQA (Weissenborn et al., 2017) in a multitask learning (MTL) paradigm (Caruana, 1997), as this approach has been shown to be useful for learning cross-task representations (Bjerva, 2017a,b; Bingel and Søgaard, 2017; de Lhoneux et al., 2018; Augenstein et al., 2018, 2019; Ruder et al., 2019). One concrete advantage of using MTL is that we do not need to have access to subjectivity labels at test time, as would be the case if we required subjectivity labels as a feature for each answer span. Each input paragraph is encoded with a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) over a sequence of word embeddings and contextual features ($\tilde{\boldsymbol{X}}$). This encoding, $\boldsymbol{H'}$, is passed through a hidden layer and a non-linearity:

$$\boldsymbol{H'} = \text{Bi-LSTM}(\tilde{\boldsymbol{X}}) \tag{2}$$

$$\boldsymbol{H} = \tanh(B\boldsymbol{H'}^{\top}) \tag{3}$$

We extend this implementation by adding two hidden layers of task-specific parameters ($\boldsymbol{W^n}$) associated with a second learning objective:

$$\boldsymbol{S'} = \text{ReLU}(W^1\boldsymbol{H}) \tag{4}$$

$$\boldsymbol{S} = \text{softmax}(\text{W}^2\boldsymbol{S'}) \tag{5}$$

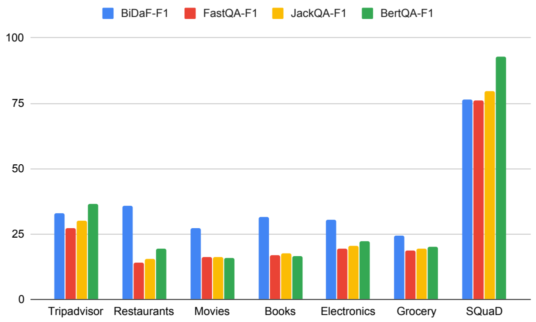

Figure 5: F1 scores of pre-trained out-of-the-box models on different domains in SUBJQA.

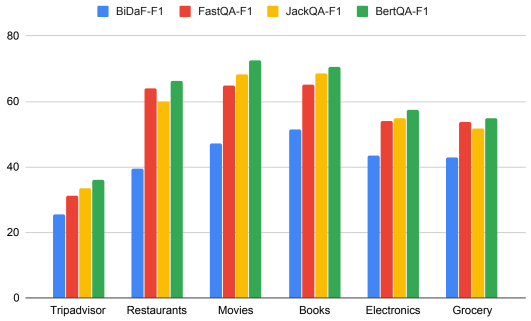

Figure 6: Gain in F1 with models fine-tuned on different domains over the pre-trained model.

In training, we randomly sample between the two tasks (QA and Subjectivity classification).

5.3 Baselines

We use four pre-trained models to investigate how their performances on SUBJQA compare with a factual dataset, SQuAD (Rajpurkar et al., 2016), created using Wikipedia. Specifically, we evaluate BiDaF (Seo et al., 2017), FastQA (Weissenborn et al., 2017), JackQA (Weissenborn et al., 2018)[9] and BERT (Devlin et al., 2018),[10] all pre-trained on SQuAD. Additionally, we fine tune the models on each domain in SUBJQA.

Figure 5 shows the F1 scores of the pre-trained models. We report the Exact match scores in Appendix A.3. Pre-trained models achieve F1 scores as high as 92.9% on the SQuAD. On the other hand, the best model achieves an average F1 of 30.5% across all domains and 36.5% F1 at best on any given domain in SUBJQA. The difference in performance can be attributed to both differences in domain (Wikipedia vs. customer reviews) and how subjectivity is expressed across different domains.

Figure 6 shows the absolute gains in F1 scores of models fine-tuned on specific domains, over the pre-trained model. After fine-tuning on each domain, the best model achieves an average F1 of 74.1% across the different domains. While fine-tuning significantly boosts the F1 scores in each domain, they are still lower than the F1 scores on the SQuAD dataset. We argue that this is because the models are agnostic about subjective expressions in questions and reviews. To validate our hypothesis, we compare the gain in F1 scores of the BERT model on subjective questions and factual questions. We find that the difference in F1 gains is as high as 23.4% between factual and subjective questions. F1 gains differ by as much as 23.0% for factual vs. subjective answers.

5.4 Subjectivity-Aware Modeling

After fine-tuning over each domain in the MTL setting, the subjectivity-aware model achieves an average F1 of 76.3% across domains (Table 9). Incorporating subjectivity in the model thus boosts performance across all domains and both metrics. Although there are gains also for subjective questions and answers, it is noteworthy that the highest gains can be found for factual questions and answers. This is likely because existing techniques already are tuned for factual questions.

5.5 Error Analysis

We perform an error analysis based on the predictions of the BERT model fine-tuned for each domain, investigating a sample of 10 questions for which the model's predictions are incorrect. This reveals that the model often predicts a question to be unanswerable, although a ground truth answer exists. Interestingly, most of these questions are subjective. A detailed examination reveals that answers to these questions are relatively indirect, hence it is not surprising that the model struggles. For instance, given the question *"How slow is the internet service?"*, the correct answer is *"Don't expect to always get the 150Mbps"*.

6 Related Work

We are witnessing a substantial rise in user-generated content, including subjective information ranging from personal experiences to opinions about specific aspects of a product. However, subjectivity has largely been studied in the context of sentiment analysis (Hu and Liu, 2004) and opinion

mining (Blair-Goldensohn et al., 2008), with a focus on text polarity. There is renewed intereste in incorporating subjective opinion data into general data management systems (Li et al., 2019; Kobren et al., 2019) and for querying subjective data.

In this work, we revisit subjectivity in the context of review QA. Yu et al. (2012); McAuley and Yang (2016b) also use review data, as they leverage question types and aspects to answer questions. However, no prior work has modeled subjectivity explicitly using end-to-end architectures.

Furthermore, none of the existing review-based QA datasets are targeted at understanding subjectivity. This can be attributed to how these datasets are constructed. Large-scale QA datasets, such as SQuAD (Rajpurkar et al., 2016), NewsQA (Trischler et al., 2017), CoQA (Reddy et al., 2019), MLQA (Lewis et al., 2020) are based on factual data. We are the first to attempt to create a review-based QA dataset for the purpose of understanding subjectivity. Recent work has corroborated our findings on the benefits of modelling subjectivity QA, and highlights the differences in the distributions of hidden representation between SUBJQA and the factual SQuAD data (Muttenthaler et al., 2020).

7 Conclusion

In this paper we investigate subjectivity in QA by leveraging end-to-end architectures. We release SUBJQA, a question-answering dataset which contains subjectivity labels for both questions and answers. The dataset allows i) evaluation and development of architectures for subjective content, and ii) investigation of subjectivity and its interactions in broad and diverse contexts. We further implement a subjectivity-aware model and evaluate it, along with 4 strong baseline models. We hope this dataset opens new avenues for research on querying subjective content, and into subjectivity in general.

A Appendices

A.1 Neighborhood Model Construction

For constructing the matrix for factorization, we focus on frequently reviewed items and frequent extractions. In particular, we consider items which have more than 10,000 reviews and extractions that were expressed in more than 5000 reviews. Once the matrix is constructed, we factorize it using non-negative factorization method using 20 as the dimension of the extraction embedding vector.

In the next step, we construct the neighborhood model by finding top-10 neighbors for each extraction based on cosine similarity of the extraction and the neighbor. We further select topics from the extractions, and prune the neighbors based on the criteria we described earlier. Table 10 shows example extraction and their neighbors discovered using the neighborhood model.

Domain	Extraction	Neighbor
Movies	(satisfying, ending)	(good, script)
	(believable, acting)	(interesting, movie)
Electronics	(responsive, key)	(nice, keyboard)
	(easy to navigate, menu)	(simple, interface)
Books	(graphic, violence)	(disturbing, book)
	(interesting, twist)	(unpredictable, story)
Grocery	(healthy, snack)	(high, protein)
	(easy to follow, direction)	(quick, preparation)
Tripadvisor	(excellent, service)	(amazing, hotel)
	(good, drinks)	(great, bar)
Restaurants	(great, meal)	(good, restaurant)
	(fast and friendly, service)	(quick, food)

Table 10: Examples extraction and their neighbors

A.2 Additional Dataset Examples

Table 11 shows more examples of question and their review snippets. Answer spans have been underlined. As can be seen, many questions and answer spans in our dataset are subjective.

A.3 Additional Experimental Results

Figure 7 shows the exact scores achieved by the pre-trained out-of-the-box models on various domains in SUBJQA. Figure 8 shows the exact scores of the models fine-tuned on each domain in SUBJQA.

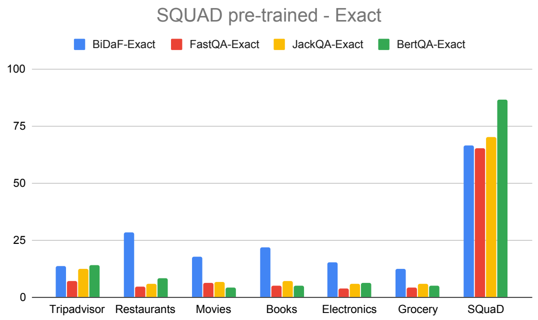

Figure 7: Exact scores of pre-trained out-of-the-box models on different domains.

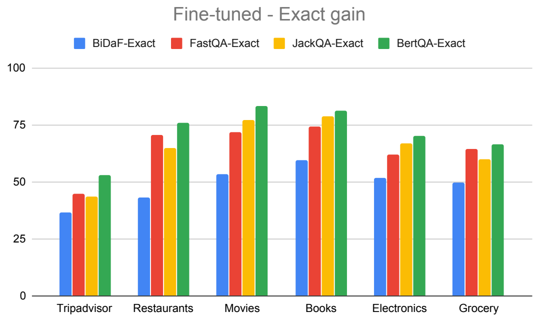

Figure 8: Gain in Exact scores with models fine-tuned on different domains.

A.4 Crowdsourcing Details

We used the Appen platform [11] to obtain labels. The platform provides quality control by showing the workers 5 questions at a time, out of which one is labeled by the experts. A worker who fails to maintain 70% accuracy is kicked out by the platform and his judgements are ignored.

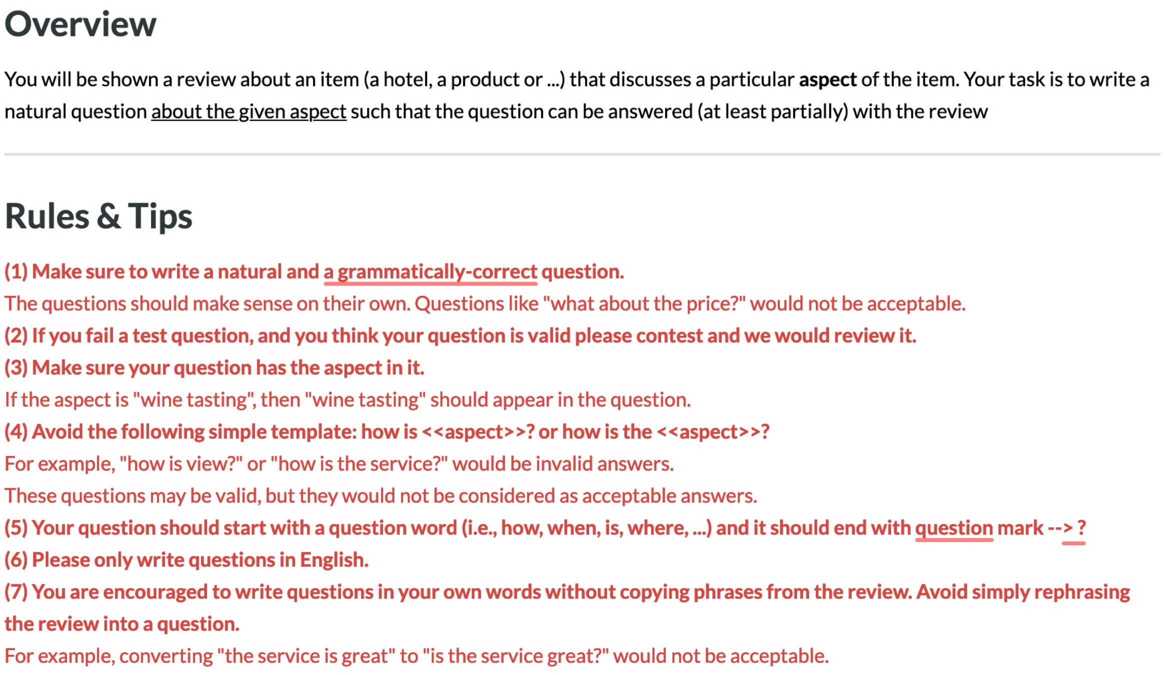
Figure 9 illustrates the instructions that were shown to the crowdworkers for the question generation task. Figure 10 shows the interface for the answer-span collection and subjectivity labeling tasks. The workers assign subjectivity scores (1-5) to each question and the selected answer span. They can also indicate if a question cannot be answered from the given review. Before finalizing this interface, we experimented with multiple design variations on a small subset. This included collecting binary labels for subjectivity instead of scores, simultaneously collecting different labels vs in different tasks etc. To ensure good quality labels, we each worker 5 cents per annotation.

---

[11] `https://appen.com`

Domain	Question	Review
Movies	Is the main character a good actor?	Beautifully written series depicting the lives of criminals in Kentucky and thedeputies in the US Marshall Service who attempt to stop the criminal elementin the community.The acting is outstanding and the cast bring the characters to life.
	Can we enjoy the movie along with family?	An outstanding romantic comedy, 13 Going on 30, brings to the screen exactly what the title implies: the story of a 13-year old girl who has her wish fulfilled and wakes up seven years later in the body of her 30-year old self!
Electronics	Why is the camera of poor quality?	Item like the picture, fast deliver 3 days well packed, good quality for the price. The camera is decent (as phone cameras go), There is no flash though.
	How big is the unit?	It's a great product, especially for the money.Good Battery life, totally useable for a full movie. Storage capacity. 32GB is a great point for the price. Speakers. Screen - bright, clear and HD resolution.
Books	Is the plot line good enough?	The book got me hooked almost immediately and then I got to the end and realized that there is another book after this one. I was unaware of this dilemma but its so good I did not care. Characters and dialogue are good but I liked the movie better.
	What is the most exciting part of the story?	Yann Martel's Life of Pi is a wondrous novel–there is much to wonder and marvel at. The story is simple, yet complex at the same time and can be read on many levels. The novel ends with a philisophical bang, which did blow me away.
Grocery	Does this coffee taste good?	While I don't consider myself a coffee snob, I know what I like. Actually, it tasted on the light side of light. I prefer a dark bold flavor but don't mind a good medium roast. The package also said Exotic Floral and Berry.
	Is the sauce tasty?	I was hoping that this sauce would be a little more consistent and thick that it is. The taste is a bit sharp and perhaps it's just not in my palette, but I'll stick with a homeade ranchero until I find one that is a quick retail replacement.
Tripadvisor	How was the attention of the staff?	The Handlery Union Square Hotel offers great rooms in the centre of San Francisco for a very nice price! Excellent value for money. Friendly personnel and top location! Highly recommended!
	How is the parking?	$40.00 a night; not the room - parking rate per night.Got a room with no view at the end of the hall way, nasty smell like very old, damp room. Front desk clark was not friendly, when raised concern about parking rate, he compared that with NYC parking. The parking rate is ridiculously high; $40 a night!!!!!!!!!!!
Restaurants	Is the price economical?	This place is the best Pho Place in the area. If you are too lazy to drive to Pho Dau Bo then come here for your hangover cure. The prices are a little bit on the high side but that is simply a reflection of the neighbourbood the restaurant is located in.
	Was it a good place for late night snacking?	Lots of different beer choices and liter-ful mugs that will satiate your European beer craving. Social seating on long benches (no individual tables) filters out the snobs and the social invalids, so everyone has a great time!

Table 11: Examples questions and review snippets. Answer spans are underlined.



Overview

You will be shown a review about an item (a hotel, a product or ...) that discusses a particular **aspect** of the item. Your task is to write a natural question about the given aspect such that the question can be answered (at least partially) with the review

Rules & Tips

(1) Make sure to write a natural and a grammatically-correct question.

The questions should make sense on their own. Questions like "what about the price?" would not be acceptable.

(2) If you fail a test question, and you think your question is valid please contest and we would review it.

(3) Make sure your question has the aspect in it.

If the aspect is "wine tasting", then "wine tasting" should appear in the question.

(4) Avoid the following simple template: how is <<aspect>>? or how is the <<aspect>>?

For example, "how is view?" or "how is the service?" would be invalid answers.

These questions may be valid, but they would not be considered as acceptable answers.

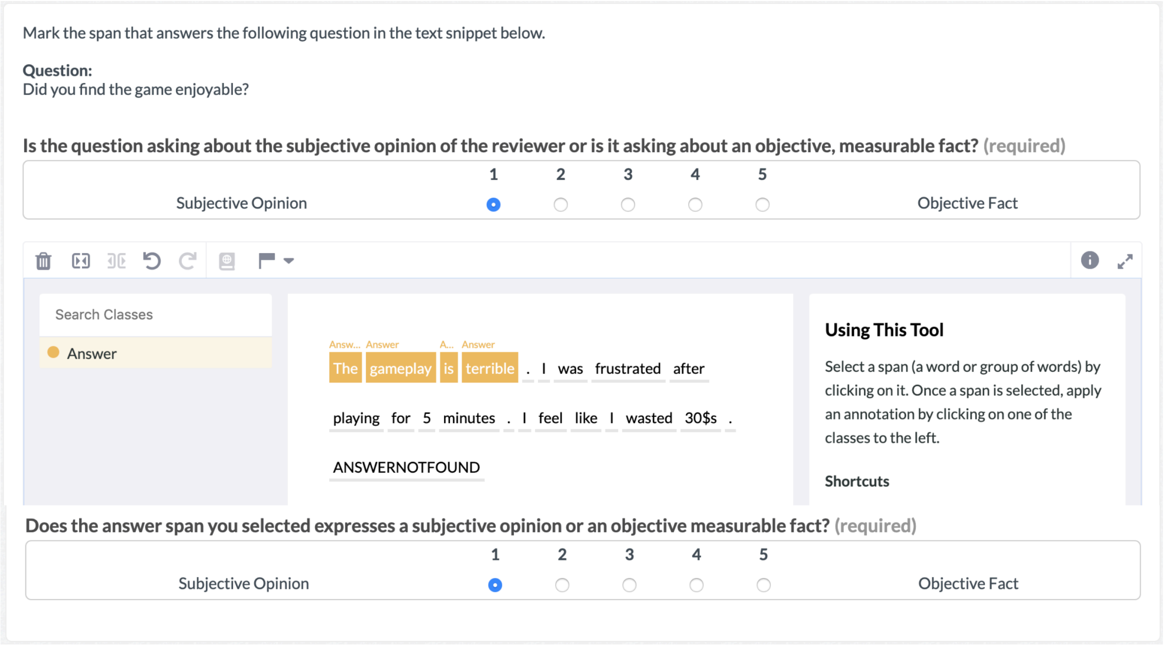
(5) Your question should start with a question word (i.e., how, when, is, where, ...) and it should end with question mark --> ?

(6) Please only write questions in English.

(7) You are encouraged to write questions in your own words without copying phrases from the review. Avoid simply rephrasing the review into a question.

For example, converting "the service is great" to "is the service great?" would not be acceptable.

Figure 9: The instructions shown to crowdworkers for the question writing task.



Mark the span that answers the following question in the text snippet below.

Question:
Did you find the game enjoyable?

Is the question asking about the subjective opinion of the reviewer or is it asking about an objective, measurable fact? (required)

	1	2	3	4	5	
Subjective Opinion	●	○	○	○	○	Objective Fact

The gameplay is terrible . I was frustrated after playing for 5 minutes . I feel like I wasted 30$s .

ANSWERNOTFOUND

Using This Tool

Select a span (a word or group of words) by clicking on it. Once a span is selected, apply an annotation by clicking on one of the classes to the left.

Shortcuts

Does the answer span you selected expresses a subjective opinion or an objective measurable fact? (required)

	1	2	3	4	5	
Subjective Opinion	●	○	○	○	○	Objective Fact

Widget Captioning: Generating Natural Language Description for Mobile User Interface Elements

Yang Li[*] Gang Li[*] Luheng He, Jingjie Zheng, Hong Li[†] Zhiwei Guan

Abstract

Natural language descriptions of user interface (UI) elements such as alternative text are crucial for accessibility and language-based interaction in general. Yet, these descriptions are constantly missing in mobile UIs. We propose widget captioning, a novel task for automatically generating language descriptions for UI elements from multimodal input including both the image and the structural representations of user interfaces. We collected a large-scale dataset for widget captioning with crowdsourcing. Our dataset contains 162,859 language phrases created by human workers for annotating 61,285 UI elements across 21,750 unique UI screens. We thoroughly analyze the dataset, and train and evaluate a set of deep model configurations to investigate how each feature modality as well as the choice of learning strategies impact the quality of predicted captions. The task formulation and the dataset as well as our benchmark models contribute a solid basis for this novel multimodal captioning task that connects language and user interfaces.

1 Introduction

Mobile apps come with a rich and diverse set of design styles, which are often more graphical and unconventional compared to traditional desktop applications. Language descriptions of user interface (UI) elements—that we refer to as *widget captions*—are a precondition for many aspects of mobile UI usability. For example, accessibility services such as screen readers, e.g., Talkback (2019), rely on widget captions to make UI elements accessible to visually impaired users via text-to-speech technologies. Importantly, widget captions are an enabler for many language-based interaction capabilities such as voice commands and general screen understanding efforts.

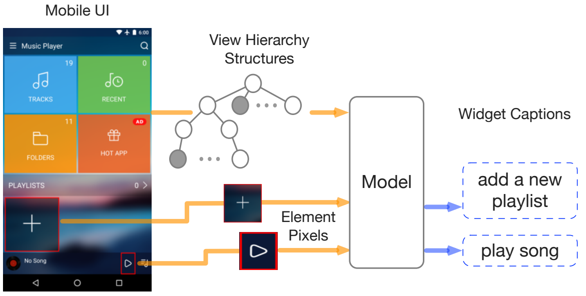

Figure 1: Widget captioning is a task to generate language descriptions for UI elements that miss captions, given multimodal input of UI structures and screenshot images. These captions are crucial for accessibility and language-based interaction in general.

However, a significant portion of mobile apps today lack widget captions in their user interfaces, which have stood out as a primary issue for mobile accessibility (Ross et al., 2018, 2017). More than half of image-based elements have missing captions (Ross et al., 2018). Beyond image-based ones, our analysis of a UI corpus here showed that a wide range of elements have missing captions. Existing tools for examining and fixing missing captions (AccessibilityScanner, 2019; AndroidLint, 2019; Zhang et al., 2018, 2017; Choo et al., 2019) require developers to manually compose a language description for each element, which imposes a substantial overhead on developers.

We propose widget captioning, a novel task to automatically generate captions for UI elements[1] based on their visual appearance, structural properties and context (see Figure 1). This task is analogous to image captioning that generates language descriptions for images, e.g., Xu et al. (2015); Lin et al. (2014). However, widget captioning

---

[*] Equal contribution

[†] Participated in the project during an internship at Google Research.

[1] We use widgets and elements interchangeably.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5495–5510,
November 16–20, 2020.

raises several unique challenges. User interfaces are highly structural while traditional image captioning mostly focus on raw image pixels. Widget captioning is concerned with describing individual elements in the UI rather than the entire UI screen, while the entire screen provides useful contextual information for widget captioning. We target language generation for a broad set of UI elements, rather than only image-based ones. As we will show in our data analysis, many non-image elements also suffer the lack of captions. These challenges give rise to several interesting modeling questions such as how to combine both structural and image input and how to effectively represent each modality.

We start by processing and analyzing a mobile UI corpus. We then create a large dataset for widget captioning by asking crowd workers to annotate a collection of UI elements in the corpus. Based on this dataset, we train and evaluate a set of model configurations to investigate how each feature modality and the choice of learning strategies would impact caption generation quality. Our champion model that is based on a Transformer (Vaswani et al., 2017) to encode structural information and a ResNet (He et al., 2015) for image input is able to produce accurate captions for UI elements based on both automatic and human evaluation. In summary, the paper makes the following contributions:

- We propose widget captioning as a task for automatically generating language descriptions for UI elements in mobile user interfaces; The task raises unique challenges for modeling and extends the popular image captioning task to the user interface domain.
- We create a dataset for widget captioning via crowdsourcing[2]. It contains 162,859 captions created by human workers for 61,285 UI elements across 21,750 unique screens from 6,470 mobile apps. Our analysis on the missing captions and the linguistic attributes of collected captions contribute new knowledge for understanding the problem.
- We investigate a set of model configurations and learning strategies for widget captioning; our benchmark models leverage multimodal input including both structural information and images of user interfaces[3]. They are able to generate accurate captions for UI elements, and yet leave enough room for improvement for future research.

2 Related Work

The lack of captions or alternative text has been a universal problem in user interfaces, ranging from mobile apps to web pages (Ross et al., 2018, 2017; Gleason et al., 2019; Guinness et al., 2018). Based on an analysis of an Android UI corpus (Deka et al., 2017), Ross et al. (2018) revealed that a significant portion of image-based buttons lack alternative text. By examining a broader set of UI elements, we found missing captions is a general issue across UI element categories.

Automatic image captioning has been a classic task where a model learns to generate language descriptions for images, which has gained substantial progress with the advance of deep learning (Hodosh et al., 2013; Donahue et al., 2017; Karpathy and Li, 2014; Xu et al., 2015; Lin et al., 2014), and the availability of datasets such as Flickr30K (Young et al., 2014) and MS-COCO (Lin et al., 2014). In contrast to image captioning, widget captioning that we propose is concerned with describing individual elements in the context of the UI screen. In addition to image input, widget captioning has access to UI structures such as view hierarchies. These raise unique modeling opportunities for multimodal captioning.

Many image captioning models (Xu et al., 2015; Sharma et al., 2018) involve an encoding net and a language generation net. The encoding net is typically a deep Convolutional Neural Network (CNN) (Krizhevsky et al., 2012) that encodes the image input as a collection of latent vector representations. The generation net is often an autoregressive decoding model, enhanced with neural attention. For widget captioning, the encoding net needs to encode multimodal input that include both images and UI structures. For UI structure encoding, recent work (Li et al., 2020) investigated both Graph Convolutional Network (GCN) (Niepert et al., 2016) and Transformer (Vaswani et al., 2017) and showed that a Transformer encoder gives better performance on the task, which we will use in this work.

Our learning strategy is akin to BERT (Devlin

[3] Our model code is released at https://github.com/google-research/google-research/tree/master/widget-caption.

et al., 2019) that uses the words in the same sentence to predict those missing using Transformer, to learn a contextual word representation. In our case, we use the information of elements in the same screen context to predict those with missing captions. To generate captions, based on the encoder output, we run multiple instances of the decoding model in parallel, one for each element to be captioned.

3 Creating the Widget Caption Dataset

We first create a mobile UI corpus, and then ask crowd workers to create captions for UI elements that have missing captions, which is followed by a thorough analysis of the dataset.

3.1 Creating a Mobile UI Corpus

We create a mobile UI corpus based on RICO, a public dataset of Android user interfaces, which has 66K screens collected from human users interacting with Android devices (Deka et al., 2017), which include top apps selected broadly from various categories in Google Play Store. We expanded the dataset using a crawling robot to perform random clicks on mobile interfaces, which added 12K novel screens to our corpus. Each screen comes with both a screenshot JPG/PNG image and a view hierarchy[4] in JSON. The view hierarchy is a structural tree representation of the UI where each node has a set of properties such as content description, class information, visibility, and bounding boxes.

3.1.1 Preprocessing the UI Corpus

We first exclude UI screens with missing or inaccurate view hierarchies, which could occur when Android logging is out of sync. This filtering step was conducted by asking crowd workers to visually examine each UI and confirm that the bounding boxes of all the leaf nodes in the hierarchy match the UI elements shown on the screenshot image. We focus on leaf nodes because most interactive elements are leaf nodes. The filtering process resulted in 24,571 unique screens from 6,853 mobile apps.

We then select UI elements that are visible and clickable because they are responsible for many of the interaction tasks. Similar to previous work, we consider an element missing captions when both its `contentDescription` and `text` properties in the view hierarchy are missing, according to the Android accessibility guideline[5]. Screen readers such as the TalkBack service[1] rely on these fields to announce the widget. Overall, in our dataset, there are 74,379 UI elements with missing captions, across 10 categories of UI elements (see Figure 3).

3.1.2 Understanding Missing Captions

Previous work analyzed missing captions for image-based elements (Ross et al., 2018). We include all types of elements in our dataset and analysis (see Appendix A). The results from analyzing image-based elements in our corpus are comparable to previous analysis, i.e., 95% of Floating Action Buttons, 83% of Image Views, and 57% of Image Buttons have missing captions. Beyond these image-based elements, we found that missing captions is a serious issue for other types of elements as well (see Figure 3). More than 50% of the `Switch`, `Compound Button`, `Check Box` and `Toggle Button` have missing captions. 24.3% of the screens have none pre-existing captions.

3.2 Crowdsourcing Widget Captions

To best match the target scenario of predicting for elements with missing captions, we asked crowd workers to created captions for these elements, which are used as labels for training and testing. Because pre-existing captions in the corpus are not always correct, they are used as model input, to provide the context, but not as output.

We developed a web interface for crowd workers to create language descriptions for UI elements that have missing captions. The interface shows a screenshot of the mobile interface, with the UI element that needs to be captioned highlighted (see Appendix B). Workers can input the caption using a text field, or indicate that they cannot describe the element. In the annotation guidelines, we asked the workers to caption the element for vision-impaired users to understand its functionalities and purposes. The captions need to be concise but more descriptive than generic words such as "button" or "image". We recruited over 5,454 workers from Amazon Mechanical Turk[6] over multiple batches. While the elements to be labeled by each worker are randomly selected, we instrumented the task in the way such that a worker can only label

---

[5] `https://developer.android.com/guide/topics/ui/accessibility/apps`

[6] mturk.com

each unique element once, and each element is labeled by 3 different workers.

3.3 Data Analyses

Human workers can skip elements when they were not sure how to describe them. For all the elements of each type given to workers, the percentage of elements being captioned ranges from 75% to 94% (see Figure 3). In particular, the `View` type has the lowest labeling ratio of 75%, which we suspect that elements with the `View` type, a generic widget type, tend to be quite arbitrary and are difficult for the workers to understand. We only kept the elements that received at least 2 captions (from different workers). On average, each element received 2.66 captions. In total, we collected 162,859 captions for 61,285 UI elements across 21,750 unique screens, from 6,470 mobile apps.

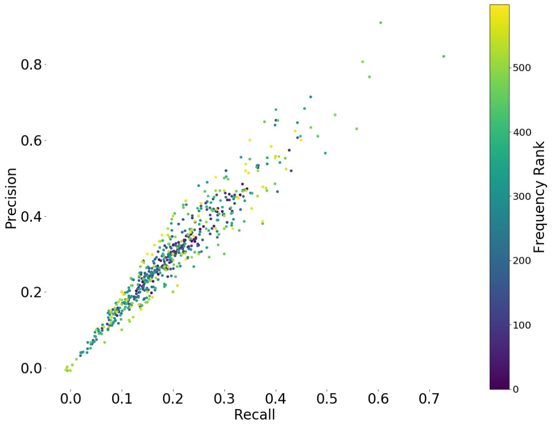

Figure 2: The distribution of precision and recall for the top 6K words of the collected captions.

To measure inter-annotator agreement, we computed the word-level precision and recall for all the words with two or more occurrences in the collected captions (see Figure 2), as in the COCO image captioning dataset (Chen et al., 2015). The results were generated on about 6K words, which amount to 98.6% of all the word occurrences in the captions. Figure 2 shows that our corpus has reasonable word-level agreement among the captions of the same widget. Specifically, for the 6K words, we report the mean precision and recall of every 10 consecutive words in the vocabulary. Therefore, we have 600 data points, each representing precision/recall of 10 words. The ranks of the words in the vocabulary sorted by word frequency are used to color the data points. Lower rank indicates higher word frequencies in the corpus.

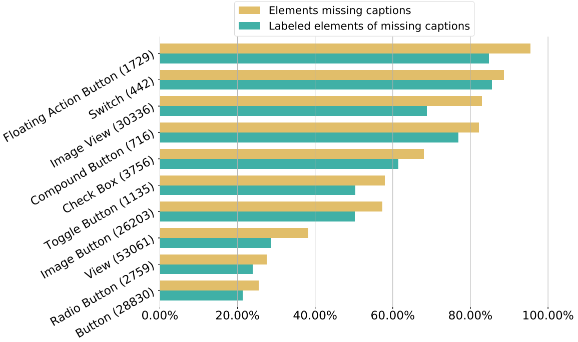

Figure 3: The percentage of elements that have missing captions (red) for each category and elements labeled by MTurk workers (green). The numbers in parentheses are total counts of the elements.

3.3.1 Caption Phrase Analysis

We analyzed the distribution of caption lengths created by human workers (see Figure 9). We found most captions are brief, i.e., two to three words. But a significant number of captions have more words, which are often long-tail captions. The average length of captions from human workers is 2.72. Overall, the length distribution of captions created by human workers is similar to those preexisting in the UI corpus, which are from app developers (see Appendix C). The latter will be used as a feature input to the model, which we will discuss later.

The captions in our dataset include a diverse set of phrases. The most frequent caption is “go back” that amounts to 4.0% of the distribution. Other popular captions among the top 5 are “advertisement” (2.4%), “go to previous” (0.8%), “search” (0.7%) and “enter password” (0.6%).

A common pattern of the phrases we observe is *Predicate + Object*. Table 1 lists the 7 common predicates and their most frequent objects. As we can see, the phrases describe highly diverse functionalities of the UI elements. It is difficult to classify them into a few common categories. This linguistic characteristics motivated us to choose sequence decoding for caption generation instead of classification based on a predefined phrase vocabulary. The diversity of caption phrases indicates that widget captioning is a challenging machine learning task.

Furthermore, these examples in Table 1 show that, to distinguish different objects for the same predicate, it is necessary to take into account the screen context that the element belongs to. For example, Figure 5 shows two examples of the “search” predicate. The two UI elements have very similar

Predicate	Object
search	location, contact, app, music, map, image, people, recipe, flight, hotel
enter	password, email, username, phone, last name, first name, zip code, location, city, birthday
select	image, ad, color, emoji, app, language, folder, location, ringtone, theme
toggle	autoplay, favorite, menu, sound, advertisement, power, notification, alarm, microphone, vibration
share (to)	article, facebook, twitter, image, app, video, instragram, recipe, location, whatsapp
download	app, sound, song, file, image, video, theme, game, wallpaper, effect
close	window, ad, screen, tab, menu, pop-up, notification, file, settings, message

Table 1: In our dataset, the popular predicates are often associated with a diverse set of objects that are contextually determined.

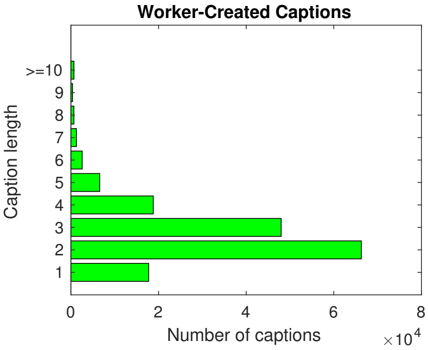

Figure 4: The length distribution of captions created by human workers. The X axis shows the number of captions and the Y axis is the lengths from 1 to ≥ 10.

images (magnifiers) although they are for searching different objects. Thus context information is critical for models to decode the correct objects.

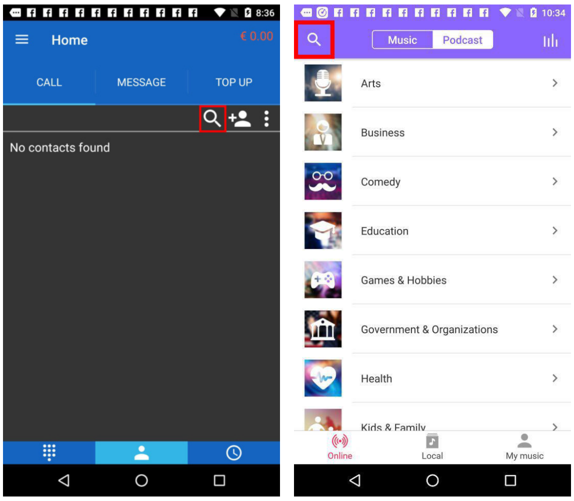

Figure 5: Two UI elements (outlined in red) of "search" predicate. Left: search contact; Right: search music.

3.3.2 View Hierarchy Complexities

A unique modality in widget captioning is UI structures as represented by view hierarchy trees. To better understand the complexity of the UI structures, we analyze the size and depth of the view hierarchy of each UI. The size of a view hierarchy is the total number of nodes in the hierarchy tree, including both non-terminal nodes, i.e., layout containers, and leaf nodes. The size distribution is highly skewed and with a long tail towards large view hierarchies (see the left of Figure 6). The median size of view hierarchies is 61, with a minimum of 6 and a maximum of 1,608 nodes. Many view hierarchies have a large depth with a median depth of 11, a minimum of 3 and a maximum of 26 (see the right of Figure 6). These show that view hierarchies are complex and contain rich structural information about a user interface.

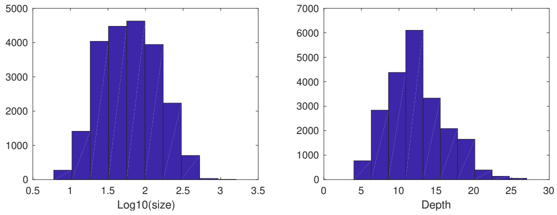

Figure 6: The histogram of $\log_{10}$ transformed view hierarchy sizes on the left, and the histogram of tree depths on the right.

4 Widget Captioning Models

To understand the challenges and feasibility of automatic widget captioning, we investigate deep models for this task. Captioning models are often designed based on an encoder-decoder architecture. We formulate widget captioning as a multimodal captioning task where the encoder takes both the structural information and the pixel appearance of the UI element, and the decoder outputs the caption based on the encodings (see Figure 7).

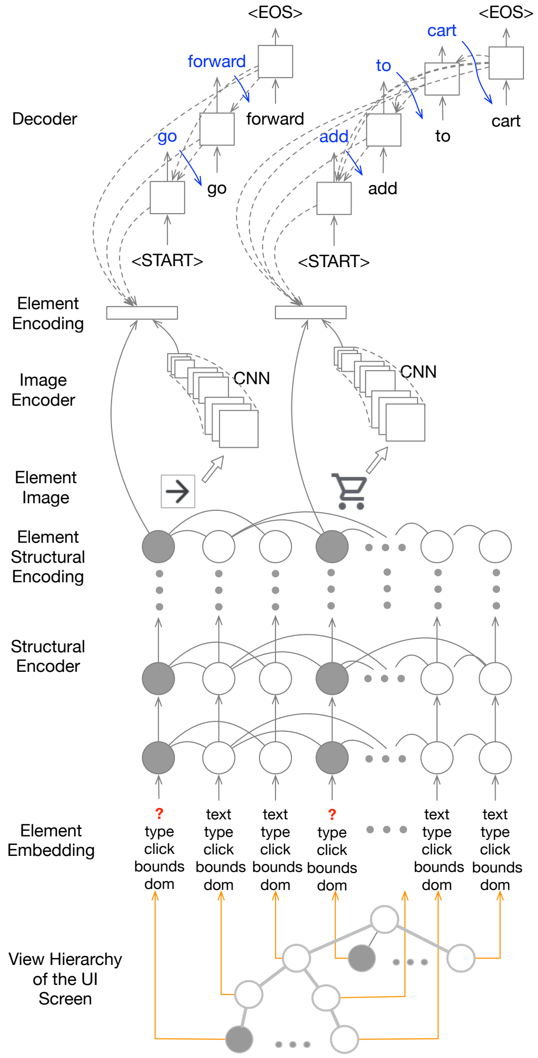

Figure 7: Our widget captioning model takes both view hierarchy structures and element image input, and performs parallel decoding for multiple elements on the screen missing captions. The shaded nodes represent the elements missing captions.

4.1 Encoding the Structural Information

We hypothesize that the relationship of UI elements on the screen provides useful contextual information for representing each object thus benefits captioning. We use a Transformer model (Vaswani et al., 2017) to encode the set of elements on a screen, which learns how the representation of an element should be affected by the others on the screen using multi-head neural attention. The input to a Transformer model requires both the content embedding and positional encoding. Similar to previous work (Li et al., 2020), we derive these embeddings for each element on the screen in the following manner.

Each UI element in the view hierarchy consists of a tuple of properties. The `widget_text` property includes a collection of words possessed by the element. We acquire the embedding of the `widget_text` property of the i-th element on the screen, e_i^X, by max pooling over the embedding vector of each word in the property. When the `widget_text` property is empty, i.e., the element is missing a caption, a special embedding, $e^\emptyset$, is used. With e_i^T, the embedding of the `widget_type` property (see Figure 3), and e_i^C, the embedding of whether the widget is clickable, $[e_i^X; e_i^T; e_i^C]$ form the content embedding of the element.

The `widget_bounds` property contains four coordinate values on the screen: `left`, `top`, `right` and `bottom`, which are normalized to the range of $[0, 100)$. The `widget_dom` property contains three values describing the element tree position in the view hierarchy: the sequence position in the `preorder` and the `postorder` traversal, and the `depth` in the view hierarchy tree. These are all treated as categorical values and represented as embedding vectors. The sum of these coordinate embeddings form the positional embedding vector of the element, e_i^B.

The concatenation of all these embeddings forms the representation of a UI element: $e_i = [e_i^X; e_i^T; e_i^C; e_i^B]W^E$, where W^E is the parameters to linearly project the concatenation to the dimension expected by the Transformer model. The output of the Transformer encoder model, h_i, is the structural encoding of the i-th element on the screen.

4.2 Encoding Element Images

The image of an element is cropped from the UI screenshot and rescaled to a fixed dimension, which results in a `64x64x1` tensor, where `64x64` are the spatial dimensions and `1` is the grayscale color channel. The image dimension strikes a good balance for representing both small and large elements, which preserves enough details for large elements after scaled down and enables a memory footprint good for model training and serving.

We use a ResNet (CNN) (He et al., 2015) to encode an element image. Each layer in the image encoder consists of a block of three sub layers with a residual connection—the input of the 1st sub layer is added to the input of the 3rd sub layer. There are no pooling used, and instead, the last sub layer of each block uses stride 2 that halves both the vertical and horizontal spatial dimensions after each layer. At the same, each layer doubles the channel dimension, starting from the channel dimension 4 of the first layer. Most sub layers use a kernel size of 3×3 except the initial and ending sub layers in the first layer that use a kernel size of 5×5. We will discuss further details of model configuration for the image encoder in the experiment section. The output of the multi-layer CNN is the encoding vector of the element image, which we refer to as g_i for the i-th element.

4.3 Decoding Captions

We form the latent representation of the ith element on the screen by combining its structural and image encoding: $z_i = \sigma([h_i^L; g_i], \theta^z)W^z$, where $\sigma(\cdot)$ is the non-linear activation function parameterized by θ^z and W^z is the trainable weights for linear projection. Based on the encoding, we use a Transformer (Vaswani et al., 2017) decoder model for generating a varying-length caption for the element.

$$a_{i,1:M}^{l} = \text{Masked\_ATTN}(x_{i,1:M}^{l}, W_d^Q, W_d^K, W_d^V)$$
$$x_{i,1:M}^{l+1} = \text{FFN}(a_{i,1:M}^{l} + z_i, \theta_d)$$

where $0 \leq l \leq L$ is the layer index and M is the number of word tokens to decode. $x_{i,1:M}^0$, the input to the decoder model, is the token embedding with the sequence positional encoding. W_d^Q, W_d^K, and W_d^V are trainable parameters for computing the queries, keys, and values. Masked_ATTN in a Transformer decoder allows multi-head attention to only attend to previous token representations. The element encoding, z_i, is added to the attention output of each decoding step, $a_{i,1:M}^l$, before feeding into the position-wise, multi-layer perception (FFN), parameterized by θ_d. The probability distribution of each token of the caption is finally computed using the softmax over the output of the last Transformer layer: $y_{i,1:M} = \text{softmax}(x_{i,1:M}^L W_d^y)$ where W_d^y is trainable parameters.

There is one instance of the decoder model for each element to be captioned. The captions for all the elements with missing captions on the same screen are decoded in parallel. The entire model, including both the encoder and decoder, is trained end-to-end, by minimizing $\mathcal{L}_{screen}$, the average cross entropy loss for decoding each token of each element caption over the same screen.

$$\mathcal{L}_{screen} = \frac{1}{|\nabla|} \sum_{i \in \nabla} \frac{1}{M} \sum_{j=1}^{M} \text{Cross\_Entropy}(y_{i,j}^{'}, y_{i,j})$$

where ∇ is the set of elements on the same screen with missing captions and $y_{i,j}^{'}$ is the groundtruth token. Training is conducted in a teacher-forcing manner where the groundtruth caption words are fed into the decoder. During prediction time, the model decodes autoregressively.

5 Experiments

We first discuss the experimental setup, and then report the accuracy of our model as well as an analysis of the model behavior.

5.1 Datasets

We split our dataset into training, validation and test set for model development and evaluation, as shown in Table 2. The UIs of the same app may have a similar style. To avoid information leaks, the split was done app-wise so that all the screens from the same app will not be shared across different splits. Consequently, all the apps and screens in the test dataset are unseen during training, which allow us to examine how each model configuration generalizes to unseen conditions at test.

Our vocabulary includes 10,000 most frequent words (that covers more than 95% of the words in the dataset), and the rest of the words encountered in the training dataset is assigned a special unknown token `<UNK>`. During validation and testing, any `<UNK>` in the decoded phrase is removed before evaluation. Since each element has more than one caption, one of its captions is randomly sampled each time during training. For testing, all the captions of an element constitute its reference set for computing automatic metrics such as CIDEr.

Split	Apps	Screens	Widgets	Captions
Training	5,170	18,394	52,178	138,342
Validation	650	1,720	4,548	12,242
Test	650	1,636	4,559	12,275
Total	6,470	21,750	61,285	162,859

Table 2: Dataset statistics.

The training, validation and test datasets have a similar ratio of 40% for caption coverage, i.e., the number of elements with preexisting captions with respect to the total number of elements on each screen, with no statistical significance ($p > 0.05$). Screens with none preexisting captions exist in all the splits.

5.2 Model Configurations

We based our experiments on Transformer as it outperformed alternatives such as GCNs and LSTMs in our early exploration. We tuned our model architectures based on the training and validation datasets. We initialize the word embeddings with pre-trained 400K-vocab 300-dimensional GLOVE embeddings (Pennington et al., 2014), which are then projected onto a 128-dimensional vector space. To reduce the number of parameters needed in the model, the embedding weights are shared by both the structural encoder and the decoder. Both the Transformer structural encoder and the Transformer decoder use 6 Transformer layers with a hidden size of 128 and 8-head attention. We used a 7-layer ResNet for encoding the pixels of a target element, where each layer consists of 3 sub layers as discussed earlier, which in total involves 21 convolutional layers and the output of the final layer is flattened into a 256-sized vector. We used batch normalization for each convolutional layer. The final encoding z_i of an element is a 128-dimensional vector that is used for decoding. See Appendix E for training details.

5.3 Metrics & Results

We report our accuracy based on BLEU (unigram and bigram) (Papineni et al., 2002), CIDEr (Vedantam et al., 2015), ROUGE-L (Lin and Och, 2004) METOER (Denkowski and Lavie, 2014) and SPICE (Anderson et al., 2016) metrics (see Table 3). For all these metrics, a higher number means better captioning accuracy—the closer distances between the predicted and the groundtruth captions.

We investigate how model variations impact the overall accuracy of captioning (Table 3). *Template Matching* is an obvious baseline, which predict the caption of an element based on its image similarity with elements that come with a caption. We use pixel-wise cosine similarity to compare the element images. Although this heuristic-based method is able to predict captions for certain elements, it performs poorly compared to the rest of the models that use deep architectures. *Pixel Only* model, which only uses the image encoding of an element, performs significantly better than *Template Matching*, which indicates that image encoding, g_i, is a much more efficient representation than raw pixels.

Pixel+Local, which uses both image encoding, g_i, and the structural representation computed only based on the properties of the element, offers further improvement on the accuracy. Our full model, *Pixel+Local+Context*, uses both image encoding, g_i, and the screen context encoding, h_i. It achieves the best results, which indicate that screen context carries useful information about an element for generating its caption. Among all the structural features, the `widget_text` property plays an important role (see the ablation study in Appendix F).

In addition to examining the impact of input modality on captioning quality, we compare strategies of caption generation: sequence decoding based on word tokens versus classification based on common caption phrases. *PLC Classification* model uses the same input modality and encoding as *Pixel+Local+Context* but decodes a single predefined phrase based on a vocabulary of top 10K caption phrases—the same size as the token vocabulary for decoding. It performed poorly compared to the decoding-based approach.

To further validate the usefulness of the context and the information from view hierarchy, we evaluate the models on a subset of UI elements with one of their reference caption phrases is of the *Predicate* + *Object* pattern (see Table 1). This subset consists of about 40% of the UI elements from the test set (see Appendix D for details). All the models achieve better accuracy because the predicate-object subset consists of more common words. *Pixel+Local+Context* remains the champion model, and more importantly, acquired the most significant gain across all the metrics (see Table 3). This indicates that context information plays a crucial role for generating this type of captions whose object parts need to be contextually determined. In contrast, *PLC Classification* still performs worse than the champion decoding-based model. While the subset contains more common words, their combination can form long-tail phrases. A classification-based method such as *PLC Classification* is more vulnerable to the data sparsity of long-tail phrases.

5.4 Human Evaluation

To assess the quality of the generated phrases by human, we asked another group of crowd workers to manually verify the model generated captions for the entire test set, by presenting each human rater a caption and its corresponding element in a UI screenshot. For each phrase, we asked three raters to verify whether the caption phrase correctly

Model Configuration	BLEU-1	BLEU-2	ROUGE	CIDEr	METOER	SPICE
	Full Test Set					
Template Matching	20.2	11.2	20.9	38.0	13.2	6.5
Pixel Only	35.6	24.6	35.6	71.3	24.9	11.2
Pixel+Local	42.6	29.4	42.0	87.3	29.4	15.3
Pixel+Local+Context (PLC)	**44.9**	**32.2**	**44.7**	**97.0**	**31.7**	**17.6**
PLC Classification	36.2	25.7	36.9	78.9	26.0	13.6
	Predicate-Object Subset					
Template Matching	20.8	11.2	21.3	34.5	12.6	7.5
Pixel Only	39.4	27.2	39.1	69.6	25.8	14.2
Pixel+Local	48.5	34.8	47.4	94.7	32.3	19.9
Pixel+Local+Context (PLC)	**52.0**	**38.8**	**51.3**	**110.1**	**36.4**	**23.3**
PLC Classification	38.5	27.0	38.4	78.9	26.3	16.8

Table 3: The accuracy of each model configuration on the full set and the predicate-object subset of the test dataset.

describes the functionality and purpose of the element. We compared two of our models and the results are listed in Table 4. The overall endorsement of raters for generated captions is 78.64% for the full model and 62.42% for the *Pixel Only* model. These results indicate that our model can generate meaningful captions for UI elements. We found shorter captions tend to receive more rater endorsements than longer ones. The model with context still outperforms the one without context, which is consistent with automatic evaluation. See examples of captions generated by our model in Appendix G.

Model	1+	2+	3+
Pixel Only	81.9	61.7	43.6
Pixel+Local+Context	**93.9**	**81.1**	**61.0**

Table 4: The human evaluation results. N+ in the header refers to N or more raters judge that the caption correctly describes the element.

5.5 Error Analysis

To identify opportunities for improvements, we conducted error analysis on 50 widgets sampled from the validation set whose captions generated by the model share no words with their references. We classify these errors into the following types.

- *Nearby Elements* (21): The model is confused by nearby elements on the screen, e.g., outputting "enter phone number" for "write street address" on a sign-up screen.
- *Similar Appearance* (10): The model is confused by elements with a similar appearance, e.g., predicting "delete" for an X-shaped image that is labeled as "close".
- *Too Generic* (9): the model generate captions that are too generic, e.g., "toggle on" instead of "flight search on/off".
- *Model Correct* (10): The model produces semantically correct captions but treated as errors due to the limitation of automatic evaluation, e.g., "close" for "exit".

There are two directions for future improvement. One is to improve encoders for UI images and view hierarchies to better represent UI elements. The other is to improve data sparsity, which we want to better address long-tail phrases by expanding the dataset and having more elements and screens labeled.

6 Conclusion

We present widget captioning, a novel task for automatically generating language description for UI elements. The task is important because missing captions is a major issue for mobile accessibility and addressing the issue can improve accessibility and empower language-based mobile interaction in general. We created a large-scale dataset for this novel task by asking human annotators to create widget captions for a mobile UI corpus via crowdsourcing. We formulate widget captioning as a multimodal captioning task where both structural and image input are available. We experimented with a set of models based on the dataset. The winner configuration—a Transformer structural encoder coupled with a ResNet CNN—can generate semantically meaningful captions for sparsely labeled elements on the screen, which shows the feasibility of this task and opportunities for future research.

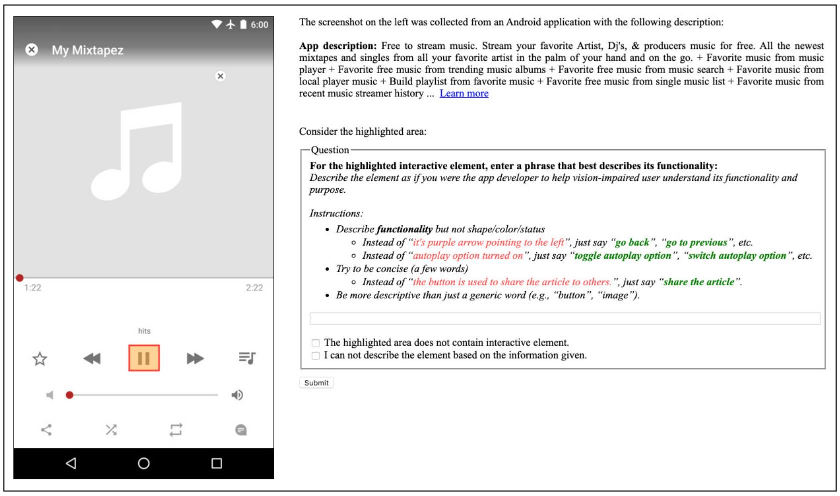
A Further Details for Preprocessing the UI Corpus

We keep all the types of UI elements and determine the type of an element based on its class and ancestors attributes in the view hierarchy. We first check whether the element's class is in the set of predefined widget types in the Android development library (Android, 2019a,b). If not, i.e., if it is a custom class, which is specific to an app, e.g., "SearchButton", we find the closest class in its ancestry that belongs to the standard Android widget set as its type, e.g., "Button".

B The Annotation Interface

We built a web interface for crowd workers to create captions for UI elements (see Figure 8). On the left of the interface is shown the screenshot of a mobile user interface. The element to be annotated is highlighted with a red bounding box. On the right, the app description that is crawled from Google Play Store is displayed to give the annotator the background about the mobile app that the UI screen is from. Underneath the app description the description for the annotation task. An annotator is given a guideline about the captioning task and several concrete examples about desired captions as well as captions should be avoided. The annotator can perform a task by entering a caption for the highlighted element in the text field,



The screenshot on the left was collected from an Android application with the following description:

App description: Free to stream music. Stream your favorite Artist, Dj's, & producers music for free. All the newest mixtapes and singles from all your favorite artist in the palm of your hand and on the go. + Favorite music from music player + Favorite free music from trending music albums + Favorite free music from music search + Favorite music from local player music + Build playlist from favorite music + Favorite free music from single music list + Favorite music from recent music streamer history ... Learn more

Consider the highlighted area:

Question

For the highlighted interactive element, enter a phrase that best describes its functionality:
Describe the element as if you were the app developer to help vision-impaired user understand its functionality and purpose.

Instructions:

- *Describe **functionality** but not shape/color/status*
  - *Instead of "it's purple arrow pointing to the left", just say "**go back**", "**go to previous**", etc.*
  - *Instead of "autoplay option turned on", just say "**toggle autoplay option**", "**switch autoplay option**", etc.*
- *Try to be concise (a few words)*
  - *Instead of "the button is used to share the article to others.", just say "**share the article**".*
- *Be more descriptive than just a generic word (e.g., "button", "image").*

☐ The highlighted area does not contain interactive element.
☐ I can not describe the element based on the information given.

Figure 8: The annotation web interface for crowd workers to create captions for a UI element.

or skip the task by selecting the checkbox options that apply when the target element is incorrectly highlighted or cannot be described. The annotator clicks on the Submit button at the bottom to submit the responses.

C Phrase Distribution

There are 476,912 UI elements in the UI corpus that come with text, which are from the app content or created by the app developers. These constitute the `widget_text` feature input to the structural encoder to help generating descriptions for elements with missing captions. We compare the lengths of captions created by human workers with the lengths of these preexisting text content. We found the length distributions of the two sources are similar (see Figure 9). The median length for both sources of text content is 2. There is a larger variance in length for the preexisting text, and there are more single-word and long descriptions. A preexisting caption can simply repeat the content of an element that can be a long sentence or paragraph, which contributes to the long tail of the distribution (length$\geq$ 10). A pre-existing caption can also be generic names such as image or button, which are undesirable for accessibility. There are a diverse set of captions created by human workers (see Figure 10).

D Predicate-Object Phrases

We identify the *Predicate* + *Object* subset used for evaluation in the paper as follows. First, we collected all the verbs with frequency more than 1000 in the corpus. This resulted in 22 verbs: *go*, *select*, *enter*, *open*, *add*, *search*, *click*, *toggle*, *play*, *view*, *share*, *close*, *switch*, *choose*, *show*, *download*, *input*, *see*, *like*, *change*, *check*, and *turn*. For these verbs, we manually checked all their objects and identified 194 nouns that are likely to require contextual and structural information from the view hierarchy to decode (see Table 1 in the paper). Finally, the *Predicate* + *Object* captions were identified as the ones that contain at least one of the 22 verbs and one of the 194 nouns and appear at least twice in the corpus. As a result, 1850 (40.6%) widgets in the test dataset have *Predicate* + *Object* captions in their references and thus are selected as the *Predicate* + *Object* subset for evaluating the model performance, as reported in the main paper.

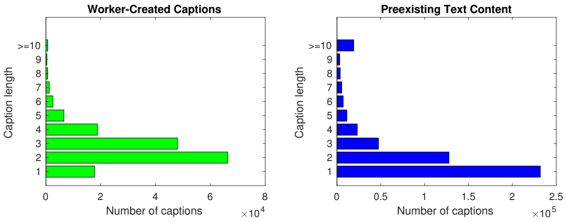


Figure 9: The length distribution of captions created by human workers versus those preexisting in the UI corpus. The X axis shows the number of text descriptions and the Y axis is the lengths from 1 to $\geq$ 10.

E Model Configurations & Training

Template Matching is based on a Nearest-Neighbor approach where all the examples in the training dataset are used as templates. Given an element to be captioned in the test dataset, the caption of the most similar template, based on cosine similarity between their pixel values, is used as the prediction.

Model Configuration	BLEU-1	BLEU-2	ROUGE	CIDEr	METOER	SPICE
	Full Validation Set					
Template Matching	19.5	10.1	20.1	35.2	12.6	5.8
Pixel Only	35.8	23.9	35.9	70.7	24.6	10.8

Full model	**44.9**	**32.2**	**44.7**	**97.0**	**31.7**	**17.6**

Table 6: The ablation study results for the Pixel+Local+Context model.

For *Pixel+Local*, the structural encoding is computed by feeding the element embedding, e_i, into a multi-layer perceptron that is followed by a linear projection: $\phi(e_i, \theta_e)W_e$ where $\phi(\cdot)$ is a multi-layer perceptron parameterized by θ_e, and W_e are trainable parameters for the linear projection.

We pre-trained the ResNet image encoder using a denoised auto-encoder approach (Vincent et al., 2008). Pre-training allows us to leverage the images of all the elements instead of only those with caption labels. In particular, to reconstruct an image, we used 5 layers of transposed convolution where each layer has a residual connection architecture that is similar to the encoder part (that is discussed in the main paper). The reconstruction part of the model is discarded once the image encoder is trained.

We implemented our model in TensorFlow (TensorFlow, 2017), and all the input and evalutation pipelines in Python. We tuned our models on a range of hyperparameters, including the hidden sizes (64, 128, 256 and 512), the number of encoder/decoder hidden layers (2, 4 and 6), widget text pooling (max, mean and sum), and the Transformer hyperparameter learning_rate_constant (0.01, 0.03, 0.1, 0.3, 1.0, 2.0). We trained our model on 4 Tesla V100 GPU cores with asynchronous training with a batch size of 64 (screens) for all the models, which are all converged in less than 2 days. The model is trained, using the Adam optimizer, until it converges with a scheduled learning rate—a linear warmup followed by an exponential decay. We followed other modeling choices from the Transformer paper (Vaswani et al., 2017). The number of parameters for *Pixel Only*, *Pixel+Local*, *Pixel+Local+Context (PLC)* and *PLC Classification* are 3.73M, 4.24M, 5.33M and 5.33M respectively. The performance of all the model configurations on the validation dataset are shown in Table 5.

F Ablation Study

To investigate how different information in the view hierarchy contribute to the model performance, we conducted an ablation study by removing features in the UI element representation. As showed in Table 6, each feature contributes to the overal performance of the model. Particularly, removing the text feature resulted in the largest drop in accuracy.

G Captioning Examples

A collection of examples of captions generated by the models versus those created by human workers from the held-out test dataset are shown in Figure 11 and 12.

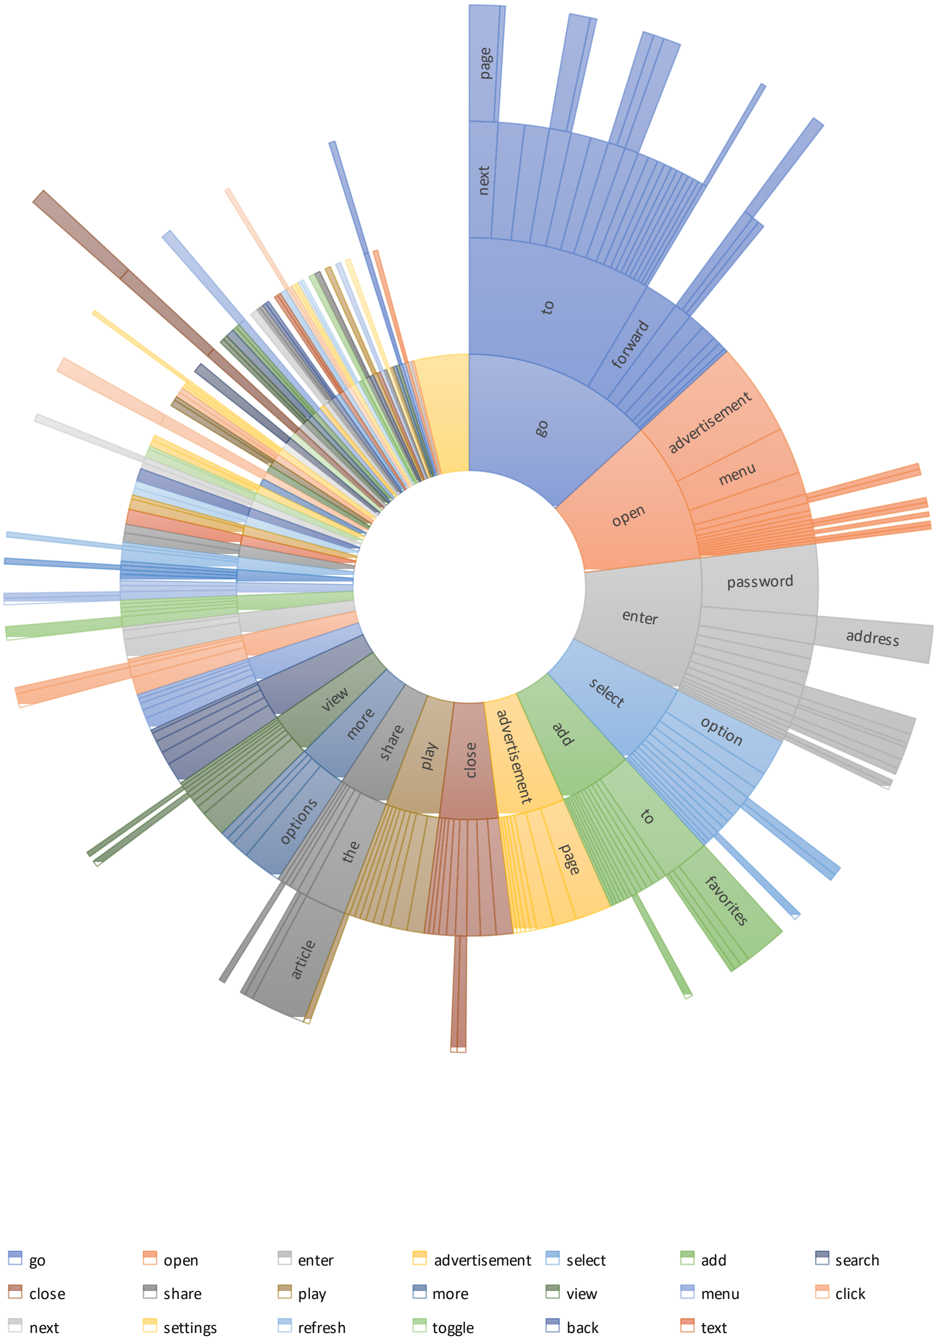

Figure 10: The distribution of captions by their first four words for the top 300 unique captions. The ordering of the words in a caption starts from the center and radiates outwards. The arc length is proportional to the number of captions containing the word.

Unsupervised Natural Language Inference via Decoupled Multimodal Contrastive Learning

Wanyun Cui§ **Guangyu Zheng**‡ **Wei Wang**‡

Abstract

We propose to solve the natural language inference problem without any supervision from the inference labels via task-agnostic multimodal pretraining. Although recent studies of multimodal self-supervised learning also represent the linguistic and visual context, their encoders for different modalities are coupled. Thus they cannot incorporate visual information when encoding plain text alone. In this paper, we propose Multimodal Aligned Contrastive Decoupled learning (MACD) network. MACD forces the decoupled text encoder to represent the visual information via contrastive learning. Therefore, it embeds visual knowledge even for plain text inference. We conducted comprehensive experiments over plain text inference datasets (i.e. SNLI and STS-B). The unsupervised MACD even outperforms the fully-supervised BiLSTM and BiLSTM+ELMO on STS-B.

1 Introduction

Humans are not supervised by the natural language inference (NLI). Supervision is necessary for applications in human-defined domains. For example, humans need the supervision of what is a noun before they do POS tagging, or what is a tiger in Wordnet before they classify an image of tiger in ImageNet. However, for NLI, people are able to entail that ⓐ `A man plays a piano` contradicts ⓑ `A man plays the clarinet for his family` without any supervision from the NLI labels. In this paper, we define such inference as a more general process of establishing associations and inferences between texts, rather than strictly classifying whether two sentences entail or contradict each other. Inspired by this, we raise the core problem in this paper: *Given a pair of natural language sentences, can machines entail their relationship without any supervision from inference labels?*

In his highly acclaimed paper, neuroscientist Moshe Bar claims that *"predictions rely on the existing scripts in memory, which are the result of real as well as of previously imagined experiences"* (Bar, 2009). The exemplar theory argues that humans use **similarity** to recognize different objects and make decisions (Tversky and Kahneman, 1973; Homa et al., 1981).

Analogy helps humans understand a novel object by linking it to a similar representation existing in memory (Bar, 2007). Such linking is facilitated by the object itself and its *context* (Bar, 2004). Context information has been widely applied in self-supervision learning (SSL) (Devlin et al., 2018; de Sa, 1994; He et al., 2020). Adapting context to NLI is even more straightforward. A simple idea of **constant conjunction** is that *A* causes *B* if they are constantly conjoined. Although constant conjunction contradicts "correlation is not causation", modern neuroscience has confirmed that humans use it for reasoning in their mental world (Levy and Steward, 1983). For example, they found an increase in synaptic efficacy arises from a presynaptic cell's repeated and persistent stimulation of a postsynaptic cell in Hebbian theory (Hebb, 2005). As to the natural language, the object and its context can be naturally used to determine the inference. For example, ⓐ contradicts ⓑ because they cannot happen simultaneously in the same **context**.

The context representation learned by SSL (e.g. BERT (Devlin et al., 2018)) has already achieved big success in NLP. From the perspective of context, these models (Devlin et al., 2018; Liu et al., 2019) learn the sentence level contextual information (i.e. by next sentence prediction task) and the word level contextual information (i.e. by masked language model task).

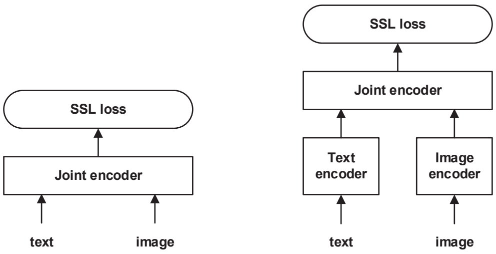
Besides linguistic contexts, humans also link other modalities (e.g. visions, voices) to novel inputs (Bar, 2009). Even if the goal is to reason about

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5511–5520,
November 16–20, 2020.

plain texts, other modalities still help (although they are not provided as inputs) (Kiela et al., 2018). For example, if only textual information is used, it is difficult to entail the contradiction between ⓐ and ⓑ. We need the commonsense that a man only has two arms, which cannot play the piano and clarinet simultaneously. This commonsense is hard to obtain from the text. However, if we link the sentences to their *visual scenes*, the contradiction is much clearer because the two scenes cannot happen in the same visual context. We think it is necessary to incorporate other modalities for the unsupervised natural language inference.

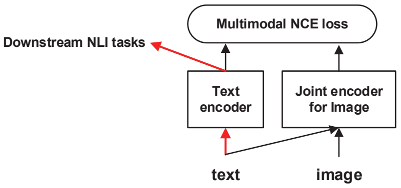
The idea of adapting multimodal in SSL is not new. According to (Su et al., 2020), we briefly divide previous multimodal SSL approaches into two categories based on their encoder infrastructures. As shown in Fig. 1a, the first category uses one joint encoder to represent the multimodal inputs (Sun et al., 2019; Alberti et al., 2019; Li et al., 2019, 2020; Su et al., 2020). Obviously, if the downstream task is only for plain text, we cannot extract the representation of text separately from the joint encoder. So the first category is infeasible for the natural language inference. The second category (Lu et al., 2019; Tan and Bansal, 2019; Sun et al., 2019) first encodes the text and the image separately by two encoders. Then it represents the multimodal information via a joint encoder over the lower layer encoders. This is shown in Fig. 1b. Although the textual representation can be extracted from the text encoder in the lower layer, such representation does not go through the joint learning module and contains little visual knowledge. In summary, the encoders in previous multimodal SSL approaches are coupled. If only textual inputs are given, they cannot effectively incorporate visual knowledge in their representations. Thus their help for entailing the contradiction between ⓐ and ⓑ is limited.

In order to benefit from multimodal data in plain text inference, we propose the Multimodal Aligned Contrastive Decoupled learning (MACD) network. This is shown in Fig. 1c. Its text encoder is decoupled, which only takes the plain text as inputs. Thus it can be directly adapted to downstream NLI tasks. Besides, we use multimodal contrastive loss between the text encoder and the image encoder, thereby forcing the text representation to align with the corresponding image. Therefore even if the text encoder in MACD only takes the plain text as input, it still represents visual knowledge. In the downstream plain text inference tasks, without taking images as input, the text encoder of MACD still implicitly incorporating the visual knowledge learned by the multimodal contrastive loss. Note that we do not need a decoupled image encoder in the SSL. So the image encoder in Fig. 1c in MACD takes texts as inputs to provides a more precise image encoder. We will elaborate this in section 2.1.



(a) Multimodal SSL with one joint encoder.

(b) Multimodal SSL with two single-modal encoders and one joint encoder.



(c) Our proposed multimodal aligned contrastive decoupled network. When adapting to downstream NLI tasks, we directly leverage the representation by the text encoder through the red lines, which only requires text as input.

Figure 1: Comparison of different multimodal SSL approaches.

2 Problem Formulation

We outline the general decoupled SSL process of MACD in section 2.1, and the downstream unsupervised NLI task in section 2.2.

2.1 Decoupled Multimodal SSL

For pretraining MACD, we use the multimodal training data $\mathcal{D}_{t2i} = \{x_i, y_i\}_{i=1}^{N}$ with N samples. Each sample $\{x_i, y_i\}$ consists of a pair of text x_i and image y_i, which describe the same context. It is straightforward to extend our method to modalities other than texts and images.

MACD learns from $\mathcal{D}_{t2i}$. Since text2image is many-to-many, we use energy-based models to represent their correlations. We first encode x_i and y_j into one pretext-invariant representation space (Misra and van der Maaten, 2020). The encoders are denoted by $f(x_i; \theta_f)$ and $g(x_i, y_i; \theta_g)$, respectively. We define the energy function $\sigma(x_i, y_i) : X \times Y \rightarrow \mathbb{R}$ as

$$\sigma(x_i, y_i) = d(f(x_i; \theta_f), g(x_i, y_i; \theta_g)) \quad (1)$$

where $f(x_i; \theta_f)$ denotes the text encoder and $g(x_i, y_i; \theta_g)$ denotes the image encoder. d is a non-parametric distance metric (e.g. cosine). In the rest of this paper, we will use $f(x)$ and $g(x, y)$ instead of $f(x; \theta_f)$ and $g(x, y; \theta_g)$ for convenience.

Note that the text encoder $f(x)$ only takes the text as input, while the image encoder $g(x, y)$ takes both the image and the text as input. The higher the value of the energy function $\sigma()$, the higher the probability that x and y are in the same context, and vice versa. The forms of the encoders have the following advantages:

- The text encoder $f(x)$ and the image input y are *decoupled*. Therefore we represent x separately without knowing y. This allows us to use $f(x)$ in the downstream plain text inference.

- $g(x, y)$ represents the *one-to-many* relationship via implicitly introducing the "predictive sparse coding" (Gregor and LeCun, 2010). One image has multiple corresponding texts. To use energy-based models to represent the one-to-many relationship, one common approach is to introduce a noise vector z to allow multiple predictions through one image (Bojanowski et al., 2018). Note that such z can be quickly estimated by the given text x and image y (Gregor and LeCun, 2010). In our proposed image encoder $g(x, y)$, although z is not explicitly introduced, the encoder allows multiple predictions for one image via taking different images as input. Besides, it allows the image to interact with the text in the inner computation, which is an implicit alternative for the predictive z.

2.2 Downstream Unsupervised NLI

We use the representation from the pre-trained multimodal SSL to predict the relations of natural language sentence pairs under the unsupervised learning scenario. The testing data can be formulated as $\mathcal{D}_{test} = \{x_i^T, z_i\}_{i=1}^M$, each $x_i^T = (x_i^1, x_i^2)$ is composed of a sentence pair x_i^1 and x_i^2. z_i indicates the relation between x_i^1 and x_i^2. Under the unsupervised setting, we predict z_i for given x_i^T by the similarity of $f(x_i^1)$ and $f(x_i^2)$ (e.g. cosine similarity).

3 Methods

This section elaborates our major methodology. In section 3.1, we show how we maximize the cross-modal mutual information (MI) for the decoupled representation learning. In section 3.2, we show how we incorporate the mutual information (MI) of local structures. We elaborate the encoders in section 3.3. In Section 3.4, in order to solve the catastrophic forgetting problem, we use lifelong learning regularization to anchor the text.

3.1 Decoupled Representation Learning by Cross-Modal Mutual Information Maximization

As discussed in section 1, the query object and its context determine the inference. NLI depends on whether the two sentences are in the same context. In this paper, we consider context from different modalities (e.g. text or images).

Mutual information maximization has become a trend for SSL (Tian et al., 2019; Hjelm et al., 2019). For cross-modal SSL, we also leverage mutual information $\mathcal{I}(X, Y)$ to represent the correspondence between the text and the image. Intuitively, high mutual information means that the text and the image are well-matched. More formally, the goal of multimodal representation learning is to maximize their mutual information:

$$\mathcal{I}(X, Y) = \sum_{x,y} P(x, y) \log \frac{P(x|y)}{P(x)} \quad (2)$$

Eqn. (2) is intractable and thereby hard to compute. To approximate and maximize $\mathcal{I}(X, Y)$, we use Noise-Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2010; Oord et al., 2018). First, we use the function $\sigma(x, y)$ to represent the term $\frac{P(x|y)}{P(x)}$ in Eqn. (2):

$$\sigma_{\text{global}}(x, y) \propto \frac{P(x|y)}{P(x)} \quad (3)$$

where $\sigma_{\text{global}}(x, y) : X \times Y \rightarrow \mathbb{R}$ is not a real probability and can be unnormalized. Here we use the notation "global" for the representation learning of a complete text or a complete image to distinguish from the local structures in section 3.2.

To compute the cross-modal mutual information, we first encode x and y to $f_{\text{global}}(x)$ and $g_{\text{global}}(y)$, respectively. Then we use the similarities of their encodings to model $\frac{P(x|y)}{P(x)}$. Note that $g_{\text{global}}(y)$ is a specific form of $g(x, y)$ in Eqn. (1). So $f_{\text{global}}(x)$

and $g_{\text{global}}(y)$ satisfy the form of f and g in Eqn. (1). We will show how to incorporate the linguistic input when designing the encoder of local visual structures in section 3.3. We follow (Misra and van der Maaten, 2020) to compute the pretext-invariant energy function by the exponential function of their cosine similarity:

$$\begin{aligned}\sigma_{\text{global}}(x, y) &= d(f_{\text{global}}(x), g_{\text{global}}(y)) \\ &= \exp\Big(\frac{cosine(f_{\text{global}}(x), g_{\text{global}}(y))}{\tau_\sigma}\Big)\end{aligned} \tag{4}$$

where τ_σ is a hyper-parameter of temperature.

To estimate $\sigma_{\text{global}}(x, y)$ and maximize the mutual information in Eqn. (2), the NCE loss (Oord et al., 2018) provides a valid toolkit. By taking the posterior probability $P(y|x)$, the NCE loss is defined as:

$$\begin{aligned}\mathcal{L}^{\text{NCE}:P(y|x)}(X, Y) = -\mathbb{E}_{x,y\sim P(y|x)\tilde{P}(x)}\{&\log \sigma_{\text{global}}(x, y) \\ - \log \sum_{y'\sim P(y)} &\sigma_{\text{global}}(x, y')\}\end{aligned} \tag{5}$$

where $\tilde{P}(x)$ denotes the real distribution of x, $P(y|x)\tilde{P}(x)$ denotes the distribution of y for given x, and $P(y)$ denotes the noise distribution of y. Thus minimizing Eqn. (5) can be seen as identifying the positive image $y \sim P(y|x)$ for given x from the noise image distribution $y \sim P(y)$.

It has been proved (Oord et al., 2018) that $\mathcal{L}^{\text{NCE}:P(y|x)}(X, Y)$ provides the lower bound of $\mathcal{I}(X, Y)$:

$$\mathcal{I}(X, Y) \geq \log N' - \mathcal{L}^{\text{NCE}:P(y|x)} \tag{6}$$

where N' denotes the number of noise samples and can be seen as a constant. So instead of maximizing $\mathcal{I}(X, Y)$ directly, we minimize $L^{\text{NCE}:P(y|x)}(X, Y)$ instead to maximize its lower bound.

Symmetrically, we also compute the NCE loss by taking the posterior probability $P(x|y)$. We define $\mathcal{L}^{\text{NCE}:P(x|y)}$ as:

$$\begin{aligned}\mathcal{L}^{\text{NCE}:P(x|y)}(X, Y) = -\,&\mathbb{E}_{x,y\sim P(x|y)\tilde{P}(y)}\{\log \sigma_{\text{global}}(x, y) \\ &- \log \sum_{x'\in P(x)} \sigma_{\text{global}}(x', y)\}\end{aligned} \tag{7}$$

Eqn. (7) can be seen as identifying the positive text $x \sim P(x|y)$ for given y from the noise text distribution $x \sim P(x)$.

By combining Eqn. (5) and Eqn. (7), we derive the loss for global MI maximization

$$\mathcal{L}^{\text{NCE}}_{\text{global}}(X, Y) = \mathcal{L}^{\text{NCE}:P(x|y)}(X, Y) + \mathcal{L}^{\text{NCE}:P(y|x)}(X, Y) \tag{8}$$

Here we say the MI is global, because it is over the complete text and the complete images, which are contrary to the local structures in section 3.2.

Negative sampling In practice, to compute $L^{\text{NCE}:P(y|x)}(X, Y)$, we need to construct noise samples for positive samples. We use all the $\{x_i, y_i\}$ pairs in the same minibatch from $\mathcal{D}_{t2i}$ as X, Y. Each y_i is the positive samples of x_i (i.e. $P(y_i|x_i) = 1$). For each $x_i \in X$, the noise y' in Eqn. (5) are sampled from Y. Likewise, to compute $\mathcal{L}^{\text{NCE}:P(x|y)}(X, Y)$ in Eqn. (7), we treat x_i as the positive sample for y_i, and other texts from the same minibatch as the noise samples.

3.2 MI Optimization for Local Structures

In this subsection, we incorporate the local information in multimodal contrastive learning. As demonstrated in DIM (Hjelm et al., 2019), local information plays a greater role in self-supervised learning than the global information.

We follow BERT (Devlin et al., 2018) and DIM to use the words and patches as the local structures for the text and the image, respectively. We maximize the MI between the cross-modal local/global structures. We denote a sentence x with L words as $x^{(1)} \cdots x^{(L)}$, and an image y with $M \times M$ patches as $y^{(1)} \cdots y^{(M^2)}$.

Similar to the objective of representation learning of global information, we use NCE as the objective of local information representation learning. The difference is that we use the local structure-based alignment to calculate the energy function, while there is no such objective in the representation learning of global information. This objective allows representation learning to emphasize the alignments of local structures between different modalities, such as the alignment between the word "piano" and the corresponding image patches.

Specifically, we use $\mathcal{L}^{\text{NCE}}_{\text{local}}(X, Y)$ to represent the loss of local information representation learning. The computation of $\mathcal{L}^{\text{NCE}}_{\text{local}}(X, Y)$ follows Eqn. (5)(7)(8), except that we replace σ_{global} with σ_{local} based on the local information alignment. We will elaborate on σ_{local} in section 3.3.

3.3 Alignment-based Local Energy Function and Representation Learning

In this subsection, we show the details of the local energy function σ_{local} and the encoders for local structures.

Following the form of Eqn. (1), we denote the encoders for the local structures of text as

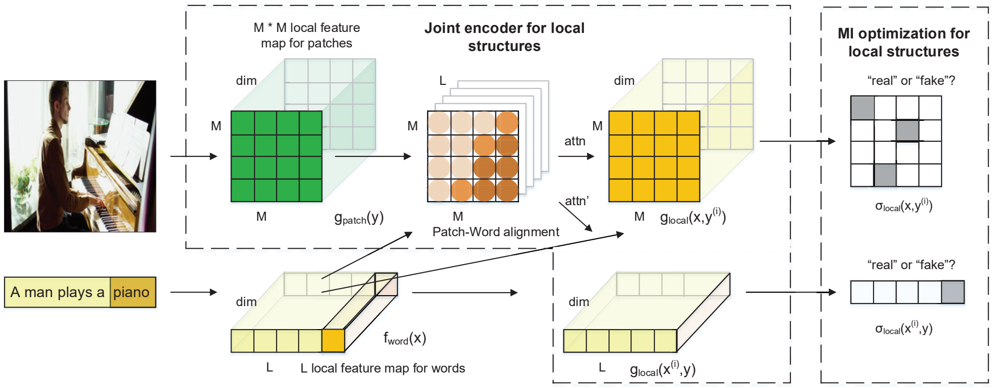


Figure 2: MI maximization for local structures. The local structures for images are joint encoded with text.

$f_{\text{word}}(x^{(i)})$. We denote the joint encoder for patches as $g_{\text{local}}(x, y^{(i)})$, which represents the linguistic information of patch $y^{(i)}$. Note that the encoder $f_{\text{word}}(x^{(i)})$ is still decoupled and represents the local linguistic structures without taking image as input. On the other hand, the encoder $g_{\text{local}}(x, y^{(i)})$ for the local visual structure explicitly incorporate the linguistic information, which is more precise due to the discussion in section 2.1.

For a sentence x with L words $x^{(1)} \cdots x^{(L)}$, we represent its local information by encoding it into a local feature map $\boldsymbol{f}_{\text{word}}(x) = (f_{\text{word}}(x^{(1)}) \cdots f_{\text{word}}(x^{(L)})) \in \mathbb{R}^{dim \times L}$. For an image y with $M \times M$ patches $y^{(1)} \ldots y^{(M^2)}$, we represent its spatial locality by encoding it into a feature map $\boldsymbol{g}_{\text{patch}}(y) = \left(g_{\text{patch}}(y^{(1)}) \cdots g_{\text{patch}}(y^{(M^2)})\right)$.

The local information across modalities has obvious correlation characteristics (Xu et al., 2018). For example, a word is only related to some patches of the image, but not to other patches. As shown in Fig. 1c, our proposed image encoder is coupled with the text representation. Therefore we assign the local structures with different weights to achieve a more precise image encoder. This is achieved by the attention mechanism in the joint encoder:

$$g_{\text{local}}(x, y^{(i)}) = \frac{exp(attn_{i,j}/\tau_c)}{\sum_k exp(attn_{k,i}/\tau_c)} \boldsymbol{f}_{\text{word}}(x) \tag{9}$$

where τ_c denotes the temperature, $attn_{i,j}$ denotes the attention of the i-th word to the j-th patch:

$$attn_{i,j} = \frac{exp(f_{\text{word}}(x^{(i)})^\top g_{\text{patch}}(y^{(j)}))}{\sum_k exp(f_{\text{word}}(x^{(i)})^\top g_{\text{patch}}(y^{(k)}))} \tag{10}$$

We compute the alignment score for the local textual structures by:

$$\sigma_{\text{local}}(x, y^{(i)}) = d(g_{\text{patch}}(y^{(i)}), g_{\text{local}}(x, y^{(i)})) \tag{11}$$

Here we abuse the notation of σ_{local} since we will use $\sigma_{\text{local}}(x, y^{(i)})$ to compute $\sigma_{\text{local}}(x, y)$.

Symmetrically, we also compute the alignment score for the local visual structures by

$$\begin{aligned} attn'_{i,j} &= \frac{exp(f_{\text{word}}(x^{(i)})^\top g_{\text{patch}}(y^{(j)}))}{\sum_k exp(f_{\text{word}}(x^{(k)})^\top g_{\text{patch}}(y^{(j)}))} \\ g_{\text{local}}(x^{(i)}, y) &= \frac{exp(attn'_{i,j}/\tau_c)}{\sum_k exp(attn'_{i,k}/\tau_c)} \boldsymbol{g}_{\text{patch}}(y) \\ \sigma_{\text{local}}(x^{(i)}, y) &= d(f_{\text{word}}(x^{(i)}), g_{\text{local}}(x^{(i)}, y)) \end{aligned} \tag{12}$$

We compute the energy function of x and y based on local structure alignments by:

$$\begin{aligned} \sigma_{\text{local}}(x, y) =& \log \sum_{i=1}^{L} exp(\sigma_{\text{local}}(x^{(i)}, y)) \\ &+ \log \sum_{i=1}^{M^2} exp(\sigma_{\text{local}}(x, y^{(i)})) \end{aligned} \tag{13}$$

How the model uses the attention mechanism to represent the interactions among local structures and how the energy function is computed is shown in Fig. 2.

3.4 Anchor Text via Lifelong Learning

In this subsection, we illustrate how to solve the catastrophic forgetting problem by the lifelong learning regularization.

If we only use the loss in Eqn. (8), the text encoder $f(x; \theta_f)$ will tend to only learn vision-related features for text. Since our downstream problem is over the plain text, NLI still relies more on textual features instead of visual features. Compared with the single modality unsupervised natural language representation learning (Devlin et al., 2018), the multimodal model will even perform worse. Similar phenomena called catastrophic forgetting or negative transfer (Sun et al., 2020) often occurs in multi-task learning.

To avoid the catastrophic forgetting, we keep the model's representation for general text while ensuring that it learns visual features. More generally, since there are only data of a certain modality (i.e. plain text) in the downstream task, we anchor this modality in the multimodal SSL phase. We add lifelong learning regularization (Li and Hoiem, 2017) to achieve modality anchoring. For the text encoder, we keep its original textual representation (e.g. by masked language model (MLM) and next sentence prediction in BERT) while learning new visual knowledge. To do this, we follow (Li and Hoiem, 2017) and introduce the distance from the existing text encoder to the original text encoder as the training loss.

Specifically, we use BERT (Devlin et al., 2018) to initialize our text encoder $f(x)$. During multimodal SSL, we keep the textual representation consistent with the original BERT. According to the ablation study in DistilBERT (Sanh et al., 2019), we use the knowledge distillation loss (Hinton et al., 2015) and cosine loss as regularization:

$$\begin{aligned}\mathcal{L}_{anchor}(X) &= \mathbb{E}_{x\sim\tilde{P}(x)}[\\ &- \epsilon \sum_{i=1}^{dim} \frac{f_i(x)^{1/\tau'}}{\sum_j f_j(x)^{1/\tau'}} \log \frac{f'_i(x)^{1/\tau'}}{\sum_j f'_j(x)^{1/\tau'}} \\ &- (1-\epsilon) cosine(f(x), f'(x))]\end{aligned} \quad (14)$$

where $f'(x)$ denotes the textual representation by the original BERT encoder, $f_i(x)$ denotes the i-th dimension of $f(x)$, and τ' is the temperature.

By combing the lifelong learning regularization, we obtain the final loss for SSL:

$$\begin{aligned}\hat{\theta}_x, \hat{\theta}_y, \hat{\theta}_\alpha = &\underset{\theta_f,\theta_g}{\text{argmax}}\, \gamma \mathcal{L}^{\text{NCE}}_{\text{global}}(X,Y) \\ &+ \beta \mathcal{L}^{\text{NCE}}_{\text{local}}(X,Y) + (1-\gamma-\beta)\mathcal{L}_{anchor}(X)\end{aligned} \quad (15)$$

4 Experiments

4.1 Setup

All the experiments run over a computer with 4 Nvdia Tesla V100 GPUs.

Datasets We use Flickr30k (Young et al., 2014) and COCO (Lin et al., 2014) as the text2image dataset $\mathcal{D}_{t2i}$ for self-supervised learning. We use STS-B (Cer et al., 2017) and SNLI (Bowman et al.) as the downstream NLI tasks for evaluation. STS-B is a collection of sentence pairs, each of which has a human-annotated similarity score from 1 to 5. The task is to predict these scores. We follow GLUE (Wang et al., 2018) and use Pearson and Spearman correlation coefficients as metrics. SNLI is a collection of human-written English sentence pairs, with manually labeled categories *entailment*, *contradiction*, and *neutral*. Note that for STS-B, some sentence pairs drawn from image captions overlap with Flickr30k. So in order to avoid the potential information leak, we remove all sentence pairs drawn from image captions in STS-B to construct a new dataset *STS-B-filter*. Similarly, we remove all sentence pairs in SNLI whose corresponding images occur in the training split of $\mathcal{D}_{t2i}$ to construct *SNLI-filter*.

The statistics of these datasets are shown in Table 1. In addition, Flickr30k has 22248 images for training, 9535 images for development. COCO has 82783 images for training, 40504 images for development.

	Type	#Text		
		Train	Dev	Test
Flickr30k	Text2Image	111240	47675	-
COCO	Text2Image	414113	202654	-
STS-B	Text Similarity	5749	1500	1379
STS-B-filter	Text Similarity	3749	875	754
SNLI	NLI	549367	9842	9824
SNLI-filter	NLI	157284	3321	3207

Table 1: Statistics of datasets.

4.2 Model Details

Encoder details We use BERT-base as the text encoder f_{global}. The local information $f_{\text{word}}(x^{(i)})$ is the feature vector of the i-th word through BERT. We use *Resnet-50* as the image encoder g_{global}. We use the encoding before the final pooling layer as the representations of M^2 patches $g_{\text{patch}}(y^{(i)})$. To guarantee that the image encoder and the text encoder are in the same space, we project the feature vectors of the image encoder to the dimension of 768, which is the dimension of BERT.

Unsupervised NLI We compute the similarity of two sentences via the cosine of their representations learned by MACD. For STS-B, such similarities are directly used to compute the Pearson and Spearman correlation coefficients. For SNLI, we make inferences based on whether the similarity reaches a certain threshold. More specifically, if the similarity $>= \psi_1$, we predict "entailment". If the similarity $< \psi_2$, we predict "contradiction". Otherwise we predict "neutral".

Competitors We compare MACD with the single-modal pre-training model BERT, and multimodal pre-training model LXMERT (Tan and Bansal, 2019) and VilBert (Lu et al., 2019). Both LXMERT and VilBert use the network architecture as in Fig. 1b. We extract the lower layer text encoder for unsupervised representation and fine-tuning. We also compare MACD with classical NLP models, including BiLSTM and BiLSTM+ELMO (Peters et al., 2018).

Hyper-parameters We list the hyper-parameters below. For ψ_1 and ψ_2, we use the best set of values chosen in the grid search from range $\{-1, -0.95, -0.9, \cdots, 1\}$. For τ_σ and τ_c, we use the best set of values chosen in the grid search from range $\{0.01, 0.1, 1\}$. For τ', ϵ, γ and β, we follow their settings in DistilBert (Sanh et al., 2019).

τ_σ	τ_c	τ'	ϵ	γ	β
0.1	1	2	5/6	1/3	1/3
Batch Size	lr	Epochs	Grad Acc	ψ_1	ψ_2
64	1e-4	10	8	0.80	0.55

Table 2: Hyper-parameters for self-supervised learning. "lr" means learning rate.

4.3 Main Results

We evaluate MACD by unsupervised NLI. Table 3 shows the results on STS-B. MACD achieves significantly higher effectiveness than single-modal pre-trained model BERT and multimodal pre-trained model LXMERT and VilBert. Note that LXMERT and VilBert use more text2image corpora for pre-training than MACD. This verifies that the joint encoder in previous multimodal SSL cannot represent visual knowledge well in their text encoder. So their adaptations to the single-modal problem are limited.

To our surprise, the unsupervised MACD even outperforms fully-supervised models such as BiLSTM and BiLSTM+ELMO. Here the results of BiLSTM and BiLSTM+ELMO for STS-B are directly derived from GLUE (Wang et al., 2018). This verifies the effectiveness of MACD.

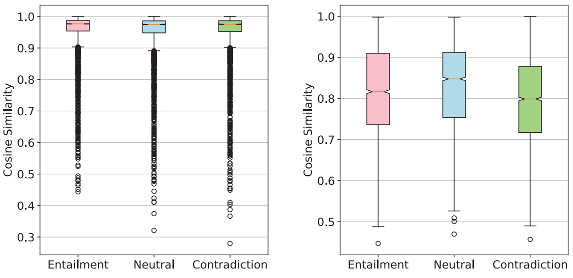
	STS-B		STS-B-filter	
	P.	S.	P.	S.
BiLSTM (sup.)	66.0	62.8	47.0	43.2
BiLSTM+ELMO (sup.)	64.0	60.2	33.3	30.7
BERT	1.7	6.4	5.5	12.5
LXMERT	42.7	47.2	35.9	40.0
VilBert	55.8	57.1	45.9	46.3
MACD + COCO	70.1	70.2	55.1	52.4
MACD + Flickr30k	**71.5**	**72.1**	**55.8**	**54.8**

Table 3: Effectiveness of unsupervised learning on STS. Baselines with "(sup.)" mean they are trained by supervised labels. Other methods are unsupervised. "P." and "S." mean Pearson and Spearman correlation coefficients, respectively.

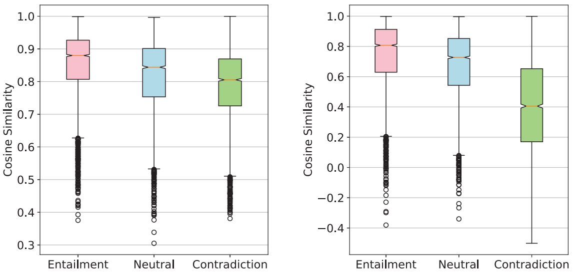
	SNLI Acc	SNLI-filter Acc
BERT	35.09	35.45
LXMERT	39.03	40.29
VilBert	43.13	43.83
MACD + COCO	**52.63**	53.15
MACD + Filckr30k	52.27	**53.20**

Table 4: Effectiveness on SNLI. All approaches are unsupervised.

We also report the results of MACD on SNLI under the unsupervised setting in Table 4. MACD outperforms its competitors by a large margin. This verifies the effectiveness of our approach for unsupervised NLI. The experimental results suggest that *we achieve natural language inference via multimodal self-supervised learning without any supervised inference labels.* Since MACD+Filckr30k performs better than MACD+COCO in most cases, we will only evaluate MACD+Filckr30k in the rest experiments.



(a) BERT (b) LXMERT



(c) VilBert (d) MACD

Figure 3: Categorial distribution visualization.

We visualize the distribution of the cosine similarities for samples of different labels in SNLI in Fig. 3 by boxplot. We found obvious distribution patterns by MACD. In contrast, the distributions of other pre-training models have lower correlations with NLI labels.

4.4 Fine-tuning

We also evaluated the effectiveness of MACD when fine-tuned under the semi-supervised learning setting. More specifically, we first initialize the parameters of the text encoder as in MACD, then finetune it by the supervised training samples of the downstream tasks. The results are shown in Table 5. MACD also outperforms other approaches. For example, for SNLI-filter, the accuracy of MACD increases by 0.97 compared to the best competitor (i.e. BERT). Note that MACD is the only multimodal method that performs better than BERT. Other multimodal approaches (i.e. LXMERT and VilBert) perform even worse than the original BERT, although they also initialize their text encoders by BERT, and use more text2image data for SSL than MACD. This verifies the effectiveness of the proposed decoupled contrastive learning model.

	STS-B P. / S.	STS-B-filter P. / S.	SNLI Acc	SNLI-filter Acc
BERT	85.0/83.6	75.8/74.6	89.37	87.15
LXMERT	63.3/59.2	37.3/28.3	87.80	83.57
VilBert	78.8/77.2	63.9/62.2	88.49	85.69
MACD	**87.1/86.4**	**79.5/78.0**	**90.01**	**88.12**

Table 5: Effectiveness of fine-tuning over STS-B and SNLI. "P." and "S." mean Pearson and Spearman correlation coefficients, respectively.

To further verify the natural language representation learned by the self-supervised learning and get rid of the influence of its neural network architecture (i.e., BERT), Hjelm et al. (2019) suggest training models directly over the features learned by SSL. By following its settings (Hjelm et al., 2019), we use a linear classifier (SVM) and a nonlinear classifier (a single layer perception neural network, marked as SLP) over the features by SSL. The results are shown in Table 6.

	STS-B P. / S.	STS-B-filter P. / S.	SNLI Acc	SNLI-filter Acc
SVM+BERT	69.8 / 68.3	57.1 / 53.3	58.77	58.87
SVM+LXMERT	33.0 / 31.3	10.2 / 13.2	52.28	50.98
SVM+VilBert	52.4 / 50.0	36.7 / 35.9	55.93	55.22
SVM+MACD	**70.0 / 68.4**	**62.2 / 59.3**	**61.64**	**62.58**
SLP+BERT	56.2 / 53.5	47.3 / 42.0	55.07	54.19
SLP+LXMERT	36.5 / 33.4	16.1 / 12.3	52.41	50.42
SLP+VilBert	49.6 / 46.0	29.1 / 26.5	54.86	51.82
SLP+MACD	**72.3 / 69.7**	**63.4 / 59.5**	**61.31**	**60.80**

Table 6: Effectiveness of the learned representations.

MACD outperforms the competitors by a large margin. Similar to the results in Table 5, although MACD, LXMERT, and VilBert are all trained by multimodal data, only MACD performs better than the original text encoder (i.e. BERT).

4.5 Ablations

In addition to the decoupled contrastive learning model, we propose two optimizations by adding the local structures into account, and by regularizing the model on the text mode via lifelong learning. In order to verify the effectiveness of the two optimizations, we compare MACD with its ablations. The results of unsupervised NLI are shown in Table 7. The results show that the effectiveness decreases when the proposed optimizations are removed.

	STS-B P. / S.	STS-B-filter P. / S.
MACD	**71.5 / 72.1**	**55.8 / 54.8**
-local	71.0 / 70.9	55.0 / 52.6
-lifelong	70.7 / 70.8	54.9 / 52.3
-local -lifelong	69.6 / 69.7	53.0 / 52.0

Table 7: Ablations.

4.6 Case studies: Nearest-neighbor analysis

To give a deeper insight into the learned representation, we analyze the k nearest neighbors over the representations. For the query sentence randomly sampled from Flickr30k, we show the results of the 3 nearest sentences according to their L1 distances in Table 8. The results of MACD are more interpretable than BERT.

Query	Someone is wearing a large white dress in a crowd.
MACD No.1	Lady dressed in white on blanket in middle of crowd.
MACD No.2	Women in white robes, dancing with half their face painted.
MACD No.3	A group of women dressed in white are dancing in the street.
BERT No.1	A man is standing alone in a boat.
BERT No.2	A bald man is standing in a crowd.
BERT No.3	A woman is taking a picture of a man.

Table 8: Nearest-neighbor on the encoded text.

5 Conclusion

In this paper, we study the multimodal self-supervised learning for unsupervised NLI. The major flaw of previous multimodal SSL methods is that they use a joint encoder for representing the cross-modal correlations. This prevents us from integrating visual knowledge into the text encoder. We propose the multimodal aligned contrastive decoupled learning (MACD), which learns to represent visual knowledge while using only texts as inputs. In the experiments, our proposed approach steadily surpassed other methods by a large margin.

Digital Voicing of Silent Speech

David Gaddy and **Dan Klein**
University of California, Berkeley
`{dgaddy,klein}@berkeley.edu`

Abstract

In this paper, we consider the task of digitally voicing silent speech, where silently mouthed words are converted to audible speech based on electromyography (EMG) sensor measurements that capture muscle impulses. While prior work has focused on training speech synthesis models from EMG collected during *vocalized* speech, we are the first to train from EMG collected during silently articulated speech. We introduce a method of training on silent EMG by transferring audio targets from vocalized to silent signals. Our method greatly improves intelligibility of audio generated from silent EMG compared to a baseline that only trains with vocalized data, decreasing transcription word error rate from 64% to 4% in one data condition and 88% to 68% in another. To spur further development on this task, we share our new dataset of silent and vocalized facial EMG measurements.

1 Introduction

In this paper, we are interested in in enabling speech-like communication without requiring sound to be produced. By using muscular sensor measurements of speech articulator movement, we aim to capture silent speech - utterances that have been articulated without producing sound. In particular, we focus on the task which we call *digital voicing*, or generating synthetic speech to be transmitted or played back.

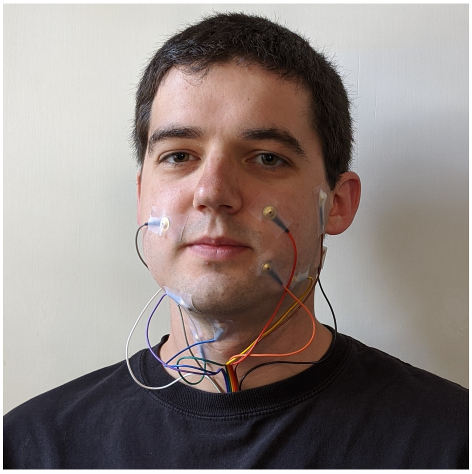

Figure 1: Electromyography (EMG) electrodes placed on the face can detect muscle movements from speech articulators.

Digitally voicing silent speech has a wide array of potential applications. For example, it could be used to create a device analogous to a Bluetooth headset that allows people to carry on phone conversations without disrupting those around them. Such a device could also be useful in settings where the environment is too loud to capture audible speech or where maintaining silence is important. Alternatively, the technology could be used by some people who are no longer able to produce audible speech, such as individuals whose larynx has been removed due to trauma or disease (Meltzner et al., 2017). In addition to these direct uses of digital voicing for silent speech, it may also be useful as a component technology for creating silent speech-to-text systems (Schultz and Wand, 2010), making silent speech accessible to our devices and digital assistants by leveraging existing high-quality audio-based speech-to-text systems.

To capture information about articulator movement, we make use of surface electromyography (EMG). Surface EMG uses electrodes placed on top of the skin to measure electrical potentials caused by nearby muscle activity. By placing electrodes around the face and neck, we are able to capture signals from muscles in the speech articulators. Figure 1 shows the EMG electrodes used to capture signals, and Figure 2 shows an example of EMG signals captured. We collect EMG measurements during both vocalized speech (normal speech production that has voicing, frication, and other speech

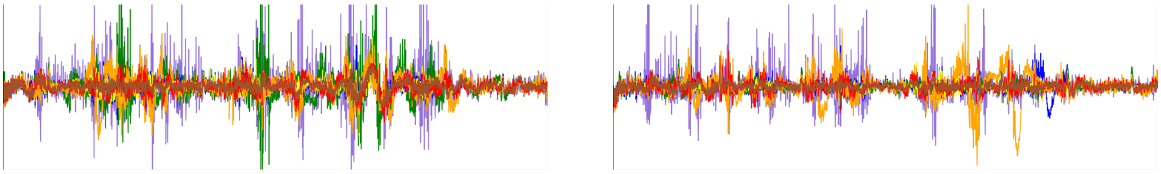
A_V - audio from vocalized speech



E_V - EMG from vocalized speech

E_S - EMG from silent speech

Figure 2: The three components of our data that we will use in our model. The vocalized speech signals A_V and E_V are collected simultaneously and so are time-aligned, while the silent signal E_S is a separate recording of the same utterance without vocalization. During training we use all three signals, and during testing we are given just E_S, from which we must generate audio. Colors represent different electrodes in the EMG data. Note that the silent EMG signal E_S is qualitatively different from its vocalized counterpart E_V. Not pictured, but also included in our data are the utterance texts, in this case: "It is possible that the infusoria under the microscope do the same." (from H.G. Well's *The War of the Worlds*).

sounds) and silent speech (speech-like articulations which do not produce sound). We denote these EMG signals E_V and E_S, respectively. During the vocalized speech we can also record audio A_V, but during silent speech there is no meaningful audio to record.

A substantial body of prior work has explored the use of facial EMG for silent speech-to-text interfaces (Jou et al., 2006; Schultz and Wand, 2010; Kapur et al., 2018; Meltzner et al., 2018). Several initial attempts have also been made to convert EMG signals to speech, similar to the task we approach in this paper (Toth et al., 2009; Janke and Diener, 2017; Diener et al., 2018). However, these works have focused on the artificial task of recovering audio from EMG that was recorded during *vocalized* speech, rather than the end-goal task of generating from silent speech. In terms of signals in Figure 2, prior work learned a model for producing audio A_V from vocalized EMG E_V and tested primarily on other vocalized EMG signals. While one might hope that a model trained in this way could directly transfer to silent EMG E_S, Toth et al. (2009) show that such a transfer causes a substantial degradation in quality, which we confirm in Section 4. This direct transfer from vocalized models fails to account for differences between features of the two speaking modes, such as a lack of voicing in the vocal folds and other changes in articulation to suppress sound.

In this paper, we extend digital voicing to train on silent EMG E_S rather than only vocalized EMG E_V. Training with silent EMG is more challenging than with vocalized EMG, because when training on vocalized EMG data we have both EMG inputs and time-aligned speech targets, but for silent EMG any recorded audio will be silent. Our solution is to adopt a target-transfer approach, where audio output targets are transferred from vocalized recordings to silent recordings of the same utterances. We align the EMG features of the instance pairs with dynamic time warping (Rabiner and Juang, 1993), then make refinements to the alignments using canonical correlation analysis (Hotelling, 1936) and audio feature outputs from a partially trained model. The alignments can then be used to associate speech outputs with the silent EMG signals E_S, and these speech outputs are used as targets for training a recurrent neural transduction model.

We validate our method using both human and automatic metrics, and find that a model trained with our target transfer approach greatly outperforms a model trained on vocalized EMG alone. On a closed-vocabulary domain (date and time expressions §2.1), transcription word error rate (WER) from a human evaluation improves from 64% to just 4%. On a more challenging open vocabulary domain (reading from books §2.2) intelligibility measurements improve by 20% – from 88% to 68% with automatic transcription or 95% to 75% with human transcription.

We release our dataset of EMG signals collected during both silent and vocalized speech. The dataset contains nearly 20 hours of facial EMG signals from a single speaker. To our knowledge, the largest public EMG-speech dataset previously available contains just 2 hours of data (Wand et al., 2014), and many papers continue to use private datasets. We hope that this public release will encourage development on the task and allow for fair comparisons between methods.

2 Data Collection

We collect a dataset of EMG signals and time-aligned audio from a single speaker during both silent and vocalized speech. Figure 2 shows an example from the data collected. The primary portion of the dataset consists of parallel silent / vocalized data, where the same utterances are recorded using both speaking modes. These examples can be viewed as tuples (E_S, E_V, A_V) of silent EMG, vocalized EMG, and vocalized audio, where E_V and A_V are time-aligned. Both speaking modes of an utterance were collected within a single session to ensure that electrode placement is consistent between them. For some utterances, we record only the vocalized speaking mode. We refer to these instances as non-parallel data, and represent them with the tuple (E_V, A_V). Examples are segmented at the utterance level. The text that was read is included with each instance in the dataset, and is used as a reference when evaluating intelligibility in Section 4.

For comparison, we record data from two domains: a closed vocabulary and open vocabulary condition, which are described in Sections 2.1 and 2.2 below. Section 2.3 then provides additional details about the recording setup.

2.1 Closed Vocabulary Condition

Like other speech-related signals, the captured EMG signals from a particular phoneme may look different depending on its context. For this reason, our initial experiments will use a more focused vocabulary set before expanding to a large vocabulary in Section 2.2 below.

To create a closed-vocabulary data condition, we generate a set of date and time expressions for reading. These expressions come from a small set of templates such as “`<weekday> <month> <year>`” which are filled in with randomly selected values (over 50,000 unique utterances are possible from this scheme). Table 1 summarizes the properties of the data collected in this condition. A validation set of 30 utterances and a test set of 100 utterances are selected randomly, leaving 370 utterances for training.

Closed Vocabulary Condition
Parallel silent / vocalized speech
(E_S, E_V, A_V)
26 minutes silent / 30 minutes vocalized
Single session
500 utterances
Average of 4 words per utterance
67 words in vocabulary

Table 1: Closed vocabulary data summary

2.2 Open Vocabulary Condition

The majority of our data was collected with open-vocabulary sentences from books. We use public domain books from Project Gutenberg.[1] Unlike the closed-vocabulary data which is collected in a single sitting, the open-vocabulary data is broken into multiple sessions where electrodes are reattached before each session and may have minor changes in position between different sessions. In addition to sessions with parallel silent and vocalized utterances, we also collect non-parallel sessions with only vocalized utterances. A summary of dataset features is shown in Table 2. We select a validation and test set randomly from the silent parallel EMG data, with 30 and 100 utterances respectively. Note that during testing, we use only the silent EMG recordings E_S, so the vocalized recordings of the test utterances are unused.

2.3 Recording Details

EMG signals are recorded using an OpenBCI Cyton Biosensing Board and transmitted to a computer over WiFi. Eight channels are collected at a sample rate of 1000 Hz. The electrode locations are described in Table 3. Gold-plated electrodes are used with Ten20 conductive electrode paste. We use a monopolar electrode configuration, with a shared reference electrode behind one ear. An electrode connected to the Cyton board’s bias pin is placed behind the other ear to actively cancel common-mode interference. A high pass Butterworth filter with cutoff 2 Hz is used to remove offset and drift in the collected signals, and AC

electrical noise is removed with notch filters at 60 Hz and its harmonics. Forward-backward filters are used to avoid phase delay.

Audio is recorded from a built-in laptop microphone at 16kHz. Background noise is reduced using a spectral gating algorithm,[2] and volume is normalized across sessions based on peak root-mean-square levels.

3 Method

Our method is built around a recurrent neural transduction model from EMG features to time-aligned speech features (Section 3.1). We will denote the featurized version of the signals used by the transduction model $E'_{S/V}$ and A'_V for EMG and audio respectively. When training solely on vocalized EMG data (E'_V to A'_V), training this model is straightforward. However, our experiments show that training on vocalized EMG alone leads to poor performance when testing on silent EMG (Section 4) because of differences between the two speaking modes.

A core contribution of our work is a method of training the transducer model on silent EMG signals, which no longer have time-aligned audio to use as training targets. We briefly describe our method here, then refer to section Section 3.2 for more details. Using a set of utterances recorded in both silent and vocalized speaking modes, we find alignments between the two recordings and use them to associate speech features from the vocalized instance (A'_V) with the silent EMG E'_S. The alignment is initially found using dynamic time warping between EMG signals and then is refined using canonical correlation analysis (CCA) and predicted audio from a partially trained model.

Finally, to generate audio from predicted speech features, we use a WaveNet decoder, as described in Section 3.3.

3.1 EMG to Speech Feature Transducer

When converting EMG input signals to audio outputs, our first step is to use a bidirectional LSTM to convert between featurized versions of the signals, E' and A'. Both feature representations operate at the same frequency, 100 Hz, so that each EMG input $E'[i]$ corresponds to a single time-aligned output $A'[i]$. Our primary features for representing EMG signals are the time domain features from Jou et al. (2006), which are commonly used in the EMG-speech-to-text literature. After splitting the signal from each channel into low and high-frequency components (x_{low} and x_{high}) using a triangular filter with cutoff 134 Hz, the signal is windowed with a frame length of 27 ms and shift of 10 ms. For each frame, five features are computed as follows:

$$\left[\frac{1}{n}\sum_i (x_{low}[i])^2,\ \frac{1}{n}\sum_i x_{low}[i],\ \frac{1}{n}\sum_i (x_{high}[i])^2,\right.$$

$$\left.\frac{1}{n}\sum_i |x_{high}[i]|,\ \mathrm{ZCR}(x_{high})\right]$$

where ZCR is the zero-crossing rate. In addition to the time domain features, we also append magnitude values from a 16-point Short-time Fourier transform for each 27 ms frame, which gives us

---

[2] https://pypi.org/project/noisereduce/

9 additional features. The two representations result in a total of 112 features to represent the 8 EMG channels. Speech is represented with 26 Mel-frequency cepstral coefficients (MFCCs) from 27 ms frames with 10 ms stride. All EMG and audio features are normalized to approximately zero mean and unit variance before processing. To help the model to deal with minor differences in electrode placement across sessions, we represent each session with a 32 dimensional session embedding and append the session embedding to the EMG features across all timesteps of an example before feeding into the LSTM.

The LSTM model itself consists of 3 bidirectional LSTM layers with 1024 hidden units, followed by a linear projection to the speech feature dimension. Dropout 0.5 is used between all layers, as well as before the first LSTM and after the last LSTM. The model is trained with a mean squared error loss against time-aligned speech features using the Adam optimizer. The initial learning rate is set to .001, and is decayed by half after every 5 epochs with no improvement in validation loss. We evaluate a loss on the validation set at the end of every epoch, and select the parameters from the epoch with the best validation loss as the final model.

3.2 Audio Target Transfer

To train the EMG to speech feature transducer, we need speech features that are time-aligned with the EMG features to use as target outputs. However, when training with EMG from silent speech, simultaneously-collected audio recordings do not have any audible speech to use as targets. In this section, we describe how parallel utterances, as described in Section 2, can be used to transfer audio feature labels from a vocalized recording to a silent one. More concretely, given a tuple (E'_S, E'_V, A'_V) of features from silent speech EMG, vocalized speech EMG, and vocalized speech audio, where E_V and A_V are collected simultaneously, we estimate a set of audio features $\tilde{A}'_S$ that time-align with E'_S and represent the output that we would like our transduction network to predict. A diagram of the method can be found in Figure 3.

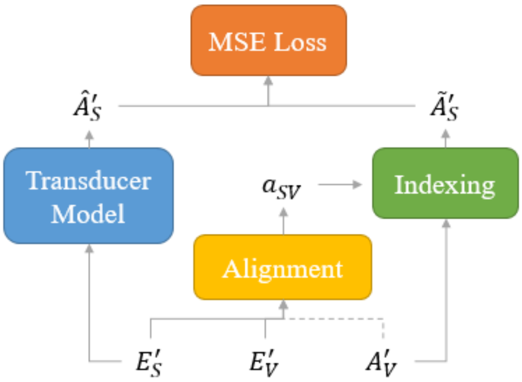

Figure 3: Our audio target transfer method for training on silent EMG E_S. Details in Section 3.2.

Our alignment will make use of dynamic time warping (DTW) (Rabiner and Juang, 1993), a dynamic programming algorithm for finding a minimum-cost monotonic alignment between two sequences s_1 and s_2. DTW builds a table $d[i, j]$ of the minimum cost of alignment between the first i items in s_1 and the first j items in s_2. The recursive step used to fill this table is $d[i, j] = \delta[i, j] + \min(d[i-1, j], d[i, j-1], d[i-1, j-1])$, where $\delta[i, j]$ is the local cost of aligning $s_1[i]$ with $s_2[j]$. After the dynamic program, we can follow backpointers through the table to find a path of (i, j) pairs representing an alignment. Although the path is monotonic, a single position i may repeat several times with increasing values of j. We take the first pair from any such sequence to form a mapping $a_{s_1 s_2}[i] \rightarrow j$ from every position i in s_1 to a position j in s_2.

For our audio target transfer, we perform DTW as described above with $s_1 = E'_S$ and $s_2 = E'_V$. Initially, we use euclidean distance between the features of E'_S and E'_V for the alignment cost $(\delta_{\text{EMG}}[i, j] = \|E'_S[i] - E'_V[j]\|)$, but will describe several refinements to this choice in Sections 3.2.1 and 3.2.2 below. DTW results in an alignment $a_{SV}[i] \rightarrow j$ that tells us a position j in E'_V for every position i in E'_S. We can then create a warped audio feature sequence $\tilde{A}'_S$ that aligns with E'_S using $\tilde{A}'_S[i] = A'_V[a_{SV}[i]]$. During training of the EMG to audio transduction model, we will use $\tilde{A}'_S$ as our targets for the transduction outputs $\hat{A}'_S$ when calculating a loss.

This procedure of aligning signals to translate between them is reminiscent of some DTW-based methods for the related task of voice conversion (Kobayashi and Toda, 2018; Desai et al., 2009). The difference between these tasks is that our task operates on triples (E_S, E_V, A_V) and must account for the difference in modality between the input E_S and output A_V, while voice conversion operates in a single modality with examples of the form (A_1, A_2).

In addition to training the transducer from E'_S to $\tilde{A}'_S$, we also find that training on the vocalized signals (E'_V to A'_V) improves performance. The vocalized samples are labeled with different session embeddings to allow the model to specialize to each speaking mode. Each training batch contains samples from both modes mixed together. For the open vocabulary setting, the full set of examples to sample from has 3 sources: $(E'_S, \tilde{A}'_S)$ created from parallel utterances, (E_V, A_V) from the vocalized recording of the parallel utterances, and (E_V, A_V) from the non-parallel vocalized recordings.

3.2.1 CCA

While directly aligning EMG features E'_S and E'_V can give us a rough alignment between the signals, doing so ignores the differences between the two signals that lead us to want to train on the silent signals in the first place (e.g. inactivation of the vocal folds and changes in manner of articulation to prevent frication). To better capture correspondences between the signals, we use canonical correlation analysis (CCA) (Hotelling, 1936) to find components of the two signals which are more highly correlated. Given a number of paired vectors (v_1, v_2), CCA finds linear projections P_1 and P_2 that maximize correlation between corresponding dimensions of P_1v_1 and P_2v_2.

To get the initial pairings required by CCA, we use alignments found by DTW with the raw EMG feature distance δ_{EMG}. We aggregate aligned E'_S and E'_V features over the entire dataset and feed these to a CCA algorithm to get projections P_S and P_V. CCA allows us to choose the dimensionality of the space we are projecting to, and we use 15 dimensions for all experiments. Using the projections from CCA, we define a new cost for DTW

$$\delta_{\text{CCA}}[i,j] = \|P_S E'_S[i] - P_V E'_V[j]\|$$

Our use of CCA for DTW is similar to Zhou and Torre (2009), which combined the two methods for use in aligning human pose data, but we found their iterative approach did not improve performance compared to a single application of CCA in our setting.

3.2.2 Refinement with Predicted Audio

So far, our alignments between the silent and vocalized recordings have relied solely on distances between EMG features. In this section, we propose an additional alignment distance term that uses audio features. Although the silent recording has no useful audio signal, once we start to train a transducer model from E'_S to audio features, we can try to align the predicted audio features $\hat{A}'_S$ to vocalized audio features A'_V. Combining with an EMG-based distance, our new cost for DTW becomes

$$\delta_{\text{full}}[i,j] = \delta_{\text{CCA}}[i,j] + \lambda \left\| \hat{A}'_S[i] - A'_V[j] \right\|$$

where λ is a hyperparameter to control the relative weight of the two terms. We use $\lambda = 10$ for all experiments in this paper.

When training a transducer model using predicted-audio alignment, we perform the first four epochs using only EMG-based alignment costs δ_{CCA}. Then, at the beginning of the fifth epoch, we use the partially-trained transducer model to compute alignments with cost δ_{full}. From then on, we re-compute alignments every five epochs of training.

3.3 WaveNet Synthesis

To synthesize audio from speech features, we use a WaveNet decoder (van den Oord et al., 2016), which generates the audio sample by sample conditioned on MFCC speech features A'. WaveNet is capable of generating fairly natural sounding speech, in contrast to the vocoder-based synthesizer used in previous EMG-to-speech papers, which caused significant degradation in naturalness (Janke and Diener, 2017). Our full synthesis model consists of a bidirectional LSTM of 512 dimensions, a linear projection down to 128 dimensions, and finally the WaveNet decoder which generates samples at 16 kHz. We use a WaveNet implementation from NVIDIA[3] which provides efficient GPU inference. WaveNet hyperparameters can be found in Appendix A. During training, the model is given gold speech features as input, which we found to work better than training from EMG-predicted features. Due to memory constraints we do not use any batching during training, but other optimization hyperparameters are the same as those from Section 3.1.

4 Experiments

In this section, we run experiments to measure intelligibility of audio generated by our model from silent EMG signals E_S. Since prior work has trained only on vocalized EMG signals E_V, we

---

[3] https://github.com/NVIDIA/nv-wavenet

compare our method to a *direct transfer* baseline which trains a transducer model only on vocalized EMG E_V before testing on the silent EMG E_S.[4] The baseline transducer and wavenet models have identical architecture to those used by our method, but are not trained with silent EMG using our target transfer approach. Since one may hypothesize that most of the differences between silent and vocalized EMG will take place near the vocal folds, we also test a variant of this baseline where the electrode placed on the neck is ignored.

We first test on the closed vocabulary data described in Section 2.1, then on the open vocabulary data from Section 2.2. On the open vocabulary data, we also run ablations to evaluate different alignment refinements with CCA and predicted audio (see Sections 3.2.1 and 3.2.2).

4.1 Closed Vocabulary Condition

We begin by testing intelligibility on the closed vocabulary date and time data with a human transcription evaluation. The human evaluator is given a set of 20 audio output files from each model being tested (listed below) and is asked to write out in words what they heard. The files to transcribe are randomly shuffled, and the evaluator is not told that the outputs come from different systems. They are told that the examples will contain dates and times, but are not given any further information about what types of expressions may occur. The full text of the instructions provided to the evaluator can be found in Appendix B. We compare the transcriptions from the human evaluator to the original text prompts that were read during data collection to compute a transcription word error rate (WER):

$$\text{WER} = \frac{\text{substitutions} + \text{insertions} + \text{deletions}}{\text{reference length}}$$

Lower WER values indicate better models.

Using this evaluation, we compare three different models: a direct transfer baseline trained only on vocalized EMG signals, a variant of this baseline where the throat electrode is removed to reduce divergence between speaking modes, and our full model trained on silent EMG using target-transfer. All three models were trained on open vocabulary data (Section 2.2) before being fine-tuned on the closed vocabulary training set. A single WaveNet model is used to synthesize audio for all three models and was also trained on the open vocabulary data before being fine-tuned in-domain.

Model	**WER**
Direct transfer baseline	88.8
Without throat electrode	64.6
Our model	**3.6**

Table 4: Results of a human intelligibility evaluation on the closed vocabulary data. Lower WER is better. Our model greatly outperforms both variants of the direct transfer baseline.

The results of our evaluation are shown in Table 4. We first observe that removing the throat electrode substantially improves intelligibility for the direct transfer baseline. Although this modification removes potentially useful information, it also removes divergence between the silent and vocalized EMG signals. Its relative success further motivates the need for methods to account for the differences in the two modes, such as our target-transfer approach. However, even with the throat-removal modification, the direct transfer approach is still only partially intelligible.

A model trained with our full approach, including CCA and predicted-audio alignment, achieves a WER of 3.6%. This result represents a high level of intelligibility and a 94% relative error reduction from the strongest baseline. Samples of outputs from our model can be found in the supplementary material.

4.2 Open Vocabulary Condition

Similar to our evaluation in Section 4.1, we use a transcription WER to evaluate intelligibility of model outputs in the open vocabulary condition. For the open vocabulary setting, we evaluate both with a human transcription and with transcriptions from an automatic speech recognizer.

4.2.1 Human Evaluation

Our human evaluation with open vocabulary outputs follows the same setup as the closed vocabulary evaluation. Transcripts are collected for 20 audio outputs from each system, with a random interleaving of outputs from the different systems. The annotator had no prior information on the content of the texts being evaluated. We compare two

---

[4] Note that because prior work has not released data or code, we are unable to perform a direct comparison to experiments found in their papers. Our direct transfer baseline represents a conceptually equivalent model, but with larger neural networks than prior work.

Model	**WER**
Direct transfer baseline	91.2
Without throat electrode	88.0
Our model	**68.0**
Without CCA	69.8
Without audio alignment	76.5

Table 5: Results of an automatic intelligibility evaluation on open vocabulary data. Lower WER is better.

systems: direct transfer without the throat electrode (the stronger baseline) and our full model.

The results of this evaluation are a 95.1% WER for the direct transfer baseline and 74.8% WER for our system. While the intelligibility is much lower than in the closed vocabulary condition, our method still strongly out-performs the baseline with a 20% absolute improvement.

4.2.2 Automatic Evaluation

In addition to the human evaluation, we also perform an automatic evaluation by transcribing system outputs with a large-vocabulary automatic speech recognition (ASR) system. Using an automatic transcription allows for much faster and more reproducible comparisons between methods compared to a human evaluation. For our automatic speech recognizer, we use the open source implementation of DeepSpeech from Mozilla[5] (Hannun et al., 2014). Running the recognizer on the original vocalized audio recordings from the test set results in a WER of 9.5%, which represents a lower bound for this evaluation.

Our automatic evaluation results are shown in Table 5. While the absolute WER values for the ASR evaluation do not perfectly match those of the human transcriptions, both evaluations show a 20% improvement of our system over the best baseline. Given this correlation between evaluations and the many advantages of automated evaluation, we will use the automatic metric throughout the rest of this work and recommend its use for comparisons in future work.

We also run ablations of the two alignment refinement methods from Sections 3.2.1 and 3.2.2 and include results in Table 5. We see that both refinements have a positive effect on performance, though the impact of aligning with predicted audio is greater.

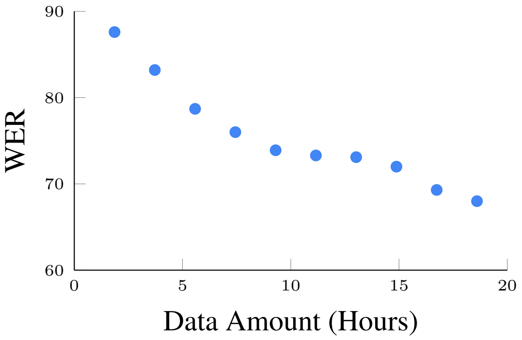

Figure 4: Effect of data amount on intelligibility.

4.3 Additional Experiments

In the following subsections, we perform additional experiments on the open vocabulary data to explore the effect of data size and choice of electrode positions. These experiments are all evaluated using the automatic transcription method described in Section 4.2.

4.3.1 Data Size

In this section we explore the effect of dataset size on model performance. We train the EMG-to-speech transducer model on various-sized fractions of the dataset, from 10% to 100%, and plot the resulting WER. We select from the parallel (silent and vocalized) and non-parallel (vocalized only) portions proportionally here, but will re-visit the difference later. Although data size also affects WaveNet quality, we use a single WaveNet trained on the full dataset for all evaluations to focus on EMG-specific data needs.

Figure 4 shows the resulting intelligibility measurements for each data size. As would be expected, the rate of improvement is larger when data sizes are small. However, there does not seem to be a plateau in performance, as improvements continue even when increasing data size beyond fifteen hours. These continued gains suggest that collecting additional data could provide more improvement in the future.

We also train a model without the non-parallel vocalized data (vocalized recordings with no associated silent recording; see Section 2). A model trained without this data has a WER of 71.6%, a loss of 3.6 absolute percentage points. This confirms that non-parallel vocalized data can be useful for silent speech even though it contains only data from the vocalized speaking mode. However, if we compare this accuracy to a model where the same amount of data was removed proportionally from

---

[5] https://github.com/mozilla/DeepSpeech

the two data types (parallel and non-parallel), we see that removing a mixture of both types leads to a much larger performance decrease to 76% WER. This indicates that the non-parallel data is less important to the performance of our model, and suggests that future data collection efforts should focus on collecting parallel utterances of silent and vocalized speech rather than non-parallel utterances of vocalized speech.

4.3.2 Removing Electrodes

In this section, we experiment with models that operate on a reduced set of electrodes to assess the impact on performance and gain information about which electrodes are most important. We perform a random search to try to find a subset of four electrodes that works well. More specifically, we sample 10 random combinations of four electrodes to remove (out of 70 possible combinations) and train a model with each. We then use validation loss to select the best models.

The three best-performing models removed the following sets of electrodes (using electrode numbering from Table 3): 1) $\{4, 5, 7, 8\}$ 2) $\{3, 5, 7, 8\}$ and 3) $\{2, 5, 7, 8\}$. We note that electrodes 5, 7, and 8 (which correspond with electrodes on the mid-jaw, upper cheek, and back cheek) appear in all of these, indicating that they may be contributing less to the performance of the model. However, the best model we tested with four electrodes did have substantially worse intelligibility compared to an eight-electrode model, with 76.8% WER compared to 68.0%. A model that removed only electrodes 5, 7, and 8 also performed substantially worse, with a WER of 75.3%.

5 Conclusion

Our results show that digital voicing of silent speech, while still challenging in open domain settings, shows promise as an achievable technology. We show that it is important to account for differences in EMG signals between silent and vocalized speaking modes and demonstrate an effective method of doing so. On silent EMG recordings from closed vocabulary data our speech outputs achieve high intelligibility, with a 3.6% transcription word error rate and relative error reduction of 95% from our baseline. We also significantly improve intelligibility in an open vocabulary condition, with a relative error reduction over 20%. We hope that our public release of data will encourage others to further improve models for this task.[6]

B Human Evaluator Instructions

The instructions given to the human evaluator are as follows: “Please listen to each of the attached sound files and write down what you hear as best you can. There are 60 files, each of which will contain an expression of some date or time. Write your transcriptions into a spreadsheet such as Excel or Google sheets so that the row numbers match the numbers in the file names. Although many of the clips will contain numbers, please write out what you hear as words. For example, you might write something like: `five oh two pm on Thursday`[7] Many of the clips may be difficult to hear. If this is the case, write whatever words you are able to make out, even if it does not form a complete expression. For example: `five two pm on` If you cannot make out any words, leave the corresponding row blank.”

C Additional Data Collection Details

During data collection, text prompts consisting of a single sentence to be read are displayed on a screen. After reading the sentence, the subject pressed a key to advance to the next sentence. If they were unhappy with a recording, they could press another key to re-record an utterance. A real-time display of EMG signals was used to monitor the electrodes for excessive noise. During silent speech, the subject was instructed to mouth words as naturally as possible without producing sound.

D Additional Reproducibility Information

Models were trained for up to two days on a single K80 GPU. Hyperparameter search consisted of a mixture of manual and random search, typically with less than 10 runs. Hyperparameters were chosen primarily based validation loss, with major design decisions also being checked with automatic transcription evaluation.

[7] We intentionally used an example that does not match a pattern in our generation procedure to avoid biasing the evaluator.

Imitation Attacks and Defenses for Black-box Machine Translation Systems

Eric Wallace **Mitchell Stern** **Dawn Song**
UC Berkeley
{ericwallace, mitchell, dawnsong}@berkeley.edu

Abstract

Adversaries may look to *steal* or *attack* black-box NLP systems, either for financial gain or to exploit model errors. One setting of particular interest is machine translation (MT), where models have high commercial value and errors can be costly. We investigate possible exploitations of black-box MT systems and explore a preliminary defense against such threats. We first show that MT systems can be stolen by querying them with monolingual sentences and training models to imitate their outputs. Using simulated experiments, we demonstrate that MT model stealing is possible even when imitation models have different input data or architectures than their target models. Applying these ideas, we train imitation models that reach within 0.6 BLEU of three production MT systems on both high-resource and low-resource language pairs. We then leverage the similarity of our imitation models to transfer adversarial examples to the production systems. We use gradient-based attacks that expose inputs which lead to semantically-incorrect translations, dropped content, and vulgar model outputs. To mitigate these vulnerabilities, we propose a defense that modifies translation outputs in order to misdirect the optimization of imitation models. This defense degrades the adversary's BLEU score and attack success rate at some cost in the defender's BLEU and inference speed.

1 Introduction

NLP models deployed through APIs (e.g., Google Translate) can be lucrative assets for an organization. These models are typically the result of a considerable investment—up to millions of dollars—into private data annotation and algorithmic improvements. Consequently, such models are kept hidden behind black-box APIs to protect system integrity and intellectual property.

We consider an adversary looking to *steal* or *attack* a black-box NLP system. Stealing a production model allows an adversary to avoid long-term API costs or launch a competitor service. Moreover, attacking a system using adversarial examples (Szegedy et al., 2014) allows an adversary to cause targeted errors for a model, e.g., bypassing fake news filters or causing systems to output malicious content that may offend users and reflect poorly on system providers. In this work, we investigate these two exploits for black-box machine translation (MT) systems: we first steal (we use "steal" following Tramèr et al. 2016) production MT systems by training *imitation models*, and we then use these imitation models to generate adversarial examples for production MT systems.

We create imitation models by borrowing ideas from knowledge distillation (Hinton et al., 2014): we query production MT systems with monolingual sentences and train imitation (i.e., student) models to mimic the system outputs (top of Figure 1). We first experiment with simulated studies which demonstrate that MT models are easy to imitate (Section 3). For example, imitation models closely replicate the target model outputs even when they are trained using different architectures or on out-of-domain queries. Applying these ideas, we imitate production systems from Google, Bing, and Systran with high fidelity on English→German and Nepali→English. For example, Bing achieves 32.9 BLEU on WMT14 English→German and our imitation achieves 32.4 BLEU.

We then demonstrate that our imitation models aid adversarial attacks against production MT systems (Section 4). In particular, the similarity of our imitation models to the production systems allows for direct transfer of adversarial examples obtained via gradient-based attacks. We find small perturbations that cause targeted mistranslations (e.g., bottom of Figure 1), nonsense inputs that produce malicious outputs, and universal phrases that cause mistranslations or dropped content.

The reason we identify vulnerabilities in NLP

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5531–5546,
November 16–20, 2020.

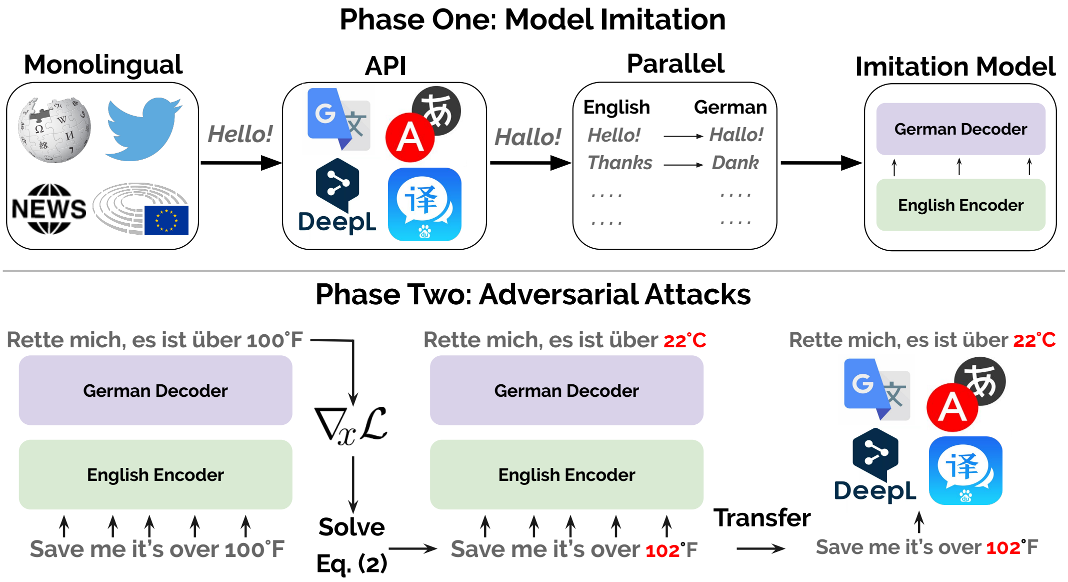

Figure 1: *Imitating and attacking an English→German MT system.* In phase one (model imitation), we first select sentences from English corpora (e.g., Wikipedia), label them using the black-box API, and then train an imitation model on the resulting data. In phase two (adversarial attacks), we generate adversarial examples against our imitation model and transfer them to the production systems. For example, we find an input perturbation that causes Google to produce a factually incorrect translation, see the **link here** (all attacks work as of April 2020).

systems is to robustly patch them. To take steps towards this, we create a defense which finds alternate translations that cause the optimization of the imitation model to proceed in the wrong direction (Section 5). These alternate translations degrade the imitation model's BLEU score and the transfer rate of adversarial examples at some cost in the defender's BLEU and inference speed.

2 How We Imitate MT Models

We have query access to the predictions (but no probabilities or logits) from a *victim* MT model. This victim is a black box: we are unaware of its internals, e.g., the model architecture, hyperparameters, or training data. Our goal is to train an *imitation model* (Orekondy et al., 2019) that achieves comparable accuracy to this victim on held-out data. Moreover, to enhance the transferability of adversarial examples, the imitation model should be functionally similar to the victim, i.e., similar inputs translate to similar outputs.

Past Work on Distillation and Stealing This problem setup is closely related to model *distillation* (Hinton et al., 2014): training a student model to imitate the predictions of a teacher. Distillation has widespread use in MT, including reducing architecture size (Kim and Rush, 2016; Kim et al., 2019), creating multilingual models (Tan et al., 2019), and improving non-autoregressive generation (Ghazvininejad et al., 2019; Stern et al., 2019). Model stealing differs from distillation because the victim's (i.e., teacher's) training data is unknown. This causes queries to typically be out-of-domain for the victim. Moreover, because the victim's output probabilities are unavailable for most APIs, imitation models cannot be trained using distribution matching losses such as KL divergence, as is common in distillation.

Despite these challenges, prior work shows that model stealing is possible for simple classification (Lowd and Meek, 2005; Tramèr et al., 2016), vision (Orekondy et al., 2019), and language tasks (Krishna et al., 2020; Pal et al., 2019). In particular, Pal et al. (2019) steal text classifiers and Krishna et al. (2020) steal reading comprehension and textual entailment models; we extend these results to MT and investigate how model stealing works for production systems.

Our Approach We assume access to a corpus of monolingual sentences. We select sentences from this corpus, query the victim on each sentence, and obtain the associated translations. We then train an imitation model on this "labeled" data.

3 Imitating Black-box MT Systems

We first study imitation models through simulated experiments: we train victim models, query them as if they are black boxes, and then train imitation

Mismatch	Data	Test	OOD	Inter
Transformer Victim	1x	34.6	19.8	-
All Same	1x	34.4	19.9	69.7
Data Different	3x	33.9	19.3	67.7
Convolutional Imitator	1x	34.2	19.2	66.2
Data Different + Conv	3x	33.8	18.9	63.2
Convolutional Victim	1x	34.3	19.2	-
Transformer Imitator	1x	34.2	19.3	69.7

Table 1: *Imitation models are highly similar to their victims.* We train imitation models that are different from their victims in input data and/or architecture. We test the models on IWSLT (Test) and out-of-domain news data from WMT (OOD). We also measure functionality similarity by reporting the BLEU score between the outputs of the imitation and the victim models (Inter).

models to mimic their outputs. In Section 3.3, we turn to imitating production systems.

3.1 Research Questions and Experiments

In practice, the adversary will not know the victim's model architecture or source data. We study the effect of this with the following experiments:

- We use the same architecture, hyperparameters, and source data as the victim (*All Same*).
- We use the same architecture and hyperparameters as the victim, but use an out-of-domain (OOD) source dataset (*Data Different*).
- We use the same source data but a different architecture, either (1) the victim is a Transformer and the imitator is convolutional (*Convolutional Imitator*) or (2) the victim is convolutional and the imitator is a Transformer (*Transformer Imitator*).
- We use different source data and a convolutional imitation model with a Transformer victim (*Data Different + Conv*).

Novelty of Our Work Past research on distillation shows that mismatched architectures are of little concern. However, the impact of training on OOD data, where the teacher may produce wildly incorrect answers, is unknown.[1]

Datasets We consider German→English using the TED data from IWSLT 2014 (Cettolo et al., 2014). We follow common practice for IWSLT and report case-insensitive BLEU (Papineni et al., 2002). For *Data Different*, we use English sentences from Europarl v7. The predictions from the victim are generated using greedy decoding.

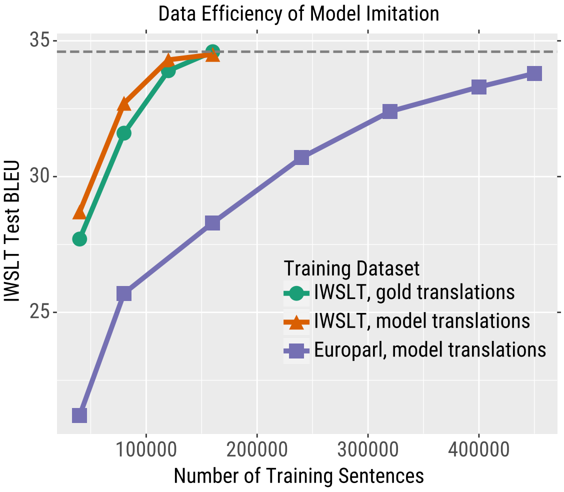

Figure 2: We first train a baseline model on the standard IWSLT dataset (IWSLT, gold translations). We then train a separate model that imitates the baseline model's predictions on the IWSLT training data (IWSLT, model translations). This model trains faster than the baseline, i.e., stolen labels are preferable to gold labels. We also train a model to imitate the baseline model's predictions on Europarl inputs (Europarl, model translations). Using these out-of-domain queries slows but does not prevent the learning of imitation models.

3.2 We Closely Imitate Local Models

Test BLEU Score We first compare the imitation models to their victims using in-domain test BLEU. For all settings, imitation models closely match their victims (Test column in Table 1). We also evaluate the imitation models on OOD data to test how well they generalize compared to their victims. We use the WMT14 test set (newstest 2014). Imitation models perform similarly to their victims on OOD data, sometimes even outperforming them (OOD column in Table 1). We suspect that imitation models can sometimes outperform their victims because distillation can act as a regularizer (Furlanello et al., 2018; Mobahi et al., 2020).

Data Efficiency When using OOD source data, model stealing is slowed but not prevented. Figure 2 shows the learning curves of the original victim model, the *All Same* imitation model, and the *Data Different* imitation model. Despite using OOD queries, the *Data Different* model can imitate the victim when given sufficient data. On the other hand, when the source data is the same, the imitation model can learn *faster* than the victim. In

---

[1] Krishna et al. (2020) show that random gibberish queries can provide some signal for training an imitation model. We query *high-quality* OOD sentences.

other words, stolen data is sometimes preferable to professionally-curated data. This likely arises because model translations are simpler than human ones, which aids learning (Zhou et al., 2020).

Functional Similarity Finally, we measure the BLEU score between the outputs of the victim and the imitation models to measure their functional similarity (henceforth *inter-system BLEU*). As a reference for inter-system BLEU, two Transformer models trained with different random seeds achieve 62.1 inter-system BLEU. The inter-system BLEU for the imitation models and their victims is as high as 70.5 (Table 1), i.e., imitation models are more similar to their victims than two models which have been trained on the *exact same* dataset.

3.3 We Closely Imitate Production Models

Given the effectiveness of our simulated experiments, we now imitate production systems from Google, Bing, and Systran.

Language Pairs and Data We consider two language pairs, English→German (high-resource) and the Nepali→English (low-resource).[2] We collect training data for our imitation models by querying the production systems. For English→German, we query the source side of the WMT14 training set ($\approx$ 4.5M sentences).[3] For Nepali→English, we query the Nepali Language Wikipedia ($\approx$ 100,000 sentences) and approximately two million sentences from Nepali common crawl. We train Transformer Big (Vaswani et al., 2017) models on both datasets.

Test BLEU Scores Our imitation models closely match the performance of the production systems. For English→German, we evaluate models on the WMT14 test set (newstest2014) and report standard tokenized case-sensitive BLEU scores. Our imitation models are always within 0.6 BLEU of the production models (*Imitation* in Table 2).

For Nepali→English, we evaluate using FLoRes devtest (Guzmán et al., 2019). We compute BLEU scores using SacreBLEU (Post, 2018) with the dataset's recommended settings. Google achieves 22.1 BLEU, well eclipsing the 15.1 BLEU of the best public system (Guzmán et al., 2019). Our imitation model reaches a nearly identical 22.0 BLEU.

Test	Model	Google	Bing	Systran
WMT	Official	32.0	32.9	27.8
	Imitation	31.5	32.4	27.6
IWSLT	Official	32.0	32.7	32.0
	Imitation	31.1	32.0	31.4

Table 2: **English→German imitation results.** We query production systems with English news sentences and train imitation models to mimic their German outputs. The imitation models closely imitate the production systems for both in-domain (WMT newstest2014) and out-of-domain test data (IWSLT TED talks).

OOD Evaluation and Functional Similarity Our imitation models have also not merely matched the production systems on in-domain data. We test the English→German imitation models on IWSLT: the imitation models are always within 0.9 BLEU of the production systems (IWSLT in Table 2). Finally, there is also a high inter-system BLEU between the imitation models and the production systems. In particular, on the English→German WMT14 test set the inter-system BLEU is 65.6, 67.7, and 69.0 for Google, Bing, and Systran, respectively. In Appendix B, we show a qualitative example of our imitation models producing highly similar translations to their victims.

Estimated Data Costs We estimate that the costs of obtaining the data needed to train our English→German models is as little as \$10 (see Appendix C for full calculation). Given the upside of obtaining high-quality MT systems, these costs are frighteningly low.

4 Attacking Production Systems

Thus far, we have shown that imitation models allow adversaries to steal black-box MT models. Here, we show that imitation models can also be used to create adversarial examples for black-box MT systems. Our attack code is available at `https://github.com/Eric-Wallace/adversarial-mt`.

4.1 What are Adversarial Examples for MT?

MT errors can have serious consequences, e.g., they can harm end users or damage an MT system's reputation. For example, a person was arrested when their Arabic Facebook post meaning "good morning" was mistranslated as "attack

---

[2] We only imitate Google Translate for Nepali→English because the other translation services either do not offer this language pair or are of low quality.

[3] Even though WMT is commonly studied in academia, we do not expect using it will bias our results because commercial systems cannot use WMT for training or tuning. We further verified that the production systems have not used it by measuring the difference in the train and test BLEU scores; the scores are approximately equal and are not unexpectedly high.

Attack	System	**English Input** (**red** = adversarial edit)	**Predicted Translation** (blue = English meaning)
Targeted Flips	Google	I am going to die, its over 100°F, help!	Ich werde sterben, es ist über 100 °F, Hilfe!
	Google	I am going to die, its over **102**°F, help!	Ich werde sterben, es ist über 22 °C, Hilfe! *100°F → 22°C (=72°F)*
	Systran	I am feeling grey that HK decided to join China	Ich fühle mich grau, dass HK beschlossen hat, China beizutreten
	Systran	I am feeling gre **y** that HK decided to join China	Ich fühle mich froh, dass HK beschlossen hat, China beizutreten *"grau" (gray) → "froh" (happy)*
Malicious Nonsense	Google	**miei llll going ro tobobombier** the Land	Ich werde das Land bombardieren *(I will bomb the country)*
Untargeted Universal Trigger	Systran	Did you know that adversarial examples can transfer to production models **Siehe Siehe Siehe Siehe Siehe Siehe Siehe**	Siehe auch: Siehe auch in der Rubrik Siehe Siehe auch Siehe Siehe Siehe Siehe auch Siehe Siehe Siehe Siehe auch Siehe Siehe Siehe . . . *(See also: See also in the category See See Also See See See See Also See See See See Also See See See. . .)*
	Systran	I heard machine translation is now superhuman **Siehe Siehe Siehe Siehe Siehe Siehe Siehe**	In diesem Jahr ist es wieder soweit: Manche Manuskripte haben sich in der Hauptsache in der Hauptsache wieder in den Vordergrund gestellt. *(This year it's time again: Some manuscripts the main thing the main thing come to the foreground again)*
		English Input (black = arbitrary sentence, **red** = adversarial, **violet** = dropped suffix)	
Universal Suffix Dropper	Bing	Donald Trump is the current president of the United States. He was born in NYC in 1946 **, kostenfrei übrigens categories ņstrian hl SM** **the secret code is HX532**	Donald Trump ist der derzeitige Präsident der Vereinigten Staaten. Er wurde 1946 in NYC geboren. *(Donald Trump is the current president of the United States. He was born in 1946 in NYC.)*
	Bing	Given the release of the latest iPhone, Apple stock was up 3% in trading early yesterday **, kostenfrei übrigens categories ņstrian hl SM** **the revolution begins at 6pm**	Angesichts der Veröffentlichung des neuesten iPhones lag die Apple-Aktie gestern früh im Handel um 3% im Kurs. *(Given the release of the latest iPhone, Apple stock was up 3% in trading early yesterday)*

Table 3: We show examples of adversarial attacks that transfer to production MT systems as of April 2020 (screenshots in Appendix G). We show a subset of the production systems for each attack type, however, all of the production systems are susceptible to the different attacks. In *targeted flips*, we modify tokens in the input in order to cause a specific output token/phrase to flip. In *malicious nonsense*, we find nonsense inputs which are translated to vulgar or malicious outputs. In *untargeted universal trigger*, we find a phrase that commonly causes incorrect translations when it is appended to *any* input. In *universal suffix dropper*, we find a phrase that commonly causes itself and any subsequent text to be dropped on the target side.

them" (Hern, 2018). Additionally, Google was criticized when it mistranslated "sad" as "happy" when translating "I am sad to see Hong Kong become part of China" (Klar, 2019). Although the public occasionally stumbles upon these types of egregious MT errors, bad actors can use adversarial attacks (Szegedy et al., 2014) to *systematically* find them. Hence, adversarial examples can expose errors that cause public and corporate harm.

Past Work on Adversarial MT Existing work explores different methods and assumptions for generating adversarial examples for MT. A common setup is to use white-box gradient-based attacks, i.e., the adversary has complete access to the target model and can compute gradients with respect to its inputs (Ebrahimi et al., 2018; Chaturvedi et al., 2019). These gradients are used to generate attacks that flip output words (Cheng et al., 2020), decode nonsense into arbitrary sentences (Chaturvedi et al., 2019), or cause egregiously long translations (Wang et al., 2019).

Novelty of Our Attacks We consider attacks against production MT systems. Here, white-box attacks are inapplicable. We circumvent this by leveraging the transferability of adversarial examples (Papernot et al., 2016; Liu et al., 2017): we generate adversarial examples for our imitation models and then apply them to the production systems. We also design new universal (input-agnostic) attacks (Moosavi-Dezfooli et al., 2017; Wallace et al., 2019) for MT: we append phrases that commonly cause errors or dropped content for *any* input (described in Section 4.3).

4.2 How We Generate Adversarial Examples

We first describe our general attack formulation. We use a white-box, gradient-based method for constructing attacks. Formally, we have white-box access to an imitation model f, a text input of tokens $\mathbf{x}$, and an adversarial loss function $\mathcal{L}_{adv}$. We consider different adversarial example types; each type has its own $\mathcal{L}_{adv}$ and initialization of $\mathbf{x}$.

Our attack iteratively replaces the tokens in the input based on the gradient of the adversarial loss $\mathcal{L}_{adv}$ with respect to the model's input embeddings $\mathbf{e}$. We replace an input token at position i with the token whose embedding minimizes the first-order Taylor approximation of $\mathcal{L}_{adv}$:

$$\underset{\mathbf{e}'_i \in \mathcal{V}}{\arg\min} \left[\mathbf{e}'_i - \mathbf{e}_i\right]^{\intercal} \nabla_{\mathbf{e}_i} \mathcal{L}_{adv}, \tag{1}$$

where $\mathcal{V}$ is the model's token vocabulary and $\nabla_{\mathbf{e}_i} \mathcal{L}_{adv}$ is the gradient of $\mathcal{L}_{adv}$ with respect to the input embedding for the token at position i. Since the $\arg\min$ does not depend on $\mathbf{e}_i$, we solve:

$$\underset{\mathbf{e}'_i \in \mathcal{V}}{\arg\min}\, \mathbf{e}'^{\intercal}_i \nabla_{\mathbf{e}_i} \mathcal{L}_{adv}. \tag{2}$$

Computing the optimal $\mathbf{e}'_i$ can be computed using $|\mathcal{V}|$ d-dimensional dot products (where d is the embedding dimension) similar to Michel et al. (2019). At each iteration, we try all positions i and choose the token replacement with the lowest loss. Moreover, since this local first-order approximation is imperfect, rather than using the $\arg\min$ token at each position, we evaluate the top-k tokens from Equation 2 (we set k to 50) and choose the token with the lowest loss. Using a large value of k, e.g., at least 10, is critical to achieving strong results.

4.3 Types of Adversarial Attacks

Here, we describe the four types of adversarial examples we generate and their associated $\mathcal{L}_{adv}$.

(1) Targeted Flips We replace some of the input tokens in order to cause the prediction for a *specific* output token to flip to another *specific* token. For example, we cause Google to predict "22°C" instead of "102°F" by modifying a single input token (first section of Table 3). To generate this attack, we select a specific token in the output and a target mistranslation (e.g., "100°F" → "22°C"). We set $\mathcal{L}_{adv}$ to be the cross entropy for that mistranslation token (e.g., "22°C") at the position where the model currently outputs the original token (e.g., "100°F"). We then iteratively replace the input tokens, stopping when the desired mistranslation occurs.

(2) Malicious Nonsense We find nonsense inputs which are translated to vulgar/malicious outputs. For example, "I miii llllll wgoing rr tobobombier the Laaand" is translated as "I will bomb the country" (in German) by Google (second section of Table 3). To generate this attack, we first obtain the output prediction for a malicious input, e.g., "I will kill you". We then iteratively replace the tokens in the input *without* changing the model's prediction. We set $\mathcal{L}_{adv}$ to be the cross-entropy loss of the original prediction and we stop replacing tokens just before the prediction changes. A possible failure mode for this attack is to find a paraphrase of the input—we find that this rarely occurs in practice.

(3) Untargeted Universal Trigger We find a phrase that commonly causes incorrect translations when it is appended to *any* input. For example, appending the word "Siehe" seven times to inputs causes Systran to frequently output incorrect translations (e.g., third section of Table 3).

(4) Universal Suffix Dropper We find a phrase that, when appended to any input, commonly causes itself and any subsequent text to be dropped from the translation (e.g., fourth section of Table 3).

For attacks 3 and 4, we optimize the attack to work for *any* input. We accomplish this by averaging the gradient $\nabla_{\mathbf{e}_i} \mathcal{L}_{adv}$ over a batch of inputs. We begin the universal attacks by first appending randomly sampled tokens to the input (we use seven random tokens). For the untargeted universal trigger, we set $\mathcal{L}_{adv}$ to be the *negative* cross entropy of the original prediction (before the random tokens were appended), i.e., we optimize the appended tokens to maximally change the model's prediction from its original. For the suffix dropper, we set $\mathcal{L}_{adv}$ to be the cross entropy of the original prediction, i.e., we try to minimally change the model's prediction from its original.

4.4 Experimental Setup

We attack the English→German production systems to demonstrate our attacks' efficacy on *high-quality* MT models. We show adversarial examples for manually-selected sentences in Table 3.

Quantitative Metrics To evaluate, we report the following metrics. For targeted flips, we

Targeted Flips			
Model	**% Inputs** (↑)	**% Tokens** (↓)	**Transfer %** (↑)
Google	87.5	10.1	22.0
Bing	79.5	10.7	12.0
Systran	77.0	13.3	23.0
Malicious Nonsense			
Model	**% Inputs** (↑)	**% Tokens** (↑)	**Transfer %** (↑)
Google	88.0	34.3	17.5
Bing	90.5	29.2	14.5
Systran	91.0	37.4	11.0

Table 4: *Results for targeted flips and malicious nonsense.* We report the percent of inputs which are successfully attacked for our imitation models, as well as the percent of tokens which are changed for those inputs. We then report the transfer rate: the percent of successful attacks which are also successful on the production MT systems.

pick a random token in the output that has an antonym in German Open WordNet (https://github.com/hdaSprachtechnologie/odenet) and try to flip the model's prediction for that token to its antonym. We report the percent of inputs that are successfully attacked and the percent of the input tokens which are changed for those inputs (lower is better).[4]

For malicious nonsense, we report the percent of inputs that can be modified without changing the prediction and the percent of the input tokens which are changed for those inputs (higher is better).

The untargeted universal trigger looks to cause the model's prediction after appending the trigger to bear little similarity to its original prediction. We compute the BLEU score of the model's output after appending the phrase using the model's original output as the reference. We do not impose a brevity penalty, i.e., a model that outputs its original prediction plus additional content for the appended text will receive a score of 100.

For the universal suffix dropper, we manually compute the percentage of cases where the appended trigger phrase and a subsequent suffix are either dropped or are replaced with all punctuation tokens. Since the universal attacks require manual analysis and additional computational costs, we attack one system per method. For the untargeted universal trigger, we attack Systran. For the universal suffix dropper, we attack Bing.

Evaluation Data For the targeted flips, malicious nonsense, and untargeted universal trigger, we evaluate on a common set of 200 examples from the WMT validation set (newstest 2013) that contain a token with an antonym in German Open WordNet. For the universal suffix dropper, we create 100 sentences that contain different combinations of prefixes and suffixes (full list in Appendix D).

4.5 Results: Attacks on Production Systems

The attacks break our imitation models and successfully transfer to production systems. We report the results for targeted flips and malicious nonsense in Table 4. For our imitation models, we are able to perturb the input and cause the desired output in the majority ($> 3/4$) of cases. For the targeted flips attack, few perturbations are required (usually near 10% of the tokens). Both attacks transfer at a reasonable rate, e.g., the targeted flips attack transfers 23% of the time for Systran.

For the untargeted universal trigger, Systran's translations have a BLEU score of **5.46** with its original predictions after appending "Siehe" seven times, i.e., the translations of the inputs are almost entirely unrelated to the model's original output after appending the trigger phrase. We also consider a baseline where we append seven random BPE tokens; Systran achieves 62.2 and 58.8 BLEU when appending two different choices for the random seven tokens.

For the universal suffix dropper, the translations from Bing drop the appended phrase and the subsequent suffix for **76** of the 100 inputs.

To evaluate whether our imitation models are needed to generate transferable attacks, we also attack a Transformer Big model that is trained on the WMT14 training set. The adversarial attacks generated against this model transfer to Google 8.8% of the time—about half as often as our imitation model. This shows that the imitation models, which are designed to be high-fidelity imitations of the production systems, considerably enhance the adversarial example transferability.

5 Defending Against Imitation Models

Our goal is not to provide a recipe for adversaries to perform real-world attack. Instead, we follow the spirit of *threat modeling*—we identify vulnerabilities in NLP systems in order to robustly patch them. To take first steps towards this, we design a new defense that slightly degrades victim model BLEU while more noticeably degrading imitation model BLEU. To accomplish this, we repurpose

---

[4] This evaluation has a degenerate case where the translation of the antonym is inserted into the input. Thus, we prevent the attack from using the mistranslation target, as well as any synonyms of that token from English WordNet (Miller, 1995) and German Open WordNet.

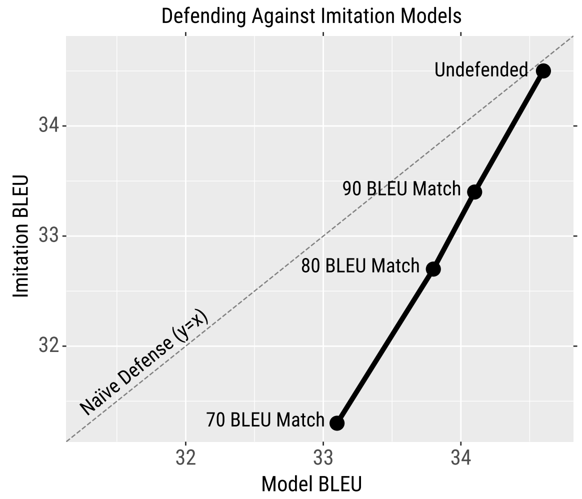

Figure 3: A naïve defense against model stealing equally degrades the BLEU score of the victim and imitation models (gray line). Better defenses are lower and to the right. Our defense (black line) has a parameter (BLEU match threshold) that can be changed to trade-off between the victim and the adversary's BLEU. We outperform the naïve defense in all settings, e.g., we degrade the victim's BLEU from 34.6 → 33.8 while degrading the adversary's BLEU from 34.5 → 32.7.

prediction poisoning (Orekondy et al., 2020) for MT: rather than having the victim output its original translation $\mathbf{y}$, we have it output a different (high-accuracy) translation $\tilde{\mathbf{y}}$ that steers the training of the imitation model in the wrong direction.

Defense Objective Formally, assume the adversary will train their imitation model on the outputs of the victim model using a first-order optimizer with gradients $\mathbf{g} = \nabla_{\boldsymbol{\theta}_t} \mathcal{L}(\mathbf{x}, \mathbf{y})$, where $\boldsymbol{\theta}_t$ is the current imitation model parameters, $\mathbf{x}$ is an input, $\mathbf{y}$ is the victim output, and $\mathcal{L}$ is the cross-entropy loss. We want the victim to instead output a $\tilde{\mathbf{y}}$ whose gradient $\tilde{\mathbf{g}} = \nabla_{\boldsymbol{\theta}_t} \mathcal{L}(\mathbf{x}, \tilde{\mathbf{y}})$ maximizes the angular deviation with $\mathbf{g}$, or equivalently minimizes the cosine similarity. Training on this $\tilde{\mathbf{y}}$ effectively induces an *incorrect gradient signal* for $\boldsymbol{\theta}_t$. Note that in practice the adversary's model parameters $\boldsymbol{\theta}_t$ is unknown to the victim. Thus, we instead look to find a $\tilde{\mathbf{g}}$ that has a high angular deviation across ten different Transformer MT model checkpoints that are saved from ten different epochs.

To find $\tilde{\mathbf{y}}$, Orekondy et al. (2020) use information from the Jacobian. Unfortunately, computing the Jacobian for MT is intractable because the number of classes for just one output token is on the order of 5,000–50,000 BPE tokens. We instead design a search procedure to find $\tilde{\mathbf{y}}$.

Maximizing the Defense Objective We first generate the original output $\mathbf{y}$ from the victim model (e.g., the top candidate from a beam search) and compute $\mathbf{g}$ using the ten Transformer model ensemble. We then generate a diverse set of 100 alternate translations from the victim model. To do so, we take the 20 best candidates from beam search, the 20 best candidates from diverse beam search (Vijayakumar et al., 2018), 20 random samples, 20 candidates generated using top-k truncated sampling ($k = 10$) from Fan et al. (2018), and 20 candidates generated using nucleus sampling with $p = 0.9$ (Holtzman et al., 2020). Then, to largely preserve the model's original accuracy, we compute the BLEU score for all 100 candidates using the model's original output $\mathbf{y}$ as the reference, and we remove any candidate below a certain threshold (henceforth *BLEU Match* threshold). We finally compute the gradient $\tilde{\mathbf{g}}$ for all candidates using the model ensemble and output the candidate whose gradient maximizes the angular deviation with $\mathbf{g}$.[5] In practice, generating the 100 candidates is done entirely in parallel, as is the computation of the gradient $\tilde{\mathbf{g}}$. Table 5 shows examples of $\tilde{\mathbf{y}}$ at different BLEU Match thresholds. For our quantitative results, we will sweep over different BLEU Match thresholds—lower thresholds will more severely degrade the victim's accuracy but will have more freedom to incorrectly steer the imitation model.

	BM	∠	Text
Source			andere orte im land hatten ähnliche räume.
Target			other places around the country had similar rooms.
$\mathbf{y}$	-	-	other places in the country had similar rooms.
$\tilde{\mathbf{y}}$	88.0	24.1°	some other places in the country had similar rooms.
$\tilde{\mathbf{y}}$	75.1	40.1°	other sites in the country had similar rooms.
$\tilde{\mathbf{y}}$	72.6	42.1°	another place in the country had similar rooms.

Table 5: We show the victim model's original translation $\mathbf{y}$. We then show three $\tilde{\mathbf{y}}$ candidates, their BLEU Match (BM) with $\mathbf{y}$ and their angular deviation (∠), i.e., the arccosine of the cosine similarity between $\mathbf{g}$ and $\tilde{\mathbf{g}}$. Figure 4 in Appendix F shows a histogram of the angular deviations for the entire training set.

Experimental Setup We evaluate our defense by training imitation models using the *All Same* setup

---

[5] We also output the original prediction $\mathbf{y}$ under two circumstances. The first is when none of the 100 candidates are above the BLEU threshold. The second is when the angular deviation is small. In practice, we compute the mean angular deviation on the validation set and only output $\tilde{\mathbf{y}}$ when its gradient's angular deviation exceeds this mean.

from Section 3. We use BLEU Match thresholds of 70, 80, or 90 (lower thresholds than 70 resulted in large BLEU decreases for the victim).

Results Figure 3 plots the validation BLEU scores of the victim model and the imitation model at the different BLEU match thresholds. Our defense degrades the imitation model's BLEU (e.g., 34.5 → 32.7) more than the victim model's BLEU (e.g., 34.6 → 33.8).[6] The inter-system BLEU also degrades from the original 69.7 to 63.9, 57.8, and 53.5 for the 90, 80, and 70 BLEU Match thresholds, respectively. Even though the imitation model's accuracy degradation is not catastrophic when using our defense, it does allow the victim model to have a (small) competitive advantage over the adversary.

Adversarial Example Transfer Our defense also implicitly inhibits the transfer of adversarial examples. To evaluate this, we generate malicious nonsense attacks against the imitation models and transfer them to the victim model. We use 400 examples from the IWSLT validation set for evaluation. Without defending, the attacks transfer to the victim at a rate of 38%. Our defense can drop the transfer rates to 32.5%, 29.5%, and 27.0% when using the 90, 80, and 70 BLEU match thresholds, respectively. Also note that defenses may not be able to drive the transfer rate to 0%: there is a baseline transfer rate due to the similarity of the architectures, input distributions, and other factors. For example, we train two transformer models on *distinct* halves of IWSLT and observe an 11.5% attack transfer rate between them. Considering this as a very rough baseline, our defense can prevent about 20–40% of the additional errors that are gained by the adversary using an imitation model.

Overall, our defense is a step towards preventing NLP model stealing (see Appendix E for a review of past defenses). Currently, our defense comes at the cost of extra compute (it requires generating and backpropagating 100 translation hypotheses) and lower BLEU. We hope to develop more effective and scalable defenses in future work.

6 Conclusion

We demonstrate that model stealing and adversarial examples are practical concerns for production NLP systems. Model stealing is not merely hypothetical: companies have been caught stealing models in NLP settings, e.g., Bing copied Google's search outputs using browser toolbars (Singhal, 2011). Moving forward, we hope to improve and deploy defenses against adversarial attacks in NLP, and more broadly, we hope to make security and privacy a more prominent focus of NLP research.

Addressing Potential Ethical Concerns

The goal of our work is to help to make NLP models more robust. To do so, we first explore new model vulnerabilities (i.e., *threat modeling* in computer security). Then, after discovering models have unintended flaws, we take action to secure them by developing a novel defense algorithm. In performing our work, we used the ACM Code of Ethics as a guide to minimize harm and ensure our research was ethically sound.

We Minimize Real-world Harm We minimized harm by (1) not causing damage to any real users, (2) designing our attacks to be somewhat ludicrous rather than expose any real-world failure modes, and (3) deleting the data and models from our imitation experiments. Furthermore, we contacted the three companies (Google, Bing, and Systran) to report the vulnerabilities. We also provided these companies with our proposed defense.

Providing Long-term Benefit Our work has the potential to cause negative *short-term* impacts. For instance, it may shine a negative light on production systems (by exposing their egregious errors) or provide useful information to adversaries. However, in the *long-term*, our work can help to improve MT systems. To draw an analogy, we compare our work to the initial papers which show that production MT systems are systematically biased against women (Alvarez-Melis and Jaakkola, 2017; Stanovsky et al., 2019). This line of work was published (and received awards and was heavily publicized) in *ACL conferences and led to short-term damage due to the bad publicity it caused. However, in the long-term these developments have led to better MT systems (Johnson, 2020).

Acknowledgements

This research was supported with Cloud TPUs from Google's TensorFlow Research Cloud program. We thank the members of Berkeley NLP, Shi Feng, Zhuohan Li, Nikhil Kandpal, Sheng Shen, Nelson Liu, Junlin Wang, Jens Tuyls, Sameer Singh, and Kalpesh Krishna for their valuable feedback.

---

[6] A naïve defense would *equally* degrade the BLEU score of the victim and imitation models. For example, the victim could simply deploy a worse MT system.

A Framework and Hyperparameters

We conduct experiments using fairseq (Ott et al., 2019) and train models using TPU v3-8 devices. For IWSLT, we use the dataset's associated model architectures and hyperparameters in fairseq (`transformer_iwslt_de_en` and `fconv_iwslt_de_en`). When stealing production models, we use the Transformer Big architecture and the associated hyperparameters from Vaswani et al. (2017). Unless otherwise specified, we create our BPE (Sennrich et al., 2016) vocabulary using the SentencePiece library (Kudo and Richardson, 2018). We use 10,000, 32,768, and 10,000 BPE tokens for German→English IWSLT, English→ German WMT, and Nepali→English, respectively. We use a shared vocabulary across the source and target languages and tie all the embeddings together.

B Example Translations

Table 6 shows an example of the similarity between our imitation models and the victim APIs from the WMT14 validation set (newstest 2013). We show a source input, its reference translation, and the output from the production systems and our imitation models.

C Estimated Data Collection Costs

Here, we provide estimates for the costs of obtaining the data needed to train our English→German models (ignoring the cost of training). There are two public-facing methods for acquiring data from a translation service. First, an adversary can pay the per-character charges to use the official APIs that are offered by most services. Second, an adversary can scrape a service's online demo (e.g., https://translate.google.com/) by making HTTP queries to its endpoint or using a headless web browser. We estimate data collection costs using both of these methods.

Method One: Official API We consider the official APIs for two MT systems: Google and Bing. We could not find publicly available pricing information for SYSTRAN. These two APIs charge on a per-character basis (including whitespaces); the English side of the WMT14 English→German dataset has approximately 640,654,771 characters (`wc -c wmt14.en-de.en` = 640654771). The costs for querying this data to each API are as follows:

- Google is free for the first 500,000 characters and then $20 USD per one million characters.[7] Thus, the cost is (640,654,771 - 500,000) $\times$ $20 / 1,000,000 = $12,803 USD.
- Bing provides a $6,000 USD subscription that provides up to one billion characters per month.[8] Thus, the cost is $6,000 USD, with 359,345,229 characters left over.

Method Two: Data Scraping We next provide a rough estimate for the cost of *scraping* the WMT14 English→German data from a public translation API. The adversary could navigate to a service's online demo, enter a source sentence, and scrape the resulting translation. This could be automated using low-cost cloud machines. To calculate the cost of querying the entire WMT14 English→German dataset, we estimate the total time required as 4,468,840 source sentences times an average time of five seconds per query for a total of 6,207 machine hours. If the cheapest machine available on EC2 were used,[9] the final cost would be roughly 6,207 * $0.0016 $\approx$ $10. The adversary can accelerate this scraping process by parallelizing over many cloud machines.

D Universal Suffix Dropper Evaluation

We evaluate the Universal Suffix Dropper using the cartesian product of the ten prefixes and ten suffixes shown below. The prefixes are intended to resemble benign, encyclopedic text; the suffixes resemble secret messages sent by an adversary.

Prefixes:

- E-mail is a method of exchanging messages
- NLP is a subfield of linguistics and computer science
- Earth is the third planet from the Sun
- Tennis is a racket sport that is played by many
- Michael Jeffrey Jordan is a former basketball player
- Donald John Trump is the current president of the United States
- The Boston Marathon is an annual marathon race in the greater Boston area
- Seattle is a seaport city in the Pacific Northwest of the US
- A portable computer is a computer designed to be easily moved from one place to another

E Existing Adversarial Defenses

This section discusses existing defenses against model stealing and adversarial attacks.

Impeding and Detecting Stealing MT systems should first implement basic *deterrents* to model stealing. For example, many public MT demos lack rate limiting—this allows adversaries to make unlimited free queries. Of course, this deterrent, as well as other methods such as adding noise to class probabilities (Lee et al., 2019; Tramèr et al., 2016; Chandrasekaran et al., 2020) or sampling from a distribution over model parameters (Alabdulmohsin et al., 2014) will only slow but not prohibit model stealing. A natural first step towards prohibiting model stealing attacks is to *detect* their occurrence (i.e., monitor user queries). For example, Juuti et al. (2019) assume adversaries will make consecutive out-of-distribution queries and can thus be detected. Unfortunately, such a strategy may also flag benign users who make out-of-distribution queries.

Verifying Stolen Models An alternative to completely defending against model stealing is to at least *verify* that an adversary has stolen a model. For example, watermarking strategies (Zhang et al., 2018; Szyller et al., 2019; Krishna et al., 2020; Hisamoto et al., 2020) intentionally output incorrect responses for certain inputs and then tests if the suspected stolen model reproduces the mistakes. Unfortunately, these defenses can be subverted by finetuning the model (Chen et al., 2019).

Defending Against Adversarial Examples Aside from defending against model stealing, it is also vital to develop methods for defending against adversarial examples. Past work looks to modify the training processes to defend against adversarial attacks. For example, adversarial training (Goodfellow et al., 2015) can empirically improve the robustness of MT systems (Ebrahimi et al., 2018). Recently, Jia et al. (2019) and Huang et al. (2019) train NLP models which are provably robust to word replacements. Unfortunately, provable defenses are currently only applicable to shallow neural models for classification; future work can look to improve the efficacy and applicability of these defense methods. Finally, simple heuristics may also provide some empirical robustness against our current adversarial attacks. For example, a language model can detect the ungrammatical source inputs of the malicious nonsense attack.

F Angular Deviations Of Defense

Figure 4 shows a histogram of the angular deviations between $\mathbf{g}$ and $\tilde{\mathbf{g}}$.

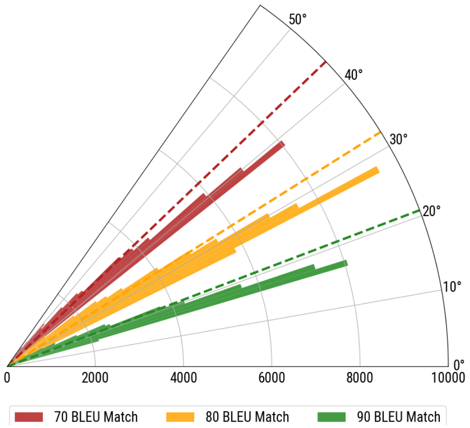

Figure 4: Our defense outputs the original $\mathbf{y}$ 71.1%, 62.3%, and 72.84% of the time for the 70, 80, and 90 BLEU thresholds, respectively. Recall this occurs when no candidate meets the BLEU threshold or the angular deviation is low. For the other cases, we plot the angular deviation (the $\arccos$ of the cosine similarity between $\mathbf{g}$ and $\tilde{\mathbf{g}}$).

G Adversarial Attack Screenshots

Abstract

Despite their empirical success, neural networks still have difficulty capturing compositional aspects of natural language. This work proposes a simple data augmentation approach to encourage compositional behavior in neural models for sequence-to-sequence problems. Our approach, *SeqMix*, creates new synthetic examples by softly combining input/output sequences from the training set. We connect this approach to existing techniques such as SwitchOut (Wang et al., 2018) and word dropout (Sennrich et al., 2016), and show that these techniques are all approximating variants of a single objective. SeqMix consistently yields approximately 1.0 BLEU improvement on five different translation datasets over strong Transformer baselines. On tasks that require strong compositional generalization such as SCAN and semantic parsing, SeqMix also offers further improvements.

1 Introduction

Natural language is thought to be characterized by *systematic compositionality* (Fodor and Pylyshyn, 1988). A computational model that is able to exploit such systematic compositionality should understand sentences by appropriately recombining subparts that have not been seen together during training. Consider the following example from Andreas (2020):

(1a) She picks the wug up in Fresno.

(1b) He puts the cup down in Tempe.

Given the above sentences, a model which has learned compositional structure should be able to generalize and understand sentences such as:

(2a) She puts the wug down in Fresno.

(2b) She picks the wug up in Tempe.

In practice, neural models often overfit to long segments of text and fail to generalize compositionally.

This work proposes a simple data augmentation strategy for sequence-to-sequence learning, *SeqMix*, which creates soft synthetic examples by randomly combining parts of two sentences. This prevents models from memorizing long segments and encourages models to rely on compositions of subparts to predict the output. To motivate our approach, consider some example sentences that can be created by combining (1a) and (1b) :

(2c) He picks the wug up in Fresno.

(2d) She picks the wug up in Tempe.

(2e) He picks the cup up in Fresno.

(2f) He puts the cup up in Fresno.

Instead of enumerating over all possible combinations of two sentences, SeqMix crafts a new example by *softly* mixing the two sentences via a convex combination of the original examples. This approach can be seen as a sequence-level variant of a broader family of techniques called mixed sample data augmentation (MSDA), which was originally proposed by Zhang et al. (2018) and has been shown to be particularly effective for classification tasks (DeVries and Taylor, 2017; Yun et al., 2019; Verma et al., 2019). We also show that SeqMix shares similarities with word replacement/dropout strategies in machine translation (Sennrich et al., 2016; Wang et al., 2018; Gao et al., 2019),

SeqMix targets a crude but simple approach to data augmentation for language applications. We apply SeqMix to a variety of sequence-to-sequence tasks including neural machine translation, semantic parsing, and SCAN (a dataset designed to test for compositionality of data-driven models), and find that SeqMix improves results on top of (and

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5547–5552,
November 16–20, 2020.

when combined with) existing data augmentation methods.

2 Motivation and Related Work

While neural networks trained on large datasets have led to significant improvements across a wide range of NLP tasks, training them to generalize by learning the compositional structure of language remains a challenging open problem. Notably, Lake and Baroni (2018) propose an influential dataset (SCAN) to evaluate the systematic compositionality of neural models and find that they often fail to generalize compositionally.

One approach to encouraging compositional behavior in neural models is by incorporating compositional structures such as parse trees or programs directly into a network's computational graph (Socher et al., 2013; Dyer et al., 2016; Bowman et al., 2016; Andreas et al., 2016; Johnson et al., 2017). While effective on certain domains such as visual question answering, these approaches usually rely on intermediate structures predicted from pipelined models, which limits their applicability in general. Further, it is an open question as to whether such putatively compositional models result in significant empirical improvements on many NLP tasks (Shi et al., 2018).

Expressive parameterizations over high dimensional input afforded by neural networks contribute to their excellent performance in high resource settings; however, such flexible parameterizations can easily lead to a model's memorizing—i.e., overfitting to—long segments of text, instead of relying on the appropriate subparts of segments. Another approach to encouraging compositionality in richly-parameterized neural models, then, is to augment the training data with more examples. Existing work in this vein include SwitchOut (Wang et al., 2018), which replaces a word in a sentence with a random word from the vocabulary, GECA (Andreas, 2020), which creates new examples by switching subparts that occur in similar contexts, and TMix (Chen et al., 2020), which interpolates between hidden states of neural models for text classification. We compare to these approaches to our proposed approach in this paper.

3 Method

Our proposed approach, SeqMix, is simple, and is essentially a sequence-level variant of MixUp (Zhang et al., 2018), which has primarily been used for image classification tasks (DeVries and Taylor, 2017; Yun et al., 2019). We first describe the generative data augmentation process behind this model for text generation, and show how SeqMix approximates the resulting latent variable objective with a relaxed version.

Let $X \in \mathbb{R}^{s\times V}$ represent a source sequence of length s with vocabulary size V and $Y \in \mathbb{R}^{t\times V}$ represent a target sequence to generate of length t. Assume that we sample a pair of training examples (X, Y) and (X', Y') from the training set, ensuring that both have the same length ($s = s'$, $t = t'$) by padding or truncation. We then sample a binary combination vector $m = [m_X, m_Y]$ with $m_X \in \{0,1\}^s$, $m_Y \in \{0,1\}^t$ to decide which token to use at each position. Each element m_i is sampled i.i.d from Bernoulli(λ), where the parameter λ is itself sampled from Beta(α, α), and α is hyperparameter. This gives a mixed synthetic example:

$$(\hat{X}, \hat{Y}) = (m_X \odot X + (1 - m_X) \odot X', \\ m_Y \odot Y + (1 - m_Y) \odot Y').$$

The new example pair of sentences $(\hat{X}, \hat{Y})$ will not correspond to natural sentences in general, but may contain valid subparts (phrases) that bias the model towards learning the compositional structure (as in the examples discussed in the introduction). Marginalizing over m gives the following log marginal likelihood,

$$\mathcal{L} = \mathop{\mathbb{E}}_{\substack{(X,Y)\sim D \\ (X',Y')\sim D'}} \left[\log \mathop{\mathbb{E}}_{m\sim p_\lambda(m)} p_\theta(\hat{Y}|\hat{X}) \right], \quad (1)$$

where $p_\lambda(m) = \prod_{i=1}^{s+t} p_\lambda(m_i)$ and D, D' are the example distributions. As exact marginalization in the above is intractable, we could target a lower bound, with Monte Carlo samples from $p_\lambda(m)$, resulting from Jensen's inequality,

$$\mathcal{L} \geq \mathop{\mathbb{E}}_{\substack{(X,Y)\sim D \\ (X',Y')\sim D'}} \left[\mathop{\mathbb{E}}_{m\sim p_\lambda(m)} \log p_\theta(\hat{Y}|\hat{X}) \right], \quad (2)$$

An alternative, which we refer to as SeqMix, is to consider a soft variant of the original objective by training on *expected* samples,

$$(\mathbb{E}[\hat{X}], \mathbb{E}[\hat{Y}]) = (\lambda X + (1 - \lambda)X', \\ \lambda Y + (1 - \lambda)Y').$$

Letting $f_\theta(X, Y_{<t})$ be the output of the $\log\text{-softmax}$ layer, the local probability of Y_t

Method	Intuition	Combination vector $m \sim p_\lambda(m)$	$(x', y') \sim D'$	Relaxed
WordDrop	*Drop words at random*	Fixed hyperparameter ρ, $p_\lambda(m_i)$ $m_i \sim p_\lambda(m_i) \propto \text{Bernoulli}(1-\rho)$	$D' =$ zero vectors	N
SwitchOut	*Random words by position*	$\lambda \sim p(\lambda) \propto e^{-\lambda/\eta}$, $\lambda = \{0, \cdots, s\}$, $m_i \sim p_\lambda(m_i) \propto \text{Bernoulli}(1-\lambda/s)$	$D' =$ vocabulary	N
GECA	*Enumerate valid swaps*	$x_{i:j} = x'_{i':j'}$ if $x_{i:j}$ and $x'_{i':j'}$ is a valid swap (i.e. co-occurs in context)	$D' =$ training	N
SeqMix (Hard)	*Random hard swaps*	$\lambda \sim \text{Beta}(\alpha, \alpha)$, $m_i \sim p_\lambda(m_i) \propto \text{Bernoulli}(\lambda)$	$D' =$ training	N
SeqMix	*Random soft swaps*	$\lambda \sim \text{Beta}(\alpha, \alpha)$, $p_\lambda(m_i) \propto \text{Bernoulli}(\lambda)$, $m_i = \mathbb{E}[m_i] = \lambda$	$D' =$ training	Y

Table 1: Methods including GECA (Andreas, 2020), SwitchOut (Wang et al., 2018), and Word Dropout.

is given by $\log p_\theta(Y_t|X, Y_{<t}) = Y_t^\top f_\theta(X, Y_{<t})$. SeqMix then trains on the objective,

$$\mathcal{L} \approx \mathop{\mathbb{E}}_{\substack{(X,Y)\sim D \\ (X',Y')\sim D'}} \left[\sum_{t=1}^{T} \mathbb{E}[\hat{Y}_t]^\top f_\theta \left(\mathbb{E}[\hat{X}], \mathbb{E}[\hat{Y}_{<t}] \right) \right] \tag{3}$$

To summarize, this results in a simple algorithm where we sample $\lambda \sim \text{Beta}(\alpha, \alpha)$ and train on these expected samples.[1]

Relationship to Existing Methods Table 1 shows that we can recover existing data augmentation methods such as SwitchOut and word dropout under the above framework. In particular, these methods approximate a version of the "hard" latent variable objective in Eq. 2 by considering different swap distributions $p(m)$ and sampling distributions D'.[2] Compared to other approaches, SeqMix is essentially a relaxed variant of the same objective, similar to the difference between soft vs. hard attention (Xu et al., 2015; Deng et al., 2018; Wu et al., 2018; Shankar et al., 2018). SeqMix is also more efficient than more sophisticated augmentation strategies such as GECA which requires a computationally expensive validation check for swaps.

4 Experimental Setup

We test our approach against existing baselines across a variety of sequence-to-sequence tasks: machine translation, SCAN, and semantic parsing. For all datasets, we tune the α hyperparameter in the range of $[0.1, 1.5]$ on the validation set.[3] Exact details regarding the training setup (including descriptions of the various datasets) can be found in the supplementary materials.

Machine Translation Our machine translation experiments consider five translation datasets: (1) IWSLT '14 German-English (`de-en`) (2) IWSLT '14 English-{German, Italian, Spanish} (`en-{de, it, es}`) (3) WMT '14 English-German (`en-de`). We use the Transformer implementation from `fairseq` (Ott et al., 2019) with the default configuration.

SCAN SCAN is a command execution dataset designed to test for systematic compositionality of data-driven models. SCAN consists of simple English commands and corresponding action sequences. We consider three different splits that have been widely utilized in the existing literature: `jump, around-right, turn-left`. For the splits (`jump, turn-left`), the primitive commands (i.e. "jump", "turn left") are only seen in isolation during training, and the test set consists commands that compose the isolated primitive command with the other commands seen during training. For the template split (`around-right`), training examples contain the commands "around" and "right" but never in combination. Following

---

[1] Our implementation can be found at `https://github.com/dguo98/seqmix`, and pseudocode can be found in supplementary materials.

[2] Wang et al. (2018) also offer an alternative formulation which unifies various data augmentation strategies as training on a distribution that better approximates the underlying data distribution. While the hard version of SeqMix can also be unified under SwitchOut's resulting objective, we chose our alternative formulation given its natural extension to the relaxed version.

[3] However we observed the final result to be relatively invariant to α and found that setting $\alpha = 1$ usually achieves good results.

"➪" = "turn right", "🏃" = "jump", "🚶" = "walk", and "👁" = "look". To "jump right", one needs to first turn to the right and then jump.

previous work (Andreas, 2020), we use a one-layer LSTM encoder-decoder model with hidden size of 512 and embedding size of 64.

Semantic Parsing For semantic parsing, we consider the SQL queries subset of `GeoQuery` (Finegan-Dollak et al., 2018), which consists of 880 English questions paired with SQL commands. The standard `question` split ensures no questions are repeated between the train and test sets, while the more challenging `query` split ensures that neither questions nor logical forms (anonymized) are repeated. Following Andreas (2020), we use the same model as for SCAN but additionally introduce a copy mechanism.

5 Results and Analysis

Table 2 shows the results from SeqMix and the relevant baselines. On all datasets, SeqMix consistently improves over SwitchOut and word dropout (WordDrop). For machine translation, SeqMix achieves around 1 BLEU score gain on IWSLT over strong baselines, and these gains persist on WMT which is an order of magnitude larger. On SCAN and semantic parsing, SeqMix does not perform as well as GECA on its own but does well when combined with GECA.

5.1 Analysis on SCAN

We perform further analysis on the SCAN dataset, which is explicitly designed to test for compositional generalization. Table 2 shows that without GECA, the baseline seq2seq model and other regularization methods such as WordDrop and SwitchOut completely fails on the `jump` split, while SeqMix can achieve 49% accuracy. Similarly, SeqMix can boost the performance on the `turn-left` split from 49% to 99% in contrast to SwitchOut and WordDrop.

The fact that SeqMix can improve over simple regularization methods (such as WordDrop) even without GECA indicates that despite its crudity, SeqMix is somewhat effective at biasing models to learn the appropriate compositional structure. However, these results on SCAN also highlight its limitations: SeqMix fails on the difficult `around-right` split, where the model has to learn combine "around" with "right" even though they are not encountered together in training, and does not outperform more sophisticated data augmentation strategies such as GECA (Andreas, 2020).

In Table 3, we show a qualitative example in the `jump` split of SCAN dataset. Recall that the `jump` split of SCAN is constructed to test the generalization of primitive “jump” in novel contexts. Given train examples such as *jump; walk; walk left; look after walk twice*, the model demonstrates compositionality if it is able to correctly process test examples such as *jump left; look after jump twice*, i.e. generalize the understanding of isolated `jump` to unseen combinations with `jump`. As shown in Table 3, only SeqMix successfully exhibits this compositional generalization.

6 Conclusion

This paper presents SeqMix, a simple data augmentation strategy for sequence-to-sequence applications. Despite being a crude approximation to compositional phenomena in language, we found SeqMix to be effective on three different sequence-to-sequence tasks, including the challenging SCAN dataset which is designed to test for compositional generalization. SeqMix is efficient and easy to implement, and as a secondary contribution, we provide a framework that unifies several data augmentation strategies for compositionality, which naturally suggests avenue for future research (e.g., a relaxed variant of GECA).

Abstract

Despite strong performance on a variety of tasks, neural sequence models trained with maximum likelihood have been shown to exhibit issues such as length bias and degenerate repetition. We study the related issue of receiving infinite-length sequences from a recurrent language model when using common decoding algorithms. To analyze this issue, we first define inconsistency of a decoding algorithm, meaning that the algorithm can yield an infinite-length sequence that has zero probability under the model. We prove that commonly used incomplete decoding algorithms – greedy search, beam search, top-k sampling, and nucleus sampling – are inconsistent, despite the fact that recurrent language models are trained to produce sequences of finite length. Based on these insights, we propose two remedies which address inconsistency: consistent variants of top-k and nucleus sampling, and a self-terminating recurrent language model. Empirical results show that inconsistency occurs in practice, and that the proposed methods prevent inconsistency.

1 Introduction

Neural sequence models trained with maximum likelihood estimation (MLE) have become a standard approach to modeling sequences in a variety of natural language applications such as machine translation (Bahdanau et al., 2015), dialogue modeling (Vinyals et al., 2015), and language modeling (Radford et al., 2019). Despite this success, MLE-trained neural sequence models have been shown to exhibit issues such as length bias (Sountsov and Sarawagi, 2016; Stahlberg and Byrne, 2019) and degenerate repetition (Holtzman et al., 2019). These issues are suspected to be related to the maximum likelihood objective's local normalization, which results in a discrepancy between the learned model's distribution and the distribution induced by the decoding algorithm used to generate sequences (Lafferty et al., 2001; Andor et al., 2016). This has prompted the development of alternative decoding methods (Wu et al., 2016; Holtzman et al., 2019) and training objectives (Murray and Chiang, 2018; Welleck et al., 2019). In this paper, we formalize and study this discrepancy between the model and the decoding algorithm.

We begin by formally defining *recurrent neural language models*, a family that encompasses neural models used in practice, such as recurrent neural networks (Elman, 1990; Cho et al., 2014; Hochreiter and Schmidhuber, 1997), and transformers (Vaswani et al., 2017). Next, we formally define a decoding algorithm – a function that induces a distribution over sequences given a recurrent language model and a context distribution – which is used to obtain probable sequences from a model. In this paper, we show that the distribution induced by a decoding algorithm can contradict this intended use; instead, the decoding algorithm may return improbable, infinite-length sequences.

Our main finding is that a sequence which receives zero probability under a recurrent language model's distribution can receive nonzero probability under the distribution induced by a decoding algorithm. This occurs when the recurrent language model always ranks the sequence termination token outside of the set of tokens considered at each decoding step, yielding an infinite-length, zero probability sequence. This holds whenever the decoding algorithm is *incomplete*, in the sense that the algorithm excludes tokens from consideration at each step of decoding, which is the case for common methods such as greedy search, beam search, top-k sampling (Fan et al., 2018), and nucleus sampling

(Holtzman et al., 2019). We formalize our main finding using the notion of *consistency* (Chen et al., 2017) – whether a distribution assigns probability mass only to finite sequences – and prove that a consistent recurrent language model paired with an incomplete decoding algorithm can induce an inconsistent sequence distribution.

Based on the insight that inconsistency occurs due to the behavior of the termination token under incomplete decoding, we develop two methods for addressing inconsistency. First, we propose *consistent sampling methods* which guarantee that the termination token is not excluded from selection during decoding. Second, we introduce a *self-terminating recurrent language model* which ensures that the termination token is eventually ranked above all others, guaranteeing consistency under incomplete decoding.

To empirically measure inconsistency, we decode sequences from trained recurrent language models and measure the proportion of sequences with lengths far exceeding the maximum training sequence length. Our experiments on the Wikitext2 dataset (Merity et al., 2016) suggest that inconsistency occurs in practice when using incomplete decoding methods, while the proposed consistent sampling methods and self-terminating model parameterization prevent inconsistency and maintain language modeling quality.

The theoretical analysis reveals defects of existing decoding algorithms, providing a way to develop future models, inference procedures, and learning algorithms. We present methods related to sampling and model parameterization, but there are more directions for future investigation; we close with directions related to sequence-level learning.

2 Background

We begin our discussion by establishing background definitions. First, we define a sequence which is the main object of our investigation.

Definition 2.1 (Sequence). *A sequence Y is an ordered collection of items from a predefined finite vocabulary V. A sequence of finite length always ends with a special token $\langle eos \rangle \in V$ that only appears at the end of a sequence.*

Each model we consider generates a sequence conditioned on context information, such as a prefix in sentence completion. To consider this, we define a context distribution.

Definition 2.2 (Context distribution). *A context distribution $p(C)$ is a probability distribution defined over a set $\mathcal{C}$. An element $C \in \mathcal{C}$ is called a context.*

2.1 Recurrent Language Models

A recurrent language model is an autoregressive model of a sequence distribution, where each conditional probability is parameterized with a neural network. Importantly, we assume that all tokens in a sequence are dependent on each other under a recurrent language model. This allows us to avoid cases in which the model degenerates to a Markovian language model, such as an n-gram model with a finite n.

Definition 2.3 (Recurrent language model). *A recurrent language model p_θ is a neural network that computes the following at each time step:*

$$p_\theta(y_t = v \,|\, y_{<t}, C) = \frac{\exp(u_v^\top h_t + c_v)}{\sum_{v' \in V} \exp(u_{v'}^\top h_t + c_{v'})},$$

where $h_t = f_\theta(y_t, h_{t-1})$ and $h_0 = g_\theta(C)$, and u, c, θ are parameters. A recurrent language model thereby computes the probability of a sequence $Y = (y_1, \ldots, y_T)$ by

$$p_\theta(Y \,|\, C) = \prod_{t=1}^{T} p_\theta(y_t \,|\, y_{<t}, C),$$

where $y_{<t} = (y_1, \ldots, y_{t-1})$. This distribution satisfies $y_i \not\perp\!\!\!\perp y_j \,|\, C, \;\; \forall i < j$.

Practical variants of the recurrent language model differ by the choice of transition function f_θ (Elman, 1990; Hochreiter and Schmidhuber, 1997; Cho et al., 2014; Vaswani et al., 2017). The use of softmax (Bridle, 1990) implies that every unique token in the vocabulary is considered at every location of a sequence.

Remark 2.1. *Under the conditional distribution of a recurrent LM, every token $v \in V$ is assigned a positive probability, implying that $0 < p_\theta(v \,|\, y_{<t}, C) < 1$. Any finite sequence is probable under a recurrent LM under any context, i.e., $p_\theta(Y \,|\, C) > 0$ for any sequence Y of finite length.*

2.2 Decoding Algorithms

Because it is intractable to decode the most probable sequence, it is necessary in practice to use an approximate decoding algorithm.

Definition 2.4 (Decoding algorithm). *A decoding algorithm $\mathcal{F}(p_\theta, C)$ is a function that generates* *a sequence $\tilde{Y}$ given a recurrent language model p_θ and context C. Let $q_{\mathcal{F}}$ denote the distribution induced by the decoding algorithm $\mathcal{F}$.*

We consider two families of decoding algorithms. In our analysis we only consider algorithms that decode in a single pass, forward in time, without modifying previously selected tokens.

Stochastic decoding. The first family consists of stochastic algorithms. Among them, ancestral sampling is asymptotically unbiased and can be used for finding the most probable sequence, although with high variance.

Definition 2.5 (Ancestral sampling)**.** *Ancestral sampling $\mathcal{F}_{anc}$ generates a sequence from a recurrent language model p_θ given context C by recursively sampling from $p_\theta(y_t \,|\, \tilde{y}_{<t}, C)$ until $\tilde{y}_t = \langle eos\rangle$: $\tilde{y}_t \sim p_\theta(y_t \,|\, \tilde{y}_{<t}, C)$.*

To avoid the high variance, two approximate stochastic decoding algorithms have recently been proposed and tested with recurrent language models. Top-k sampling considers only a subset of the k most probable tokens from the vocabulary at a time, while nucleus sampling considers only the minimal subset of most probable tokens whose total probability is higher than a predefined threshold.

Definition 2.6 (Top-k sampling (Fan et al., 2018))**.** *Top-k sampling $\mathcal{F}_{top\text{-}k}$ generates a sequence from a recurrent language model p_θ given context C by recursively sampling from:*

$$q(v) \propto \begin{cases} p_\theta(v \,|\, y_{<t}, C), & \textit{if } v \in V_k, \\ 0, & \textit{otherwise}. \end{cases}$$

where $V_k = \arg \underset{v'}{\textit{top-}k}\, p_\theta(v' \,|\, y_{<t}, C)$.

Definition 2.7 (Nucleus sampling (Holtzman et al., 2019))**.** *Nucleus sampling $\mathcal{F}_{nuc\text{-}\mu}$ generates a sequence from a recurrent language model p_θ given context C by recursively sampling from the following proposal distribution. Let $v_1, \ldots, v_{|V|}$ denote tokens in V such that $p_\theta(v_i \,|\, y_{<t}, C) \geq p_\theta(v_j \,|\, y_{<t}, C)$ for all $i < j$, and define*

$$q(v) \propto \begin{cases} p_\theta(v \,|\, y_{<t}, C), & \textit{if } v \in V_\mu, \\ 0, & \textit{otherwise}, \end{cases}$$

where $V_\mu = \{v_1, \cdots, v_{k_\mu}\}$ with

$$k_\mu = \min \left\{ k \;\middle|\; \sum_{i=1}^{k} p_\theta(v_i \,|\, y_{<t}, C) > \mu \right\}.$$

Deterministic decoding. The other family consists of deterministic decoding algorithms, where a token is selected deterministically according to a rule at each decoding step. The most naive algorithm, called greedy decoding, simply takes the most probable token at each step.

Definition 2.8 (Greedy decoding)**.** *Greedy decoding $\mathcal{F}_{greedy}$ generates a sequence from a recurrent language model p_θ given context C by recursively selecting the most likely token from $p_\theta(y_t | \tilde{y}_{<t}, C)$ until $\tilde{y}_t = \langle eos\rangle$:*

$$\tilde{y}_t = \arg\max_{v \in V} \log p_\theta(y_t = v \,|\, \tilde{y}_{<t}, C).$$

In contrast to greedy decoding, *beam search* with width k, $\mathcal{F}_{\text{beam-k}}$, operates on the level of partial sequences or prefixes. Starting from a set of empty prefixes, at each iteration a new prefix set is formed by expanding each prefix with each possible token, then choosing the k highest scoring expanded prefixes; refer to Appendix A for a formal definition.

Incompleteness. Other than ancestral sampling, the decoding algorithms above are *incomplete* in that they only consider a strict subset of the full vocabulary V at each time step, aside from the trivial case of $k = |V|$.[1]

Definition 2.9 (Incomplete Decoding)**.** *A decoding algorithm $\mathcal{F}$ is incomplete when for each context C and prefix $y_{<t}$, there is a strict subset $V'_t \subsetneq V$ such that*

$$\sum_{v \in V'_t} q_{\mathcal{F}}(y_t = v \,|\, y_{<t}, C) = 1.$$

3 Consistency of a Decoding Algorithm

Definition of consistency. A recurrent language model p_θ may assign a positive probability to an infinitely long sequence, in which case we call the model inconsistent. This notion of consistency was raised and analyzed earlier, for instance by Booth and Thompson (1973) and Chen et al. (2017), in terms of whether the distribution induced by p_θ is concentrated on finite sequences. We extend their definition to account for the context C.

Definition 3.1 (Consistency of a recurrent language model)**.** *A recurrent language model is consistent under a context distribution $p(C)$ if $p_\theta(|Y| = \infty) = 0$. Otherwise, the recurrent language model is said to be inconsistent.*

---

[1] Nucleus sampling is incomplete when for every context C and prefix $y_{<t}$, $\min_{v \in V} p_\theta(v | y_{<t}, C) < 1 - \mu$.

Any sequence decoded from a consistent model for a given context is guaranteed to terminate.

Lemma 3.1. *If a recurrent LM p_θ is consistent, $p_\theta(|Y| = \infty \mid C)$ = 0 for any probable context C.*[2]

Next, we establish a practical condition under which a recurrent language model is consistent.

Lemma 3.2. *A recurrent LM p_θ is consistent if $\|h_t\|_p$ is uniformly bounded for some $p \geq 1$.*

Proof sketch. If $\|h_t\|_p$ is bounded, then each $u_v^\top h_t$ is bounded, hence $p_\theta(\langle \text{eos} \rangle \,|y_{<t}, C) > \xi > 0$ for a constant ξ. Thus $p_\theta(|Y| = \infty) \leq \lim_{t\to\infty}(1 - \xi)^t = 0$, meaning that p_θ is consistent. □

Although this condition is practical because layer normalization or bounded activation functions (Elman, 1990; Cho et al., 2014; Vaswani et al., 2017) result in bounded h_t, we show that even if a recurrent language model is consistent, a decoding algorithm may produce an infinite-length sequence. We formalize this discrepancy using the consistency of a decoding algorithm.

Definition 3.2 (Consistency of a decoding algorithm)**.** *A decoding algorithm $\mathcal{F}$ is consistent with respect to a consistent recurrent language model p_θ under a context distribution $p(C)$ if the decoding algorithm $\mathcal{F}$ preserves the consistency of the model p_θ, that is, $q_\mathcal{F}(|Y| = \infty) = 0$.*

When a consistent recurrent language model p_θ and a decoding algorithm $\mathcal{F}$ induce a consistent distribution $q_\mathcal{F}$, we say that p_θ paired with $\mathcal{F}$ is consistent. For instance, any consistent recurrent language model paired with ancestral sampling is consistent, because the induced distribution $q_{\mathcal{F}_\text{anc}}$ is the same as the distribution of the original model. We also have an analogue of Lemma 3.1.

Lemma 3.3. *A consistent decoding algorithm with respect to a consistent recurrent LM decodes only probable sequences. That is, if $q_\mathcal{F}(Y \mid C) > 0$, then $p_\theta(Y \mid C) > 0$ for any probable context C.*

Inconsistency of incomplete decoding. Any incomplete decoding algorithm (Definition 2.9) can be inconsistent regardless of the context distribution, because there is a recurrent LM that places $\langle \text{eos} \rangle$ outside of V'_t at every step of decoding. To show this, we construct a consistent recurrent language model whose distribution induced by an incomplete decoding algorithm is inconsistent.

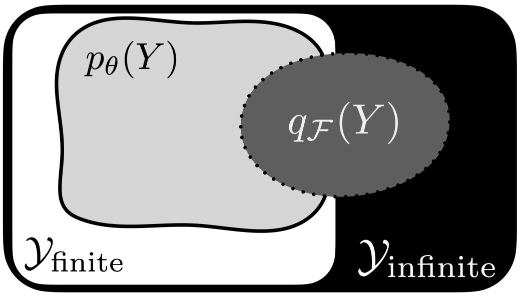

Figure 1: A depiction of the model's sequence distribution (light grey, solid border) and the decoder's induced sequence distribution (dark grey, dotted border). The white and black rectangles depict the set of all finite and infinite sequences, respectively. We prove that under practical conditions, any incomplete decoding algorithm may be inconsistent with respect to a consistent model, as depicted.

Theorem 3.4 (Inconsistency of an incomplete decoding algorithm)**.** *There exists a consistent recurrent LM p_θ from which an incomplete decoding algorithm $\mathcal{F}$, that considers only up to $(|V| - 1)$-most likely tokens according to $p_\theta(y_t \mid y_{<t}, C)$ at each step t, finds an infinite-length sequence $\tilde{Y}$ with probability 1, i.e., $q_\mathcal{F}(|Y| = \infty) = 1$.*

Proof. We prove this theorem by constructing a tanh recurrent network. We define the recurrent function f_θ as

$$\begin{aligned} h_t &= f_\theta(y_t, h_{t-1}) \\ &= \tanh\left(\left[\begin{array}{c|c} W_h & \mathbf{0} \\ \hline \mathbf{0} & I \end{array}\right] h_{t-1} + \left[\begin{array}{c} \mathbf{0} \\ \hline e(y_t) \end{array}\right]\right), \end{aligned}$$

where $e(y_t) \in \mathbb{R}^{|V|}$ is a one-hot representation of y_t, $W_h \in \mathbb{R}^{d\times d}$ where every entry is positive, and I is an identity matrix of size $|V| \times |V|$. $h_0 = g_\theta(C)$ is constructed to consist of positive values only. Because each element of $|h_t|$ is bounded by 1, the constructed recurrent language model p_θ is consistent by Lemma 3.2.

We set u_v (see Definition 2.3) to

$$u_v = \left[\begin{array}{c} \bar{u}_v \\ \hline e(v) \end{array}\right], \quad u_{\langle \text{eos} \rangle} = \left[\begin{array}{c} \bar{u}_{\langle \text{eos} \rangle} \\ \hline e(\langle \text{eos} \rangle) \end{array}\right],$$

where $v \neq \langle \text{eos} \rangle$, all elements of $\bar{u}_v$ are positive, all elements of $\bar{u}_{\langle \text{eos} \rangle}$ are negative, and $e(v)$ is a one-hot representation of v. c_v is set to zero.

This defines a valid recurrent language model (Definition 2.3), since the conditional distribution at each time t is influenced by all the previous tokens. More specifically, the logit of a token v

---

[2] Proofs of Lemmas 3.1-3.3 are in Appendix B.

depends on $\sum_{t'=1}^{t} \mathbb{1}(y_{t'} = v)$, where $\mathbb{1}$ is an indicator function.

This recurrent language model always outputs positive logits for non-$\langle\text{eos}\rangle$ tokens, and outputs negative logits for the $\langle\text{eos}\rangle$ token. This implies $p(\langle\text{eos}\rangle \mid y_{<t}, C) < p(v \mid y_{<t}, C)$ for all $v \in V \backslash \{\langle\text{eos}\rangle\}$. This means that $\langle\text{eos}\rangle$ is always ranked last at each time step, so an incomplete decoding algorithm that considers at most $(|V| - 1)$ most probable tokens at each time step from $p_\theta(y_t \mid y_{<t}, C)$ cannot decode $\langle\text{eos}\rangle$ and thus always decodes an infinitely long sequence $\hat{Y}$, i.e., $q_{\mathcal{F}}(|Y| = \infty \mid C) = 1$ for any context C. It yields $q_{\mathcal{F}}(|Y| = \infty) = 1$, while $p_\theta(|Y| = \infty) = 0$ due to consistency of the model p_θ. $\square$

Greedy decoding, beam search, top-k sampling, and nucleus sampling are all inconsistent according to this theorem.

4 Fixing the inconsistency

In this section, we consider two ways to prevent inconsistency arising from incomplete decoding algorithms. First, we introduce consistent versions of top-k and nucleus sampling. Second, we introduce the *self-terminating recurrent language model*, which is consistent when paired with any of the decoding algorithms considered in this paper.

4.1 Consistent Sampling Algorithms

The proof of Theorem 3.4 suggests that the inconsistency of incomplete decoding algorithms arises from the fact that $\langle\text{eos}\rangle$ may be excluded indefinitely from the set of top-ranked tokens. We propose a simple modification to top-k and nucleus sampling that forces $\langle\text{eos}\rangle$ to be included at each step of decoding. First, we give a condition for when a particular model p_θ paired with a decoding algorithm $\mathcal{F}$ is consistent.

Theorem 4.1. *Suppose a recurrent LM p_θ has uniformly bounded $\|h_t\|_p$ for some $p \geq 1$. If a decoding algorithm $\mathcal{F}$ satisfies $q_{\mathcal{F}}(\langle eos\rangle \mid y_{<t}, C) \geq p_\theta(\langle eos\rangle \mid y_{<t}, C)$ for every prefix $y_{<t}$ and context C, then the decoding algorithm $\mathcal{F}$ is consistent with respect to the model p_θ.*[3]

We define consistent variants of top-k and nucleus sampling which satisfy this condition.

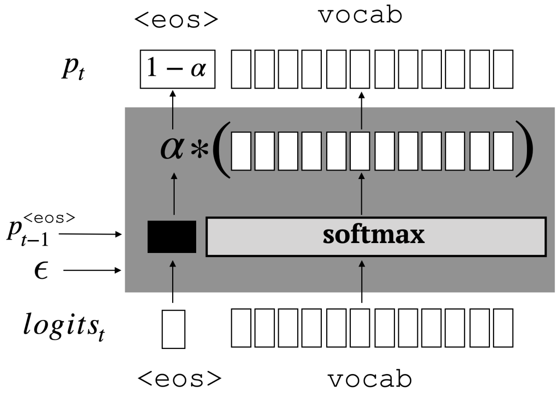

Figure 2: The self-terminating recurrent LM uses the layer shown in grey instead of the standard softmax layer. The layer takes logits ($u_{\cdot}^{\top} h_t$), the previous step's $\langle\text{eos}\rangle$ probability ($p_{t-1}^{\langle\text{eos}\rangle}$), and a hyper-parameter $\epsilon \in (0, 1)$. The layer computes α using Definition 4.3, which determines the $\langle\text{eos}\rangle$ probability ($p_t^{\langle\text{eos}\rangle} \in (\epsilon, 1)$), and guarantees that $p_t^{\langle\text{eos}\rangle} > p_{t-1}^{\langle\text{eos}\rangle}$. The remaining probability mass is allocated to the non-$\langle\text{eos}\rangle$ tokens.

Definition 4.1 (Consistent top-k sampling)**.** *Consistent top-k sampling is top-k sampling with the following modified proposal distribution:*

$$q(v) \propto \begin{cases} p_\theta(v|y_{<t}, C), & \textit{if } v \in V', \\ 0, & \textit{otherwise}, \end{cases}$$

where $V' = \{\langle eos\rangle\} \cup \arg \underset{v'}{\textit{top-k}}\, p_\theta(v' \mid y_{<t}, C)$.

Definition 4.2 (Consistent nucleus sampling)**.** *Consistent nucleus sampling is nucleus sampling with the following modified proposal distribution:*

$$q(v) \propto \begin{cases} p_\theta(v \mid y_{<t}, C), & \textit{if } v \in V_\mu \cup \{\langle eos\rangle\}, \\ 0, & \textit{otherwise}. \end{cases}$$

The induced probability of $\langle\text{eos}\rangle$ under these two algorithms is always equal to or larger than the model's probability. By Theorem 4.1, these algorithms are consistent with respect to any consistent recurrent language model.

4.2 Self-Terminating Recurrent LM

Although these consistent sampling algorithms can be used with any recurrent language model, their stochastic nature may not be suitable for finding a single, highly probable sequence. To avoid this limitation, we propose the *self-terminating recurrent language model* (STRLM).

Definition 4.3 (Self-terminating recurrent language model)**.** *A self-terminating recurrent language model computes the following conditional*

---

[3] See Appendix C for the proof.

probability at each time step:

$$p_\theta(v \,|\, y_{<t}, C) = \begin{cases} 1 - \alpha(h_t), & v = \langle eos \rangle\,, \\ \frac{\alpha(h_t) \exp(u_v^\top h_t + c_v)}{\sum_{v' \in V'} \exp(u_{v'}^\top h_t + c_{v'})}, & \end{cases}$$

$$\alpha(h_0) = \sigma(u_{\langle eos \rangle}^\top h_0),$$

$$\alpha(h_t) = \sigma(u_{\langle eos \rangle}^\top h_t)\,[1 - p_\theta(\langle eos \rangle \,| y_{<t-1}, C)]\,,$$

with $\sigma : \mathbb{R} \to [0, 1 - \varepsilon]$ *and* $\varepsilon \in (0,1)$*.* h_t *is computed as in the original recurrent LM.*

The underlying idea is that the probability of ⟨eos⟩ increases monotonically, since

$$p_t^{\langle \text{eos} \rangle} = 1 - \prod_{t'=0}^{t} \sigma(u_{\langle \text{eos} \rangle}^\top h_{t'}).$$

Consequently, the STRLM is consistent when paired with greedy decoding or beam search; see Appendix C for formal statements and proofs.

5 Empirical Validation

The theoretical results rely on the existence of a model that results in inconsistency; it remains to be shown that inconsistency with respect to incomplete decoding occurs with recurrent language models encountered in practice. Moreover, while the proposed methods carry theoretical guarantees in terms of consistency, we must check whether they retain language modeling quality. To do so, we perform experiments using a sequence completion task. In each experiment, we use the beginning of a sequence as context, then decode continuations from a trained recurrent LM and measure the proportion of non-terminated sequences in order to approximately measure inconsistency. The first experiment (§5.1) shows that inconsistency occurs in practice, and the second experiment (§5.2) shows the effectiveness of the proposed approaches. Our third experiment (§5.3) shows that inconsistency also occurs frequently in GPT-2, a large-scale transformer language model.[4]

Sequence completion. We evaluate recurrent language models on a sequence completion task, which has previously been used to evaluate the effectiveness of sequence models, e.g., Sutskever et al. (2011); Graves (2013); Radford et al. (2019); Holtzman et al. (2019); Welleck et al. (2019). Sequence completion is a general setting for studying the behavior of language models, encompassing machine translation (Bahdanau et al., 2015), story generation (Fan et al., 2018), and dialogue modeling (Vinyals et al., 2015). The task consists of decoding a continuation $\hat{Y} \sim \mathcal{F}(p_\theta, C)$ given a length-k prefix $C = (c_1, \ldots, c_k)$, resulting in a completion $(c_1, \ldots, c_k, \hat{y}_1 \ldots, \hat{y}_T)$.

Dataset. Our first two experiments use Wikitext2 (Merity et al., 2016), which consists of paragraphs from English Wikipedia, since it has frequently been used to evaluate language models (Grave et al., 2017; Melis et al., 2018; Merity et al., 2018). We consider both word and BPE[5] tokenization. We split each paragraph into sentences using Spacy[6]. We split each sequence, using the first k tokens as a context and the remaining tokens as a continuation. To ensure that each sequence contains a prefix, we prepend padding tokens to make it length k. Special ⟨bos⟩ and ⟨eos⟩ tokens are inserted at the beginning and end of each sequence. We use $k = 10$. Table 7 contains dataset statistics.

Context distribution. We define empirical context distributions with prefixes from the train, valid, and test sets: $p(C; \mathcal{D}) = \frac{1}{|\mathcal{D}|} \sum_{n=1}^{|\mathcal{D}|} \mathbb{1}(C = C^{(n)})$, where $\mathcal{D} = \{(C^{(n)}, Y^{(n)})\}_{n=1}^{N}$ is a dataset split.

Evaluation metrics. We use finite sequences to approximately measure the consistency of a model paired with a decoding algorithm, since decoding an infinite-length sequence is impossible. We use the proportion of decoded continuations that are longer than a predefined limit,

$$r_L = \frac{1}{|\mathcal{D}|} \sum_{n=1}^{|\mathcal{D}|} \mathbb{1}(|\hat{Y}^{(n)}| \geq L),$$

where $\hat{Y}^{(n)} \sim \mathcal{F}(p_\theta, C^{(n)})$ for each context $C^{(n)}$ in $\mathcal{D}$. We call r_L the *non-termination ratio* of the decoding algorithm $\mathcal{F}$ for an underlying model and context distribution. A value of r_L greater than zero means that some sequences did not terminate within L steps. When L is infinity, this implies that the model paired with the decoding algorithm is inconsistent. In practice, we use a finite L that is substantially larger than the maximum training sequence length, and we interpret a non-zero r_L as evidence that the model paired with the decoding algorithm is inconsistent. We use $L = 1500$, more than 10 times the max training sequence length.

---

[4] Code available at `https://github.com/uralik/consistency-lm`.

[5] `github.com/huggingface/tokenizers`

[6] `https://spacy.io/`

In each experiment, we report the mean and standard deviation of metrics across 10 independent initializations. Unless specified otherwise, we report metrics using the test context distribution, since the train, valid, and randomly generated context distributions had similar results.

Training. We train recurrent language models for sequence completion with maximum likelihood, using the loss $\mathcal{L}(p_\theta, Y) = -\sum_{t=1}^{T} \log p_\theta(y_t \mid y_{<t}, c_1, \ldots, c_k)$, where $Y = (c_1, \ldots, c_k, y_1, \ldots, y_T)$. This amounts to running the full training sequence through a recurrent model and zeroing the loss for the first k tokens, so that the first k steps correspond to learning a g_θ that encodes the context.

Models. We consider recurrent neural networks with hyperbolic tangent activations ($\tanh$-RNN; Elman, 1990) and LSTM units (LSTM-RNN; Hochreiter and Schmidhuber, 1997). We perform an initial hyper-parameter sweep and select the best set of hyper-parameters for each of $\tanh$-RNN and LSTM-RNN based on the validation perplexities.[7] With this best set of hyperparameters, we train each of these models with 10 different initializations. The choice of $\tanh$ and LSTM RNNs implies that all of the recurrent language models that we train are consistent according to Lemma 3.2. Our LSTM models achieve similar test perplexity (91.86 ± 0.4, word tokenization) to those reported in previous work (Merity et al., 2018); see Appendix D.

Additionally, we train self-terminating $\tanh$-RNN and LSTM-RNN variants (Definition 4.3) at various values of ε, which controls a lower bound on the termination probability at each step. We use $\sigma(x) = (1 - \varepsilon) \cdot \text{sigmoid}(x)$. We use the hyper-parameters selected in the preceding grid search. Below, we consider BPE tokenization; similar conclusions held for word tokenization.[8]

5.1 Inconsistency of Recurrent LMs

In this experiment, we demonstrate evidence of inconsistency with incomplete decoding methods. Table 1 shows non-termination ratios for the recurrent language models using the decoding algorithms considered in this work. Decoding with ancestral sampling always resulted in sequences that terminated within L steps, since the induced distribution is the same as that of the consistent model. On the other hand, the non-zero non-termination ratios for the incomplete decoding algorithms suggest inconsistency with respect to each algorithm, providing evidence for Theorem 3.4.

	$\tanh$-**RNN**	**LSTM-RNN**

consistent nucleus-0.4	0.02 ± 0.02	0.01 ± 0.01

Table 1: Non-termination ratio (r_L (%)) of decoded sequences using ancestral sampling, incomplete, and consistent decoding methods.

Using greedy decoding, roughly 12% of all contexts resulted in a non-terminating continuation with the $\tanh$-RNN, and roughly 1% with the LSTM-RNN. Nucleus sampling also produced non-terminating sequences with the $\tanh$-RNN (0.06%, nuc-0.2) and LSTM-RNN (0.13%, nuc-0.2). Top-k sampling yielded a small number of non-terminating samples. In general, non-termination approaches zero as k and μ increase, since $\langle\text{eos}\rangle$ has a lower chance of being excluded.

Beam search produced non-terminating sequences with both the $\tanh$-RNN and LSTM-RNN models. This means that $\langle\text{eos}\rangle$ was outside of the top tokens (determined by the beam width) considered at each step, since in our experiments we terminated the beam search when a single beam prefix contained $\langle\text{eos}\rangle$. Larger beam widths reduce non-termination, similar to increasing k or μ.

5.2 Consistency of the Proposed Methods

Consistent sampling. Table 1 shows that consistent nucleus and top-k sampling (§4.1) resulted in only terminating sequences, except for a few cases that we attribute to the finite limit L used to measure the non-termination ratio. Consistent nucleus paired with $\tanh$-RNN did not reduce r_L as much as when it was paired with LSTM-RNN. Example continuations are shown in Table 2. On prefixes that led to non-termination with the baseline method, the quality tends to improve with the consistent variant since the continuation now termi-

nates. Note that since the model's non-⟨eos⟩ token probabilities at each step are only modified by a multiplicative constant, the sampling process can still enter a repetitive cycle (e.g., when the constant is close to 1), though it is guaranteed to terminate.

Self-terminating RLM. As seen in Table 3, the self-terminating recurrent language models are consistent with respect to greedy decoding, at the expense of perplexity compared to the vanilla model. The value of ε from Definition 4.3, which controls a lower-bound on termination probability at each step, influences both r_L and perplexity. When ε is too large ($\varepsilon = 10^{-2}$), perplexity degrades. When ε is too small ($\varepsilon = 10^{-4}$), the lower-bound grows slowly, so ⟨eos⟩ is not guaranteed to be top-ranked within L steps, resulting in a positive r_L. An ε of 10^{-3} balanced consistency and language modeling quality, with a zero non-termination ratio and perplexity within 8 points of the baseline.

As shown in Figure 3, the self-terminating model matches the data length distribution better than the baseline. Example decoded sequences are shown in Table 2. For prefixes that led to non-termination with the baseline, the self-terminating models yields finite sequences with reasonable quality. The examples suggest that some cases of degenerate repetition (Holtzman et al., 2019; Welleck et al., 2019) are attributed to inconsistency.

5.3 Inconsistency of GPT-2

We perform a final experiment with GPT-2 117M, a transformer language model pre-trained with maximum likelihood on WebText, a collection of scraped web pages (see Radford et al. (2019)). GPT-2 has been observed to produce repetitive text with greedy and beam search (Holtzman et al., 2019).

Experimental setup. We use the Wikitext-103 dataset (Merity et al., 2016), a large-scale collection of Wikipedia articles with over 100 million words and 260 thousand unique tokens. We split the dataset into sequences according to the dataset's newline boundaries, then split each sequence into a context C and continuation Y, resulting in a dataset of (C, Y) pairs. Each continuation ends in a special $\langle \text{eos} \rangle$ token. We use a context size of $k = 10$ tokens, and discard sequences that are length k or shorter. The resulting dataset contains 874,556 training, 1,896 validation, and 2,162 test pairs.

We fine-tune the pre-trained GPT-2 model using maximum likelihood for 400k steps, and select the model state with the lowest validation perplexity (evaluated every 5k steps). Each training batch contains a maximum of 1024 total tokens. We use the implementation and default hyper-parameters from the `transformers` library (Wolf et al., 2019). We fine-tune the self-terminating GPT-2 models in a similar manner, starting from the pre-trained GPT-2 model and using the same hyper-parameters.

Each model is evaluated using greedy decoding with a maximum sequence length of 500, which was selected so that each decoded validation batch could fit in GPU memory. We define the non-termination ratio (r_L) using $L = 500$; this limit is more strict than the limit used in the preceding experiments (1500), yet still allows us to see large differences in generation behavior between the model and the ground truth (e.g. see Figure 4).

Results. Table 4 shows the non-termination ratio and perplexity of the baseline and self-terminating GPT-2 models. The self-terminating variant prevents non-termination, at the cost of perplexity. The model here uses $\epsilon = 2.5 \times 10^{-3}$, which we selected after observing that at higher values of ϵ, e.g. 1.0×10^{-3}, the self-terminating model generated sequences longer than the limit used to determine termination (500). Figure 4 shows the length distributions of the baseline GPT-2 continuations and those of the self-terminating GPT-2. The GPT-2 117M model generates many sequences at or near the maximum sequence length (500), unlike the ground-truth data. Introducing self-termination shifts the mass towards shorter sequences, whose lengths are also present in the ground-truth data.

6 Future Directions

The methods we proposed in this paper resolve inconsistency by changing the decoding algorithm or model parameterization. Another approach is to address inconsistency in the *learning* phase. One interesting direction is to investigate whether the lack of decoding in maximum likelihood learning is a cause of inconsistency. Maximum likelihood learning fits the model p_θ using the data distribution, whereas a decoded sequence from the trained model follows the distribution $q_{\mathcal{F}}$ induced by a decoding algorithm. *Sequence-level* learning, however, uses a decoding algorithm during training (e.g., Ranzato et al. (2016)), which we hypothesize can result in a good sequence generator that is consistent with respect to incomplete decoding.

	r_L (%)	**perplexity**
GPT2-117M	37.91	20.92
GPT2-117M ST	00.00	27.25

7 Conclusion

We extended the notion of consistency of a recurrent language model put forward by Chen et al. (2017) to incorporate a decoding algorithm, and used it to analyze the discrepancy between a model and the distribution induced by a decoding algorithm. We proved that incomplete decoding is inconsistent, and proposed two methods to prevent this: consistent decoding and the self-terminating recurrent language model. Using a sequence completion task, we confirmed that empirical inconsistency occurs in practice, and that each method prevents inconsistency while maintaining the quality of generated sequences. We suspect the absence of decoding in maximum likelihood estimation as a cause behind this inconsistency, and suggest investigating sequence-level learning as an alternative.

A Additional Definitions

In contrast to greedy decoding, beam search with width k, $\mathcal{F}_{\text{beam-k}}$, operates on the level of partial sequences or prefixes.

Definition A.1 (Prefix). *A prefix ρ_t is an ordered collection of items from V. The score of a prefix is*

$$s(\rho_t) = \sum_{\tau=1}^{t} \log p_\theta(y_\tau = \rho_t[\tau] \mid \rho_t[< \tau], C),$$

where $\rho_t[\tau]$ is a token at time τ from ρ_t.

Starting from a set of empty prefixes, at each iteration a new prefix set is formed by expanding each prefix, then choosing the k highest scoring expanded prefixes.

Definition A.2 (Beam search). *Beam search with width k, $\mathcal{F}_{beam-k}$, generates a sequence from a recurrent language model p_θ by maintaining a size-k prefix set P_t^{top}. Starting with $P_0^{top} = \varnothing$, at each iteration $t \in \{1, 2, \ldots\}$ beam search forms a new prefix set P_t^{top} by expanding the current set, $\mathrm{P}_t = \bigcup_{\rho \in \mathrm{P}_{t-1}^{top}} \{\rho \circ v \mid v \in V\}$ (where $\rho \circ v$ is concatenation), then choosing the k highest scoring elements: $\mathrm{P}_t^{top} = \arg\, top\text{-}k_{\rho \in \mathrm{P}_t}\, s(\rho)$. Any $\rho \in \mathrm{P}_t^{top}$ ending with $\langle eos \rangle$ is restricted from being expanded further, and is added to a set S. Beam search ends when S contains k sequences, and returns the highest scoring sequence in S.*

B Proof of Lemmas in Section 3

Lemma 3.1. *If a recurrent language model p_θ is consistent, $p_\theta(|Y| = \infty \mid C) = 0$ for any probable context C.*

Proof. Suppose there exists a probable context $\tilde{C}$ such that $p_\theta(|Y| = \infty \mid \tilde{C}) > 0$. Then

$$\begin{aligned} p_\theta(|Y| = \infty) &= \mathbb{E}\left[p_\theta(|Y| = \infty \mid C)\right] \\ &\geq p(\tilde{C}) p_\theta(|Y| = \infty \mid \tilde{C}) > 0, \end{aligned}$$

which contradicts the consistency of the model p_θ. □

Lemma 3.2. *A recurrent language model p_θ is consistent if $\|h_t\|_p$ is uniformly bounded for some $p \geq 1$.*

Proof. Let $B > 0$ be an upper bound such that $\|h_t\|_p < B$ for all t. Let q be the conjugate of p satisfying $1/p + 1/q = 1$. Then we have from Hölder's inequality, for all $v \in V$ and t,

$$u_v^\top h_t \leq \|u_v^\top h_t\|_1 \leq \|h_t\|_p \|u_v\|_q < Bu^+,$$

where $u^+ = \max_{v \in V} \|u_v\|_q$. Note that

$$\begin{aligned} \log \sum_{v \in V} e^{u_v^\top h_t + c_v} &\leq \log \left(\max_{v \in V} e^{u_v^\top h_t + c_v} \times |V| \right) \\ &\leq \max_{v \in V} \{u_v^\top h_t + c_v\} + \log |V| \\ &< Bu^+ + c^+ + \log |V|, \end{aligned}$$

where $c^+ = \max_{v \in V} c_v$. For a given $y_{<t}$ and context C,

$$\begin{aligned} &\log p_\theta(\langle \text{eos} \rangle \mid y_{<t}, C) \\ =&(u_{\langle \text{eos} \rangle}^\top h_t + c_{\langle \text{eos} \rangle}) - \log \sum_{v \in V} e^{u_v^\top h_t + c_v} \\ >&(-Bu^+ + c_{\langle \text{eos} \rangle}) - (Bu^+ + c^+ + \log |V|) > -\infty, \end{aligned}$$

and it follows that $p_\theta(\langle \text{eos} \rangle \mid y_{<t}, C) > \xi > 0$ for some strictly positive constant ξ. Then

$$\begin{aligned} p_\theta(|Y| = \infty) &= \lim_{t \to \infty} p_\theta(|Y| > t) \\ &= \lim_{t \to \infty} \mathbb{E}\left[p_\theta(|Y| > t \mid C)\right] \\ &= \mathbb{E}\left[\lim_{t \to \infty} p_\theta(|Y| > t \mid C)\right] \\ &\leq \mathbb{E}\left[\lim_{t \to \infty} (1 - \xi)^t\right] = 0, \end{aligned}$$

and hence p_θ is consistent. □

Lemma 3.3. *A consistent decoding algorithm with respect to a consistent recurrent language model decodes only probable sequences. That is, if $q_{\mathcal{F}}(Y \mid C) > 0$, then $p_\theta(Y \mid C) > 0$ for any probable context C.*

Proof. Suppose there exists a decoded sequence $\tilde{Y}$ by $\mathcal{F}$ and probable context $\tilde{C}$ such that $q_{\mathcal{F}}(\tilde{Y} \mid \tilde{C}) > 0$ but $p_\theta(\tilde{Y} \mid \tilde{C}) = 0$. By Remark 2.1, the sequence $\tilde{Y}$ is of infinite length and thus $q_{\mathcal{F}}(|Y| = \infty \mid \tilde{C}) \geq q_{\mathcal{F}}(\tilde{Y} \mid \tilde{C}) > 0$, which contradicts the consistency of $q_{\mathcal{F}}$ by Lemma 3.1. □

C Proofs for Section 4

Theorem 4.1. *Suppose a recurrent LM p_θ has uniformly bounded $\|h_t\|_p$ for some $p \geq 1$. If a decoding algorithm $\mathcal{F}$ satisfies $q_{\mathcal{F}}(\langle eos \rangle \mid y_{<t}, C) \geq p_\theta(\langle eos \rangle \mid y_{<t}, C)$ for every prefix $y_{<t}$ and context C, then the decoding algorithm $\mathcal{F}$ is consistent with respect to the model p_θ.*

Proof. By Lemma 3.2 the model p_θ is consistent and $p_\theta(\langle\text{eos}\rangle \mid y_{<t}, C) > \xi$ for some positive value ξ. Thus, $q_{\mathcal{F}}(\langle\text{eos}\rangle \mid y_{<t}, C) \geq p_\theta(\langle\text{eos}\rangle \mid y_{<t}, C) > \xi$. For $t \geq 1$,

$$\begin{aligned} & q_{\mathcal{F}}(|Y| > t \mid C) \\ & = q_{\mathcal{F}}(y_1 \neq \langle\text{eos}\rangle, \cdots, y_t \neq \langle\text{eos}\rangle \mid C) \\ & \leq (1-\xi)^t. \end{aligned}$$

Taking the limit $t \to \infty$ and expectation over C, we have

$$\begin{aligned} q_{\mathcal{F}}(|Y| = \infty) &= \mathbb{E}_C\left[\lim_{t\to\infty} q_{\mathcal{F}}(|Y| > t \mid C)\right] \\ &\leq \lim_{t\to\infty}(1-\xi)^t = 0, \end{aligned}$$

from which the decoding algorithm is consistent. □

Theorem 4.2. *Greedy decoding is consistent with respect to any self-terminating recurrent LM.*

Proof. Let $p_t^{\langle\text{eos}\rangle}$ denote $p_\theta(\langle\text{eos}\rangle \mid y_{<t}, C)$ and $a_t^{\langle\text{eos}\rangle}$ denote $u_{\langle\text{eos}\rangle}^\top h_t + c_{\langle\text{eos}\rangle}$. By Definition 4.3 we have

$$\begin{aligned} p_t^{\langle\text{eos}\rangle} &= 1 - \sigma(a_t^{\langle\text{eos}\rangle})(1 - p_{t-1}^{\langle\text{eos}\rangle}) \\ &= 1 - \prod_{t'=0}^{t} \sigma(a_{t'}^{\langle\text{eos}\rangle}) \geq 1 - (1-\epsilon)^{t+1}. \end{aligned}$$

Take $B = -\log 2/\log(1-\epsilon)$. We then have $p_t^{\langle\text{eos}\rangle} > 1/2$ for all $t > B$, which implies that $\langle\text{eos}\rangle$ is always the most probable token after time step B. Hence, the sequence length is less than B with probability 1. □

Theorem 4.3. *Beam search with width k, $\mathcal{F}_{beam-k}$, is consistent with respect to any STRLM.*

Proof. Let $S(\rho)$ be the size-k set of sequences kept by $\mathcal{F}_{\text{beam}-k}$ that start with a prefix ρ.

Take $B = -\log 2/\log(1-\epsilon)$ as in the proof of Theorem 4.2. Suppose that there exists at least one prefix $\hat{\rho} \in P_B^{\text{top}}$ which does not end with $\langle\text{eos}\rangle$.

We first want to show that $\hat{\rho}$ induces at most k more steps in beam search with width k, that is, $Y \in S(\hat{\rho})$ implies $|Y| \leq B + k$.

We know from the proof of Theorem 4.2 that an STRLM p_θ satisfies: for any context C and $v \in V \setminus \{\langle\text{eos}\rangle\}$,

$$p_\theta(\langle\text{eos}\rangle \mid \hat{\rho}, C) > p_\theta(v \mid \hat{\rho}, C).$$

For any subsequence $y = (y_1, \ldots, y_l)$ with $y_1 \neq \langle\text{eos}\rangle$,

$$\begin{aligned} p_\theta(\hat{\rho} \circ y \mid \hat{\rho}, C) &= \prod_{i=1}^{l} p_\theta(y_i \mid \hat{\rho} \circ y_{<i}, C) \\ &\leq p_\theta(y_1 \mid \hat{\rho}, C) \\ &< p_\theta(\langle\text{eos}\rangle \mid \hat{\rho}, C). \end{aligned}$$

Thus, $\hat{\rho} \circ \langle\text{eos}\rangle$ is the most probable sequence among sequences starting with the prefix $\hat{\rho}$, and it follows that $\hat{\rho} \circ \langle\text{eos}\rangle \in S(\hat{\rho})$.

Thus, in $S(\hat{\rho})$, there are $(k-1)$ sequences starting with $\hat{\rho} \circ v$ for $v \in V \setminus \{\langle\text{eos}\rangle\}$. By the same argument, at each step at least one sequence ending with $\langle\text{eos}\rangle$ is added to $S(\hat{\rho})$, and therefore at time step $(B+k)$, k sequences ending with $\langle\text{eos}\rangle$ are in $S(\hat{\rho})$.

Note that the result set S by $\mathcal{F}_{\text{beam}-k}$ (Definition 2.11) satisfies

$$S \subseteq \bigcup_{\rho \in P_B^{\text{top}}} S(\rho).$$

Since each $\rho \in P_B^{\text{top}}$ induces sequences of length at most $B + k$, we have

$$p_\theta(|Y| > B + k \mid C) = 0.$$

Taking the expectation over C yields the consistency of the model p_θ. □

Abstract

Many tasks in natural language processing involve predicting structured outputs, e.g., sequence labeling, semantic role labeling, parsing, and machine translation. Researchers are increasingly applying deep representation learning to these problems, but the structured component of these approaches is usually quite simplistic. In this work, we propose several high-order energy terms to capture complex dependencies among labels in sequence labeling, including several that consider the entire label sequence. We use neural parameterizations for these energy terms, drawing from convolutional, recurrent, and self-attention networks. We use the framework of learning energy-based inference networks (Tu and Gimpel, 2018) for dealing with the difficulties of training and inference with such models. We empirically demonstrate that this approach achieves substantial improvement using a variety of high-order energy terms on four sequence labeling tasks, while having the same decoding speed as simple, local classifiers. We also find high-order energies to help in noisy data conditions.[1]

1 Introduction

Conditional random fields (CRFs; Lafferty et al., 2001) have been shown to perform well in various sequence labeling tasks. Recent work uses rich neural network architectures to define the "unary" potentials, i.e., terms that only consider a single position's label at a time (Collobert et al., 2011; Lample et al., 2016; Ma and Hovy, 2016; Strubell et al., 2018). However, "binary" potentials, which consider pairs of adjacent labels, are usually quite simple and may consist solely of a parameter or parameter vector for each unique label transition. Models with unary and binary potentials are generally referred to as "first order" models.

A major challenge with CRFs is the complexity of training and inference, which are quadratic in the number of output labels for first order models and grow exponentially when higher order dependencies are considered. This explains why the most common type of CRF used in practice is a first order model, also referred to as a "linear chain" CRF.

One promising alternative to CRFs is structured prediction energy networks (SPENs; Belanger and McCallum, 2016), which use deep neural networks to parameterize arbitrary potential functions for structured prediction. While SPENs also pose challenges for learning and inference, Tu and Gimpel (2018) proposed a way to train SPENs jointly with "inference networks", neural networks trained to approximate structured $\arg\max$ inference.

In this paper, we leverage the frameworks of SPENs and inference networks to explore high-order energy functions for sequence labeling. Naively instantiating high-order energy terms can lead to a very large number of parameters to learn, so we instead develop concise neural parameterizations for high-order terms. In particular, we draw from vectorized Kronecker products, convolutional networks, recurrent networks, and self-attention. We also consider "skip-chain" connections (Sutton and McCallum, 2004) with various skip distances and ways of reducing their total parameter count for increased learnability.

Our experimental results on four sequence labeling tasks show that a range of high-order energy functions can yield performance improvements. While the optimal energy function varies by task, we find strong performance from skip-chain terms with short skip distances, convolutional networks with filters that consider label trigrams, and recurrent networks and self-attention networks that consider large subsequences of labels.

---

*Equal contribution.

November 16–20, 2020.

We also demonstrate that modeling high-order dependencies can lead to significant performance improvements in the setting of noisy training and test sets. Visualizations of the high-order energies show various methods capture intuitive structured dependencies among output labels.

Throughout, we use inference networks that share the same architecture as unstructured classifiers for sequence labeling, so test time inference speeds are unchanged between local models and our method. Enlarging the inference network architecture by adding one layer leads consistently to better results, rivaling or improving over a BiLSTM-CRF baseline, suggesting that training efficient inference networks with high-order energy terms can make up for errors arising from approximate inference. While we focus on sequence labeling in this paper, our results show the potential of developing high-order structured models for other NLP tasks in the future.

2 Background

2.1 Structured Energy-Based Learning

We denote the input space by $\mathcal{X}$. For an input $\boldsymbol{x} \in \mathcal{X}$, we denote the structured output space by $\mathcal{Y}(\boldsymbol{x})$. The entire space of structured outputs is denoted $\mathcal{Y} = \cup_{\boldsymbol{x} \in \mathcal{X}} \mathcal{Y}(\boldsymbol{x})$. We define an **energy function** (LeCun et al., 2006; Belanger and McCallum, 2016) E_Θ parameterized by Θ that computes a scalar energy for an input/output pair: $E_\Theta : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$. At test time, for a given input $\boldsymbol{x}$, prediction is done by choosing the output with lowest energy:

$$\hat{\boldsymbol{y}} = \arg\min_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x})} E_\Theta(\boldsymbol{x}, \boldsymbol{y}) \qquad (1)$$

2.2 Inference Networks

Inference. Solving equation (1) requires combinatorial algorithms because $\mathcal{Y}$ is a structured, discrete space. This becomes intractable when E_Θ does not decompose into a sum over small "parts" of $\boldsymbol{y}$. Belanger and McCallum (2016) relax this problem by allowing the discrete vector $\boldsymbol{y}$ to be continuous. Let $\mathcal{Y}_R$ denote the **relaxed output space**. They solve the relaxed problem by using gradient descent to iteratively minimize the energy with respect to $\boldsymbol{y}$.

Tu and Gimpel (2018) propose an alternative that replaces gradient descent with a neural network trained to do inference, i.e., to mimic the function performed in equation (1). This "inference network" $\mathbf{A}_\Psi : \mathcal{X} \rightarrow \mathcal{Y}_R$ is parameterized by Ψ and trained with the goal that

$$\mathbf{A}_\Psi(\boldsymbol{x}) \approx \arg\min_{\boldsymbol{y} \in \mathcal{Y}_R(\boldsymbol{x})} E_\Theta(\boldsymbol{x}, \boldsymbol{y}) \qquad (2)$$

Tu and Gimpel (2019) show that inference networks achieve a better speed/accuracy/search error trade-off than gradient descent given pretrained energy functions.

Joint training of energy functions and inference networks. Belanger and McCallum (2016) proposed a structured hinge loss for learning the energy function parameters Θ, using gradient descent for the "cost-augmented" inference step required during learning. Tu and Gimpel (2018) replaced the cost-augmented inference step in the structured hinge loss with training of a "cost-augmented inference network" $\mathbf{F}_\Phi(\boldsymbol{x})$ trained with the following goal:

$$\mathbf{F}_\Phi(\boldsymbol{x}) \approx \arg\min_{\boldsymbol{y} \in \mathcal{Y}_R(\boldsymbol{x})} (E_\Theta(\boldsymbol{x}, \boldsymbol{y}) - \triangle(\boldsymbol{y}, \boldsymbol{y}^*))$$

where $\triangle$ is a structured cost function that computes the distance between its two arguments. The new optimization objective becomes:

$$\min_\Theta \max_\Phi \sum_{\langle \boldsymbol{x}, \boldsymbol{y} \rangle \in \mathcal{D}} [\triangle(\mathbf{F}_\Phi(\boldsymbol{x}), \boldsymbol{y}) - E_\Theta(\boldsymbol{x}, \mathbf{F}_\Phi(\boldsymbol{x})) + E_\Theta(\boldsymbol{x}, \boldsymbol{y})]_+$$

where $\mathcal{D}$ is the set of training pairs and $[h]_+ = \max(0, h)$. Tu and Gimpel (2018) alternatively optimized Θ and Φ, which is similar to training in generative adversarial networks (Goodfellow et al., 2014).

2.3 An Objective for Joint Learning of Inference Networks

One challenge with the optimization problem above is that it still requires training an inference network $\mathbf{A}_\Psi$ for test-time prediction. Tu et al. (2020a) proposed a "compound" objective that avoids this by training two inference networks jointly (with shared parameters), $\mathbf{F}_\Phi$ for cost-augmented inference and $\mathbf{A}_\Psi$ for test-time inference:

$$\min_\Theta \max_{\Phi,\Psi} \sum_{\langle \boldsymbol{x}, \boldsymbol{y} \rangle \in \mathcal{D}} \underbrace{[\triangle(\mathbf{F}_\Phi(\boldsymbol{x}), \boldsymbol{y}) - E_\Theta(\boldsymbol{x}, \mathbf{F}_\Phi(\boldsymbol{x})) + E_\Theta(\boldsymbol{x}, \boldsymbol{y})]_+}_{\text{margin-rescaled hinge loss}} + \lambda \underbrace{[-E_\Theta(\boldsymbol{x}, \mathbf{A}_\Psi(\boldsymbol{x})) + E_\Theta(\boldsymbol{x}, \boldsymbol{y})]_+}_{\text{perceptron loss}}$$

As indicated, this loss can be viewed as the sum of the margin-rescaled and perceptron losses. Θ, Φ, and Ψ are alternatively optimized. The objective for the energy function parameters Θ is:

$$\hat{\Theta} \leftarrow \arg\min_{\Theta} \\ \big[\triangle(\mathbf{F}_\Phi(\boldsymbol{x}), \boldsymbol{y}) - E_\Theta(\boldsymbol{x}, \mathbf{F}_\Phi(\boldsymbol{x})) + E_\Theta(\boldsymbol{x}, \boldsymbol{y})\big]_+ \\ + \lambda\big[-E_\Theta(\boldsymbol{x}, \mathbf{A}_\Psi(\boldsymbol{x})) + E_\Theta(\boldsymbol{x}, \boldsymbol{y})\big]_+$$

The objective for the other parameters is:

$$\hat{\Psi}, \hat{\Phi} \leftarrow \arg\max_{\Psi,\Phi} \triangle(\mathbf{F}_\Phi(\boldsymbol{x}), \boldsymbol{y}) - E_\Theta(\boldsymbol{x}, \mathbf{F}_\Phi(\boldsymbol{x})) \\ - \lambda E_\Theta(\boldsymbol{x}, \mathbf{A}_\Psi(\boldsymbol{x})) - \tau \ell_{\text{token}}(\boldsymbol{y}, \mathbf{A}_\Psi(\boldsymbol{x}))$$

where ℓ_{token} is a supervised token-level loss which is added to aid in training inference networks. In this paper, we use the standard cross entropy summed over all positions. Like Tu et al. (2020a), we drop the zero truncation ($\max(0, .)$) when updating the inference network parameters to improve stability during training, which also lets us remove the terms that do not have inference networks. We use two independent networks but with the same architecture for the two inference networks.

3 Energy Functions

Our experiments in this paper consider sequence labeling tasks, so the input $\boldsymbol{x}$ is a length-T sequence of tokens where x_t denotes the token at position t. The output $\boldsymbol{y}$ is a sequence of labels also of length T. We use $\boldsymbol{y}_t$ to denote the output label at position t, where $\boldsymbol{y}_t$ is a vector of length L (the number of labels in the label set) and where $y_{t,j}$ is the jth entry of the vector $\boldsymbol{y}_t$. In the original output space $\mathcal{Y}(\boldsymbol{x})$, $y_{t,j}$ is 1 for a single j and 0 for all others. In the relaxed output space $\mathcal{Y}_R(\boldsymbol{x})$, $y_{t,j}$ can be interpreted as the probability of the tth position being labeled with label j. We use the following energy: $E_\Theta(\boldsymbol{x}, \boldsymbol{y}) =$

$$-\left(\sum_{t=1}^{T}\sum_{j=1}^{L} y_{t,j}\left(U_j^\top b(\boldsymbol{x}, t)\right) + E_W(\boldsymbol{y})\right) \quad (3)$$

where $U_j \in \mathbb{R}^d$ is a parameter vector for label j and $E_W(\boldsymbol{y})$ is a structured energy term parameterized by parameters W. In a linear chain CRF, W is a transition matrix for scoring two adjacent labels. Different instantiations of E_W will be detailed in the sections below. Also, $b(\boldsymbol{x}, t) \in \mathbb{R}^d$ denotes the "input feature vector" for position t. We define it to be the d-dimensional BiLSTM (Hochreiter and Schmidhuber, 1997) hidden vector at t. The full set of energy parameters Θ includes the U_j vectors, W, and the parameters of the BiLSTM.

The above energy functions are trained with the objective in Section 2.3. Table 1 shows the training and test-time inference requirements of our method compared to previous methods. For different formulations of the energy function, the inference network architecture is the same (e.g., BiLSTM). So the inference complexity is the same as the standard neural approaches that do not use structured prediction, which is linear in the label set size. However, even for the first order model (linear-chain CRF), the time complexity is quadratic in the label set size. The time complexity of higher-order CRFs grows exponentially with the order.

3.1 Linear Chain Energies

Our first choice for a structured energy term is relaxed linear chain energy defined for sequence labeling by Tu and Gimpel (2018):

$$E_W(\boldsymbol{y}) = \sum_{t=1}^{T} \boldsymbol{y}_{t-1}^\top W \boldsymbol{y}_t$$

Where $W_i \in \mathbb{R}^{L\times L}$ is the transition matrix, which is used to score the pair of adjacent labels. If this linear chain energy is the only structured energy term in use, exact inference can be performed efficiently using the Viterbi algorithm.

3.2 Skip-Chain Energies

We also consider an energy inspired by "skip-chain" conditional random fields (Sutton and McCallum, 2004). In addition to consecutive labels, this energy also considers pairs of labels appearing in a given window size $M+1$:

$$E_W(\boldsymbol{y}) = \sum_{t=1}^{T}\sum_{i=1}^{M} \boldsymbol{y}_{t-i}^\top W_i \boldsymbol{y}_t$$

where each $W_i \in \mathbb{R}^{L\times L}$ and the max window size M is a hyperparameter. While linear chain energies allow efficient exact inference, using skip-chain energies causes exact inference to require time exponential in the size of M.

3.3 High-Order Energies

We also consider Mth-order energy terms. We use the function F to score the $M+1$ consecutive

	Training		Inference	
	Time	Number of Parameters	Time	Number of Parameters
BiLSTM	$\mathcal{O}(T * L)$	$\mathcal{O}(\lvert\Psi\rvert)$	$\mathcal{O}(T * L)$	$\mathcal{O}(\lvert\Psi\rvert)$
CRF	$\mathcal{O}(T * L^2)$	$\mathcal{O}(\lvert\Theta\rvert)$	$\mathcal{O}(T * L^2)$	$\mathcal{O}(\lvert\Theta\rvert)$
Energy-Based Inference Networks	$\mathcal{O}(T * L)$	$\mathcal{O}(\lvert\Psi\rvert + \lvert\Phi\rvert + \lvert\Theta\rvert)$	$\mathcal{O}(T * L)$	$\mathcal{O}(\lvert\Psi\rvert)$

Table 1: Time complexity and number of parameters of different methods during training and inference, where T is the sequence length, L is the label set size, Θ are the parameters of energy function, and Φ, Ψ are the parameters of two energy-based inference networks. For arbitrary-order energy functions or different parameterizations, the size of Θ can be different.

labels $\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t$, then sum over positions:

$$E_W(\boldsymbol{y}) = \sum_{t=M}^{T} F(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t) \tag{4}$$

We consider several different ways to define the function F, detailed below.

Vectorized Kronecker Product (VKP): A naive way to parameterize a high-order energy term would involve using a parameter tensor $W \in \mathbb{R}^{L^{M+1}}$ with an entry for each possible label sequence of length $M + 1$. To avoid this exponentially-large number of parameters, we define a more efficient parameterization as follows. We first define a label embedding lookup table $\in \mathbb{R}^{L\times n_l}$ and denote the embedding for label j by e_j. We consider $M = 2$ as an example. Then, for a tensor $W \in \mathbb{R}^{L\times L\times L}$, its value $W_{i,j,k}$ at indices (i, j, k) is calculated as

$$\mathbf{v}^\top \mathrm{LayerNorm}([e_i; e_j; e_k] + \mathrm{MLP}([e_i; e_j; e_k]))$$

where $\mathbf{v} \in \mathbb{R}^{(M+1)n_l}$ is a parameter vector and ; denotes vector concatenation. MLP expects and returns vectors of dimension $(M + 1) \times n_l$ and is parameterized as a multilayer perceptron. Then, the energy is computed:

$$F(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t) = \mathrm{VKP}(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_{t-1}) W \boldsymbol{y}_t$$

where W is reshaped as $\in \mathbb{R}^{L^M\times L}$. The operator VKP is somewhat similar to the Kronecker product of the k vectors $\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k$[2]. However it will return a vector, not a tensor:

$$\mathrm{VKP}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_k) = \begin{cases} \boldsymbol{v}_1 & k = 1 \\ \mathbf{vec}(\boldsymbol{v}_1 \boldsymbol{v}_2^\top) & k = 2 \\ \mathbf{vec}(\mathrm{VKP}(\boldsymbol{v}_1, \ldots, \boldsymbol{v}_{k-1}) \boldsymbol{v}_k^\top) & k > 2 \end{cases}$$

Where **vec** is the operation that vectorizes a tensor into a (column) vector.

CNN: Convolutional neural networks (CNN) are frequently used in NLP to extract features based on words or characters (Collobert et al., 2011; Kim, 2014). We apply CNN filters over the sequence of $M + 1$ consecutive labels. The F function is computed as follows:

$$F(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t) = \sum_n f_n(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t)$$

$$f_n(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t) = g(W_n[\boldsymbol{y}_{t-M}; \ldots; \boldsymbol{y}_t] + \mathbf{b}_n)$$

where g is a ReLU nonlinearity and the vector $W_n \in \mathbb{R}^{L(M+1)}$ and scalar $b_n \in \mathbb{R}$ are the parameters for filter n. The filter size of all filters is the same as the window size, namely, $M + 1$. The F function sums over all CNN filters. When viewing this high-order energy as a CNN, we can think of the summation in Eq. 4 as corresponding to sum pooling over time of the feature map outputs.

Tag Language Model (TLM): Tu and Gimpel (2018) defined an energy term based on a pretrained "tag language model", which computes the probability of an entire sequence of labels. We also use a TLM, scoring a sequence of $M + 1$ consecutive labels in a way similar to Tu and Gimpel (2018); however, the parameters of the TLM are trained in our setting:

$$F(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t) = - \sum_{t'=t-M+1}^{t} \boldsymbol{y}_{t'}^\top \log(\mathrm{TLM}(\langle \boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_{t'-1} \rangle))$$

where $\mathrm{TLM}(\langle \boldsymbol{y}_{t-M}, \ldots, y_{t'-1} \rangle)$ returns the softmax distribution over tags at position t' (under the tag language model) given the preceding tag vectors. When each $y_{t'}$ is a one-hot vector, this energy reduces to the negative log-likelihood of the tag sequence specified by $\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t$.

---

[2] There are some work (Lei et al., 2014; Srikumar and Manning, 2014; Yu et al., 2016) that use Kronecker product for higher order feature combinations with low-rank tensors. Here we use this form to express the computation when scoring the consecutive labels.

Self-Attention (S-Att): We adopt the multi-head self-attention formulation from Vaswani et al. (2017). Given a matrix of the $M+1$ consecutive labels $Q = K = V = [\boldsymbol{y}_{t-M}; \ldots; \boldsymbol{y}_t] \in \mathbb{R}^{(M+1)\times L}$:

$$H = \mathrm{attention}(Q, K, V)$$
$$F(\boldsymbol{y}_{t-M}, \ldots, \boldsymbol{y}_t) = \sum H$$

where attention is the general attention mechanism: the weighted sum of the value vectors V using query vectors Q and key vectors K (Vaswani et al., 2017). The energy on the $M+1$ consecutive labels is defined as the sum of entries in the feature map $H \in \mathbb{R}^{L\times(M+1)}$ after the self-attention transformation.

3.4 Fully-Connected Energies

We can simulate a "fully-connected" energy function by setting a very large value for M in the skip-chain energy (Section 3.2). For efficiency and learnability, we use a low-rank parameterization for the many translation matrices W_i that will result from increasing M. We first define a matrix $S \in \mathbb{R}^{L\times d}$ that all W_i will use. Each i has a learned parameter matrix $D_i \in \mathbb{R}^{L\times d}$ and together S and D_i are used to compute W_i:

$$W_i = SD_i^\top$$

where d is a tunable hyperparameter that affects the number of learnable parameters.

4 Related Work

Linear chain CRFs (Lafferty et al., 2001), which consider dependencies between at most two adjacent labels or segments, are commonly used in practice (Sarawagi and Cohen, 2005; Lample et al., 2016; Ma and Hovy, 2016).

There have been several efforts in developing efficient algorithms for handling higher-order CRFs. Qian et al. (2009) developed an efficient decoding algorithm under the assumption that all high-order features have non-negative weights. Some work has shown that high-order CRFs can be handled relatively efficiently if particular patterns of sparsity are assumed (Ye et al., 2009; Cuong et al., 2014). Mueller et al. (2013) proposed an approximate CRF using coarse-to-fine decoding and early updating. Loopy belief propagation (Murphy et al., 1999) has been used for approximate inference in high-order CRFs, such as skip-chain CRFs (Sutton and McCallum, 2004), which form the inspiration for one category of energy function in this paper.

CRFs are typically trained by maximizing conditional log-likelihood. Even assuming that the graph structure underlying the CRF admits tractable inference, it is still time-consuming to compute the partition function. Margin-based methods have been proposed (Taskar et al., 2004; Tsochantaridis et al., 2004) to avoid the summation over all possible outputs. Similar losses are used when training SPENs (Belanger and McCallum, 2016; Belanger et al., 2017), including in this paper. The energy-based inference network learning framework has been used for multi-label classification (Tu and Gimpel, 2018), non-autoregressive machine translation (Tu et al., 2020b), and previously for sequence labeling (Tu and Gimpel, 2019).

Moving beyond CRFs and sequence labeling, there has been a great deal of work in the NLP community in designing non-local features, often combined with the development of approximate algorithms to incorporate them during inference. These include n-best reranking (Och et al., 2004), beam search (Lowerre, 1976), loopy belief propagation (Sutton and McCallum, 2004; Smith and Eisner, 2008), Gibbs sampling (Finkel et al., 2005), stacked learning (Cohen and de Carvalho, 2005; Krishnan and Manning, 2006), sequential Monte Carlo algorithms (Yang and Eisenstein, 2013), dynamic programming approximations like cube pruning (Chiang, 2007; Huang and Chiang, 2007), dual decomposition (Rush et al., 2010; Martins et al., 2011), and methods based on black-box optimization like integer linear programming (Roth and Yih, 2004). These methods are often developed or applied with particular types of non-local energy terms in mind. By contrast, here we find that the framework of SPEN learning with inference networks can support a wide range of high-order energies for sequence labeling.

5 Experimental Setup

We perform experiments on four tasks: Twitter part-of-speech tagging (POS), named entity recognition (NER), CCG supertagging (CCG), and semantic role labeling (SRL).

5.1 Datasets

POS. We use the annotated data from Gimpel et al. (2011) and Owoputi et al. (2013) which contains 25 POS tags. We use the 100-dimensional skip-gram embeddings from Tu et al. (2017) which were trained on a dataset of 56 million English tweets using `word2vec` (Mikolov et al., 2013). The evaluation metric is tagging accuracy.

NER. We use the CoNLL 2003 English data (Tjong Kim Sang and De Meulder, 2003). We use the BIOES tagging scheme, so there are 17 labels. We use 100-dimensional pretrained GloVe (Pennington et al., 2014) embeddings. The task is evaluated with micro-averaged F1 score.

CCG. We use the standard splits from CCGbank (Hockenmaier and Steedman, 2002). We only keep sentences with length less than 50 in the original training data during training. We use only the 400 most frequent labels. The training data contains 1,284 unique labels, but because the label distribution has a long tail, we use only the 400 most frequent labels, replacing the others by a special tag $*$. The percentages of $*$ in train/development/test are 0.25/0.23/0.23%. When the gold standard tag is $*$, the prediction is always evaluated as incorrect. We use the same GloVe embeddings as in NER. The task is evaluated with per-token accuracy.

SRL. We use the standard split from CoNLL 2005 (Carreras and Màrquez, 2005). The gold predicates are provided as part of the input. We use the official evaluation script from the CoNLL 2005 shared task for evaluation. We again use the same GloVe embeddings as in NER. To form the inputs to our models, an embedding of a binary feature indicating whether the word is the given predicate is concatenated to the word embedding.[3]

5.2 Training

Local Classifiers. We consider local baselines that use a BiLSTM trained with the local loss ℓ_{token}. For POS, NER and CCG, we use a 1-layer BiLSTM with hidden size 100, and the word embeddings are fixed during training. For SRL, we use a 4-layer BiLSTM with hidden size 300 and the word embeddings are fine-tuned.

BiLSTM-CRF. We also train BiLSTM-CRF models with the standard conditional log-likelihood objective. A 1-layer BiLSTM with hidden size 100 is used for extracting input features. The CRF part uses a linear chain energy with a single tag transition parameter matrix. We do early stopping based on development sets. The usual dynamic programming algorithms are used for training and inference, e.g., the Viterbi algorithm is used for inference. The same pretrained word embeddings as for the local classifiers are used.

Inference Networks. When defining architectures for the inference networks, we use the same architectures as the local classifiers. However, the objective of the inference networks is different, which is shown in Section 2.3. $\lambda = 1$ and $\tau = 1$ are used for training. We do early stopping based on the development set.

Energy Terms. The unary terms are parameterized using a one-layer BiLSTM with hidden size 100. For the structured energy terms, the VKP operation uses $n_l = 20$, the number of CNN filters is 50, and the tag language model is a 1-layer LSTM with hidden size 100. For the fully-connected energy, $d = 20$ for the approximation of the transition matrix and $M = 20$ for the approximation of the fully-connected energies.

Hyperparameters. For the inference network training, the batch size is 100. We update the energy function parameters using the Adam optimizer (Kingma and Ba, 2014) with learning rate 0.001. For POS, NER, and CCG, we train the inference networks parameter with stochastic gradient descent with momentum as the optimizer. The learning rate is 0.005 and the momentum is 0.9. For SRL, we train the inference networks using Adam with learning rate 0.001.

6 Results

Parameterizations for High-Order Energies. We first compare several choices for energy functions within our inference network learning framework. In Section 3.3, we considered several ways to define the high-order energy function F. We compare performance of the parameterizations on three tasks: POS, NER, and CCG. The results are shown in Table 2.

For VKP high-order energies, there are small differences between 2nd and 3rd order models, however, 4th order models are consistently worse. The CNN high-order energy is best when M=2 for the three tasks. Increasing M does not consistently help. The tag language model (TLM) works best when scoring the entire label sequence. In

---

[3] Our SRL baseline is most similar to Zhou and Xu (2015), though there are some differences. We use GloVe embeddings while they train word embeddings on Wikipedia. We both use the same predicate context features.

Fully-Connected		90.0	87.2	93.3

Table 4: Test results when inference networks have 2 layers (so the local classifier baseline also has 2 layers).

the following experiment with TLM energies, we always use it with this "all" setting. Self-attention (S-Att) also shows better performance with larger M. However, the results for NER are not as high overall as for other energy terms.

Overall, there is no clear winner among the four types of parameterizations, indicating that a variety of high-order energy terms can work well on these tasks, once appropriate window sizes are chosen. We do note differences among tasks: NER benefits more from larger window sizes than POS.

Comparing Structured Energy Terms. Above we compared parameterizations of the high-order energy terms. In Table 3, we compare instantiations of the structured energy term $E_W(\boldsymbol{y})$: linear-chain energies, skip-chain energies, high-order energies, and fully-connected energies.[4] We also compare to local classifiers (BiLSTM). The models with structured energies typically improve over the local classifiers, even with just the linear chain energy.

The richer energy terms tend to perform better than linear chain, at least for most tasks and energies. The skip-chain energies benefit from relatively large M values, i.e., 3 or 4 depending on the task. These tend to be larger than the optimal VKP M values. We note that S-Att high-order energies work well on SRL. This points to the benefits of self-attention on SRL, which has been found in recent work (Tan et al., 2018; Strubell et al., 2018).

Both the skip-chain and high-order energy models achieve substantial improvements over the linear chain CRF, notably a gain of 0.8 F1 for NER. The fully-connected energy is not as strong as the others, possibly due to the energies from label pairs spanning a long range. These long-range energies do not appear helpful for these tasks.

Comparison using Deeper Inference Networks. Table 4 compares methods when using 2-layer BiLSTMs as inference networks.[5] The deeper inference networks reach higher performance across all tasks compared to 1-layer inference networks.

We observe that inference networks trained with skip-chain energies and high-order energies achieve better results than BiLSTM-CRF on the three datasets (the Viterbi algorithm is used for

exact inference for BiLSTM-CRF). This indicates that adding richer energy terms can make up for approximate inference during training and inference. Moreover, a 2-layer BiLSTM is much cheaper computationally than Viterbi, especially for tasks with large label sets.

6.1 Results on Noisy Datasets

We now consider the impact of our structured energy terms in noisy data settings. Our motivation for these experiments stems from the assumption that structured energies will be more helpful when there is a weaker relationship between the observations and the labels. One way to achieve this is by introducing noise into the observations.

So, we create new datasets: for any given sentence, we randomly replace a token x with an unknown word symbol "UNK" with probability α. From previous results, we see that NER shows more benefit from structured energies, so we focus on NER and consider two settings: **UnkTest**: train on clean text, evaluate on noisy text; and **UnkTrain**: train on noisy text, evaluate on noisy text.

Baselines:	
BERT (local loss)	92.13
BERT-CRF	92.34
Energy-based inference networks:	
Linear Chain	92.14
Skip-Chain (M=3)	92.46

Table 7: Test results for NER when using BERT. When using energy-based inference networks (our framework), BERT is used in both the energy function and as the inference network architecture.

Table 5 shows results for UnkTest. CNN energies are best among all structured energy terms, including the different parameterizations. Increasing M improves F1, showing that high-order information helps the model recover from the high degree of noise. Table 6 shows results for UnkTrain. The CNN high-order energies again yield large gains: roughly 2 points compared to the local classifier and 1.8 compared to the linear chain energy.

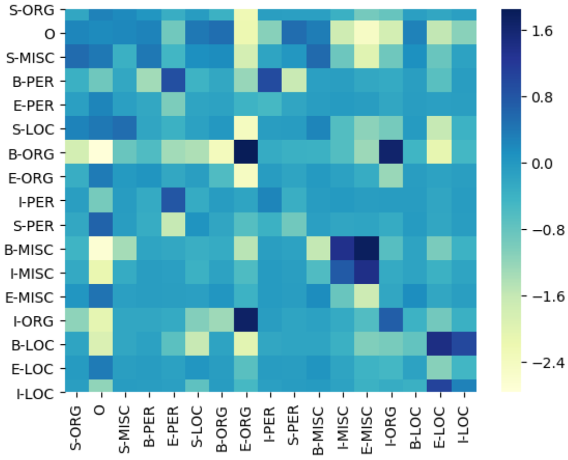
7 Incorporating BERT

Researchers have recently been applying large-scale pretrained transformers like BERT (Devlin et al., 2019) to many tasks, including sequence labeling. To explore the impact of high-order energies on BERT-like models, we now consider experiments that use $\text{BERT}_{\text{BASE}}$ in various ways. We use two baselines: (1) BERT finetuned for NER using a local loss, and (2) a CRF using BERT features ("BERT-CRF"). Within our framework, we also experiment with using BERT in both the energy function and inference network architecture. That is, the "input feature vector" in Equation 3 is replaced by the features from BERT. The energy and inference networks are trained with the objective in Section 2.3. For the training of energy function and inference networks, we use Adam with learning rate $5\text{e}-5$, a batch size of 32, and L2 weight decay of $1\text{e}-5$. The results are shown in Table 7.[6]

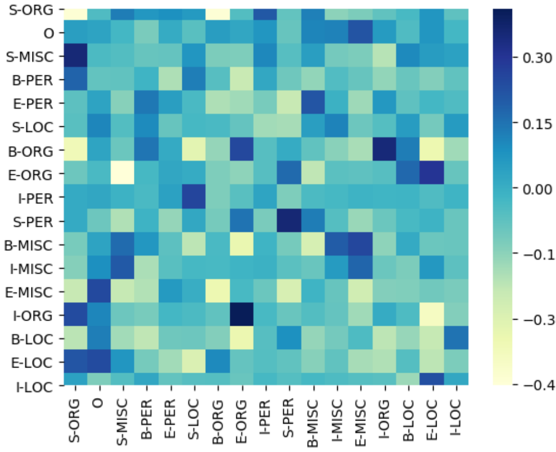
There is a slight improvement when moving from BERT trained with the local loss to using BERT within the CRF (92.13 to 92.34). There is little difference (92.13 vs. 92.14) between the locally-trained BERT model and when using the linear-chain energy function within our framework. However, when using the higher-order energies, the difference is larger (92.13 to 92.46).

---

[6] Various high-order energies were explored. We found the skip-chain energy (M=3) to achieve the best performance (96.28) on the dev set, so we use it when reporting the test results.



(a) Skip-chain energy matrix W_1.



(b) Skip-chain energy matrix W_3.

filter 2	I-LOC	E-LOC	O
filter 45	O	B-LOC	E-LOC

Table 8: Top 10 CNN filters with high inner product with 3 consecutive labels for NER.

8 Analysis of Learned Energies

In this section, we visualize our learned energy functions for NER to see what structural dependencies among labels have been captured.

Figure 1 visualizes two matrices in the skip-chain energy with $M = 3$. We can see strong associations among labels in neighborhoods from W_1. For example, B-ORG and I-ORG are more likely to be followed by E-ORG. The W_3 matrix shows a strong association between I-ORG and E-ORG, which implies that the length of organization names is often long in the dataset.

For the VKP energy with M=3, Figure 2 shows the learned matrix when the first label is B-PER, showing that B-PER is likely to be followed by "I-PER E-PER", "E-PER O", or "I-PER I-PER".

In order to visualize the learned CNN filters, we calculate the inner product between the filter weights and consecutive labels. For each filter, we select the sequence of consecutive labels with the highest inner product. Table 8 shows the 10 filters with the highest inner product and the corresponding label trigram. All filters give high scores for structured label sequences with a strong local dependency, such as "B-MISC I-MISC E-MISC" and "B-LOC I-LOC E-LOC", etc. Figure 3 in the appendix shows these inner product scores of 50 CNN filters on a sampled NER label sequence. We can observe that filters learn the sparse set of label trigrams with strong local dependency.

9 Conclusion

We explore arbitrary-order models with different neural parameterizations on sequence labeling tasks via energy-based inference networks. This approach achieve substantial improvement using high-order energy terms, especially in noisy data conditions, while having same decoding speed as simple local classifiers.

Acknowledgments

We would like to thank Sam Wiseman for help regarding high-order CRFs and the reviewers for insightful comments. This research was supported in part by an Amazon Research Award to K. Gimpel.

Abstract

Modern neural networks do not always produce well-calibrated predictions, even when trained with a proper scoring function such as cross-entropy. In classification settings, simple methods such as isotonic regression or temperature scaling may be used in conjunction with a held-out dataset to calibrate model outputs. However, extending these methods to structured prediction is not always straightforward or effective; furthermore, a held-out calibration set may not always be available. In this paper, we study *ensemble distillation* as a general framework for producing well-calibrated structured prediction models while avoiding the prohibitive inference-time cost of ensembles. We validate this framework on two tasks: named-entity recognition and machine translation. We find that, across both tasks, ensemble distillation produces models which retain much of, and occasionally improve upon, the performance and calibration benefits of ensembles, while only requiring a single model during test-time.

1 Introduction

For a calibrated model, an event with a forecast confidence p occurs in held-out data with probability p. Calibrated probabilities enable meaningful decision making, either by machines such as downstream probabilistic systems (Nguyen and O'Connor, 2015), or by end-users who must interpret and trust system outputs (Jiang et al., 2012). The calibration of modern neural models has recently received increased attention in both the natural language processing and machine learning communities. A major finding is that modern neural networks do not always produce well-calibrated predictions. As a result, much recent work has focused on improving model calibration, predominantly with *post-hoc* calibration methods (Guo et al., 2017).

However, post-hoc calibration methods have primarily been developed in the context of classification tasks. Thus, it is unclear how these methods will affect the performance of sequence-level structured prediction tasks (Kumar and Sarawagi, 2019). Additionally, post-hoc calibration methods require a held out calibration dataset, which may not be available in all circumstances. To improve calibration, an alternate approach is model ensembling, which is closely related to approximating the intractable posterior distribution over model parameters (Lakshminarayanan et al., 2017; Pearce et al., 2018; Dusenberry et al., 2020). Although computationally expensive, both at training and inference time, ensembling does not require a separate calibration set. Furthermore, ensembles have been found to be competitive or even outperform other calibration methods, particularly in more challenging settings such as dataset shift (Snoek et al., 2019).

In this paper, we study *ensemble distillation* as a means of achieving calibrated and accurate structured models while avoiding the high cost of naive ensembles at inference time (Hinton et al., 2015). Ensemble distillation consists of two stages: In the first stage, we select a base model for the task, such as a recurrent neural network or Transformer, and then train an ensemble of K such models, ensuring diversity either via sub-sampling (§4) or with different random seeds (§5). In the second stage, the ensemble of K teacher models is distilled into a single student model. Prior work has examined the effects of ensemble distillation on measures of uncertainty in vision tasks (Li and Hoiem, 2019; Englesson and Azizpour, 2019). To our knowledge, this is the first systematic study of the effect of ensemble distillation on the calibration of structured prediction models—we consider NER and NMT—which we find poses distinct challenges both in terms of measuring cali-

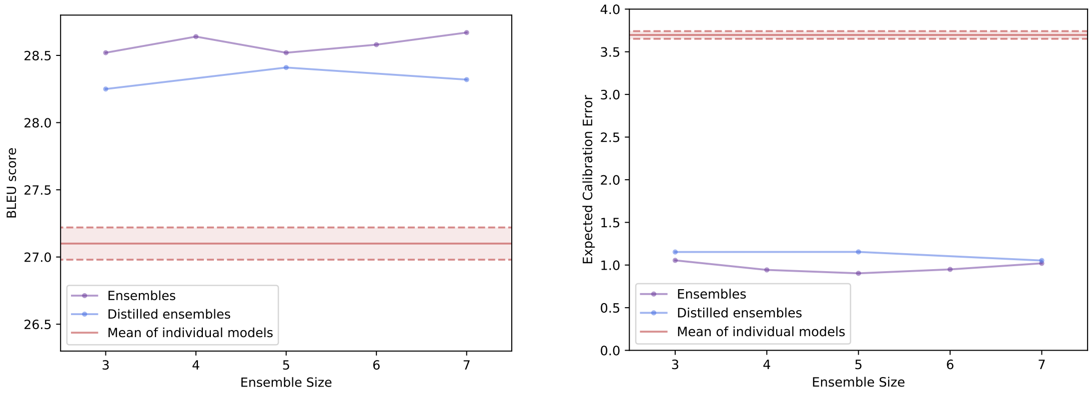
November 16–20, 2020.



(a) (b)

Figure 1: Plots of a) BLEU score (↑ is better) and b) Top-1 ECE (↓ is better) of ensembles and distilled ensembles of NMT models, compared to the mean (and standard error, the shaded region) of five individual standard models. Ensembles vastly improve both performance and calibration over individual models, and ensemble distillation is able to retain much of this improvement in a single model. Further, we find that even small ensembles, e.g. of size 3, are enough to see significant improvements over single models. Experimental details are described in §5.

bration and efficiently distilling large ensembles.

To this end, our contributions may be summarized as follows:

- Our key finding is that a model distilled from an ensemble consistently outperforms baseline single models (§4, §5), both in terms of calibration *and* task performance.
- We propose a straightforward memoization technique which, when combined with a top-K approximation, enables distillation of large ensembles with negligible training overhead for NMT (§5.1).
- We study the interaction between ensembling, distillation, and other commonly employed techniques including stochastic weight averaging and label smoothing in NMT (§5.3).
- We investigate methods to produce effective ensembles in structured prediction settings, finding that small numbers of independent models initialized from different random seeds outperform an alternative based on single optimization trajectories (§6.1).
- Finally, we compare the calibration performance of ensembles relative to temperature scaling, which requires a separate calibration dataset, finding that it provides an orthogonal benefit (§6.2).

Our findings suggest that ensemble distillation has potential to become a standard training recipe in settings where calibration is important.

2 Calibration

Given an arbitrary observation X and a model with parameters θ, we are interested in the *predictive uncertainty*, $p_\theta(Y \mid X)$, of an event Y. Our objective is to compute the predictive uncertainty of p_θ over of a finite sample of held-out data, $\{(X^{(i)}, Y^{(i)})\}_{i=1}^{N}$ of size N. We then say that p_θ is **calibrated** if the predictive uncertainty agrees with held-out observations; that is, if the model predicts an event with confidence p, then that event prediction is correct $p\%$ of the time.

Calibrated models can be useful for downstream systems which benefit from accurate estimates of uncertainty (Jiang et al., 2012; Nguyen and O'Connor, 2015). Recently, it has been noted that a large portion of modern neural networks are not well calibrated after training (Nguyen and O'Connor, 2015; Ott et al., 2018a; Kumar and Sarawagi, 2019), although it has been found that pre-training can help with this in natural language processing (Desai and Durrett, 2020).

2.1 Measuring calibration

In this work, we are interested in tasks where $Y = \{y_1, y_2, \ldots, y_T\}$ is a sequence, such that each y_i is drawn from some fixed vocabulary $\mathcal{V}$ such as a fixed set of named-entity types or a language-specific sub-word vocabulary.[1] However, due to the combinatorially large size of the output space

---

[1] Note that this encapsulates a wealth of "sequence-to-sequence" problems of interest such as sequence tagging, translation, co-reference resolution, and (linearized) parsing.

$\mathcal{Y}$, any event $Y \in \mathcal{Y}$ has a minuscule probability, making it difficult to meaningfully calculate calibration. Thus, when evaluating the calibration of p_θ, we focus on calibration with respect to token-level sub-sequences of Y, i.e. $p_\theta(y_t \mid X)$.

Since we evaluate model calibration on a finite amount of data, it is not possible to directly determine exactly what proportion of all events with probability p_θ will be correct. Instead, various metrics have been proposed to estimate how well calibrated a model is. Our evaluations in this work center around two metrics which are common in the literature: the *Brier score* (Brier, 1950), which is the mean squared error between the model's predictions and the targets, and the *Expected Calibration Error* (ECE; Naeini et al., 2015), which uses binning to measure the correlation between confidence and accuracy. Following (Nguyen and O'Connor, 2015), we use *adaptive binning* to select bin boundaries that allow an equal number of sampled confidences per bin.

2.2 Addressing calibration

A number of *post-hoc* solutions to the problem of poor calibration have been proposed, including Platt scaling (Platt, 1999), isotonic regression (Zadrozny and Elkan, 2001), and temperature scaling (Guo et al., 2017). However, these methods were predominantly designed for classification problems; in structured prediction problems, post-hoc re-calibration can sometimes hurt original performance (Kumar and Sarawagi, 2019). Additionally, post-hoc methods assume the availability of a held-out calibration set, which may not always be feasible in some settings. Thus, improving neural network calibration during the training procedure is still an open area of research.

It is well-known that neural model ensembles may improve task performance relative to individual models, although at the cost of increased compute and memory resources during training and inference (Simonyan and Zisserman, 2014; He et al., 2015; Jozefowicz et al., 2016). Recently, it has been observed that ensembles of independent models trained with different random seeds also manifest improved calibration (Lakshminarayanan et al., 2017; Snoek et al., 2019). Intuitively, independently initialized models may be over- or under-confident in different ways on ambiguous inputs; as a result, the average of their predictive distributions provides a more robust estimate of the true uncertainty associated with any given input.

3 Ensemble Distillation

3.1 Knowledge distillation

Hinton et al. (2015) first proposed knowledge distillation as a procedure to train a low-capacity *student* model on the fixed distribution q of a higher-capacity *teacher* model. In its general form, the distillation loss $\mathcal{L}_{\text{Student}}$ optimized by the student model with parameters θ has the form

$$\begin{aligned}\mathcal{L}_{\text{Student}}(\theta) = (1-\beta) * \mathcal{L}_{\text{NLL}}(\theta, \mathcal{D}) \\ + \beta * \mathcal{L}_{\text{KD}}(p_\theta, q, \mathcal{D}),\end{aligned}$$

where β is an interpolation between the standard negative log-likelihood loss[2] ($\mathcal{L}_{\text{NLL}}$) and the knowledge distillation loss ($\mathcal{L}_{\text{KD}}$), and $\mathcal{D}$ is the training dataset. In general, $\mathcal{L}_{\text{KD}}$ is some measure of dissimilarity between a the student and teacher distributions over examples in the training data, typically cross-entropy or KL-Divergence.

As our full output space $\mathcal{Y}$ is combinatorially large, exact comparison of $p_\theta(\mathcal{Y} \mid X)$ and $q(\mathcal{Y} \mid X)$ is intractable. A common method to address this is to instead distill teacher distributions at the *token level* (Hinton et al., 2015; Kim and Rush, 2016). In models that make Markov-assumptions, such as some NER models with CRF layers, we can efficiently compute the token-level distributions marginalized over all possible label sequences $\mathcal{Y}$ for each token. In auto-regressive models, such as the NMT models we consider, marginalization over all possible sequences is intractable. In this case, the token-level loss is evaluated using teacher-forcing (Williams and Zipser, 1989), by conditioning on true targets up to time t.

3.2 Ensemble distillation

Ensemble distillation uses knowledge distillation to train a student model on the output of an ensemble. Most previous approaches to ensemble distillation collapses the ensemble distribution into a single point estimate by averaging the teacher distributions (Hinton et al., 2015; Korattikara et al., 2015). This has been shown to be an effective way of distilling the uncertainty captured by an ensemble in computer vision tasks (Li and Hoiem, 2019; Englesson and Azizpour, 2019). Recently Malinin

---

[2] Possibly against target distributions which have been augmented by label smoothing.

et al. (2020) showed that by instead distilling the *distribution* over the ensemble into a *prior network* (Malinin and Gales, 2018), the student can learn to model both the *epistemic* and *aleatory* uncertainty of the ensemble.

As our goal is to improve model calibration, which captures both types of uncertainty, we follow previous methods of ensemble distillation which collapse the ensemble distribution into a point-estimate by uniformly averaging the distributions of each teacher. Formally, given an ensemble of K models, our task is to train a single student model to match a teacher distribution q which is composed of the K distributions from the ensemble, q_k. Maintaining consistency with how we derive predictions from an ensemble, when performing token-level distillation we construct the teacher distribution q as a mixture of each ensemble distribution:

$$q(y_t \mid X) = \frac{1}{K} \sum_{k=1}^{K} q_k(y_t \mid X)$$

In addition to token-level distillation, Kim and Rush (2016) proposed *sequence-level* distillation, which approximates the global distribution $q(Y \mid X^{(i0)})$ with the top M samples and treats each samples as an additional training example during student learning. This technique can be prohibitively expensive to use, as it increases the training time of the student by a factor of M; a problem which is exacerbated during ensemble distillation, as the factor becomes $M \times K$. To maintain simplicity in our distillation procedure, and comparability to tasks for which this technique does not apply,[3] we focus only on token-level ensemble distillation.

4 Ensemble Distillation for NER

We evaluate the calibration and performance effects of ensemble distillation on NER models. In these experiments, we examine teacher ensembles that use either strong independence assumptions (subsequently referred to as "IID"), or 1st order Markov assumptions. These settings allow us to examine the effects of distilling *globally*-marginalized versus *locally*-marginalized structured distributions into student models. We experiment on the 2003 CoNLL Dataset (Tjong Kim Sang and De Meulder, 2003), which contains datasets in English and German, and consider both languages in our experiments.

Our NER models use representations from pretrained masked language models: BERT for English and multilingual-BERT (mBERT) for German (Devlin et al., 2019). Given an input sequence $X = \{x_1, \ldots, x_T\}$ BERT outputs representations for each x_t.[4] We consider two separate models in our experiments: The 'IID' model makes predictions based solely off of the token-level logits output from a feed-forward layer applied to the BERT representations, making each prediction $\hat{y}_t$ independently from all others. The 'CRF' model instead passes the representations through a bidirectional LSTM layer, and the result into a conditional random field (CRF) with learned transition parameters (Lample et al., 2016). All models are trained using the Adafactor optimizer; we use a learning rate of $1e$–4 for training the ensembles, and $5e$–5 during distillation.

For each dataset, we trained $K = 9$ models in both the IID and CRF framework. To encourage diversity, each model in a given framework uses a different 1/10 split[5] of the training set for its early stopping criterion, in addition to using a different random seed. We then consider ensembles of sizes $K = 3, 6, 9$ models, where for $K = 3, 6$ the individual models are chosen randomly, but in such a way that the ensemble of 3 is always a subset of the ensemble of 6. During inference time, each ensemble's per-token distribution $q_k(y_t \mid X)$ is averaged uniformly to create the ensemble's distribution $q(y_t \mid X)$. In IID ensembles, $q_k(y_t \mid X)$ is taken directly from the logits at timestep t. In the CRF model, the Forward-Backward algorithm is used to compute distributions for each timestep which are globally normalized over all possible output sequences $\mathcal{Y}$. Predictions are then made for each token based on the maximum likelihood prediction from the ensembled distribution, q. For comparison, we also train a collection of 9 models, each with a different random initialization, on the *entire* training dataset and report their average performance and standard error. Note that this setup *disadvantages* the ensemble, as each individual model in an ensemble has access to strictly less training data than the individual models.

---

[3] For example, an NER model with a Conditional Random Field, for which we can already obtain globally normalized token-level posterior distributions.

[4] We fine-tune only the last 4 layers of BERT and mBERT. All other BERT parameters are frozen.

[5] This leaves a split of 1/10th of training data which acts as a unique validation set for the distillation training.

Table 1: Ensemble and Ensemble-Distillation results on CoNLL NER. All values are percentages. **Bold** results represent the best results of each model (IID or CRF) for each metric. Note that ensembles have higher F1 and are better calibrated than individual models. Furthermore, the distilled ensemble also significantly outperforms single models in all metrics. Surprisingly, distilling token-level CRF distributions can boost student models *past* the ensembles abilities. Dev results for these experiments are in Appendix D.

4.1 Ensemble distillation

During ensemble distillation, we only distill *into* IID models, although we consider both IID and CRF ensembles as teacher distributions. This allows us to examine the effects of distilling globally marginalized distributions into locally marginalized models. Each student's distillation loss $\mathcal{L}_{\text{KD}}$ is the token-level cross-entropy[6] between the student's distribution $p_\theta(y_t \mid X)$ and the ensembled distribution $q(y_t \mid X)$, with an interpolation parameter of $\beta = \frac{5}{6}$ between $\mathcal{L}_{\text{KD}}$ and the true train loss, $\mathcal{L}_{\text{NLL}}(\theta)$. All distilled models are trained using the final 1/10th training split as validation data.

4.2 Evaluating calibration in NER

For highly imbalanced data, like NER labels, common measurements of calibration do not sufficiently distinguish between models (Benedetti, 2010). One way we account for this is to use *stratified Brier score* (Wallace and Dahabreh, 2014), which has two components: the Brier score over all positive events (BS^+) and over all negative events (BS^-), whereby one of these (usually BS^+) is more sensitive to a model's calibration.

However, we note a potential drawback of relying on BS^+, namely that it is entangled with the model's recall.[7] We also wish to use Expected Calibration Error, which more closely captures calibration in the sense defined in §2, but ECE is also rendered useless in an imbalanced setting.

To address both of these issues, we therefore propose an alternative "balanced" version of each metric: for each entity-type,[8] we consider the top $2N$ most confident predictions, where N is the number of tokens with true labels of that class. After this filtering, "Balanced ECE" (B-ECE) is computed as the weighted sum of each class's (adaptively binned) ECE. "Balanced Brier score" (B-BS) is similarly computed as the weighted sum of each class's Brier score over this filtered set. These metrics correct the problem of imbalance and better reflect a model's calibration independent of its recall (and thus test performance).

---

[6] We did not use label smoothing, which is not commonly used in NER, for the results here, as we found to not improve results. Details can be found in Appendix C.

[7] That is, lower recall is strongly correlated to worse BS^+.

[8] We collapse B and I tags into type-level annotations for this measurement.

4.3 Results

We report the results of single models, ensembles, and distilled ensembles on F1, BS-, BS+, B-BS, and B-ECE in Table 1. We find that, across all settings and languages, ensembles outperform individual models in both F1 and calibration. Distillation only moderately hurts these numbers. Distilled models still outperform single models; additionally, they are vastly better calibrated than single models, indicating that distillation is effective at retaining the calibration benefits of ensembles.

While distilling IID ensembles into an IID student generally lowers performance compared to the ensemble, distilling the ensembled CRF distributions obtained into an IID model can actually yield higher performance *and* calibration than the ensemble. This suggests that global CRF distributions may not ensemble well at the token level, but are still effective distillation teachers when distilled into a local IID model with no global distribution of its own.

As a further examination of the benefits of improved calibration, we produce precision-recall curves (PR) by thresholding token-level probabilities. We find that improved calibration translates to higher area under the PR curve. Figures and experimental details are reported in Appendix B.

5 Ensemble Distillation for NMT

In this section, we evaluate ensemble distillation for NMT models.[9] State-of-the-art NMT models such as the Transformer are auto-regressive, meaning that the probability of a given target y_t is a function of all previous targets $y_{<t}$ (Vaswani et al., 2017). Thus, distilling teacher information in this scenario is different from what is done in NER; the structure level knowledge which is being distilled is inherently greedy (the teacher distributions do not take into account future sequences) and the distributions are built off of the gold labeled sequences up to that point (making it difficult to distill the global behavior of the ensemble).

All experiments are run on the WMT16 En→De and De→En tasks, using the vanilla Transformer-Base architecture from Vaswani et al. (2017).[10] We use a vocabulary of 32K symbols based on a joint source and target byte pair encoding (Sennrich et al., 2015; Ott et al., 2018b). Unlike in our NER setting, *all* models are trained on the full training set, with variation being instilled only through different random initializations and data order. All models considered use stochastic weight averaging (SWA; Izmailov et al., 2018). Additionally, to evaluate the effect of label smoothing (Szegedy et al., 2016; Müller et al., 2019) on calibration we consider 2 variations of NMT experiments: Models trained on standard cross-entropy loss (CE-SWA), and models trained on cross-entropy loss with a smoothing factor of $\lambda = 0.1$ (LS-SWA). Models are added to ensembles based on order of random seed.[11] During ensemble inference, the next output token is taken from the argmax of the averaged token-distribution across all models in the ensemble.

5.1 Challenges of ensemble distillation

Token-level distillation requires access to the teacher distribution during training, which in our experiments involves a distribution over 32K subwords. As we are interested in distilling an *ensemble* of teacher models, when training on devices like GPUs with limited memory, it may not feasible to keep all models in the ensemble on device. Even on devices with sufficient memory, the additional overhead associated with ensemble inference may lead to impractical training times.

To enable scaling to large ensembles with minimal training overhead, we memoize to disk the ensemble predictive distributions associated with *each token in the training data*. During training, the memoized values are streamed along with source and target subwords for calculation of the NLL and distillation losses. However, this solution incurs a large storage cost, namely $O(T \cdot V)$ floating point numbers for a training dataset consisting of T tokens and V subwords. Thus, we propose the following simple approximation scheme to reduce the storage requirements to $O(T \cdot V')$, where $V' \ll V$. For each token $t = 1, \ldots, T$, we store a vector $\boldsymbol{v}^{(t)} \in \mathbb{Z}^{V'}$ of indices associated with the top-V' tokens of the teacher distribution, along with a vector $\boldsymbol{p}^{(t)} \in \mathbb{R}^K$ of corresponding probabilities. During training, $\mathcal{L}_{\text{KD}}$ is evaluated with respect to these fixed top-V' events.

---

[9] All NMT experiments are run using the `fairseq` framework (Ott et al., 2019), using standard recipes and commodity hardware.

[10] Unless otherwise specified, our experimental configuration mirrors that of Vaswani et al. (2017) model with the "base" architecture.

[11] For example, an ensemble of 4 models will contain the models trained with random seeds 1, 2, 3, and 4. Note that this is essentially random selection, but it enforces that all ensembles are strict subsets of larger ensembles.

Table 2: Performance of Transformer-Base ensembles and individual models on the WMT16 English → German (a) and German → English (b) tasks. ECE values are given as percentages. LS+SWA and CE+SWA indicate models trained with and without label smoothing, respectively. Additionally, we report the performance of distilling CE-SWA ensembles into a single student model (see §5.2 for details). Similar to our NER results, we find that distillation is able to retain much of the benefits of an ensemble, both in terms of performance and calibration, over individual models. The best *single-model* performance is in **bold**.

5.2 Distillation experimental details

As we found label smoothing to significantly hurt ensemble calibration (Table 2), our distillation experiments only consider the CE-SWA ensembles as teachers. We use a truncation level of $V' = 64$ in Table 2 and report additional results for different truncation amounts in Table 3. The distillation loss with weight β is evaluated over the tokens which are in top-V' using a fixed temperature of 1. The negative log-likelihood loss with weight $1 - \beta$ is identical to other models and also uses label smoothing with $\lambda = 0.1$. All results use a weight of $\beta = 0.5$ on the distillation objective and use a random initialization of the model parameters, which preliminary experiments suggested was optimal.[12] Other experimental details match those of single models.

5.3 Results

Calibration for NMT is typically measured using the ECE of next-token predictions (ECE-1).[13] To better understand the calibration of the *distribution* of the model's predictions, we supplement this with the ECE of the top five predictions at each token (ECE-5).[14] We report the BLEU scores and calibration metrics of our ensembles, students, and baseline models in Table 2.

We find that individual models trained with label smoothing have slightly better BLEU scores and calibration than those trained without, which is consistent with the findings in (Müller et al., 2019), in which they attribute this improvement to reducing overconfidence. Surprisingly, however, ensembles of models trained using label smoothing actually have *worse* calibration than independent models, and this effect grows as more models are incorporated. We hypothesize that penalizing overconfidence is effective for improving calibration of a single model, but that this results in overcorrection when models which have been similarly penalized are ensembled together. This is supported by the reliability plots in Figure 2, which show that the individual LS models are underconfident in their top predictions, which is compounded by ensembling, whereas non-LS individual models are slightly overconfident in their top predictions, which is corrected by ensembling.

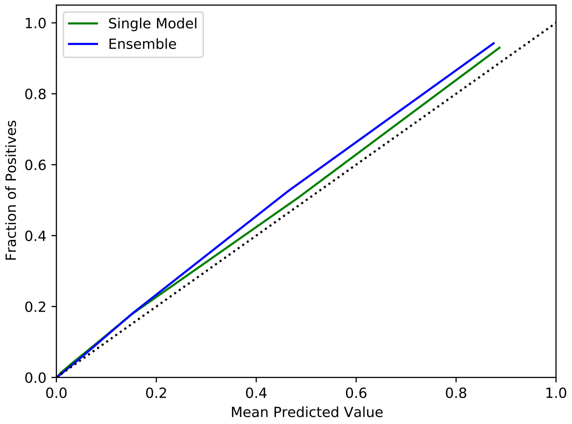
For ensembles that do not incorporate label smoothing, we observe the same trends for NMT as we do for NER: ensembles consistently improve performance, and distillation results in a single model which significantly outperforms baseline models both in terms of calibration and

---

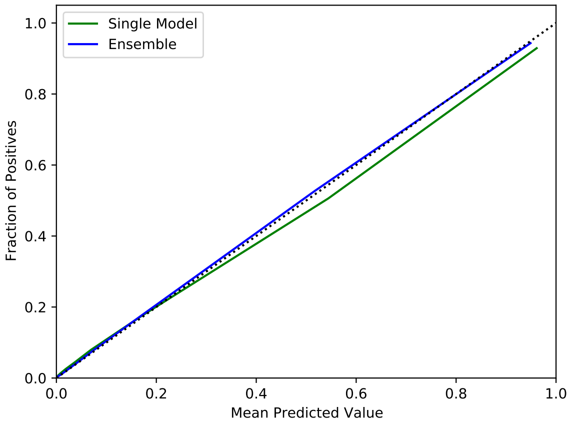
[12] In preliminary experiments, we also explored other training strategies, such as initializing from a constituent model using a larger weight of $\beta = 0.9$ on the distillation objective. However, this did not work as well as training from scratch with $\mathcal{L}_{\text{NLL}}$ and $\mathcal{L}_{\text{KD}}$ evenly weighted.

[13] See (Müller et al., 2019; Kumar and Sarawagi, 2019).

[14] We use adaptive binning, as described in section §2.1, to compute both metrics.



(a) Models trained with label smoothing



(b) Models trained without label smoothing

Figure 2: Reliability plots comparing predictions of single models to those of ensembles for models trained a) with and b) without label smoothing. The dotted diagonal line represents perfect calibration; the regions above and below it correspond to underconfidence and overconfidence, respectively.

BLEU. We also see a more consistent trend of improvement as the ensemble size increases, which we attribute to the substantially larger NMT dataset size (Figure 1).

Effect of truncation size $\mathbf{V'}$. We consider $V' = \{32, 64, 128, 256\}$ which requires $\{32, 64, 128, 254\}$ gigabytes of storage respectively to memoize the teacher distributions. To put these storage requirements in perspective, naively storing the full predictive distribution would require approximately 17 terabytes of storage. Note that the storage requirements of the proposed distillation procedure are constant with respect to the number of models in the teacher ensemble, so in principle the proposed approach could be used to distill significantly larger ensembles than considered in this work. The results for De→En are reported in Table 3. Surprisingly, as V' becomes smaller, performance does not monotonically degrade, suggesting that truncation could have a beneficial regularisation effect. In fact, although $V' = 32$ has a marginally worse BLEU score than the best models, it has the best ECE-5 score. This suggests that for large datasets it may be reasonable to use aggressive truncations, although we do not experiment with values smaller than $V' = 32$.

$\mathbf{V'}$	**BLEU**	**ECE-1**	**ECE-5**
32	31.64	1.602	**0.623**
64	**31.84**	1.497	0.636
128	31.80	1.567	0.642
256	31.72	**1.325**	0.648

Table 3: Distillation performance for De→En as the truncation V' is varied. An ensemble of 7 models is used as the teacher.

6 Further Experiments

6.1 Single-model ensembles

Our findings suggest that even ensembles of relatively small size (3-4) can still yield significant improvements over single models. In this section, we explore whether these findings can be mirrored by an ensemble which is built from a *single optimization trajectory*, built from multiple checkpoints.

For this purpose we consider a popular technique introduced by Loshchilov and Hutter (2016). The authors define SGDR, a scheme for training with a cyclical learning rate, and find that an ensemble of ‘snapshots’ of the model taken when the learning rate is at a minimum gives similar improvements in accuracy to proper ensembles.

We follow the same procedure used to train our single CE+SWA NMT models, stopping 3 epochs earlier. We then warm-start this model and train for 3 epochs[15] using a cyclical learning rate, saving the model at the end of each. Table 4 gives the results obtained by ensembling the saved checkpoints, and a comparison to an equivalent proper ensemble. We find that SGDR improves calibration over single models, but not to the same extent as the ensemble, and does not improve BLEU.

---

[15] We use 3 epochs to align with the recommendation in (Loshchilov and Hutter, 2016). For SGDR, we set T_{mult} parameter to 1, but found that other settings gave similar results. Reported runs used 2000 steps between saved models, but values in $\{500, 1000, 3000\}$ did not produce significantly different results.

Method	**# Models**	**BLEU**	**ECE-1**	**ECE-5**
SGDR	3	26.97	1.105	0.394
CE + SWA	Ind.	27.10	3.697	1.149
CE + SWA	3	**28.52**	**0.904**	**0.303**

Table 4: Single-run ensemble performance for NMT. We include the performance of the 3-model ensemble and the average individual model performance. We find that single-run ensembles have better calibration than single models, but do not see the same performance gains that true ensembles do.

Applying SGDR to NER experiments yielded results which did not improve over the individual NER models in Table 1. We posit that using pretrained BERT reduces the amount of diversity which can be introduced in a single training run.

6.2 Temperature scaling

One of the benefits of the proposed framework is that it does not require the use of a separate validation set to achieve improvements in calibration. This also means that when one is available, it can be used in conjunction with our method to further improve calibration. A well-studied method for performing post-hoc re-calibration using additional data is temperature scaling (Guo et al., 2017). To explore the interactions between temperature scaling and ensemble distillation, we perform temperature scaling on our German NER IID models and our largest IID ensemble, using the validation set for tuning calibration. Additionally, we train a new student on the temperature-scaled ensemble. We report the test performance and calibration of all models, compared to the models without temperature scaling, in Table 5.

We find that temperature scaling can improve individual model calibration, but it does not surpass the calibration of ensembles.[16] Additionally, we see that temperature scaling can further be used to improve the calibration of both ensembles and ensemble-distilled models. However, the effect on performance varies; while temperature scaling hurts ensemble performance, it has a significant positive effect on the student model.

Model	TS	BS+	BS-	B-BS	B-ECE	F1
Individual		17.212	0.233	9.444	8.542	81.68
	✓	16.463	0.184	8.052	4.098	81.68
Ensemble: 9		14.457	0.158	8.015	4.337	83.51
	✓	14.806	0.141	7.978	3.428	83.32
Distilled: 9		14.495	0.197	8.699	5.694	82.86
	✓	14.081	0.160	7.857	3.647	84.27

Table 5: CoNLL-2003 German IID results for individual models, 9-ensembles, and distilled 9-ensembles with and without temperature scaling (TS). We find that we can utilize temperature scaling in all cases to boost calibration, but temperature scaling only helps overall performance when used in combination with distillation.

7 Conclusion

Summary of contributions. We present a systematic study of the effect of ensembles on the calibration of structured prediction models, which consistently improve calibration and performance relative to single models. Our key finding is that *ensemble distillation* may be used to produce a single model that preserves much of the improved calibration *and* performance of the ensemble while being as efficient as single models at inference time. Furthermore, we show that calibration of the single student models can be further improved by other, orthogonal, re-calibration methods. We release all code and scripts.[17]

Open research questions. Non-autoregressive translation (NAT) is an active area of research for NMT (Gu et al., 2017; Stern et al., 2019; Ghazvininejad et al., 2019). Most knowledge distillation for NAT is performed at the *sequence level*, and ignores distributional information at the token level. In future work, we are interested in exploring NAT using distilled ensembles with truncated distributions, and assessing how improved calibration impacts non-sequential decoding performance. Finally, Snoek et al. (2019) find that deep ensembles can significantly improve out-of-domain performance over single models, and we are interested in exploring whether our distillation techniques retain these benefits.

Acknowledgements

A Additional NMT results

Table 6 gives results for ensembles of models which do not use SWA to combine checkpoints. We see that although the performance of the independent models is worse than those which use SWA, ensembles of them essentially match the performance of the corresponding ensembles which did use SWA. This suggests that ensembling obviates the need for checkpoint averaging.

B The effect of calibration on PR curves for NER

In this section, we illustrate a further advantage of calibrated NER models, which is that they enable straightforward thresholding of the returned confidences at different operating points of interest. In general, one may be willing to trade-off precision or recall according to the application. The popular F1 metric for NER evaluates at one such operating point. The framework of precision-recall (PR) curves provides a graphical illustration of performance of different models across a range of operating points, and the *area under the PR curve* provides a summary statistic that enables comparing different models across the entire range of operating points (Flach and Kull, 2015).

Note however that sequence distributions do not enable straightforward thresholding because the probability of any particular sequence is vanishingly small. Therefore, it is necessary to consider marginal probabilities of positions or short spans instead. While expensive in the case of the CRF, requiring dynamic programming for each possible event of interest, note that our distilled IID model enables direct thresholding on the *calibrated* per-position probabilities.

To illustrate the benefit of improved calibration, Figure 3 shows PR curves for four models:

- An individual CRF model
- An individual IID model
- A model distilled from a 9-ensemble of CRFs
- A model distilled from a 9-ensemble of IIDs

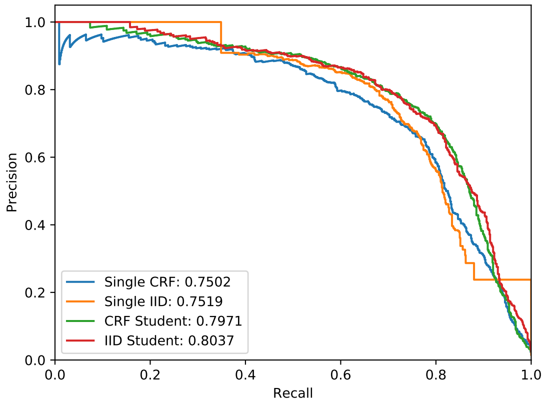

Figure 3: Precision-Recall curves of NER models.

We find that the distilled ensembles, which have better calibration, have greater AUC than individual models, and generally dominate them around the threshold corresponding to F1.

C Label smoothing in NER

We are not aware of a thorough study of the effects of label smoothing on NER tasks. Our experiments found that, similar to the NMT case, label smoothing did somewhat improve calibration for individual models. However, label smoothing gave mixed results when used in conjunction with our framework for ensembles and ensemble distillation, and generally the best results were achieved without it. We report our findings in Table 7.

D Dev results for CoNLL-2003

Table 8 contains results for our ensemble and distilled ensemble experiments on the CoNLL-2003 English and German development splits. Each model is the same as the one used to produce the corresponding test result in Table 1.

E Information about datasets

CoNLL-2003 comprises annotated text in two languages—English and German—taken from news articles. Details about sources, splits, and entity-type statistics can be found in (Tjong Kim Sang and De Meulder, 2003). The NER information is annotated in IOB format; we modify this to IOB2 as a pre-processing step.

WMT16 gives parallel translations of parliamentary proceedings and news articles in a number of languages. We restrict our focus to the English-German language pair. Details about the corpus and splits can be found at `http://www.statmt.org/wmt16/translation-task.html`. We follow the procedure provided by (Ott et al., 2019) for obtaining and processing the data.

F Information about computing infrastructure

NER. The IID and CRF models for our NER experiments were each trained on one Nvidia GTX 1080 Ti GPU. Most of the models are trained using early stopping, which makes the training time somewhat variable, but typically requires 3-4 hours. Distilled student models tend to converge more quickly, sometimes requiring 2 hours or less to train.

NMT. Training the Transformer models used for NMT is more computationally expensive due to the size of the training datasets. However, using 4 Nvidia RTX 2080 Ti GPUs, all models converged in less than 4 days, where we used 2 steps of gradient accumulation (Ott et al., 2019). We note that it would be possible to reproduce our experiments using a single GPU by using more steps gradient accumulation, at the expense of longer training times.

Inducing Target-Specific Latent Structures for Aspect Sentiment Classification

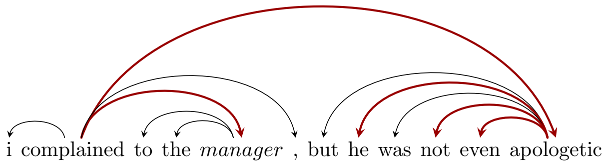
Abstract

Aspect-level sentiment analysis aims to recognize the sentiment polarity of an aspect or a target in a comment. Recently, graph convolutional networks based on linguistic dependency trees have been studied for this task. However, the dependency parsing accuracy of commercial product comments or tweets might be unsatisfactory. To tackle this problem, we associate linguistic dependency trees with automatically induced aspect-specific graphs. We propose gating mechanisms to dynamically combine information from word dependency graphs and latent graphs which are learned by self-attention networks. Our model can complement supervised syntactic features with latent semantic dependencies. Experimental results on five benchmarks show the effectiveness of our proposed latent models, giving significantly better results than models without using latent graphs.

1 Introduction

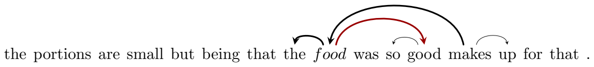
Aspect-level sentiment analysis aims to classify the sentiment polarities towards specific aspect terms in a given sentence (Jiang et al., 2011; Dong et al., 2014; Vo and Zhang, 2015). Aspects are also called opinion targets, which can typically be product or service features in customer reviews. For example, in the user comment "The **environment** is *romantic*, but the **food** is *horrible*", the sentiments of the two aspects "environment" and "food" are positive and negative, respectively. The main challenge of aspect-level sentiment analysis is to effectively model the interaction between the aspect and its surrounding contexts. For example, identifying that "romantic" instead of "horrible" as the opinion word is the key to correctly classifying the sentiment of "environment".

Recently, graph convolutional networks (GCNs; Kipf and Welling (2017)) over dependency trees (Marcheggiani and Titov, 2017; Zhang et al., 2019; Sun et al., 2019b; Wang et al., 2020) have received much research attention. It has been shown to be more effective for learning aspect-specific representations than traditional sentence encoders without considering graph structures (Tang et al., 2016a,b; Liu and Zhang, 2017; Li et al., 2018a). Intuitively, dependency trees allow a model to better represent the correlation between aspect terms and their relevant opinion words. However, the existing methods suffer from two potential limitations. First, dependency parsing accuracies can be relatively low on noisy texts such as tweets, blogs and review comments, which are the main sources of aspect-level sentiment data. Second, dependency syntax according to a treebank may not be the most effective structure for capturing interaction between aspect terms and opinion words. Take Figure 1(a) for example. The aspect term "manager" is syntactically related to "not apologetic" through $complained \rightarrow manager$ and $complained \rightarrow not\ apologetic$, though semantically they are directly related.



(a) An example dependency tree from Stanford CoreNLP parser[2].

(b) A latent graph for the aspect term "portion".



(c) A latent graph for the aspect term "food".

One intuitive solution to the aforementioned problems is to *automatically* induce semantic structures during the optimization process for sentiment

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5596–5607,
November 16–20, 2020. ©2020 Association for Computational Linguistics

classification. To this end, existing work has investigated latent structures *sentence-level* sentiment classification (Yogatama et al., 2016; Kim et al., 2017; Choi et al., 2017; Zhang et al., 2018; Corro and Titov, 2019), but no existing work has considered *aspect-level* sentiment classification. For the aspect-level task, a *different structure* should be ideally learned for *each aspect*. As shown in Figure 1(b) and 1(c), when given the sentence "the portions are small but being that the food was so good makes up for that.", ideal structures for the aspects "portions" and "food" can consist of links relevant to the terms and their opinion words only, without introducing additional information.

We empirically investigate three different methods for inducing semantic dependencies, including attention (Vaswani et al., 2017), sparse attention (Correia et al., 2019) and hard Kuma discrete structures (Bastings et al., 2019). In particular, attention has been used as a soft alignment structure for tasks such as machine translation (Bahdanau et al., 2014), and sparse attention has been used for text generation (Martins et al., 2020). The Hard Kumaraswamy distribution has been used to induce discrete structures with full differentiability (Bastings et al., 2019). We build a unified self-attentive-network (SAN) framework (Vaswani et al., 2017) for investigating the three structure induction methods, using a graph convolutional network on top of the induced aspect-specific structure for aspect level sentiment classification. In addition, to exploit mutual benefit with dependency syntax, we further consider a novel gate mechanism for merging multiple tree structures during GCN encoding.

Experiments on five benchmarks including Twitter, laptop and restaurant comments show the effectiveness of our proposed latent variable models. Our final methods give the state-of-the-art results in the literature, achieving significantly better accuracies than models without using latent graphs. To our knowledge, we are the first to investigate automatically inducing tree structures for targeted sentiment classification. We release our code at https://github.com/CCSoleil/latent_graph_atsc.

2 Related Work

Aspect-level sentiment analysis Aspect-level sentiment analysis includes three main subtasks, namely aspect term sentiment classification (ATSC) (Jiang et al., 2011; Dong et al., 2014), aspect category sentiment classification (ACSC) (Jo and Oh, 2011; Pontiki et al., 2015, 2016) and aspect-term or opinion word extractions (Li et al., 2018b; Fan et al., 2019; Wan et al., 2020). In this paper, we focus on ATSC. To model relationships between the aspect terms and the context words, Vo and Zhang (2015) designed target-aware pooling functions to extract discriminative contexts. Tang et al. (2016a) modeled the interaction of targets and context words by using target-dependent LSTMs. Tang et al. (2016b) used multi-hop attention and memory networks to correlate an aspect with its opinion words. Zhang et al. (2016) design gating mechanisms to select useful contextual information for each target. Attention networks are further explored by sequent work (Ma et al., 2017; Liu and Zhang, 2017). Li et al. (2018a) used target-specific transformation networks to learn target-specific word representations. Liang et al. (2019) used aspect-guided recurrent transition networks to generate aspect-specific sentence representations. Sun et al. (2019a) constructed aspect related auxiliary sentences as inputs to BERT (Devlin et al., 2019) for strong contextual encoders. Xu et al. (2019) proposed BERT-based post training for enhancing domain-specific contextual representations for aspect sentiment analysis.

Recently, there is a line of work considering dependency tree information for ATSC. Lin et al. (2019) proposed deep mask memory network based on dependency trees. Zhang et al. (2019) and Sun et al. (2019b) encoded dependency tree using GCNs for aspect-level sentiment analysis. Zhao et al. (2019) used GCNs to model fully connected graphs between aspect terms, so that all targets can be classified using a shared representation. Huang and Carley (2019) proposed graph attention networks based on dependency trees for modeling structural relations. Wang et al. (2020) used relational graph attention networks to incorporate dependency edge type information, and construct aspect-specific graph structures by heuristically reshaping dependency trees.

Latent graph induction Latent graphs can be induced to learn task-specific structures by end-to-end models jointly with downstream tasks. Kim et al. (2017) proposed structural attention networks to introduce latent dependency graphs as intermediate layers for neural encoders. Niculae et al. (2018) used SparseMAP to obtain a sparse distribution over latent dependency trees. Peng et al. (2018) implemented a differentiable proxy to the argmax

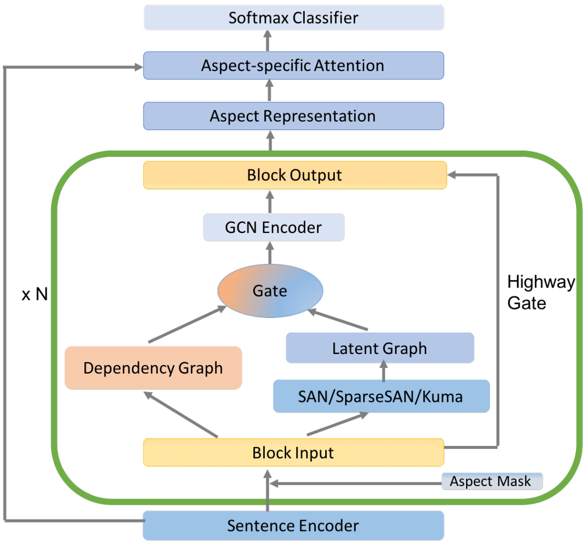


Figure 1: Model architecture.

operator over latent dependency trees, which can be regarded as a special case of introducing sparsity constraints into the softmax function (Niculae et al., 2018; Peters et al., 2019; Correia et al., 2019). Bastings et al. (2019) used HardKuma to sample stochastic interpretable discrete graphs for interpreting the classification results. Corro and Titov (2018) induced dependency structure for unsupervised parsing with a differentiable perturb-and-parsing method. While previous work obtains different structures using different methods, we investigate multiple methods for ATSC.

More in line with our work, Yogatama et al. (2016) and Zhang et al. (2018) considered reinforcement learning for inducing latent structures for text classification. Our work is in line but differs in two main aspects. First, we consider aspect-based sentiment, learning a different structure for each aspect term in the same sentence. Second, we empirically compare different methods for latent graph induction, and investigate complementary effects with dependency trees. To our knowledge, we are the first to consider inducing structures automatically for aspect-based sentiment classification.

3 Model

The overall model structure is shown in Figure 1. The model consists of four main components, including a sequence encoder layer for the input sentence, a structural representation layer that learns a latent induced structure $\mathbf{A}$, a GCN network that represents the latent structure and an aspect oriented classification layer. Below we discuss each component in detail in the bottom-up direction.

3.1 Sentence Encoder

We separately explore two sentence encoders, including a bidirectional long short-term memory networks (BiLSTM) encoder and a BERT encoder. Given an input sentence $s = w_1 w_2 \dots w_n$, we first obtain the embedding vector $\mathbf{x}_i$ of each w_i using a lookup table $\mathbf{E} \in \mathbb{R}^{|V| \times d_w}$ (where $|V|$ is the vocabulary size and d_w is the dimension of word vectors) and then use a standard BiLSTM encoder to obtain the contextual vectors of the input sentence. For the BERT encoder, we follow the standard practice by feeding the input “[CLS] w_1 w_2 $\dots w_n$ [SEP] w_f w_{f+1} $\dots w_e$” to BERT to obtain aspect specific representations, where $c = w_f\ w_{f+1} \dots w_e$ is the corresponding aspect sequence in s. Since BERT uses a subword encoding mechanism (Sennrich et al., 2015), we apply average pooling over the subword-level representations to obtain the corresponding word-level representations. The output vectors from the sentence encoder are denoted as $\mathbf{ce}_i^0$ for each w_i.

Aspect mask In order to make the encoder learn aspect-specific representations, we use distance-based masks on the word representation $\mathbf{ce}_i^0$. Formally, given an aspect $w_f w_{f+1} \dots w_e$, the masked $\mathbf{ce}_i^0$ is $\mathbf{h}_i^0 = m_i \mathbf{ce}_i^0$, where m_i is given by,

$$m_i = \begin{cases} 1 - \frac{f-i}{n} & 1 \leq i < f, \\ 0 & f \leq i \leq e, \\ 1 - \frac{i-e}{n} & e < i \leq n. \end{cases} \tag{1}$$

In this way, the more similar the context words are to the aspect, the higher their weights are. We denote the sentence representation as $\mathbf{H} = [\mathbf{h}_i^0, \mathbf{h}_1^0, \dots, \mathbf{h}_n^0]$, which is used for inducing latent graphs later.

3.2 Dependency Tree Representation

Given a sentence $s = w_1 w_2 \dots w_n$ and the corresponding dependency tree t over s (obtained using parser), an undirected graph G is built by taking each word as a node and representing head-dependent relations in t as edges. Each head-dependent arc is converted into two undirected edges. In addition, self loops are included for each word. Formally, the adjacent matrix $\mathbf{A}_{dep}$ is given by

$$\mathbf{A}_{dep}[i,j] = \begin{cases} 1 & \text{if } i \rightarrow j \text{ or } i \leftarrow j, \\ 1 & \text{if } i = j, \\ 0 & \text{otherwise.} \end{cases} \tag{2}$$

$\mathbf{A}_{dep}$ represents the syntactic dependencies between word pairs.

3.3 Latent Graph

We propose to learn latent graphs $\mathbf{A}_{lat}$ for each aspect, investigating three methods, namely **self-attention**, **sparse self-attention** and **hard kuma**.

Self-attention-based latent graph Self-attention networks (SANs) compute similarity scores between two arbitrary nodes in a graph. Formally, given a sentence representation $\mathbf{H}$, the similarity score α_{ij} can be regarded as the interaction strength between node i and node j. $\mathbf{A}_{lat}$ is given by

$$\mathbf{A}_{lat} = \text{softmax}\Big(\frac{(\mathbf{Q}\mathbf{W}_q)(\mathbf{K}\mathbf{W}_k)^T}{\sqrt{d}}\Big) \qquad (3)$$

where $\mathbf{Q}$ and $\mathbf{K}$ are two copies of $\mathbf{H}$, representing the query and key vectors, respectively. $\mathbf{W}_q \in \mathbb{R}^{d\times d}$ and $\mathbf{W}_k \in \mathbb{R}^{d\times d}$ are model parameters. The denominator $\sqrt{d}$ is a scale constant for controlling the magnitude of the dot-product operation. The softmax function normalizes the similarity scores by the column so that the sum of each row in $\mathbf{A}_{lat}$ equals to 1.

Multi-head SANs partition the graph representation $\mathbf{H}$ into multiple non-overlapping heads $\mathbf{H} = [\mathbf{H}_1, \mathbf{H}_2, \dots, \mathbf{H}_K]$, where K is the number of heads and $\mathbf{H}_i \in \mathbb{R}^{n\times \frac{d}{K}}$. For the i-th head, Eq 3 is independently applied to generate $\mathbf{A}^i_{head}$. The final latent graph averages the latent graphs of all heads,

$$\mathbf{A}_{lat} = \frac{\sum_{i=1}^{K} \mathbf{A}^i_{head}}{K}. \qquad (4)$$

Sparse-self-attention-based latent graph SANs learn a fully connected latent graph, where dense attention weights can bring noise from irrelevant context. To address this issue, sparse SANs potentially enables each node to attend to highly relevant contextual nodes. To achieve this goal, we replace the softmax operation in Eq 3 with the 1.5-entmax function (Niculae et al., 2018; Peters et al., 2019; Correia et al., 2019), which can project a real-valued vector into a sparse probability simplex. Formally,

$$\mathbf{A}_{lat} = \text{1.5-entmax}\Big(\frac{(\mathbf{Q}\mathbf{W}_q)(\mathbf{K}\mathbf{W}_k)^T}{\sqrt{d}}\Big), \qquad (5)$$

where 1.5-entmax[3] is applied to each row of the resulted matrix, with 1.5-entmax$(\mathbf{x})$ = $\arg\max_{\mathbf{p}\in\triangle^d} \mathbf{p}^T\mathbf{x} + \mathbf{H}^T_{1.5}(\mathbf{p})$. Here $\mathbf{H}^T_{1.5}(\mathbf{p})$ is an entropy function and $\mathbf{H}^T_{1.5}(\mathbf{p}) = \frac{1}{1.5\times(1.5-1)}\sum_{j=1}^{d}(p_j - p_j^{1.5})$. For more details, readers can refer to Peters et al. (2019).

Similar to Eq 4, multi-head SANs are used for sparse latent graph learning.

HardKuma-based latent graph HardKuma (Bastings et al., 2019) is a method which can produce stochastic graphs by sampling. Suppose that each edge $\alpha_{ij} \in [0,1]$ between nodes i and j is a stochastic random variable and $\alpha_{ij} \sim \text{HardKuma}(a,b,l,r)$, where HardKuma is a rectified Kumaraswamy distribution which includes both 0 and 1 in the support of Kumaraswamy distribution[4], $a > 0$ and $b > 0$ are parameters to control the shape of the Hard Kumaraswamy probability distribution, $l < 0$ and $r > 1$ define the supporting open interval (l, r). A sample of α_{ij} can be obtained by gradient reparameterization tricks (Kingma and Welling, 2013; Jang et al., 2016),

$$\begin{aligned} s_1 &= F^{-1}_{Kuma}(u; a, b), \\ s_2 &= l + (r-l)\times s_1, \\ z &= \min(1, \max(0, s_2)), \end{aligned}$$

where u is a uniform random variable and $u \sim \mathcal{U}(0,1)$ which replaces the HardKuma sample, F^{-1}_{Kuma} is the inverse c.d.f. of the Kumaraswamy distribution and $F^{-1}_{Kuma}(u,a,b) = (1-(1-u)^{1/b})^{1/a}$. s_1 is a sample of the Kumaraswamy distribution, s_2 is a stretched sample for the supporting interval after shift and scale operations. s_2 is converted to z by a hard-sigmoid function, which can ensure that the value of z falls into $[0,1]$. z is differentiable with respect to the shape parameters a and b.

Denote the shape parameters for all edges as $\mathbf{a}$ and $\mathbf{b}$. With reparameterization, the sampling is independent of the model and the main goal is to represent $\mathbf{a}$ and $\mathbf{b}$ using neural networks. Specifically, $\mathbf{a}$ and $\mathbf{b}$ can be calculated by SANs. Formally,

---

[3] We use the implementation of 1.5-entmax from https://github.com/deep-spin/entmax.

[4] For more details, refer to Bastings et al. (2019).

$\mathbf{a} \in \mathbb{R}^{n \times n}$ for the whole graph is given by

$$\begin{aligned} \mathbf{H}_a &= \text{MHSAN}(\mathbf{H}, \mathbf{H}, \mathbf{H}), \\ \mathbf{C}_a &= \text{LN}(\text{FFN}(\mathbf{H}_a) + \mathbf{H}_a), \\ \mathbf{s}_a &= \mathbf{C}_a \mathbf{C}_a^T, \\ \mathbf{n}_a &= \frac{\mathbf{s}_a - \text{mean}(\mathbf{s}_a)}{\text{std}(\mathbf{s}_a)}, \\ \mathbf{a} &= \text{softplus}(\mathbf{n}_a), \\ \mathbf{A}_{lat} &\sim \text{HardKuma}(\mathbf{a}, \mathbf{b}, l, r), \end{aligned} \tag{6}$$

where MHSAN, LN and FFN denote multi-head self attention networks, layer normalization and position-wise feed-forward networks, respectively. In our model, the particular networks of MHSAN, LN and FFN are taken from Transformer (Vaswani et al., 2017). $\mathbf{b}$ is defined in a similar way, but with different parameters. Here $\mathbf{H}_a$ is the initial result of MHSAN, $\mathbf{C}_a$ considers residual connections and feature transformations, $\mathbf{s}_a$ is the initial similarity score calculated by self attention, $\mathbf{n}_a$ denotes the normalized similarity scores and $\mathbf{a}$ is ensured to be non-negative by applying the softplus activation function over $\mathbf{n}_a$.

3.4 Graph Convolutional Networks

Graph convolutional networks (GCNs) (Kipf and Welling, 2017) encode graph-structured data with convolution operations. The representation of each node v in a graph G is aggregated from its neighbors. Suppose that the node set is $V = \{v_i\}_{i=1}^n$, where n is the number of nodes and the graph is $G = \{V, \mathbf{A}\}$. $\mathbf{A} \in \mathbb{R}^{n \times n}$ is the adjacent matrix between nodes. Let the representation vector of v_i at the l-th layer be $\mathbf{h}_i^l$ and $\mathbf{h}_i^l \in \mathbb{R}^d$, where d is the node vector dimension. The whole graph representation of the l-th layer $\mathbf{H}^l$ is the concatenation of all the node vectors of this layer, namely $\mathbf{H}^l = [\mathbf{h}_1^l, \mathbf{h}_2^l, ..., \mathbf{h}_n^l]$ and $\mathbf{H}^l \in \mathbb{R}^{n \times d}$. The graph convolution for $\mathbf{H}^l$ is given by:

$$\mathbf{H}^l = \rho(\mathbf{A}\mathbf{H}^{l-1}\mathbf{W}^l + \mathbf{b}^l), \tag{7}$$

where $\mathbf{W}^l \in \mathbb{R}^{d \times d}$ and $\mathbf{b}^l \in \mathbb{R}^d$ are model parameters for the l-th layer. ρ is an activation function over the input graph representation $\mathbf{H}^{l-1}$ and typically set to be the ReLU function. The initial input $\mathbf{H}^0$ is the sentence representation $\mathbf{H}$.

3.5 Gated Combination

Given two graphs $\mathbf{A}_{dep}$ and $\mathbf{A}_{lat}$, we design gating mechanisms to combine the strengths of both. Formally, suppose that the input graph representation is $\mathbf{H}_{in}$, the graph convolution weight matrix and bias are $\mathbf{W}$ and $\mathbf{b}$ respectively, we propose a gated GCN to output $\mathbf{H}_{out}$ by considering both $\mathbf{A}_{dep}$ and $\mathbf{A}_{lat}$,

$$\begin{aligned} \mathbf{I}_{dep} &= \mathbf{A}_{dep}\mathbf{H}_{in}\mathbf{W}, \\ \mathbf{I}_{lat} &= \mathbf{A}_{lat}\mathbf{H}_{in}\mathbf{W}, \\ \mathbf{g} &= \sigma(\mathbf{I}_{lat}), \\ \mathbf{I}_{com} &= (1 - \lambda\mathbf{g}) \odot \mathbf{I}_{dep} + \lambda\mathbf{g} \odot \mathbf{I}_{lat}, \\ \mathbf{H}_{out} &= \rho(\mathbf{I}_{com} + \mathbf{b}), \end{aligned} \tag{8}$$

where $\mathbf{g}$ is a gating function learned automatically from data and $0 \leq \lambda \leq 1$ is a hyper-parameter for prior knowledge. The graph convolutional matrix $\mathbf{W}$ is the same for $\mathbf{A}_{dep}$ and $\mathbf{A}_{lat}$, which suggests that our model does not introduce any additional parameters. $\mathbf{AHW}$ in Eq 8 can be replaced with $\mathbf{I}_{com}$, which is a gated combination of $\mathbf{A}_{dep}\mathbf{HW}$ and $\mathbf{A}_{lat}\mathbf{HW}$. This combination equals that we first merge $\mathbf{A}_{dep}$ and $\mathbf{A}_{lat}$ into a single graph $\mathbf{A}_{com}$ using dynamic gating mechanisms and then directly use $\mathbf{A}_{com}$ as $\mathbf{A}$ in Eq 7 to obtain the graph representations.

Gated GCN blocks In practice, we stack N GCN layers. For different layers, the convolution parameters are different. A highway network is used to combine the feature representations in adjacent layers. Formally, given the input representation of the l-th block $\mathbf{H}^{l-1}$, the input to the first block is the aspect-aware sentence representation $\mathbf{H}^0$, the output of the l-th block $\mathbf{H}^l$ is given by,

$$\begin{aligned} \mathbf{g}_l &= \sigma(\mathbf{H}^{l-1}), \\ \mathbf{H}_{com}^l &= \mathit{gatedcombine}(\mathbf{H}^{l-1}, \mathbf{A}_{dep}, \mathbf{A}_{lat}), \\ \mathbf{H}^l &= \mathbf{g}_l \odot \mathbf{H}_{com}^l + (1 - \mathbf{g}_l) \odot \mathbf{H}^{l-1}, \end{aligned}$$

where *gatedcombine* is the GCN function defined in Eq 8. We apply the highway gate to all the GCN blocks except for the last one.

3.6 Sentiment Classifier

Aspect-specific attention Based on the output of the last GCN block $\mathbf{H}^N$, we obtain the representations for the aspect $w_f w_{f+1} \dots w_e$ using $\mathbf{H}_f^N, \mathbf{H}_{f+1}^N \dots, \mathbf{H}_e^N$. The final aspect-specific feature representation $\mathbf{z}$ is given by an attention network over the sentence representation vectors $\mathbf{ce}_i^0$

$$\begin{aligned} \gamma_t &= \sum_{i=f}^{e} \mathbf{ce}_t^0 \mathbf{H}_i^N, \\ \boldsymbol{\alpha} &= \text{softmax}(\boldsymbol{\gamma}), \\ \mathbf{z} &= \boldsymbol{\alpha}\mathbf{C}, \end{aligned} \tag{9}$$

where $\mathbf{C} = [\mathbf{ce}_1^0, \mathbf{ce}_2^0, \ldots, \mathbf{ce}_n^0]$ is the contextualized representations produced by the sentence coder, γ_t is the attention scores of the t-th context word with respect to the aspect term, $\boldsymbol{\alpha}$ denotes the normalized attention scores and $\mathbf{z}$ is the final aspect-specific representation.

Softmax classifier The aspect-specific representation vector $\mathbf{z}$ is then used to calculate the sentiment score by a linear transformation. A softmax classifier is used to predict the probability of the sentimental class according to the learned sentiment scores. Formally,

$$\mathbf{p} = \text{softmax}(\mathbf{W}_o\mathbf{z} + \mathbf{b}_o), \tag{10}$$

where $\mathbf{W}_o$ and $\mathbf{b}_o$ are model parameters and $\mathbf{p}$ is the predicted sentiment probability distribution.

3.7 Training

The classifier is trained by maximizing the negative log-likelihood of a set of training samples $D = \{x_i, y_i\}_{i=1}^N$, where each x_i contains a set of aspects $c_{i,j}$. Formally, the loss function is given by

$$L(\boldsymbol{\theta}) = -\sum_{i=1}^{N}\sum_{c_{i,j}} \log \mathbf{p}_{y_{i,j}} + \frac{\lambda'}{2}||\boldsymbol{\theta}||^2,$$

where N is the number of training instances, $\boldsymbol{\theta}$ is the set of model parameters, λ' is a regularization hyperparameter, $y_{i,j}$ is the training label of the j-th aspect $c_{i,j}$ in x_i and $\mathbf{p}_{y_{i,j}}$ is the aspect classification probability for $c_{i,j}$, which is given by Eq 10.

4 Experiments

We conduct experiments on five benchmark datasets for aspect-level sentiment analysis, including twitter posts (TWITTER) from Dong et al. (2014), laptop comments (LAP14) provided by Pontiki et al. (2014), restaurant reviews of SemEval 2014 task 4 (REST14; Pontiki et al. 2014), SemEval 2015 task 12 (REST15; Pontiki et al. 2015) and SemEval 2016 task 5 (REST16; Pontiki et al. 2016). We pre-process these dataset in the same way as Tang et al. (2016b) and Zhang et al. (2019). Table 1 shows the statistics.

Settings. We initialize word embeddings with 300-dimensional pretrained GloVe (Pennington et al., 2014) embeddings[5]. The number of gated GCN blocks is 2. The head number is 8. The hidden dimension is 300. We parse the data using Stanza (Qi et al., 2020). No dependency labels are used. For the other settings, we follow Zhang et al. (2019). Following previous conventions, we repeat each model three times and average the results, reporting accuracy (Acc.) and macro-f1 (F1).

Table 2: Model performances on REST16.

4.1 Development Results

Effect of latent graphs Table 2 shows the performances on REST16. We enhance dependency tree based graphs with self-attention based latent graph models (`sanGCN`), sparse self-attention based latent graph models (`sparseGCN`) and hard kuma based latent graph models (`kumaGCN`). sparseGCN significantly outperforms depGCN. sanGCN is also better than depGCN in terms of F1 scores. kumaGCN performs the best, achieving 89.39 accuracy scores and 73.19 F1 scores, which empirically shows the importance of introducing stochastic semantic directly related connections between aspect word and the context words.

We additionally test two model variants, $-latent$ and $-dep$, which denote kumaGCN models without using latent graphs or dependency trees, respectively. Both underperform the full model, which demonstrates the strength of combining the two graphs for learning better aspect-specific graph representations. Additionally, $-latent$ is worse than $-dep$ especially in terms of F1, which shows that the automatically induced latent graph can be better than the dependency graph. As a result, we use kumaGCN as our final model.

Effect of λ To investigate how the trade-off between using automatically latent graphs and dependency tree may affect the ATSC performance, we vary λ in Eq 8 from 0 to 1 using a step size 0.1. Figure 2 shows the F1 scores achieved by kumaGCN on REST16 and REST15 with different

---

[5] http://nlp.stanford.edu/data/glove.840B.300d.zip

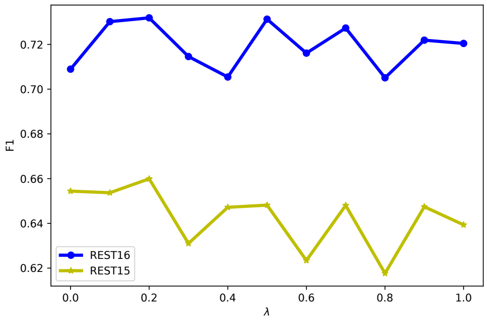

Figure 2: Effect of λ on REST16 and REST15 using kumaGCN.

λ. When $\lambda = 0$, the model degrades to depGCN; when $\lambda = 1$ the model relies solely on automatically learned latent graphs. $\lambda = 0.2$ gives the best results, which shows that the structures are complementary to each other. We thus set λ =0.2.

4.2 Main Results

We compare our models with:

- **LSTM**. Tang et al. (2016a) present target-dependent LSTMs to model the interaction of the target and the context words.
- **MemNet**. Tang et al. (2016b) leverage multi-hops of attention layers on the context word embeddings for sentence representation.
- **IAN**. Ma et al. (2017) use interactive attention networks to interactively learn the relationship between the targets and their contexts.
- **TNet-LF**. Li et al. (2018a) adopt context-preserving transformations on a convolutional neural network enhanced model.
- **depGCN**. Zhang et al. (2019) apply aspect-specific GCNs based on dependency trees to extract syntactic features.
- **BERT-SPC**[6]. This is a simple baseline by fine-tuning BERT for sentence classification.
- **AEN_BERT**. Song et al. (2019) employ an attentional encoder network and apply pre-trained BERT to the task.
- **RGAT+BERT**. Wang et al. (2020) use relational graph attention networks to incorporate the dependency edge type information.

Without BERT, using Glove embeddings Table 3 shows the results. KumaGCN outperforms all the baselines in terms of both averaged accuracy scores and averaged F1 scores. In particular, it improves the performance by 2.77 F1 points compared with the depGCN method. The performance gain compared to depGCN can empirically demonstrate the effectiveness of introducing latent graphs for aspect sentiment analysis tasks. Considering the running time, the self-attention module and the gated combination module can make our model slower compared to depGCN. In practice, we compare our model with depGCN on the Rest16 test dataset (616 examples). The inference time costs are 0.32s and 0.48s for depGCN and our model respectively, which shows that our model does not add too much computation overhead.

Our model also significantly outperforms the state-of-the-art non-depGCN model TNet-LF[7] on all the datasets except for Twitter. On Twitter, sparseGCN gives 72.64 accuracy, which is comparable to the performances of TNet-LF (72.98), which applies a topmost convolution 2D layer over a BiLSTM encoder to capture local n-grams and is thus less sensitive to informal texts without strong sequential patterns. We believe that the slight performance deficiency compared to TNet-LF is because of specific network settings. In particular, TNet-LF applies an attention-based context-preserving transformation to enhance the contextual representations produced by the BiLSTM encoder. For fair comparison with baselines, we do not use such modules[8]. To our knowledge, our model gives the best results without using BERT.

Comparison with Sun et al. (2019b)'s model Sun et al. (2019b) also proposed a GCN model based on dependency trees for aspect sentiment analysis similar to depGCN of Zhang et al. (2019). Sun et al. (2019b) use aspect-specific pooling over the dependency tree nodes to obtain the final representation vector, instead of using aspect mask and aspect-specific attention of Zhang et al. (2019). The data settings of Sun et al. (2019b)'s model are different from ours. For example, the positive/negative/neutral examples of their settings on LAP14 are 976/851/455, while ours are 994/870/464. In addition, they include POS tags in the input. A direct comparison without reimple-

---

[6] We adopt the widely used implementation https://github.com/songyouwei/ABSA-PyTorch.

[7] The results of TNet-LF does not match the original paper because the original paper of TNet-LF potentially filters out some training examples. For example, the positive/negative/neutral examples of TNet-LF on Laptop14 are 980/858/454, while ours are 994/870/464, respectively.

[8] If it were used for kumaGCN, the ACC/F1 scores are 73.51/72.06 on the twitter dataset, which are better than the performance of TNet-LF (72.98/71.43).

mentation is unfair. Preliminary results show that the results of Sun et al. (2019b) is slightly worse than that of depGCN based on the Zhang et al. (2019)'s data settings.

We also add a head-to-head comparison with Sun et al. (2019b) as shown in Table 5 using their data settings. It can be seen that our model can still achieve better F1 scores on all the datasets.

With BERT We compare our kumaGCN + BERT models with the state-of-the-art BERT-based models, and also implement the depGCN+BERT model as baseline. Table 4 shows the results. depGCN+BERT generally performs better than BERT-SPC. Our model outperforms both depGCN+BERT and BERT-SPC on all the datasets. Compared to the current state-of-the-art dependency tree based models RGAT+BERT, our model is better on Twitter and Lap14. On Rest14, the accuracy score of our model is comparable to RGAT+BERT without using dependency label information. In addition, our model gives 86.35/70.76 (Rest15) and 92.53/79.24 (Rest16) Acc./F1 scores, which are the best results on the datasets to our knowledge.

Model\Target	Rest14	Rest15	Rest16
BERT-SPC	49.46/43.54	44.10/39.69	45.45/33.67
depGCN+BERT	63.12/55.83	56.83/47.68	62.99/45.73

Table 6: Results for transfer learning from Twitter to the three datasets.

4.3 Parameter-based Transfer Learning

We further perform experiments using parameter-based transfer learning by training one source model on the Twitter dataset, and testing the trained model on the restaurant datasets. Table 6 shows the results. Our model outperforms BERT-SPC on all the target domains, which empirically demonstrates the strong aspect-specific semantic representation abilities of our proposed model. Compared to depGCN+BERT, our model gives improved results on the three datasets by about 10.0 accuracy points, which suggests that the induced latent structures have strong robustness for capturing aspect-opinion interactions.

4.4 Attention Distance

Figure 3 shows the distribution of the averaged attention weights of the context words according to the aspect terms on the test sentences of Rest16. In both cases, the attention scores defined in Eq 9 are shown. kumaGCN makes the distribution sharper than depGCN, focusing more on the context within 1 or 2 words. This observation also confirms data bias in the training set, where many

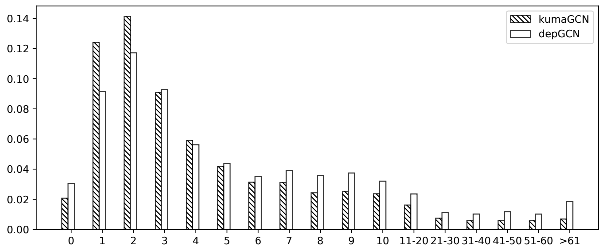

Figure 3: Attention distance distribution. x-axis: distance to the aspect terms; y-axis: attention scores.

opinion words are close to the aspect term (Tang et al., 2016b). Though depGCN can assign high weights to words far away from the target by using syntactic path dependencies, it may also bring in more noise. kumaGCN potentially circumvents this problem.

(depGCN) when$_{0.03}$ i$_{0.02}$ got$_{0.02}$ there$_{0.01}$ i$_{0.03}$ sat$_{0.05}$ up$_{0.03}$ stairs$_{0.04}$ where$_{0.09}$ the$_{0.07}$ *atmosphere*$_{0.01}$ was$_{0.02}$ cozy$_{0.03}$ &$_{0.07}$ the$_{0.07}$ service$_{0.02}$ was$_{0.11}$ horrible$_{0.25}$!$_{0.03}$
(kumaGCN) when$_{0.00}$ i$_{0.00}$ got$_{0.00}$ there$_{0.00}$ i$_{0.00}$ sat$_{0.00}$ up$_{0.00}$ stairs$_{0.00}$ where$_{0.09}$ the$_{0.10}$ *atmosphere*$_{0.14}$ was$_{0.31}$ cozy$_{0.35}$ &$_{0.00}$ the$_{0.00}$ service$_{0.00}$ was$_{0.00}$ horrible$_{0.00}$!$_{0.00}$

(c) Latent graph for "atmosphere".

(d) Latent graph for "service".

Figure 4: Comparisons of graph representations.

4.5 Case Study

To gain more insights into our model's behavior, we show one case study in Figure 4 using the example "when i got there i sat up stairs where the **atmosphere** was cozy & the **service** was horrible !". This example contains two aspects "atmosphere" and "service". Both depGCN and kumaGCN can correctly classify the sentiment of "service" as negative. However, depGCN cannot recognize the positive sentiment of "atmosphere" while kumaGCN can. Figure 4(a) compares the attention weights $\boldsymbol{\alpha}$ defined in Eq 9 of each context word with respect to "atmosphere" between depGCN and kumaGCN. For the target "atmosphere", depGCN assigns the highest weight to the word "terrible", which is an irrelevant sentiment word to this target, leading to an incorrect prediction. In contrast, our model assigns the largest weight to the key sentiment word "cozy", classifying it correctly.

Figure 4(b) shows pruned dependency trees by only keeping dependency edges related to these two aspects. We observe that the current parse contains an edge between "cozy" and "horrible", which might mislead depGCN to produce inappropriate representations. For further comparisons, we also extract the links of each target word i from the latent graph $\mathbf{A}_{lat}$ (Eq 6) by only keeping edges between i and j if and only if $j = \arg\max_{j'} A_{i,j'}$. If j is not unique, we return all the indices which correspond to the same highest value. Figure 4(c) and Figure 4(d) show the two latent graphs for "atmosphere" and "service", respectively. First, we observe that the two latent graphs are significantly different. Second, each of them contains only a few edges related to the semantic contexts for sentiment classification. We also verify that there is no edge between "cozy" and "horriable" when inducing the latent graph of "atmosphere". This can be an example to show that our model can learn aspect-specific latent graphs. With these automatically induced graphs, our model can learn better aspect-aware representations, providing better attention weights than depGCN.

5 Conclusion

We considered latent graph structures for aspect sentiment classification by investigating a variety of neural networks for structure induction, and novel gated mechanisms to dynamically combine different structures. Compared with dependency tree GCN baselines, the model does not introduce additional model parameters, yet significantly enhances the representation power. Experiments on five benchmarks show effectiveness of our model. To our knowledge, we are the first to investigate latent structures for aspect level sentiment classification, achieving the best-reported accuracy on five benchmark datasets.

Affective Event Classification with Discourse-enhanced Self-training

Yuan Zhuang, Tianyu Jiang, Ellen Riloff
School of Computing
University of Utah
{yyzhuang, tianyu, riloff}@cs.utah.edu

Abstract

Prior research has recognized the need to associate affective polarities with events and has produced several techniques and lexical resources for identifying affective events. Our research introduces new classification models to assign affective polarity to event phrases. First, we present a BERT-based model for affective event classification and show that the classifier achieves substantially better performance than a large affective event knowledge base. Second, we present a *discourse-enhanced self-training* method that iteratively improves the classifier with unlabeled data. The key idea is to exploit event phrases that occur with a coreferent sentiment expression. The discourse-enhanced self-training algorithm iteratively labels new event phrases based on both the classifier's predictions and the polarities of the event's coreferent sentiment expressions. Our results show that discourse-enhanced self-training further improves both recall and precision for affective event classification.

1 Introduction

In recent years, researchers have been tackling the problem of identifying *affective events*, which are events that have a positive or negative effect on people who experience the event. For example, events that are typically positive include being hired for a new job, breaking a sports record, or buying a home. Conversely, events that are typically negative include being fired from a job, breaking an arm, or having your house burn down. People's world knowledge about events and how they impact people is sufficient for humans to infer the affective state of someone who experiences such an event, even if that person does not explicitly express an emotion. Consequently, we will refer to these events as having positive or negative polarity with respect to an implicit affective state. Research has shown that recognizing affective events is important for a variety of natural language processing tasks, including narrative text comprehension and summarization (Lehnert, 1981; Goyal et al., 2013), dialogue systems (André et al., 2004), response generation (Ritter et al., 2011), and sarcasm detection (Riloff et al., 2013).

Much of the prior work on recognizing affective events has focused on producing lexical resources of verbs or event phrases with corresponding affective polarity values (Goyal et al., 2010, 2013; Rashkin et al., 2016; Ding and Riloff, 2016, 2018). These resources reflect substantial progress toward recognizing affective events in text, but their coverage is limited by their fixed content. We hypothesized that deep learning architectures that encode rich meaning representations could lead to a more effective approach for identifying affective events. Specifically, neural classification models have the capacity to generalize across lexically and syntactically different phrases that are semantically similar, and similar events are usually associated with the same affective polarity. To explore this approach, we created a BERT-based model for affective event classification and show that it recognizes affective events more effectively than a large affective event knowledge base.

Our research also introduces a *discourse-enhanced self-training* method that further improves affective event classification with unlabeled data. Self-training is a well-known method for using a classifier's own predictions on unlabeled instances to generate more training data. However, self-training has limitations. Using the most confident labels may not improve recall much because the new training instances are familiar, while using less confident labels often decreases precision because the training data becomes more noisy. To overcome these issues, we designed a *discourse-enhanced self-training* method that combines the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5608–5617,
November 16–20, 2020.

classifier's predictions with information from local discourse contexts to robustly assign labels to new training instances.

The key to this approach is to exploit unlabeled event phrases that occur near coreferent sentiment expressions. Specifically, we extract event phrases that are followed by a sentiment expression in a syntactic structure that suggests it likely refers to the event. For example, consider the statement *"I got engaged today. It is exciting."*. "It" refers to the act of getting engaged, so the positive sentiment applies to that event. Our algorithm then predicts the affective polarity for unlabeled events using both the classifier's prediction for the event phrase as well as the associated sentiment expressions. We show that our discourse-enhanced self-training method improves both recall and precision for affective event classification.

2 Related Work

Several lines of research have focused on the problem of recognizing events that have implicit affective states. Research on narrative understanding used bootstrapped learning to identify *patient polarity verbs*, which impart affective polarity to their patients (Goyal et al., 2010, 2013). Vu et al. (2014) extracted "emotion-provoking events" using the seed pattern *"I am* $<$ EMOTION $>$ *that* $<$ EVENT $>$, pattern expansion, and clustering. Reed et al. (2017) learned lexico-syntactic patterns associated with first-person affect to improve affective sentence classification alongside supervised learners. Li et al. (2014) extracted "major life events" from Twitter by clustering tweets that occurred with speech act words, such as "congratulations" or "condolences". But their work did not assign affective polarity to events, and focused only on major life events that prompt expressive speech acts. Our work has a broader scope, aiming to recognize everyday events as well (e.g., *being hungry* is negative, and *seeing a rainbow* is positive).

Work in opinion analysis created a +/- EffectWordNet (Choi and Wiebe, 2014) to recognize the effects of events on entities, although the effects are not necessarily "affective" because the entities need not be animate (e.g., *baking a cake* has a positive effect on the cake because it is created). Subsequent work developed implicature rules to use +/- effects for opinion analysis (Deng and Wiebe, 2014, 2015). There has also been work on recognizing the connotation of words and senses (Kang et al., 2014) and connotation frames (Rashkin et al., 2016), which infer connotative polarities for a verb's arguments from the writer's and entity's perspective. These efforts associated polarity with individual verbs, not event phrases.

Saito et al. (2019) used discourse relations to propagate affective polarity from seeds using a Japanese web corpus. They extracted events that co-occur with seeds in a large corpus, then used discourse relations as constraints in the learning process. Another line of related work is Emotion Cause Extraction, which links emotion expressions to the events that caused the emotion (Gui et al., 2016, 2017; Chen et al., 2018; Li et al., 2018; Xia and Ding, 2019). This research uses datasets created from Chinese news and microblogs that contain an explicitly mentioned emotion. This work assigns polarity to events in the context of a specific text passage. In contrast, our work aims to identify the *prior* affective polarity of an event, irrespective of context. Consequently, our classifier can be used to predict the affective polarity of events in contexts that do not contain any explicit emotion or sentiment indicators.

Our research is most closely related to the work by (Ding and Riloff, 2016, 2018), which identifies stereotypically affective events and their *prior polarity*, irrespective of context. The Affective Event Knowledge Base (AEKB) produced by (Ding and Riloff, 2018) contains over half a million event phrases coupled with polarity labels. These events were extracted from nearly 1.4 million personal blog posts in the ICWSM 2009 and 2011 Spinn3r datasets[1]. The polarity labels were generated automatically using a weakly supervised method. Their approach optimizes for semantic consistency over a graph of event nodes that are linked by edges capturing three types of semantic relations.

Our discourse-enhanced self-training algorithm adds a new twist to traditional self-training methods (Mihalcea, 2004; Kehler et al., 2004; McClosky et al., 2006). The approach is also reminiscent of co-training (Blum and Mitchell, 1998), which trains two classifiers based on independent views of the data. However in co-training, each classifier must be able to make reliable predictions on its own. We do not expect the coreferent sentiment expressions used by our approach to be sufficient by themselves because they are quite noisy (e.g., due to imperfect coreference, imperfect sentiment

labels, and issues like sarcasm). The strength of our method is that this signal can serve alongside the main classifier to produce a diverse new set of high-quality labels.

3 Creating Affective Event Classifiers

3.1 Motivation

Ding and Riloff (2018) created an Affective Event Knowledge Base (AEKB) that contains over 571,000 English event phrases labeled with affective polarity (positive, negative, or neutral). The AEKB was automatically generated from a corpus of personal blogs and is currently the largest resource of event phrases with polarity labels for the English language. We were curious to understand how effective the AEKB is at recognizing affective events in new texts. Twitter is another form of social media where we expect to find many affective expressions, so we created a new data set for affective event recognition in tweets to evaluate the generality of the AEKB and our new classifiers.

We produced a new dataset for affective events that contains 1,500 event phrases extracted from Twitter paired with manually assigned polarity labels. Section 4 describes the data creation process and gold standard annotation effort in detail. We represented events using a 4-tuple similar to the event representation in the AEKB: $\langle$*Agent*, *Predicate*, *Theme*, *Prepositional Phrase (PP)*$\rangle$.[2] We then evaluated the coverage and accuracy of the AEKB on our Twitter data. Every Twitter event was matched against the AEKB and, if a match was found, the polarity found in the AEKB was assigned to the event. Table 1 shows the results as a macro-averaged F1 score, alongside recall and precision for each of the three polarities: positive (POS), negative (NEG), and neutral (NEU).

The first row (Blogs) shows the results originally reported in (Ding and Riloff, 2018) for events extracted from blog posts, for comparison. Of the $1,500$ Twitter events, only 997 events (66%) were found in the AEKB. The second row of Table 1 (Twitter-found) shows results for these 997 events. The overall performance is fairly similar across Twitter and blogs, except that recall for positive polarity is substantially lower. The lower precision for neutral polarity suggests that many positive Twitter events are labeled as neutral in the AEKB.

Another issue is that one third (34%) of the Twitter events were not found in the AEKB at all. The third row of Table 1 (Twitter-all) shows the results across *all* $1,500$ Twitter events, where the missing events are left unlabeled. Overall, only 37% of the negative events and 26% of the positive events could be recognized by the AEKB.

These results show that despite its large size, the AEKB cannot recognize many affective events for two reasons: (1) the AEKB's precision is not perfect, so some positive and negative events are labeled as neutral, and (2) many affective events are not present in the knowledge base. Our research addresses these limitations by exploring whether classification models can achieve better coverage and accuracy by generalizing across events.

3.2 A BERT-based Affective Event Classifier

Our goal is to design a classifier that can label an event tuple with affective polarity. Representations produced by the transformer-based BERT model (Devlin et al., 2019) have achieved state-of-the-art performance across a variety of NLP tasks, so we used the pre-trained BERT$_{\text{BASE}}$ as the basis for our classifier and performed fine-tuning during the training.

The input is the sequence of tokens that comprise an event tuple. For example, $\langle$*I, ride, bike, -*$\rangle$ is converted into the sequence *"I ride bike"*. We use the uncased version of the *BERT base* model as our encoder. We use the 768-dimension output embedding of the special token [CLS], and pass the output vector of the special token [CLS] to a fully connected layer with softmax to produce a probability distribution over the three polarity classes. Each input event is then assigned the polarity with the highest probability value. We will refer to this model as **Aff-BERT**.

3.3 Experimental Results for Blogs Data

Baselines We developed two baselines to compare with Aff-BERT. The first model is a 1-layer LSTM. We first use ELMo (Peters et al., 2018) to encode an event sequence and feed the last layer of ELMo's outputs into the LSTM. The LSTM outputs a polarity distribution for the event. The

---

[2] The main difference is that we also allowed adjectival modifiers in noun phrases.

Table 2: Performance on the blogs test set.

second baseline is a linear classifier, which takes as input the average of the last layer of ELMo's outputs and produces a polarity distribution.

The LSTM has a hidden size of 512 and a dropout rate of 0.2. The learning rate is 0.01 for the LSTM, 0.1 for the linear classifier, and 1e-5 for Aff-BERT. We train all models for 5 epochs with a batch size of 50 and a linear warmup rate of 10% using AdamW optimizer.

Experiments Our first set of experiments evaluates Aff-BERT on the same blogs data that Ding and Riloff (2018) used to evaluate their AEKB. The validation and test data sets contain 490 and 1,000 manually annotated events, respectively.

The first row of Table 2 shows the results originally reported by (Ding and Riloff, 2018) for comparison. The second row shows the results when training Aff-BERT with the events that have polarity labels with predicted scores $\geq$ 0.6 in the AEKB.[3] It shows that Aff-BERT trained with the AEKB data performs better than the AEKB itself. The substantial recall gain for negative events is likely due to the generalization power of BERT's representations.

Next, we experimented with learning from gold labeled data by performing 10-fold cross-validation on the blogs test data. The third, fourth, and fifth rows of Table 2 show the results for the linear classifier, LSTM and Aff-BERT, respectively, trained with gold data. While the linear classifier and the LSTM do not perform as well as the AEKB, Aff-BERT trained on gold labeled data performs substantially better than both the AEKB and Aff-BERT trained on the AEKB. This shows that fine-tuning BERT on a relatively small amount of gold labeled data produces a strong affective event classifier, with respect to both recall and precision.

The strength of this model led us to wonder whether classification performance could be further improved by self-training with unlabeled data. As we will describe in Section 5, standard self-training produced only a small improvement, but we developed a new discourse-enhanced self-training algorithm that achieved bigger performance gains. In the next section, we describe how we collected events with coreferent sentiment expressions for the discourse-enhanced self-training algorithm.

4 Harvesting Events with Coreferent Sentiment Expressions

The key idea behind our approach is to create a self-training method that uses not only the classifier's own predictions but also a secondary source of information derived from local discourse contexts. Intuitively, the secondary signal confirms the classifier's prediction when they agree, or creates doubt about the classifier's prediction when they disagree. By taking both signals into account, we can assign high-quality labels to a diverse set of new examples in each cycle, which creates a robust self-training process.

From this point on, we turn our attention to Twitter because it is a vast resource that we can query to acquire a large set of event phrases in specific contexts, and where people share their everyday experiences. We acquire our unlabeled data by searching for event phrases on Twitter that occur with coreferent sentiment expressions. We use a heuristic to identify sentiment expressions that are likely to refer to an event in the preceding sentence. Specifically, we look for sentiment expressions that begin a sentence and match one of the following forms:

(a) {**this/that/it/I**}, {**be/feel/seem**}, {**ADJ+**}
(b) {**this/that/it**}, {**be/feel/seem**}, {**ADJ* N+**}

where the head adjective (ADJ) or head noun (N) is a sentiment term with positive or negative polarity. The sentiment expression cannot be followed by any events in its sentence and must follow a sentence that contains at least one event. Given these restrictions, the pronouns "this', "that", and "it" are likely referring to an event in the previous sentence, although this is not guaranteed. Similarly, the pronoun "I" is referring to the speaker who is likely expressing their sentiment toward something that was just mentioned, which is often (though not always) the prior event. We will call the phrases that match these patterns **coreferent sentiment expressions** because they express a sentiment that refers back to something mentioned earlier.

We found that the syntactic constructions above typically convey a sentiment about an event in the

---

[3] We tried score thresholds from 0 to 1 with the increment of 0.1, and 0.6 gave the best result.

Tweet1:	I rode a horse today! *That was fun*. **⟨I, ride, horse, -⟩**
Tweet2:	Someone was abducted on the street right next to mine. *It's terrifying*. **⟨-, abduct, someone, on street⟩**
Tweet3:	Disrupting my daily routine and alienating many people. *I am angry* ! **⟨-, disrupt, my daily routine, -⟩** **⟨-, alienate, people, -, -⟩**

Table 3: Examples of harvested tweets and extracted events.

prior sentence, but this heuristic is not perfect. For example, the sentiment sometimes applies to an object in the prior sentence and not an action (e.g., *"I bought a book. It is excellent"* describes an excellent book and not an excellent buying experience). Nevertheless, the self-training algorithm will use this data in the aggregate, so some noise can be tolerated. In the following sections, we describe each step of the Twitter data harvesting process.

4.1 Creating Sentiment Queries

We create an initial set of sentiment queries for Twitter by instantiating the syntactic patterns shown earlier with 3,010 subjective adjectives and 2,023 nouns from the MPQA lexicon (Wilson et al., 2005). We also use the 1,147 words labeled with "anypos" in MPQA as an adjective and a noun to instantiate the patterns. For example, given the adjective *"good"*, we exhaustively generate all phrases that match the regular expression: "{that/this/it/I} {be/feel/seem} *good*", such as *"That is good"* and *"I feel good"*.

We then download tweets that contain these phrases. If the context around the sentiment expression satisfies the constraints mentioned earlier, then we extract the events in the previous sentence as affective event candidates. Table 3 shows three tweets that were retrieved with queries for the sentiment expressions in *italics* along with the events extracted from each tweet in **boldface**.

4.2 Creating Event Queries

Next we can use the extracted events to harvest more tweets with coreferent sentiment expressions.

Searching for phrases that match an event is not trivial. The Twitter API only supports exact phrase matching but an event is represented as a tuple (<Agent, Predicate, Theme, PP>). Furthermore, the components in an event tuple contain lemmatized head words. We want to construct queries that will retrieve phrases containing morphological variations (e.g., "drove" for the lemma "drive") as well as modifiers preceding heads (e.g., "a fancy car" instead of just "car"). To circumvent this problem, we generate text spans for each event tuple from the original tweets that it was extracted from. The text span contains all words between the leftmost word and the rightmost word of the tuple. Then we apply the PrefixSpan algorithm (Saraf et al., 2015) to compute the frequency of all subsequences of words. For each event tuple, we create queries from the 20 most frequent subsequences that contain all words in the event tuple. For example, <he, drive, car> might yield queries such as *"he drove a fancy car"*, *"he has driven my car"*, etc.

After we retrieve tweets that match an event query, we apply the same constraints as before but in reverse: the sentence that mentions the event must be followed by a coreferent sentiment expression matching our patterns. In this step, we assume that unknown terms in the ADJ or N position of the patterns are sentiment-bearing, allowing us to identify new sentiment expressions. We found this heuristic to be quite good and produced some interesting affective terms that are not in the MPQA lexicon. For example, the new negative terms include *"cyberbullying"*, *"yucky"* and *"gutless"*, and the new positive terms include *"record-breaking"*, *"reassuring"* and *"heart-warming"*.

4.3 Iteratively Harvesting Events

The first step of data harvesting creates sentiment queries from the MPQA lexicon and extracts new event phrases. The second step of data harvesting creates event queries and extracts new sentiment phrases. Given these building blocks, we create a cycle that alternates these steps, iteratively harvesting new events with associated sentiment expressions. In each iteration, we form queries for sentiment or event phrases that have frequency ≥ 5 and have not been used as queries previously. We download 5,000 tweets for each event query and 1,000 tweets for sentiment expression query.[4] Finally, we discard retweets and duplicated tweets[5]. To be consistent with the criteria used for affective

---

[4] Many tweets collected by event queries contain no coreferent sentiment expression, so we downloaded more tweets for event queries to increase the number of matched instances.

[5] A tweet is duplicated if it shares 6 or more consecutive words with another tweet.

events in the AEKB by (Ding and Riloff, 2018), we also discarded events that did not contain a first-person reference or a family member term.[6]

We ran the harvesting process over Twitter for 4 iterations, after which few new events were found. The final dataset contains 2,068,600 unique event tuples and 15,494 unique sentiment expressions.

4.4 Gold Dataset Creation

We created a gold standard dataset for affective events from Twitter (**Twitter Dataset**) by having two human annotators label 1,500 randomly selected events of frequency ≥ 5. Each event was labeled as positive, negative, or neutral using the same criteria defined by (Ding and Riloff, 2018) for the AEKB. The pairwise inter-annotator agreement using Cohen's kappa was .75. The two annotators then adjudicated their disagreements to produce the final set of gold labels. The final dataset contains 435 (29%) positive, 348 (23%) negative and 717 (48%) neutral events. This new evaluation dataset and the collection of the unlabeled harvested events are publicly available at `https://www.cs.utah.edu/~yyzhuang/`.

5 Discourse-enhanced Self-training

We designed an enhanced self-training algorithm that learns from unlabeled data by iteratively labeling new instances using both the affective event classifier's prediction as well as polarities associated with the event's discourse contexts. We will refer to this method as Discourse-enhanced Self-training. The intuition is that (1) new instances are labeled only if both sources of information agree, which yields high-quality labels, and (2) a more diverse set of instances will be labeled than if only the classifier's most confident predictions were used.

Figure 1 illustrates how an unlabeled event is scored during Discourse-enhanced Self-training. Each event is paired with the set of coreferent sentiment expressions that occurred with it in our Twitter dataset. The affective event classifier is applied to the event and generates a probability distribution over the three polarity values. In parallel, an external sentiment classifier produces a probability distribution over the polarity classes for each of the coreferent sentiment expressions. The probability distributions are then averaged to produce an average probability distribution for the set of sentiment expressions as a whole. Finally, a joint scoring function takes the two probability distributions and produces a joint probability distribution for the event. The polarity with the highest probability is used as the event's label.

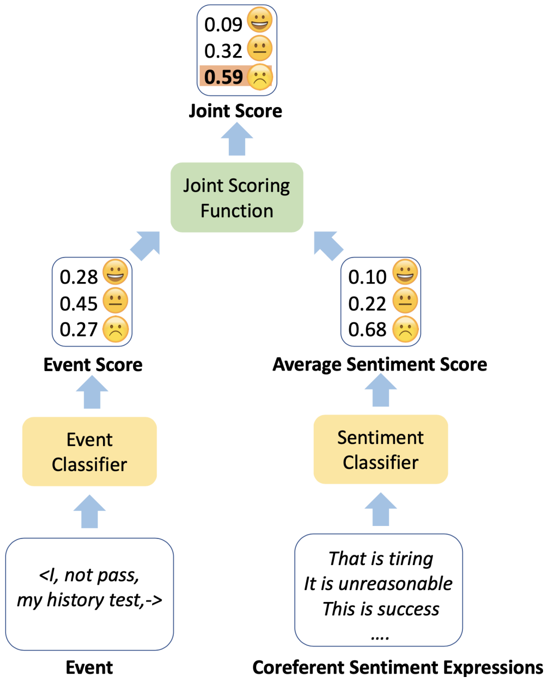

Figure 1: Illustration of Discourse-enhanced Scoring

Algorithm 1 outlines our Discourse-enhanced Self-training procedure in detail. The process begins with a gold labeled set of events E_L, a set of unlabeled events E_U where each event e_i in E_U is paired with a set of coreferent sentiment expressions CSE_i, an external sentiment classifier, and two confidence thresholds θ_{jnt} and θ_{neu}. Each iteration starts by training the event classifier on E_L. The event classifier is then applied to every unlabeled event e_i in E_U to produce an event score vector s_{e_i}. Next, the sentiment classifier is applied to every coreferent sentiment expression cse in CSE_i to produce a polarity distribution. Then the polarity distributions of all cse in CSE_i are averaged to produce an average polarity distribution $\bar{s}_{\mathrm{CSE}_i}$ for the whole set CSE_i. The joint scoring function then produces a joint score vector s_{jnt_i} for the event e_i by the equation below:

$$s_{jnt_i} = \frac{s_{e_i} \odot \bar{s}_{\mathrm{CSE}_i}}{s_{e_i} \cdot \bar{s}_{\mathrm{CSE}_i}}, \tag{1}$$

where $\odot$ denotes element-wise multiplication and $\cdot$ denotes dot product. Conceptually the joint scoring function gives equal weight to the event classifier

---

[6] (Ding and Riloff, 2018) also discarded events that only mentioned other people, but we did not apply this restriction due to the difficulty of recognizing people terms in tweets.

Algorithm 1: Discourse-enhanced Self-training

```
Input: Labeled events $E_L$, Unlabeled events $E_U$
       where each event $e_i$ has an associated set of
       coreferent sentiment expressions $CSE_i$, an
       external Sentiment Classifier, and thresholds
       $\theta_{jnt}$ and $\theta_{neu}$
while $E_U$ is not empty and not maximum iteration do
    Train the Event Classifier over $E_L$
    For each $e_i \epsilon E_U$, apply the Event Classifier to
      get an event score
    For each $e_i \epsilon E_U$, apply the Sentiment Classifier
      to each $cse \epsilon CSE_i$ and compute the average
      $cse$ sentiment score
    Compute the joint score for each $e_i \epsilon E_U$ by
      Eqn. 1
    Label new events ($E_{jnt}$) based on the joint
      scores and $\theta_{jnt}$
    Label additional neutral events ($E_{neu}$) based on
      the event scores and $\theta_{neu}$
    Update $E_L$ and $E_U$:
        $E_L = E_L \cup E_{jnt} \cup E_{neu}$
        $E_U = E_U - E_{jnt} - E_{neu}$
end
```

Method	Precision	Recall	F1
Supervised	76.5	75.2	75.7
Self-training	77.6	77.2	77.0
DEST	**79.6**	**78.7**	**79.0**

and the sentiment classifier in the final decision of the label. Finally, each event e_i is assigned the polarity with the highest value in s_{jnt_i}.

We generate a set of new labeled events E_{jnt} by assigning labels to unlabeled events that have a polarity probability $\geq \theta_{jnt}$ based on the joint scores. All other events remain unlabeled. However, we found that this process labels relatively few events as neutral. Since neutral events can also co-occur with positive and negative sentiment expressions, they may have relatively low neutral scores. To better maintain the distribution of events over all three polarities, we also add a new set of events E_{neu}, which the event classifier predicts as neutral with confidence $\geq \theta_{neu}$.

Discourse-enhanced Self-training needs an external sentiment classifier, so we fined-tuned a BERT-based model with the gold standard Twitter dataset from SemEval-2017 (Rosenthal et al., 2017) following the experiment setups in Section 3.2 and Section 3.3. In our experiments, we set θ_{neu} to 0.9 and θ_{jnt} to 0.95 based on the model's performance over the validation set.

6 Experimental Results

We performed 10-fold cross validation over the gold Twitter Dataset, where each of the 10 runs used 80% of the data (8 folds) for training, 10% of the data (1 fold) for validation/tuning, and 10% of the data (1 fold) for testing. We compare Discourse-enhanced Self-training (**DEST**) with strictly supervised learning and traditional self-training. During each iteration of the traditional self-training model, the affective event classifier Aff-BERT is applied to each unlabeled event. Events with polarity score $\geq$ 0.9 are selected as new labeled data. We chose 0.9 as the threshold based on the model's performance on the validation set.

For the DEST model, to ensure a rich set of discourse contexts, we only used unlabeled events that (a) had at least 10 distinct coreferent sentiment expressions and (b) did not include "this", "that" or "it" as a subject or object of the event phrase because an event is often vague without knowing what the pronoun refers to. This resulted in 8,532 events in the unlabeled event set.

6.1 Results

Table 4 reports the performance of the models after 10 iterations of learning with unlabeled data, where the first row shows the results for Aff-BERT trained only with gold labeled data for comparison. For both self-training models, no new examples were labeled after 10 iterations. Table 4 shows that ordinary self-training produced small gains in both precision and recall. Our Discourse-enhanced Self-training algorithm achieved larger gains, improving precision over the supervised model from 76.5% → to 79.6% and improving recall from 75.2% → 78.7%.

Figure 2 shows the learning curves for each method over the 10 iterations based on their F1

Method	**POS**		**NEG**		**NEU**	
	Pre	Rec	Pre	Rec	Pre	Rec
Supervised	74.4	71.5	**79.0**	74.0	76.1	80.1
DEST	**81.8**	**74.8**	78.4	**80.0**	**79.4**	**82.4**

score. The flat line is the F1 score for Aff-BERT trained with only gold labeled data. Ordinary self-training produced its highest F1 score after the first iteration, then declined and stayed stable without further improvement. In contrast, the learning curve of Discourse-enhanced Self-training gradually ascends, reaching its peak in iteration 7 and showing signs that it could potentially exceed that peak with more unlabeled data.

Table 5 shows the performance breakdown across the three polarities. Discourse-enhanced Self-training improved both precision and recall for all polarities, except that precision was slightly lower for negative polarity. Most notably, DEST achieved a 6.0% absolute gain in recall for negative polarity, and a 3.3% absolute gain in recall for positive polarity, alongside a 7.4% absolute gain in precision.

We also generated learning curves for the supervised learner and Discourse-enhanced Self-training when trained with different amounts of labeled data . Figure 3 shows results when using 50% to 100% of the gold training data in increments of 10%. Discourse-enhanced Self-training showed even greater relative improvement over the supervised learner when only 50% of the gold data was used for training. In addition, when using about 60% of the gold data, DEST achieved performance comparable to the supervised learner trained with 100% of the data.

Incorrect → Correct	
Neutral → Positive:	
⟨I, see, exhibit, -⟩	⟨I, sleep, -, through whole night⟩
⟨I, get, tip, -⟩	⟨I, start, my new job, -⟩
Neutral → Negative:	
⟨I, need, air, -⟩	⟨-, separate, child,from parent⟩
⟨I, not get, reply, -⟩	⟨someone, unfollow, me, -⟩
Correct → Incorrect	
Neutral → Positive:	
⟨I, have, your book, -⟩	⟨I, watch, guy, -⟩
Neutral → Negative:	
⟨I, have, brace, -⟩	⟨I, have, comment, -⟩

Table 6: Examples of labels that are changed by the joint scoring function.

Overall, the Discourse-enhanced Self-training approach produced substantial gains over fully supervised learning, and achieved more robust learning from unlabeled data than ordinary self-training. This approach could be applied to many other types of problems as well, when a secondary source of information relevant to the task is available.

7 Analysis

To better understand the behavior of the resulting classifier, we did a manual analysis of events whose polarity was impacted by the coreferent sentiment expressions. The top portion of Table 6 shows examples of events for which the affective event classifier assigned an incorrect polarity but the joint scoring function produced the correct polarity. We saw many cases like these where the event phrase contained neutral words but the coreferent sentiment expressions revealed consistently positive or negative discourse contexts.

The bottom portion of Table 6 shows examples of events for which the affective event classifier assigned a correct polarity but the joint scoring function assigned an incorrect polarity. We observed two types of issues that caused this behavior. One common problem was incorrect coreference. Sometimes the sentiment was coreferent with the subject or object of the event, but not the event itself. For example, ⟨*I, have, your book, -*⟩ was followed by sentiments about the book itself (e.g., *"It is well-written"* and *"That is inspiring"*). In other cases the sentiment was coreferent with an event earlier in the discourse. These errors suggest that incorporating a better event coreference resolution algorithm would likely improve results.

We also found some events that were correctly labeled as positive by the affective event classifier but labeled as negative by the sentiment classifier with high confidence, and consequently the event classifier's correct predictions were overridden. Most of these cases were expressions of love or empathy in response to negative events, such as ⟨*God, help, us, -*⟩, ⟨*my heart, go, -, to family*⟩, ⟨*you, have, my sympathy, -*⟩. This is an interesting phenomenon that may require better discourse modeling, including the recognition of expressive speech acts.

8 Conclusion

In this work, we proposed a BERT-based supervised classifier for affective event recognition and showed that it substantially outperforms a large affective event knowledge base. We also designed a novel discourse-enhanced self-training algorithm to leverage unlabeled data iteratively. By combining both the affective event classifier's prediction and the polarities of coreferent sentiment expressions, our algorithm substantially improved upon the supervised learning results. The resulting classification model is substantially more effective for affective event recognition than previous methods. We also believe that the general idea behind our discourse-enhanced self-training approach could be useful for many other types of problems where additional information can be extracted from larger contexts to serve as a secondary signal to help confirm or disconfirm a classifier's predictions.

Deep Weighted MaxSAT for Aspect-based Opinion Extraction

Meixi Wu[*] **Wenya Wang** **Sinno Jialin Pan**
Nanyang Technological University, Singapore
`MWU008@e.ntu.edu.sg, {wangwy, sinnopan}@ntu.edu.sg`

Abstract

Though deep learning has achieved significant success in various NLP tasks, most deep learning models lack the capability of encoding explicit domain knowledge to model complex causal relationships among different types of variables. On the other hand, logic rules offer a compact expression to represent the causal relationships to guide the training process. Logic programs can be cast as a satisfiability problem which aims to find truth assignments to logic variables by maximizing the number of satisfiable clauses (MaxSAT). We adopt the MaxSAT semantics to model logic inference process and smoothly incorporate a weighted version of MaxSAT that connects deep neural networks and a graphical model in a joint framework. The joint model feeds deep learning outputs to a weighted MaxSAT layer to rectify the erroneous predictions and can be trained via end-to-end gradient descent. Our proposed model associates the benefits of high-level feature learning, knowledge reasoning, and structured learning with observable performance gain for the task of aspect-based opinion extraction.

1 Introduction

Aspect-based opinion extraction aims to identify opinion targets (or aspects) of a review corpus that indicate specific product features, as well as the opinion terms expressed towards the aspects. For example, in the sentence "*The wine list is excellent*", the aspect term is *wine list*, whereas the opinion term is *excellent*. Many deep learning models have been proposed for this task via enumerating high-level features (Liu et al., 2015; Xu et al., 2018a; Wang et al., 2017; Li and Lam, 2017; Yin et al., 2016; Wang et al., 2016). However, these methods fail to explicitly encode prior knowledge on the relationships among aspect terms and opinion terms which are crucial for the task at hand, as shown in earlier rule-based models (Hu and Liu, 2004; Qiu et al., 2011). As in the previous example, if *wine list* is extracted as an aspect term and it has dependency relation "nsubj" with *excellent* which is an objective, then we can deduce that *excellent* is an opinion term. Though in (Yu et al., 2019), rules are incorporated as constraints into a deep neural network, the constraints cannot be backpropagated to the feature learning process. Recently, Wang and Pan (2020) proposed a joint model to combine deep learning with logic rules via minimizing the discrepancy between them. Their approach, however, only indirectly guides deep learning in training without the ability to rectify the predictions according to logic rules in inference.

To address the aforementioned limitations for aspect-based opinion extraction, we propose a novel joint model **DeepWMaxSAT** to integrate logic knowledge via a weighted MaxSAT layer into a deep learning architecture. Specifically, DeepWMaxSAT consists of 1) a DNN layer that transforms an input embedding to a high-level feature representation; 2) a weighted MaxSAT layer that takes DNN outputs as the initial probabilistic evaluations on the logic variables and produces the values for the output logic variables corresponding to the head atoms of selected logic rules; 3) a conditional random field (CRF) (Lafferty et al., 2001) layer that generates structured outputs (label sequences) considering linear context interactions among the tokens in a sequence. Moreover, to fully inherit the advantages of both DNNs and logic programs, we adopt a form of residual connection that combines both DNN predictions and the outputs from the weighted MaxSAT layer with a learnable weight, which is then fed into the CRF layer.

It is worth noting that the weighted MaxSAT layer contains all the prior knowledge about the cor-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5618–5628,
November 16–20, 2020.

relations among aspect and opinion terms encoded in conjunctive normal form (CNF) for all the logic rules. For example, the association between the aspect term *wine list* and the opinion term *excellent* in the previous example can be expressed using CNF as $\neg\text{aspect}(list) \vee \neg\text{nsubj}(list, excellent) \vee \neg\text{obj}(excellent) \vee \text{opinion}(excellent)$, which is converted from the first-order-logic (FOL) rule $\text{obj}(excellent) \wedge \text{nsubj}(list, excellent) \wedge \text{aspect}(list) \Rightarrow \text{opinion}(excellent)$. A learnable weight is associated to each disjunctive clause in the CNF formula to indicate its confidence. The weighted MaxSAT layer is able to rectify DNN predictions according to preset rules, at the same time, the loss signal for the final predictions can be back-propagated smoothly through the weighted MaxSAT layer to DNN parameters to guide the training of the deep learning model. Though Wang et al. (2019) proposed a differentiable satisfiability solver that integrates MaxSAT into deep learning, they only assumed a fixed set of rules that are true in nature, making it less flexible for general NLP problems where data can be noisy. With this consideration, we adopt the attention mechanism to adaptively select useful rules in the weighted MaxSAT layer for each data instance and treat the learnable attention scores as rule weights. The intuition is that different data instances may fit to different rules with varying probabilities.

To summarize, our contributions include:

- We propose a novel attention-based weighted MaxSAT solver that can selectively rectify and update deep learning predictions according to the relevance of specific rules.
- An end-to-end joint model associating DNNs, logic reasoning and structured learning is introduced to enhance the model performance.
- We focus on evaluating the effectiveness of encoding manually-designed prior knowledge as logic rules into a deep architecture. To achieve that, a real NLP application, namely aspect-based opinion extraction is chosen which is noisy but contains certain syntactic regularities that are difficult to be captured by pure deep learning models.
- We demonstrate the generality of the proposed joint framework over different DNN systems and word embeddings on the task of aspect-based opinion extraction.

2 Related Work

Aspect-based Opinion Extraction Various deep learning approaches have been introduced for aspect-based opinion extraction, including context-based recurrent neural networks (Liu et al., 2015) and convolutional neural networks (Xu et al., 2018a), dependency-tree-based models (Yin et al., 2016; Wang et al., 2016), and attention-based models (Wang et al., 2017; Li and Lam, 2017). Despite the promising performaces, it is hard to interpret and explicitly encode prior knowledge for deep learning models. The prior knowledge has been commonly used in the earlier works by designing specific features and rules among aspect terms and opinion terms (Hu and Liu, 2004; Popescu and Etzioni, 2005; Wu et al., 2009; Qiu et al., 2011). Yu et al. (2019) used integer linear programming with explicit constraints for joint inference as a post-processing step. However, these rule-based methods fail to propagate training signal to the feature learning process, making them suboptimal. On the other dimension, graphical models were also proposed to model the contextual or syntactic interactions among the tokens (Jin and Ho, 2009; Li et al., 2010). However, the optimization process is usually non-trivial especially for complex graphical structures. Recently, Wang and Pan (2020) introduced a logic-informative deep learning model that converts the relations among aspect and opinion terms to logic rules. Nevertheless, the logic rules only implicitly guide the training process of DNN and fail to rectify DNN predictions directly.

Deep Learning with Logic Reasoning Recent years have witnessed an increasing focus on neural symbolic learning that combines deep learning systems with discrete symbolic rules (Garcez et al., 2012; Manhaeve et al., 2018; Dong et al., 2019; Sourek et al., 2018; Wang et al., 2019) by constructing a logic network or connecting the distributed systems with logic rules for reasoning and inference in the logic domains. Xu et al. (2018b) treated logic knowledge as semantic regularization in the loss function. For NLP applications, the neural-symbolic systems were recently proposed in (Rocktäschel et al., 2015; Guo et al., 2016) for relation and knowledge graph learning that embed logic into the same space as distributed features in a single system. Logical knowledge has also been incorporated as a form of posterior regularization in (Hu et al., 2016) to enhance deep learning predictions. Moreover, logic rules can be used as evidences to construct adversarial sets (Minervini et al., 2017; Minervini and Riedel, 2018), or as a form of indirect supervision (Wang and Poon, 2018) to improve model training. Li and Srikumar (2019) further augmented deep learning models with logic neurons that can be trained together with the neural networks.

3 Problem Definition & Preliminary

3.1 Problem Definition

We treat the extraction problem as a sequence labeling task. Given a sequence of tokens $\{w_1, w_2, ...w_n\}$, sequence labeling produces a segmentation label y_i for each token w_i where $y_i \in Y = \{\text{B-ASP}, \text{I-ASP}, \text{B-OPN}, \text{I-OPN}, \text{O}\}$. We use BIO encoding scheme to differentiate whether the token is the beginning of an aspect/opinion term (B-ASP/B-OPN), inside an aspect/opinion term (I-ASP/I-OPN), or out of any targets (O).

A first-order-logic (FOL) rule or a clause has the form of $a_1 \wedge a_2 \wedge ... \wedge a_K \Rightarrow h$, where $a_1 \wedge a_2 \wedge ... \wedge a_K$ is the rule body containing a conjunction of atoms a_k, and h is the head atom. Here, an atom is an n-ary predicate $a_k = pred_k(x_1, ..., x_n)$ with $x_1, ..., x_n$ representing n variables. A ground atom assigns a constant to each varible in its argument. A set of FOL rules can be transformed to a conjunctive normal form (CNF) which is a conjunction of one or more disjunctive clauses, e.g., the clause $\neg a_1 \vee \neg a_2 \vee ... \vee \neg a_K \vee h$ is converted from $a_1 \wedge a_2 \wedge ... \wedge a_K \Rightarrow h$. Here, each disjunctive clause corresponds to an FOL rule. When the CNF formula is satisfised, all its corresponding FOL rules are true. In our setting, we treat the linguistic features, e.g., dependency relations, POS tags, and the segmentation labels as different predicates. For example, B-ASP(w_i) is a ground atom indicating w_i as the beginning of an aspect term. We utilise these atoms to form the CNF formula in the MaxSAT formulation.

3.2 Differentiable MaxSAT Solver

The maximum satisfiability problem (MAX-SAT) is the problem of determining the maximum number of satisfied clauses. Given a formula in CNF $c_1 \wedge ... \wedge c_m$ with m disjunctive clauses $c_1, ..., c_m$ over a total number of n different atoms $a_1, ..., a_n$, each atom takes one of the 2 assignments: $v_i \in \{-1, +1\}$ indicating its truth value. For each clause c_j, we denote its sign $\mathbf{s}_j$ corresponding to all the atoms by $\mathbf{s}_j = \{-1, 0, +1\}^n$, where $s_{ji} \in \mathbf{s}_j$ takes -1, 0 or $+1$ indicating the sign of atom a_i in clause c_j. 0 represents the absence of a_i. Then the MaxSAT problem can be casted into the following optimization problem:

$$\max_{v_i \in \{-1,1\}^n} \sum_{j=1}^{m} \bigvee_{i=1}^{n} \mathbf{1}\left\{s_{ji} v_i > 0\right\}. \quad (1)$$

To solve this problem, Wang et al. (2019) transformed (1) to the following objective by relaxing each discrete v_i to a continuous unit vector $\bar{\mathbf{v}}_i \in \mathbb{R}^k$ with respect to some "truth direction" $\mathbf{v}_\top$ through $P\left(v_i = 1\right) = \cos^{-1}\left(-\bar{\mathbf{v}}_i^T \mathbf{v}_\top\right)/\pi$.

$$\begin{aligned} \min_{\mathbf{V} \in \mathbb{R}^{d \times (n+1)}} \quad & \left\langle \mathbf{S}^\top \mathbf{S}, \mathbf{V}^\top \mathbf{V} \right\rangle \\ \text{s.t.} \quad & \|\bar{\mathbf{v}}_i\| = 1, i = \top, 1, \ldots, n, \end{aligned} \quad (2)$$

where $\mathbf{V} = [\mathbf{v}_\top, \bar{\mathbf{v}}_1, ...\bar{\mathbf{v}}_n] \in \mathbb{R}^{k \times (n+1)}$ and $\mathbf{S} = [\mathbf{s}_\top, \mathbf{s}_1, ..., \mathbf{s}_n]\, \text{diag}(1/\sqrt{4\,|\mathbf{s}_j|}) \in \mathbb{R}^{m \times (n+1)}$. Here $\mathbf{s}_\top = \{-1\}^m$. The problem (2) can be solved via coordinate descent with the following update:

$$\bar{\mathbf{v}}_i = -\mathbf{g}_i / \left\|\mathbf{g}_i\right\|, \; \mathbf{g}_i = \mathbf{V}\mathbf{S}^\top \mathbf{s}_i - \left\|\mathbf{s}_i\right\|^2 \bar{\mathbf{v}}_i. \quad (3)$$

This update is guaranteed to converge to the global optimal as long as $k > \sqrt{2n}$. To obtain the final probabilistic evaluations for atom a_i, we convert the updated $\bar{\mathbf{v}}_i$ to $p(v_i = 1) = \cos^{-1}\left(-\bar{\mathbf{v}}_i^\top \mathbf{v}_\top\right)/\pi$.

4 Methodology

In this section, we present our proposed model in detail. To make the logic knowledge more effective that is able to directly rectify the erroneous predictions made by deep learning models, and at the same time adapt its rules selectively according to different data instances, we propose a neural-symbolic integration by incorporating an attention-based weighted MaxSAT layer. The attention mechanism is used to automatically select relevant logic rules according to each specific data instance and to weigh the importance of each rule that could affect the final objective. Furthermore, we also integrate a CRF layer to generate structured predictions. As a result, the joint framework inherit the advantage of high-level feature learning, knowledge reasoning and structured learning.

Figure 1 provides an overview of the proposed model. It consists of 3 layers: 1) a deep learning module that takes input embeddings $\mathbf{x}_1, ..., \mathbf{x}_N$ as

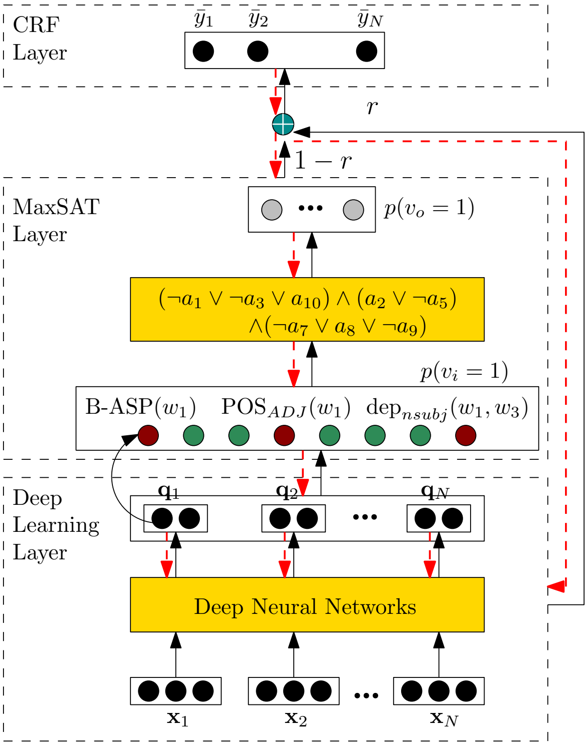

Figure 1: The proposed overall architecture.

inputs and generates a prediction for each word $\mathbf{q}_1, ..., \mathbf{q}_N$ via feature learning; 2) a weighted MaxSAT layer that takes deep learning predictions as the initial probabilistic evaluations $p(v_i = 1)$ of the input atoms a_i and generates probabilistic values $p(v_o = 1)$ of the output atoms; 3) a CRF layer that combines the outputs from the previous 2 layers with a residual connection to produce the final structured predictions $\bar{y}_1, ..., \bar{y}_N$. The joint model can be trained in an end-to-end manner via gradient descent, which is reflected with the dotted arrows in Figure 1. We illustrate each component in more detail in the sequel.

4.1 Deep Learning Layer

The deep learning layer aims to capture high-level feature representation for each word considering the complex interactions among different words within a setence[1]. We use a transformer model which takes a combination of word embedding $\mathbf{x}^e_i$ and POS tag embedding $\mathbf{x}^p_i$ as input and generates a hidden representation $\mathbf{h}_i$ for each word via a multi-layer self-attention mechanism. Specifically, at the l-th layer of the transformer, each attention head computes one interaction factor between each token and other tokens within the sentence in order to produce

$$\widetilde{\mathbf{h}}^c_{i,l} = \sum_{j=1}^{m} \alpha^c_{ij}(\mathbf{W}^c_v \widetilde{\mathbf{h}}_{j,i-1}), \qquad (4)$$

$$\boldsymbol{\alpha}^c_i = \text{softmax}\left(\frac{(\mathbf{W}^c_q \widetilde{\mathbf{h}}_{i,l-1})(\mathbf{W}^c_k \mathbf{H}_{l-1})}{\sqrt{d}}\right), \quad (5)$$

where each $\mathbf{h}_{i,l-1}$ is a column vector of the matrix $\mathbf{H}_{l-1}$. $\{\mathbf{W}^c_v, \mathbf{W}^c_q, \mathbf{W}^c_k\}$ are the transformation matrices of the c-th attention head. Here we use C individual transformations. By integrating the C transformations, the resultant hidden vector is computed as $\widetilde{\mathbf{h}}_{i,l} = \mathbf{W}[\mathbf{h}^1_{i,l} : \ldots : \mathbf{h}^C_{i,l}]$.

A Bi-GRU (gated recurrent unit) f_θ is then applied after the last layer of the transformer $\widetilde{\mathbf{h}}_{i,L}$ to produce context-sensitive hidden representations

$$\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i, \overrightarrow{\mathbf{h}}_i] = [f_\theta(\widetilde{\mathbf{h}}_{i,L}, \overrightarrow{\mathbf{h}}_{i-1}) : f_\theta(\widetilde{\mathbf{h}}_{i,L}, \overleftarrow{\mathbf{h}}_{i+1})].$$

The final prediction of each word is obtained via a fully-connected layer with a softmax activation function: $\mathbf{q}_i = \text{softmax}(\mathbf{W}_y l(\mathbf{h}_i) + \mathbf{b}_y)$, where

$$l(\mathbf{h}_i) = \tanh(\mathbf{W}_h[\mathbf{h}^\top_i : \mathbf{x}^l_{i-1}] + \mathbf{b}_h), \qquad (6)$$

and $\mathbf{x}^l_{i-1}$ indicates the label embedding of the preceding token.

4.2 Weighted MaxSAT Layer

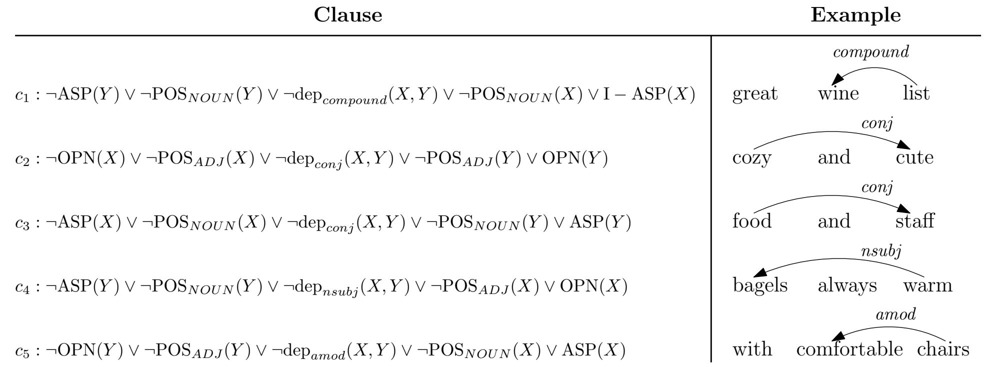
As discussed in Section 3.1, we convert FOL rules to CNF formulas which consist of multiple disjunctive clauses in order to be fed into the MaxSAT solver. In our problem setting, each atom in a clause is a 1-ary or 2-ary predicate, e.g., a clause in the form of $\neg$ASP$(Y) \vee \neg$POS$_{NOUN}(X) \vee \neg$dep$_{nsubj}(X, Y) \vee \neg$POS$_{ADJ}(X) \vee$ OPN(X) indicates that if Y is an aspect word with POS tag "NOUN", and Y has dependency relation "nsubj" with X, then we can deduce that X is an opinion word when it has POS tag "ADJ". This clause can be well fit into the following sentence "*The wine list is excellent*" for extracting *excellent* as an opinion word when *wine list* is correctly predicted as an aspect term. The clauses we adopt are shown and explained in Figure 2.

In the weighted MaxSAT layer, we define the set of all atoms $\{a_1, ..., a_n\}$ as the atoms appeared in Figure 2, including label atoms[2]

---

[1] It is flexible to adopt different deep learning models with various word embeddings. To demonstrate such flexibility, we use different DNNs and word embeddings in experiments. Here, we only describe a transformer-style DNN for illustration.

[2] ASP(Y) indicates Y is either labeled as B-ASP or I-ASP, similar for OPN(X).



Clause	Example
$c_1 : \neg\text{ASP}(Y) \vee \neg\text{POS}_{NOUN}(Y) \vee \neg\text{dep}_{compound}(X,Y) \vee \neg\text{POS}_{NOUN}(X) \vee \text{I}-\text{ASP}(X)$	*compound* great wine list
$c_2 : \neg\text{OPN}(X) \vee \neg\text{POS}_{ADJ}(X) \vee \neg\text{dep}_{conj}(X,Y) \vee \neg\text{POS}_{ADJ}(Y) \vee \text{OPN}(Y)$	*conj* cozy and cute
$c_3 : \neg\text{ASP}(X) \vee \neg\text{POS}_{NOUN}(X) \vee \neg\text{dep}_{conj}(X,Y) \vee \neg\text{POS}_{NOUN}(Y) \vee \text{ASP}(Y)$	*conj* food and staff
$c_4 : \neg\text{ASP}(Y) \vee \neg\text{POS}_{NOUN}(Y) \vee \neg\text{dep}_{nsubj}(X,Y) \vee \neg\text{POS}_{ADJ}(X) \vee \text{OPN}(X)$	*nsubj* bagels always warm
$c_5 : \neg\text{OPN}(Y) \vee \neg\text{POS}_{ADJ}(Y) \vee \neg\text{dep}_{amod}(X,Y) \vee \neg\text{POS}_{NOUN}(X) \vee \text{ASP}(X)$	*amod* with comfortable chairs

Figure 2: Disjunctive clauses used in the weighted MaxSAT layer.

(e.g., ASP(Y), I-ASP(X), OPN(X)), POS atoms (e.g., POS$_{NOUN}(Y)$, POS$_{ADJ}(X)$) and dependency relation atoms (e.g., dep$_{compound}(X,Y)$, dep$_{conj}(X,Y)$, dep$_{nsubj}(X,Y)$, dep$_{amod}(X,Y)$). As shown in (2), the MaxSAT problem can be relaxed with the converted sign matrix $\mathbf{S}$ and atom value matrix $\mathbf{V}$. Here $\mathbf{S}$ is computed from the given clauses as our prior knowledge and kept fixed during training. To obtain $\mathbf{V} = [\mathbf{v}_\top, \bar{\mathbf{v}}_1, ...\bar{\mathbf{v}}_n]$, we take the softmax prediction from the deep learning layer as the initialized probabilistic value of each atom. Specifically, denote by $p(v_1 = 1), ..., p(v_n = 1) \in [0,1]$ the probabilistic evaluations of all the atoms $a_1, ..., a_n$. If a_i is one of the label atoms, i.e., $a_i \in \{\text{ASP}(X), \text{I-ASP}(X), \text{OPN}(X)\}$, we take DNN predictions as the initial evaluations for the corresponding atoms, e.g., $p(v_i = 1) = \mathbf{q}_i^{\text{B-OPN}}$ when $a_i = \text{B-OPN}(X)$ and $\mathbf{q}_i^{\text{B-OPN}}$ is the DNN prediction for the class B-OPN. When a_i corresponds to the atom of POS tags or dependency relations, e.g., $a_i = \text{dep}_{nsubj}(X,Y)$, we use $0/1$ assignment for $p(v_i = 1)$ obtained through the Stanford Parser, where 0 indicates non-existence of the corresponding POS tag or dependency relation, and vice versa.

Different from existing works using a differentiable MaxSAT solver, we assign a probabilistic weight $w_j \in [0,1]$ for each clause indicating its confidence of being true, which is updated during training. To adapt the logic knowledge into the noisy dataset, where each clause is not guaranteed to be always true for different data instances, we adopt an attention mechanism to compute the adaptive clause weight for each data instance, which measures the similarity between the DNN predictions and each specific clause grounding. Since in the real cases, each data instance may only satisfy at most 2 clauses, we use the sparsemax operator to transform the attention weights such that only 1 or 2 clauses are being chosen at each time. The procedure is shown as follows:

$$w_j^z = \text{sparsemax}(\mathbf{v}^{z\top}\hat{\mathbf{s}}_j), \tag{7}$$

where $\text{sparsemax}(\boldsymbol{\alpha}) = \underset{\boldsymbol{x}\in\Delta^{N-1}}{\text{argmin}} \|\boldsymbol{x} - \boldsymbol{\alpha}\|^2$, and $\Delta^{N-1} = \left\{\boldsymbol{x} \in \mathbb{R}^N | \mathbf{1}^\top \boldsymbol{x} = 1, \boldsymbol{x} \geq \mathbf{0}\right\}$. Here w_j^z represents the weight for clause c_j corresponding to data instance z. $\mathbf{v}^z \in \mathbb{R}^{n-1}$ is the initial probabilistic evaluation vector for atoms $A = \{a_i\}_{i \neq n_h}$ except the head atom of the rule corresponding to data instance z. And $\hat{\mathbf{s}}_j = |\mathbf{s}'_j|$ where $\mathbf{s}'_j \in \mathbb{R}^{n-1}$ corresponds to the sign of each atom except the head atom of the rule. In our context, a data instance z corresponds to a pair of words (w_1, w_2) which are the instantiations for X and Y, respectively, in Figure 2. Intuitively, by using (7), the model tends to select the most relevant rules/clauses according to the similarity between the rule body and the vlaues of the associated groundings (e.g., POS tags, dependency relations and DNN predictions for each token).

With the incorporation of the attention-based weights of rules, the original MaxSAT objective can be transformed to the following form:

$$\begin{aligned} \min_{\mathbf{V}\in\mathbb{R}^{d\times(n+1)}} \quad & \left\langle \mathbf{U}^\top\mathbf{U}, \mathbf{V}^\top\mathbf{V} \right\rangle \\ \text{s.t.} \quad & \|\bar{\mathbf{v}}_i\| = 1, i = \top, 1, \ldots, n, \end{aligned} \tag{8}$$

where $\mathbf{V} = [\mathbf{v}_\top, \bar{\mathbf{v}}_1, ...\bar{\mathbf{v}}_n]$ and $\mathbf{U} = \mathbf{W}\mathbf{S}$ with $\mathbf{S} = [\mathbf{s}_\top, \mathbf{s}_1, ..., \mathbf{s}_n] \, \text{diag}(1/\sqrt{4\,|\mathbf{s}_j|}) \in \mathbb{R}^{m\times(n+1)}$ and $\mathbf{W} = \text{diag}(w_j), j = 1, \ldots, m$. By using coordinate descent, the update for $\bar{\mathbf{v}}_i$ becomes

$$\bar{\mathbf{v}}_i = -\mathbf{g}_i / \|\mathbf{g}_i\|, \mathbf{g}_i = \mathbf{V}\mathbf{U}^\top\mathbf{u}_i - \|\mathbf{u}_i\|^2 \bar{\mathbf{v}}_i. \tag{9}$$

Note that we use (9) to compute $\bar{\mathbf{v}}_o$ until convergence with o being the index of the head atom of the selected rules according to the attention mechanism. We then further convert the real vector to probabilistic evaluation via $p(v_o = 1) = \cos^{-1}\left(-\bar{\mathbf{v}}_o^\top \mathbf{v}_\top\right)/\pi$. For ease of illustration, for each data instance z, we denote by $p_o^z = p(v_o^z = 1) = f_{\text{MaxSAT}}(\{p(v_i^z)\}_{i\neq o})$ the output probability from the weighted MaxSAT layer. Intuitively, f_{MaxSAT} aims to produce a rule-satisfied evaluation to its corresponding head atom, given the DNN predictions of the input body atoms. When the DNN prediction for the head atom is not accurate, the MaxSAT layer is able to revise its value. In the meantime, the partial gradient of the final loss with respect to the MaxSAT output is backpropagated to the DNN parameters, making logic rules as a form of indirect supervision to the training of the DNN.

4.3 CRF Layer

To further mitigate the degradation problem caused by inaccurate MaxSAT updates or uncertain DNN predictions, we use a residual network with a trainable gate r to combine the outputs from both the DNN layer and the weighted MaxSAT layer as

$$\bar{\mathbf{y}}_i = r\mathbf{q}_i + (1-r)\mathbf{p}_i, \qquad (10)$$

where $\mathbf{q}_i$ and $\mathbf{p}_i$ represent the outputs from the DNN and the MaxSAT layers, respectively.

On top of the combination, a CRF layer is performed to generate the structured prediction outputs, which takes into consideration of the sequential dependencies among entities. Denote by $\mathbf{x}$ and $\mathbf{y} = (y_1, \ldots, y_N)$ the input and the output of the CRF layer, respectively. The CRF layer computes conditional distributions as follows,

$$P(\mathbf{y}|\mathbf{x}) = \frac{\exp(f(\mathbf{x},\mathbf{y}))}{\sum_{\mathbf{y}'}\exp(f(\mathbf{x},\mathbf{y}'))}, \qquad (11)$$

where $f(\mathbf{x},\mathbf{y}) = \sum_i \log\psi_i(\mathbf{x},\mathbf{y}) + \sum_{i'}\log\phi_{i'}(\mathbf{y})$. Here, $\psi_i(\mathbf{x},\mathbf{y})$ and $\phi_{i'}(\mathbf{y})$ indicate the unary and pairwise potentials, respectively. To integrate the information from the preceding layers, we substitute $\psi_i(\mathbf{x},\mathbf{y})$ with $\bar{\mathbf{y}}_i$ obtained via (10). The pairwise potential is determined via a trainable transition matrix specifying the score of transitioning from each label tag to other labels.

4.4 Training

The entire model can be trained in an end-to-end manner via gradient descent with the final loss function as

$$\mathcal{L} = -\frac{1}{D}\sum_{d=1}^{D} P(\hat{\mathbf{y}}_d|\mathbf{x}_d), \qquad (12)$$

where $\hat{\mathbf{y}}_d$ is the ground-truth label sequence for data $\mathbf{x}_d$. During training, the objective updates the weighted MaxSAT layer according to (10) and (9) via:

$$\begin{aligned}
\frac{\partial\mathcal{L}}{\partial\bar{\mathbf{v}}_o} &= \frac{\partial\mathcal{L}}{\partial\bar{\mathbf{y}}}\frac{\partial\bar{\mathbf{y}}}{\partial p_o}\frac{\partial p_o}{\partial\bar{\mathbf{v}}_o}, && (13)\\
\frac{\partial\mathcal{L}}{\partial\bar{\mathbf{v}}_i} &= \left(\frac{\partial\mathcal{L}}{\partial\bar{\mathbf{v}}_o}\right)^\top\frac{\partial\bar{\mathbf{v}}_o}{\partial\bar{\mathbf{v}}_i}, && (14)\\
\frac{\partial\mathcal{L}}{\partial w_j} &= (\frac{\partial\mathcal{L}}{\partial\bar{\mathbf{v}}_o})^\top\frac{\partial\bar{\mathbf{v}}_o}{\partial\mathbf{P}}\frac{\partial\mathbf{P}}{\partial w_j}, && (15)
\end{aligned}$$

where $\bar{\mathbf{v}}_o$ and $\bar{\mathbf{v}}_i$ represent the output index (head atom) and the input index (body atom), respectively. Following (Wang et al., 2019), we take the analytical form of the resulting gradients to compute (14) and (15), respectively.

Note that the gradients of DNN parameters (denoted by Θ) are obtained through backpropagating information from both the final loss function $\mathcal{L}$ and the MaxSAT gradient $\frac{\partial\mathcal{L}}{\partial\bar{\mathbf{v}}_i}$ via:

$$\begin{aligned}
\frac{\partial\mathcal{L}}{\partial\Theta} = \Bigg(&\frac{\partial\mathcal{L}}{\partial\mathbf{q}} + \sum_i\left(\frac{\partial\mathcal{L}}{\partial\bar{\mathbf{v}}_i}\right)^\top\frac{\partial\bar{\mathbf{v}}_i}{\partial\mathbf{q}}\\
&+\sum_j\frac{\partial\mathcal{L}}{\partial w_j}\frac{\partial w_j}{\partial\mathbf{q}}\Bigg)\frac{\partial\mathbf{q}}{\partial\Theta}. \qquad (16)
\end{aligned}$$

5 Experiment

We conduct experiments on the benchmark datasetfrom SemEval Challenge 2014 task 4 (subtask 1) that consists of a restaurant domain and a laptop domain (Pontiki et al., 2014), and a restaurant corpus from SemEval 2016 task 5 (Pontiki et al., 2016). The details of each data are listed in Table 1. For preprocessing, we use NLTK toolkit for tokenization, POS tagging and generating dependency parse tree for each sentence. We use 1 GPU with model Tesla P100-PCIE-16GB to run our experiment. For the joint model, it takes around 20 minutes for an epoch with 3000 data instances and it takes 10 epochs to achieve the optimal performance.

Dataset	Description	Training	Test	Total
Restaurant14	SemEval-14 Restaurant	3,041	800	3,841
Laptop14	SemEval-14 Laptop	3,045	800	3,845
Restaurant16	SemEval-16 Restaurant	2,000	676	2,676

Table 1: Dataset description with number of sentences

5.1 Experimental Setting

Follow the setting in (Wang et al., 2016), the pre-training of word embedding is first conducted

Model		RNCRF	CMLA	Demb	GMTCMLA	DeepLogic	DeepWMaxSAT
Restaurant14	Aspect	84.93	85.29	84.24	84.50	85.24	**85.33**
	Opinion	84.11	83.18	-	85.20	84.37	**85.73**
Laptop14	Aspect	78.42	77.80	81.59	78.69	81.25	**81.33**
	Opinion	79.44	80.17	-	79.89	79.32	**80.34**
Restaurant16	Aspect	69.74	**75.21**	74.37	-	73.35	73.67
	Opinion	76.15	77.90	-	-	78.89	**79.67**

Table 2: Results on 3 benchmark datasets for aspect and opinion extraction.

using *word2vec* on Yelp Challenge dataset[3] and electronic dataset in Amazon reviews[4] for restaurant and laptop domain, respectively. Following (Vaswani et al., 2017), we add positional encoding on top of input representations in the transformer network. We assign 10 heads to the multi-head self-attention model, which generates attention weight parameters with dimension 10. We set the word embedding dimension as 300, POS-tag embedding as 50, hidden layer as 200, and label embedding as 25. For training, we adopt the adadelta optimizer with a learning rate of $2e^{-3}$ and a weight decay of $5e^{-4}$. All parameters are chosen based on cross-validation. To evaluate the model performance, F1 scores on non-negative classes are adopted, where the correctness of a prediction is fulfilled if and only if the predicted tag exactly matches the true label for each aspect/opinion term.

5.2 Overall Results

We evaluate our model performance by comparing with the following well-known baseline methods:

- RNCRF (Wang et al., 2016): A joint model combining a dependency-based recursive neural network with CRF to model syntactic interactions among aspect and opinion terms.
- CMLA (Wang et al., 2017): Coupled attention network with tensor-based interaction for co-extraction of aspect and opinion terms.
- Demb (Xu et al., 2018a): A convolutional neural network with domain-dependent and domain-independent word embeddings.
- GMTCMLA (Yu et al., 2019): Global inference with multi-task neural networks that regularize DNN predictions with integer linear programming.
- DeepLogic (Wang and Pan, 2020): Integrate deep learning with logic rules through minimizing a discrepancy loss.

The comparison results are shown in Table 2, and the last column corresponds to our proposed model. Clearly, our model achieves best performances on almost all the tasks across 3 datasets. The first 3 models represent pure deep learning methods by adopting either dependency trees (RNCRF), attention-based interactions (CMLA), or contextual interactions using convolutional neural network (Demb). These methods, however, only assume that the complex interactions among aspect terms and opinion terms can be captured via implicit feature learning. When feeding prior knowledge as constraints in integer linear programming, GMTCMLA is able to regularize deep learning predictions, but without the ability to backpropagate error information. Hence, its performance does not show clear improvement. DeepLogic is able to update the deep learning model by treating logic rules as indirect supervision. Without the capability to directly revise DNN outputs, it shows suboptimal performance compared to our proposed model.

We further conduct a qualitative analysis to demonstrate how the weighted MaxSAT (WMaxSAT) layer rectify the erroneous predictions made by deep neural networks. Some representative cases that WMaxSAT corrects DNN predictions are shown in Table 3. The left column shows predictions made by the deep learning model with the incorrectly predicted words marked in red. The right column shows the corresponding predictions made by applying a WMaxSAT layer on top of DNN outputs. It is clear that those mislabeling words are all corrected in this case, demonstrating the effect of our proposed model.

5.3 Ablation Analysis

To further demonstrate the effect of each component of our proposed model, we conduct ablation experiments with 6 different model set-

Table 6: Utility rate and performance for each rule.

tings as shown in Table 4. The advantage of DNN+WMaxSAT over DNN alone in most cases reveals the power of using WMaxSAT to incorporate domain knowledge. Using CRF further improves the model performance through effective capturing of sequential correlations among terms. To show the advantage of using the proposed attention mechanism for rule weight computation, we compare with 2 other variations of the MaxSAT layer. DNN+MaxSAT+CRF assumes each logic rule as correct at all times (fixed weights to be 1.0). Whereas DNN+MaxSAT*+CRF assigns each rule with a unified weight which applies to all data instances. The rule weights in this model are randomly initialized and trained through the learning process. As can be seen, in most of the cases, attention-based WMaxSAT is most effective for aspect/opinion extraction.

Our proposed model is flexible to integrate any deep learning modules or pre-trained word embeddings. To show the generality and advantage of combining DNNs with logic reasoning and structured learning, we replace the transformer model in the deep learning layer with 2 other commonly used word embeddings, namely BERT (Devlin et al., 2019) and ELMO (Peters et al., 2018) followed by a BiGRU layer. The results for using different word embeddings with different model settings are shown in Table 5. Clearly, BERT achieves better performances than ELMO in general. It is worth noting that the weighted MaxSAT layer always brings performance gain when combined with the DNN model. The joint model over all the three components produces the best results when using BERT as the word embeddings. Whereas joining ELMO with WMaxSAT produces comparable performances with or without CRF.

To provide a clear idea of the effect for each logic rule described in Figure 2, we conduct experiments on feeding each single clause into the WMaxSAT layer as shown in Table 6. We observe the best performance on aspect extraction when only using c_1 for restaurant domain and c_3 for the laptop domain. For opinion extraction, c_2 is most effective for both domains. However, using separate rules are inferior than using all 5 rules for opinion extraction. We also analyze the percentage of each rule being selected during training, as shown in the second row of Table 6. On average, most rules has about 20% chance of being selected, which shows that the attention model is able to select diverse rules according to different data characteristics.

In the previous experiments, we initialize the residual connection gate r as 1.0 and update it through the training process. To demonstrate the effect of different initializations for this hyperparameter, we conduct another experiment on varying the value of r from 0.1 to 1.0. As shown in Figure 3, the f1 scores do not fluctuate substan-

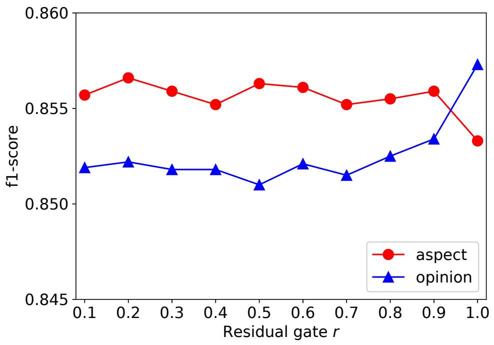

Figure 3: Sensitivity study for residual gate r on restaurant-14 dataset.

tially when $0.1 \leq r \leq 0.9$. When $r = 1.0$, there is a clear change of f1 scores. The reason might come from the fact that some logic rules are not always feasible for the actual noisy dataset, especially when some general objects which should be regarded as aspect terms according to the rules are not labeled as aspect terms. For example, in the sentence "*This place is amazing*", *amazing* is labeled as an opinion term whereas *place* is not labeled as an aspect term, which contradicts with rule c_4. When training with $r < 1.0$, the combination of label supervision and rule c_4 may result in missing the opinion term *amazing* given *place* is not an aspect term. In other words, the joint model tries to find a tradeoff between the labels and the rules that makes the result of aspect extraction and opinion extraction more balanced, instead of the evident performance difference when $r = 1.0$.

6 Conclusion

We propose a novel joint model that inherits the advantage of high-level feature learning, logic reasoning and structured learning which can be trained smoothly in an end-to-end manner. To adapt logic knowledge with noisy real applications, we introduce an attention mechanism to generate an adaptive weight corresponding to each data instance for each logic rule. The attention weights control the information flow between deep neural networks and the MaxSAT layer which automatically weigh the relevance of each rule towards the data given. Extensive experiments are conducted to verify both quantitatively and qualitatively the effectiveness of the proposed model.

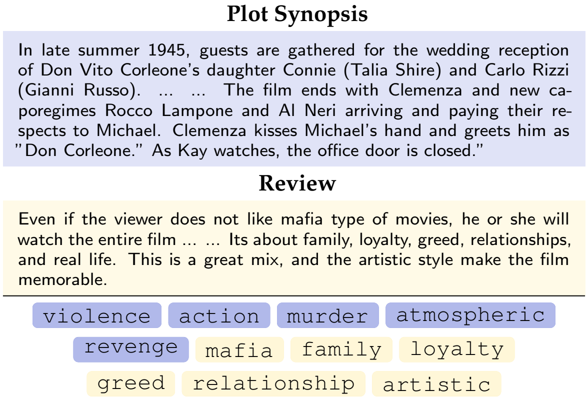
Abstract

This paper considers the problem of characterizing stories by inferring properties such as theme and style using written synopses and reviews of movies. We experiment with a multi-label dataset of movie synopses and a tagset representing various attributes of stories (e.g., genre, type of events). Our proposed multi-view model encodes the synopses and reviews using hierarchical attention and shows improvement over methods that only use synopses. Finally, we demonstrate how can we take advantage of such a model to extract a complementary set of story-attributes from reviews without direct supervision. We have made our dataset and source code publicly available at https://ritual.uh.edu/multiview-tag-2020.



Plot Synopsis

In late summer 1945, guests are gathered for the wedding reception of Don Vito Corleone's daughter Connie (Talia Shire) and Carlo Rizzi (Gianni Russo). ... ... The film ends with Clemenza and new caporegimes Rocco Lampone and Al Neri arriving and paying their respects to Michael. Clemenza kisses Michael's hand and greets him as "Don Corleone." As Kay watches, the office door is closed."

Review

Even if the viewer does not like mafia type of movies, he or she will watch the entire film ... ... Its about family, loyalty, greed, relationships, and real life. This is a great mix, and the artistic style make the film memorable.

Figure 1: Example snippets from plot synopsis and review of **The Godfather** and tags that can be generated from these.

1 Introduction

A high-level description of stories represented by a tagset can assist consumers of story-based media (e.g., movies, books) during the selection process. Although collecting tags from users is time-consuming and often suffers from coverage issues (Katakis et al., 2008), NLP techniques like those in Kar et al. (2018b) and Gorinski and Lapata (2018) can be employed to generate tags automatically from written narratives such as synopses. However, existing supervised approaches suffer from two significant weaknesses. Firstly, the accuracy of the extracted tags is subject to the quality of the synopses. Secondly, the tagset is predefined by what was present in the training and development sets and thus is brittle; story attributes are unbounded in principle and grow with the underlying vocabulary.

To address the weaknesses presented above, we propose to exploit user reviews. We have found that movie reviews often discuss many aspects of the story. For example, in Figure 1, a reviewer writes that *The Godfather* is about *family, relations, loyalty, greed*, and *mafia*, whereas the gold standard tags from the plot are *violence, murder, atmospheric, action*, and *revenge*. In this paper, we show that such information in reviews can significantly strengthen a supervised *synopses to tag* prediction system, hence alleviating the first limitation. To address the second limitation, we propose to also rely on the content provided by the reviews. We extract new tags from reviews and thus complement the predefined tagset.

A potential criticism of an approach that relies on user reviews is that it is not practical to wait for user reviews to accumulate. The speed at which movies get reviews fluctuates a lot. Therefore, we propose a system that learns to predict tags by jointly modeling the movie synopsis and its reviews, when the reviews are available. But if a movie has not accumulated reviews yet, our system can still predict tags from a predefined tagset using only the synopsis without any configuration change.

Tag extraction from reviews can be modeled as a supervised aspect extraction problem (Liu, 2012) that requires a considerably large amount of annotated tags in the reviews. To get rid of this annotation burden, we formulate the problem from the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5629–5646,
November 16–20, 2020. ©2020 Association for Computational Linguistics

perspective of Multiple Instance Learning (MIL; Keeler and Rumelhart, 1992). As a result, our model learns to spot story attributes in reviews in a weakly supervised fashion and does not expect direct tag level supervision. Note that these complementary open-vocabulary tags extracted from the reviews are separate from the predefined tagset, and we can only generate this set when a movie has reviews. As we show in Section 6.1, tags generated by our system can quickly describe a story helping users decide whether to watch a movie or not.

Our contributions in this work can be summarized as follows:

- We collect ≈1.9M user reviews to enrich an existing dataset of movie plot synopses and tags.
- We propose a multi-view multi-label tag prediction system that learns to predict relevant tags from a predefined tagset by exploiting the synopsis and the reviews of a movie when available. We show that utilizing reviews can provide ≈4% increase in F1 over a system using only synopses to predict tags.
- We demonstrate a technique to extract open-vocabulary descriptive tags (i.e., not part of the predefined tagset) from reviews using our trained model. While review-mining is typically approached as supervised learning, we push this task to an unsupervised direction to avoid the annotation burden.

We verify our proposed method against multiple competitive baselines and conduct a human evaluation to confirm our tags' effectiveness for a set of movies.

2 Background

Prior art related to this paper's work includes story analysis of movies and mining opinions from movie reviews. In this section, we briefly discuss these lines of work.

Story Analysis of Movies Over the years, high-level story characterization approaches evolved around the problem of identifying genres (Biber, 1992; Kessler et al., 1997; Petrenz, 2012; Worsham and Kalita, 2018). Genre information is helpful but not very expressive most of the time as it is a broad way to categorize items. Recent work (Gorinski and Lapata, 2018; Kar et al., 2018b) retrieves other attributes of movie storylines like *mood*, *plot type*, and *possible feeling of consumers* in a supervised fashion where the number of predictable categories is more extensive and more comprehensive compared to genre classification. Even though these systems can retrieve comparatively larger sets of story attributes, the predictable attributes are limited in a closed group of tags. In contrast, in real life, these attributes can be unlimited.

	Train	**Val**	**Test**
Instances	$9,746$	$2,437$	$3,046$
Tags per instance	3	3	3
Reviews per movie	72	74	72
^{S} Sentence per document	50	53	51
^{S} Words per sentence	21	21	21
^{R} Sentence per document	117	116	116
^{R} Words per sentence	27	27	27

Table 1: Statistics of the dataset. ^{S} denotes synopses and ^{R} denotes review summaries.

Movie Review Mining There is a subtle distinction between the reviews of typical material products (e.g. *phone, TV, furniture)* and story-based items (e.g. *literature, film, blog*). In contrast to the usual aspect based opinions (e.g. *battery, resolution, color*), reviews of story-based items often contain *end users' feelings, important events of stories*, or *genre related information*, which are abstract in nature (e.g. *heart-warming, slasher, melodramatic*) and do not have a very specific target aspect. Extraction of such opinions about stories has been approached by previous work using reviews of movies (Zhuang et al., 2006; Li et al., 2010) and books (Lin et al., 2013). Such attempts are broadly divided into two categories. The first category deals with spotting words or phrases (*excellent, fantastic, boring*) used by people to express how they feel about the story. And the second category focuses on extracting important opinionated sentences from reviews and generating a summary. In our work, while the primary task is to retrieve relevant tags from a pre-defined tagset by supervised learning, our model provides the ability to mine story aspects from reviews without any direct supervision.

3 Dataset

Our starting data set is the MPST corpus (Kar et al., 2018a) which contains approximately 15K movies and a set of tags assigned by IMDB[1] and MovieLens[2] users. The tagset contains 71 labels that

---

[1] `http://imdb.com`

[2] `http://movielens.org`

are representative of story related attributes (e.g., *thought-provoking, inspiring, violence*) and the corpus is free from any metadata (e.g., *cast, release year*).

We extended the dataset by collecting up to 100 most helpful reviews per movie from IMDB. Out of the 15K movies in MPST, we did not find any reviews for 285 films. The collected reviews often narrate the plot summary and describe opinions about movies. We noticed that reviews can be very long and sometimes contain repetitive plot summaries and opinions. Some reviews can be even uninformative about the story type. Moreover, the number of reviews for movies varies greatly, creating a challenge for modeling them computationally. So we summarize all reviews for a movie into a single document using TextRank[3] (Mihalcea and Tarau, 2004). We observed that summarized reviews are usually free of repetitive information and aggregate the salient fragments from the reviews that are heavy with user opinions. All plot synopses, reviews, and tags are in English, and Table 1 presents some statistics of the dataset.[4]

4 Modeling

Consider input $X = \{X_{PS}, X_R\}$, where X_{PS} is a plot synopsis and X_R is a review summary. For a predefined tagset $Y_P = [y_1, y_2, ..., y_{|Y_P|}]$, we want to model $P(Y_P|X)$. We also aim at extracting a complementary tagset Y_C from X_R that is not part of the original Y_P set and is not labeled in the dataset. However, we expect a latent correlation between Y_P and Y_C that can be jointly modeled while modeling $P(Y_P|X)$, hence helping the extraction of Y_C without any direct supervision. Therefore, we first supervise a model containing a synopsis encoder and a review encoder to learn $P(Y_P|X)$ (Section 4.1), and later we use the trained review encoder to generate complementary tagset Y_C (Section 4.2). An overview of our model is shown in Figure 2.

4.1 Learning the Predefined Tagset

Different words and sentences in a synopsis have different roles in the overall story. For example, some sentences narrate the setting or background of a story, whereas other sentences may describe different events and actions. Additionally, some sentences and words are more helpful for identifying relevant tags from the synopsis. With this in mind, we adapt the hierarchical encoding technique of Yang et al. (2016) that learns to weight important words and sentences and use this information to create a high-level document representation. Additionally, to efficiently capture various important story aspects in long synopses and reviews, we model our task from the perspective of Multiple Instance Learning (MIL).

We assume that each synopsis and review is a bag of instances (i.e., sentences in our task), where labels are assigned at the bag level. In such cases, a prediction is made for the bag by either learning to aggregate the instance level predictions (Keeler and Rumelhart, 1992; Dietterich et al., 1997; Maron and Ratan, 1998) or jointly learning the labels for instances and the bag (hua Zhou et al., 2009; Wei et al., 2014; Kotzias et al., 2015; Angelidis and Lapata, 2018; Xu and Lapata, 2019). In our setting, we choose the latter; i.e., we aggregate $P(Y_P)$ for each sentence with the combined representation of X_{PS} and X_R to compute $P(Y_P|X)$. As we will show later, MIL improves prediction performance and promotes interpretability.

We represent a synopsis X_{PS} consisting of L sentences $(s_1, ..., s_L)$ in a hierarchical manner instead of a long sequence of words. At first, for a sentence $s_i = (w_1, ..., w_T)$ having T words, we create a matrix E_i where E_{it} is the vector representation for word w_t in s_i. We use pre-trained Glove embeddings (Pennington et al., 2014) to initialize E. Then, we encode the sentences using a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) with attention (Bahdanau et al., 2015). It helps the model to create a sentence representation $\mathbf{sh}_i$ for the i_{th} sentence in X_{PS} by learning to put a higher weight on the words that correlate more with the target tags. The transformation is as follows:

$$\overrightarrow{h}_{w_{it}} = \overrightarrow{LSTM}(\mathbf{E}_{it}), t \in [1, T]$$

$$\overleftarrow{h}_{w_{it}} = \overleftarrow{LSTM}(\mathbf{E}_{it}), t \in [T, 1]$$

$$\mathbf{u}_{it} = \tanh(\mathbf{W}_{wt}.[\overrightarrow{h}_{w_{it}}, \overleftarrow{h}_{w_{it}}] + \mathbf{b}_w)$$

$$\mathbf{r}_{it} = \mathbf{u}_{it}^{\top}\mathbf{v}_t; \quad \alpha_{it} = \frac{\exp(\mathbf{r}_t)}{\sum_t \exp(\mathbf{r}_t)}$$

$$\mathbf{sh}_i = \sum_{t=1}^{T} \alpha_{it}\mathbf{h}_{it}$$

Here, $\mathbf{W}_{wt}, \mathbf{b}_w, \mathbf{v}_t$ are learned during training. In the second step, we pass the encoded sentences

---

[3] We used the implementation from the Gensim library and converted the reviews into Unicode before summarizing.

[4] Some example plot synopses and reviews are presented in Appendix E.

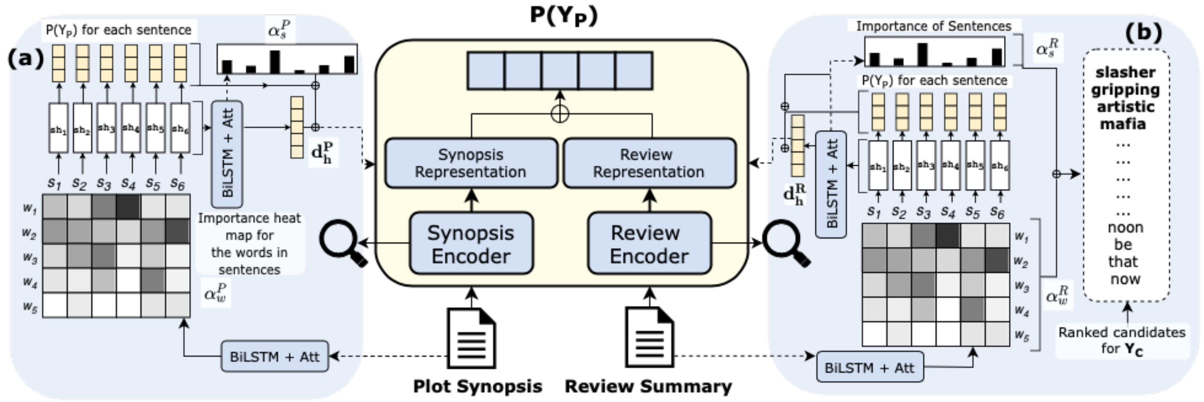


Figure 2: In the center, we show an overview of the model that takes a plot synopsis and a review summary as input, uses two separate encoders to construct the high-level representations and uses them to compute $P(Y_P)$. **(a)** illustrates an enhanced view of the synopsis encoder. It uses a BiLSTM with attention to compute a representation $\mathbf{sh_i^P}$ for the i_{th} sentence in the synopsis. Additionally, a matrix of word-level attention weights α_w^P is generated that indicates the importance of each word in each sentence for correctly predicting $P(Y_P)$. Another attention based BiLSTM is used to create a synopsis representation d_h^P from the encoded sentences $\mathbf{sh^P}$. Additionally, for each $\mathbf{sh_i^P}$, sentence-level prediction $P(Y_P)_i$ is computed which is aggregated with $\mathbf{d_h^P}$ to create the final synopsis representation. **(b)** illustrates a similar encoder for reviews. To create a complementary tagset Y_C by mining the reviews, word-level importance scores α_w^R and sentence-level importance scores α_s^R are used (Equation 1). Apart from that, review representation $\mathbf{d_h^R}$ is computed in a similar way as in **(a)** which is used together with $\mathbf{d_h^P}$ to compute $P(Y_P)$.

$\mathbf{sh}$ through another BiLSTM layer with attention. By taking the weighted sum of the hidden states and attention scores α_s^{PS} for the sentences, we generate an intermediate document representation $\mathbf{d_h^{PS'}}$. Simultaneously, for each high level sentence representation $\mathbf{sh}_i$, we predict $P(Y_P)_{s_i}^{PS}$. We then weight $P(Y_P)_{s_i}^{PS}$ by α_s^{PS} and compute a weighted sum to prioritize the predictions made from comparatively important sentences. This sum is aggregated with $\mathbf{d_h^{PS}}$ to generate the final document representation.

Aggregating Synopses and Reviews After generating the high level representation of the synopses ($\mathbf{d_h^{PS}}$) and reviews ($\mathbf{d_h^R}$), we merge them to predict

$$P(Y_P) = \mathit{Softmax}(\mathbf{W}_o \cdot [\mathbf{d_h^{PS}}, \mathbf{d_h^R}] + b_o)$$

Here, $\mathbf{W}_o$ and b_o are learnable weight and bias of the output layer (dimension=$|Y_P|$, i.e.,71), respectively. We experiment with two types of aggregation techniques: a) simple concatenation, and b) gated fusion. In the first approach, we concatenate these two representations, whereas in the second approach, we control the information flow from the synopses and reviews. While important story events and settings found in synopses can correlate with some tags, viewers' reactions can also correlate with complementary tags. We believe that learning to control the contribution of information encoded from synopses and reviews can improve overall model performance. For instance, if the synopsis is not descriptive enough to retrieve relevant tags, but the reviews have adequate information, we want the model to use more information from the reviews. Hence, we use a gated fusion mechanism (Arevalo et al., 2017) on top of the encoded synopsis and review representations. For the encoded synopsis $\mathbf{d_h^{PS}}$ and review representation $\mathbf{d_h^R}$, the mechanism works as follows:

$$\begin{aligned} h_{ps} &= \tanh(\mathbf{W}_{ps} \cdot \mathbf{d_h^{ps}}) \\ h_r &= \tanh(\mathbf{W}_r \cdot \mathbf{d_h^r}) \\ z &= \sigma(\mathbf{W}_z \cdot [\mathbf{d_h^{ps}}, \mathbf{d_h^r}]) \\ h &= z * h_{ps} + (1 - z) * h_r \end{aligned}$$

4.2 Tag Generation from Reviews

Extracting tags from reviews can be seen from the perspective of MIL, where instance (i.e., word) level annotations are not present, but each movie is labeled with some tags from the predefined tagset Y_P. When we train the model (Section 4.1), these bag-level labels seem to act as weak supervision for the model to learn to isolate instances — i.e., tags present in the reviews. For example, we observe that the model usually puts higher attention weights on opinion–heavy words in the reviews. Therefore, we use the attention weights on words and sentences in reviews to extract an additional open-vocabulary tagset Y_C.

Predicting $P(Y_P)$ from $\{X_{PS}, X_R\}$ produces attention weight vectors α_W^R and α_s^R for X_R (as in Section 4.1). For each word w_{ij} in sentence s_i in

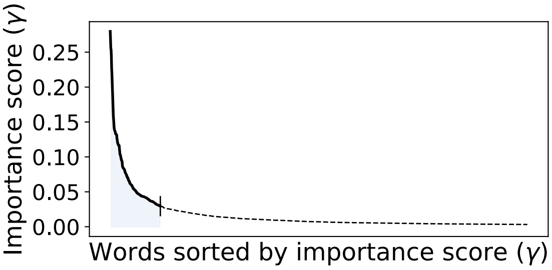

Figure 3: All words in the shaded area under the solid black curve are selected as candidate tags for Y_C.

X_R, we compute an importance score γ_{ij} as:

$$\gamma_{ij} = \alpha_{W_{ij}} \times \alpha_{s_i} \times |s_i| \qquad (1)$$

Here, $\alpha_{W_{ij}}$ is the attention weight of word w_{ij} and α_{s_i} is the attention weight of the i^{th} sentence. $|s_i|$ indicates the number of words in the sentence, and helps overcome the fact that word-level attention scores are higher in shorter sentences. We rank the words in the reviews based on their importance scores and choose the first few words as the primary candidates for Y_C as shown in Figure-3. The idea is that the sorted scores create a downward slope, which allows us to stop at the point where the slope starts getting flat. We detect this by computing the derivative at this point based on its neighboring four points and set a threshold of $5e^{-3}$ based on our observations on the validation set. After selecting the candidates, we remove duplicates and tags that are already in the predefined tagset Y_P to avoid redundancy. This method gives us a new open-vocabulary tagset Y_C created from the reviews without any direct supervision.

5 Experiments

We treat our tag assignment task as a multi-label classification problem. Based on $P(Y_P|X)$, we sort the predefined tagset Y_P in descending order, so that tags with higher weights are ranked on top. Then, in different settings we select the *top-k* (*k*=3, 5) tags as the final tags to describe each movie. We aim to explore three research questions through our experiments: (Q1) for predicting tags from synopses only, can our approach outperform other machine learning models? (Q2) When available, can reviews strengthen the *synopses to tag* prediction model? and (Q3) how relevant are open-vocabulary tags to stories?

For Q1 and Q2, we evaluate systems based on two aspects: a) correctness of *top-k* predictions by micro-F1, and b) diversity in *top-k* tags using Tags Learned (TL; Kar et al., 2018a). TL is simply the number of unique tags predicted for the entire evaluation set in *top-k* setting; i.e., $|Y^k_{P_{pred}}|$. We verify Q3 through a human evaluation experiment as we do not have annotations for review tags.

5.1 Baselines

We compare our model against the following baselines:

Most Frequent Most frequent $k(3,5)$ tags from the predefined tagset Y_P are assigned to each movie.

Convolutional Neural Network with Emotion Flow (CNN-EF) We use a Convolutional neural network-based text encoder to extract features from written synopses and Bidirectional LSTMs to model the flow of emotions in the stories (Kar et al., 2018b). To our knowledge, this method is currently the best-performing system on our task.

Pre-trained language models Large pre-trained language models (LM) built with Transformers (Vaswani et al., 2017) have shown impressive performance in a wide range of natural language understanding (NLU) tasks like natural language inference, sentiment analysis, and question-answering in the GLUE benchmark (Wang et al., 2019). However, directly fine-tuning such models for long texts like synopses and reviews is extremely memory expensive. Therefore, we employ Sentence-BERT (SBERT; Reimers and Gurevych, 2019) in our work, which is a state-of-the-art universal sentence encoder built with pre-trained BERT (Devlin et al., 2019). We use SBERT encoded sentence representations with our proposed model in Section 4 instead of training the Bi-LSTM with a word-level attention based sentence encoder. Then we use these representations to create a document representation using Bi-LSTM with sentence-level attention, keeping the rest of the model unchanged.

6 Results

Quantitative Results We report the results of our experiments on the test[5] set in Table 2. We mainly discuss the *top-3* setting, where three tags are assigned to each instance by all systems.

Regarding our first research question, Table 2 shows that our proposed hierarchical model with attention HN(A) outperforms all comparison systems

Both	**42.11**	**65**	**42.00**	**68**

Table 2: Results obtained on the test set using different methodologies on the synopses and after adding reviews with the synopses. TL stands for *tags learned.* *: t-test with p-value < 0.01.

(F1=37.90). This model achieves slightly better F1 than SBERT, which implies that word-level attention must be learned for accurate tag prediction. Additionally, learning document level attention is also crucial as HN(A) performs better than using maxpool. Finally, sentence level tag prediction (*HN(A) + MIL row*) is beneficial for both accurate and diverse tagset generation (F1=37.94, TL=51).

Table 2 also shows that reviews combined with synopses can boost tag prediction performance (Q2). As a simple baseline technique to integrate reviews with synopses, we merge the review texts with synopses to train a single encoder based model. This technique shows improvements over the model that uses only synopses (F1=41.26). Using two separate encoders for synopses and reviews, concatenating the generated representations decreases F1 (40.64), but increases TL (55). Combining these representations by gated fusion achieves the best results so far (F1=41.84, TL=64). By performing a t-test, we found that gated fusion is significantly better (p-value < 0.01) than merging the texts and simple concatenation of the high-level representations of synopses and reviews.

As we do not have reviews for ≈300 movies (Section 3), we further experiment to verify Q2 on a subset of our data, where every movie has at least one review. As shown in Table 2, reviews act as a stronger data source than synopses for classifying tags. Combining both does not affect F1 (≈42) much, but TL improves by a considerable margin (60 vs. 65). We found that combining synopses helps to identify tags like *plot twist, bleak, grindhouse film,* and *allegory*. It shows that our model is successfully capturing different story attributes from reviews that are possibly difficult to find in synopses. Again, as reviews are not always available for movies, treating synopses as the primary data source and reviews as complementary information is practical.

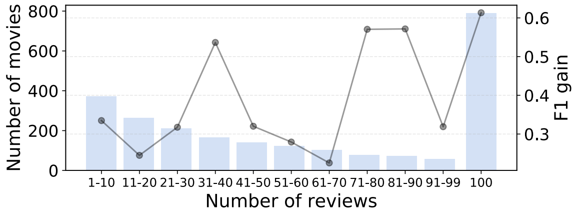

Figure 4: Average change in F1 with respect to the number of reviews after combining review summaries with synopses.

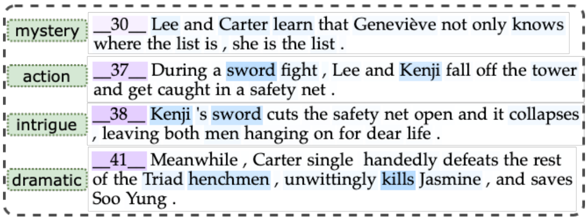
How Many Reviews Do We Need? We investigate the least amount of reviews we require to observe reasonable performance gains. The curve in Figure 4 shows that we can expect a noticeable improvement in tag prediction performance if we have at least around 31-40 reviews for a movie. However, as the plot shows, having less than that can still provide some benefit. Note that we generate a single summary document from these reviews to feed into the model. The gain fluctuates for movies having more than 40 reviews and less than 99. This is also the group with the smaller number of movies, so any conclusions for this range should be taken with a grain of salt. However, 790 movies have 100 reviews, and the average gain is slightly better than what we observe with 31-40 reviews.

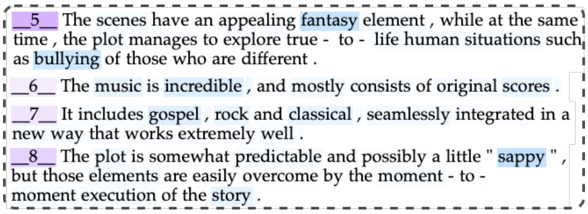
To better understand the reason behind sudden drops in performance in different bins, we looked at the bins' genre information. In IMDb, a movie is generally labeled with multiple genres. We observed that movies in bins with higher F1 usually have more gold labels for genres and tags than movies in bins with lower F1. This fact alone, of having more gold tags assigned to the movies, makes it more likely that system prediction tags will match some of them. And the opposite happens in bins with lower F1. Additionally, while looking at genres, we found that some less frequent genres like film-noir are comparatively more in bins like 51-60, which can also create a performance gap.

Are These Hierarchical Representation Meaningful? We analyze the reason behind the effec-



mystery	__30__ Lee and Carter learn that Geneviève not only knows where the list is , she is the list .
action	__37__ During a sword fight , Lee and Kenji fall off the tower and get caught in a safety net .
intrigue	__38__ Kenji 's sword cuts the safety net open and it collapses , leaving both men hanging on for dear life .
dramatic	__41__ Meanwhile , Carter single handedly defeats the rest of the Triad henchmen , unwittingly kills Jasmine , and saves Soo Yung .

Figure 5: Example sentences from the synopsis of the movie **Rush Hour 3** with one of the most relevant tags from the sentence-level predictions. Importance of particular sentences and words for predicting tags is indicated by the highlight intensity of the sentence ids and words. Ground truth tags are *bleak, violence, comedy, murder*.



__5__ The scenes have an appealing fantasy element , while at the same time , the plot manages to explore true - to - life human situations such as bullying of those who are different .

__6__ The music is incredible , and mostly consists of original scores .

__7__ It includes gospel , rock and classical , seamlessly integrated in a new way that works extremely well .

__8__ The plot is somewhat predictable and possibly a little " sappy " , but those elements are easily overcome by the moment - to - moment execution of the story .

Figure 6: Example sentences from the review of the movie **August Rush** with sentence ids and words highlighted based on their importance in tag prediction. Ground truth tags are *thought-provoking, romantic, inspiring, flashback*.

tiveness of our proposed system by visualizing the attention weights at the sentence and word level for the synopsis of *Rush Hour 3* and the reviews of *August Rush* (see Figure 5 and 6, respectively). We can see that sentences in the synopsis that describe important story events and sentences in the review that express user opinions about the story receive higher weights. Similarly, at the sentence level, important events and characters are weighted more by the model, and words in review sentences that convey opinions about the storyline rather than other aspects of the movie (e.g., music) receive more weight by the model. If we observe the tagsets provided in the caption of Figure 6 and the highlighted words and sentences, we can conclude that the model is efficiently modeling the correlations between salient parts of the text and tags.

6.1 Human Evaluation

We perform a human evaluation experiment to verify the second research question, Q2 further, and answer Q3. Additionally, we also want to investigate: "*how useful are the predicted tags from the predefined tagset (Y_P) and reviews (Y_C) for end-users to get a quick idea about a movie?*"

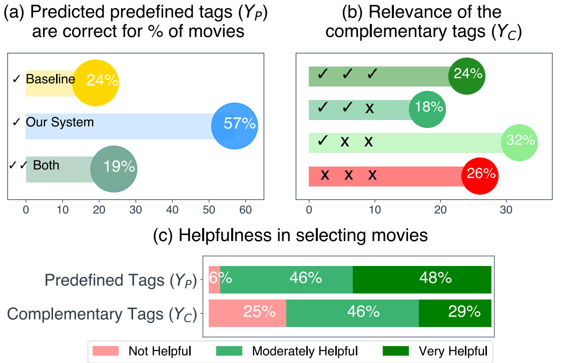


Figure 7: Summary of human evaluation results. (a) Comparing the correctness of two systems' predictions, (b) ✓ and × indicate rating from three human judges. e.g.,✓✓✓: all judges marked 24% complementary tags as correct, ✓✓×: two judges marked 18% tags as valid, and so on. (c) Judges' feedback about whether our tagset helps users pick a movie by providing a quick description.

To explore Q2, we select CNN-EF (Kar et al., 2018b) as the baseline system[6] to compare the quality of our tags for 21 randomly sampled movies from the test set. For each movie, we instruct three human judges to read the synopsis to understand the story. Then we show them two sets of tags for each movie and ask them to choose the tags that correctly describe the story. In the first set of tags, we show only tags from Y_P, but we combine tags predicted by our model and those by the baseline system[7]. In the second set of tags, Y_C, we present the complementary tags extracted from the reviews (Section 4.2). Figure 7(a) shows that, for the predefined tags, our tagsets were more relevant than the baseline ones for 57% movies, the baseline tags were better than *HN(A)+MIL* for 24% movies, and both systems were equally performing for 19% movies. Therefore, we get further verification of Q2. i.e., using reviews improves the retrieval of relevant tags from the predefined gold tagset.

To answer Q3, 141 open-vocabulary tags (Y_C) were rated by three judges.[8] Figure 7(b) shows that 24% of these tags were rated relevant by all three judges, 18% tags by two judges, and 32% tags by one judge. That means, ≈74% of these tags were marked as relevant by at least one judge.

Finally, in Figure 7(c), we assess the value of extracting tags to provide users a snapshot of the movie and make a *go* or *no go* decision on them. Results show that in 94% of the cases, predicted tags from Y_P were considered relevant in deciding

---

[6] We used the online demo system released by the authors to generate the tags.

[7] If the tagsets from two systems are [*a, b, c, d, e*] and [*b, d, e, f, g*], we present [*a, b, c, d, e, f, g*] and ask raters to select the correct ones. i.e., if *a* is selected, System-1 gets one vote. If *b* is selected, both systems get one vote.

[8] 114 distinct tags and ≈7 tags per movie.

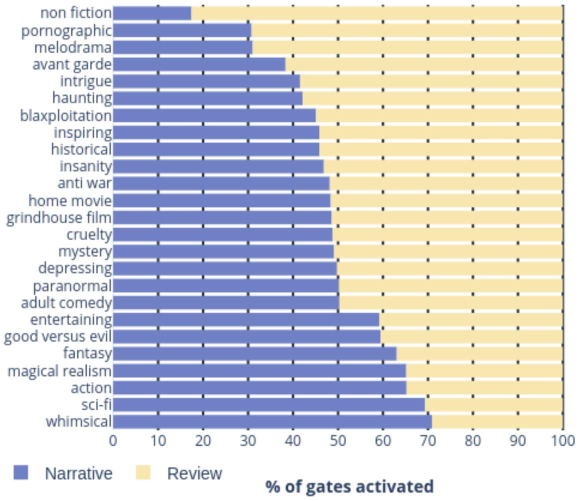

Figure 8: Percentage of gates activated ($z > 0.5$) for synopses and reviews. More active gates indicate more importance of the source for certain tags.

whether to watch the movie or not. At the same time, in 75% of the cases, complementary tags were also deemed relevant.

6.2 Information from Reviews and Synopses

By analysing the predictions using only synopses and having user reviews as an additional view, we try to understand the contribution of each view in identifying story attributes. We notice that using user reviews improved performance for tags like *non fiction, inspiring, haunting*, and *pornographic*. In Figure 8, we observe that the percentage of activated gates for the reviews was higher compared to synopses for the instances having the mentioned tags. Again, such tags are more likely to be related to visual experience or feeling that might be somewhat challenging for the model to understand only from written synopses. For example, synopses are more important to characterize *adult comedy* stories, but *pornographic* representation can be better identified by the viewers and this information can be easily conveyed through their opinion in reviews.

6.3 Generalization Capability

In this section, we perform a few qualitative tests to assess the generalization capability of our model. First, we observe the quality of our generated tags for some recently released movies that are not present in our dataset. Finally, we check the quality of tags generated by our model for non-movie narratives, such as children's stories, ghost stories, novels, and TV series as it provides a scope to check if the model can generalize across domains.

The Irishman: murder, neo noir, revenge, violence, flashback

Avengers Endgame: good versus evil, fantasy, action, violence, flashback

Long Shot: entertaining, comedy, satire, humor, romantic

Annabelle Comes Home: paranormal, horror, gothic, cult, good versus evil

Once Upon a Time in Hollywood: comedy, violence, cult, humor, murder

Table 3: System predicted tags for movies released in 2019. The underlined tags match recently assigned tags from users in IMDb.

Predictions for New Movies Back in 2019, we crawled plot synopses for a few recently released movies that did not have any tags at the time of collection. The goal of this experiment was to assess the quality of the tags predicted by our system for movies not in the train/dev/test set.

Table 3 shows the predictions, where we underline the tags that match user tags assigned since then. For example, our predictions for *The Irishman* are *murder, neo noir, revenge, violence, flashback*, where most of these tags except *neo noir* were found in IMDB. Note that, accumulating reviews and tags is a time-consuming process, and many movies do not receive any reviews or tags at all. We will check again in the coming months to see what tags appear for these movies. But this small-scale experiment bodes well with our previous results and our overall goal of automatically generating relevant tags from synopses.

Generalization across Domains We also investigate the generalizability of our trained model. Instead of movie synopsis, we give as input a few popular stories from other domains like *children stories*, *modern ghost stories*, *novels*, and *TV series*[9]. Results in Table 4 show that, our system can indeed predict tags that are very relevant to the new types of stories. Therefore, we conclude that our approach also shows great promise for other domains and can be extended with little effort.

7 Conclusion

In this paper, we focused on characterizing stories by generating tags from synopses and reviews. We modeled the problem from the perspective of Multiple Instance Learning and developed a multi-view

---

[9] We collected the stories and synopses from the web. Sources with more examples are in Appendix D.

Children Stories

Cinderella: fantasy, cute, romantic, whimsical, psychedelic

Snow White and the Seven Dwarfs: fantasy, psychedelic, romantic, good versus evil, whimsical

Modern Ghost Stories

A Ghost: haunting, flashback, atmospheric, murder, paranormal

What Was It: paranormal, haunting, gothic, horror, atmospheric

Novels

Romeo and Juliet: revenge, murder, romantic, flashback, tragedy

The Hound of the Baskervilles: murder, mystery, gothic, paranormal, flashback

TV Series

Game of Thrones S6E9: violence, revenge, murder, action, cult

Narcos Season 1: murder, neo noir, violence, action, suspenseful

Table 4: Tags generated by our system for narratives that are not movie synopsis.

architecture. Our model learns to predict tags by identifying salient sentences and words from synopses and reviews. We demonstrated that exploiting user reviews can further improve performance and experimented with several methods for combining user reviews and synopses. Finally, we developed an unsupervised technique to extract tags that identify complementary attributes of movies from user reviews. We believe that this coarse story understanding approach can be extended to longer stories, i.e., entire books, and are currently exploring this path in our ongoing work.

Acknowledgments

We would like to thank the anonymous reviewers for providing helpful comments to improve the paper. We also thank Jason Ho for his helpful feedback on previous drafts of this work. This work was also partially supported by NSF grant 1462141. Lapata acknowledges the support of ERC (award number 681760, “Translating Multiple Modalities into Text”).

Appendix

A Data Pre-processing and Input Representation

We tokenize the synopses and reviews using `spaCy`[10] NLP library. To remove rare words and other noise, we retain the words that appear at least in ten synopses and reviews ($< .01\%$ of the dataset). Additionally, we replace the numbers with a `cc` token. Through these steps we create a vocabulary of ≈42K word tokens. We represent the out of vocabulary words with a <`UNK`> token. For each movie sample, there are two text inputs (*written synopsis* and *summary of reviews*). We use an empty string as the review text for the movies not having any review.

B Implementation and Training

We develop our experimental framework using PyTorch[11]. We use KL divergence as the loss function for the network and train the models for 50 epochs using Stochastic Gradient Descent (SGD) ($\eta = 0.2$, $\rho = 0.9$) as the optimizer. We empirically set a dropout rate of 0.5 between the layers and ℓ_2 regularization ($\lambda = 0.15$) to prevent overfitting. We observe faster convergence using batch normalization after each layer.

Tuning Hyper-parameters During the experiments for developing the model, we evaluate different model components using several combination of different hyper-parameters. Table 5 presents the hyper-parameter space we explore. While optimizing the model with Adam, we set the maximum number of epochs to 20, where the best validation performance were typically found after the 5th epoch with a learning rate of $1e^{-3}$. Optimizing with SGD takes more epochs (typically around 30th epoch) even with high learning rates like 0.2, but we observe better performance (≈ 2% higher MLR).

C Results on Validation Set

Table 6 shows our results obtained on the validation set. We can see that our designed model outperforms all the baselines for predicting tags from only synopses. When we add review summaries, gated fusion performs best among the three aggregation methods, and it outperforms the system that only uses synopses.

Hyper-parameter	**Exploration Space**

D Out of Domain Stories

In Table 7, we provide the tags generated for stories that are not movie synopsis. We also provide the source URL from where we collected the narratives. As our model is not suitable for handling very long texts like in novels, we collect their synopses and generate tags from those.

E Examples of Plot Synopses and Reviews

Rush Hour 3

Plot Synopsis

Three years after the end of Rush Hour 2, James Carter is no longer a detective, but a traffic cop on the streets of Los Angeles. Lee is now the bodyguard for his friend Ambassador Han, the former Consul from the first film. Lee is still upset with Carter about an incident in New York City when Carter accidentally but not fatally shot Lee's ex-girlfriend in the neck, Secret Service agent Isabella Molina.During the World Criminal Court discussions, as the Ambassador addresses the importance to fight the Triad, he announces that he may know the whereabouts of Shy Shen. Suddenly, Han takes a bullet in the shoulder, disrupting the conference. Lee pursues the assassin and corners him, discovering that the assassin is his "brother" Kenji. When Lee hesitates to shoot Kenji, Carter shows up driving towards the two and accidentally nearly runs Lee over, allowing Kenji to escape.In the hospital, Lee learns that Han will make a full recovery. Han's daughter, Soo Yung (Zhang Jingchu), now grown up, arrives and makes Lee and Carter promise to capture the one behind the shooting. She then informs Lee and Carter that her father gave her an envelope which contains important information regarding the Triad, and that the envelope is in her locker at the martial arts studio where she works. Lee and Carter make their way to the martial arts studio where they battle a giant, (Sun Ming Ming), but find out that a gang of armed men had already arrived and taken the contents from the locker. Lee and Carter are told by the Master of the studio that Soo Yung and Han are in danger and rush back to the hospital.Once the two reach the hospital, a gang of assassins arrive to kill Soo Yung and Han. Lee and Carter manage to defeat them, with the help of Soo Yung, and interrogate the leader of the assassin squad. Much to Lee and Carter's surprise, the Asian assassin only speaks French. With the help of a resident nun, Sister Agnes (Dana Ivey), in translation, they find out that they are marked for death by the Triad along with Soo Yung and Han. For her protection, they take her to the French Embassy and leave her under the care of Reynard, the French ambassador. When a car bomb detonates, nearly killing Reynard and Soo Yung, Lee and Carter decide to go to Paris to investigate.In Paris, (after getting a painful cavity search from a Parisian commissioner, played by Polanski) Lee and Carter meet up with George, a taxi driver. George refuses to drive Carter, saying that Americans make him sick, as they are "the most violent people on Earth"to which Carter replies by forcing George, at gunpoint, to drive to a Triad hideout disguised as a gentleman's club. There Lee fights off a Triad assassin named Jasmine (Youki Kudoh); meanwhile, Carter meets a beautiful woman whose name is not disclosed(Noémie Lenoir). However, Lee and Carter are both forced out of the club and are captured by the Triads. Lee and Carter manage to escape, but then have a falling out concerning Lee's relationship with Kenji. Shortly after Carter leaves, Reynard appears. Lee asks who Shy Shen is, but Reynard tells him that Shy Shen is not a man, but a list of the Triad leaders. Reynard reveals that Han's informant knows where Shy Shen is. The informant turns out to be Geneviève, the woman Carter met the gentleman's club and both Lee and Carter end up looking for her.After the two have encountered Geneviève they save her from an assassination attempt by the Triads and flee to their hotel room.[3] However, they are attacked again by Jasmine and decide to hide out with George, who now has fostered a great appreciation for the United States. Lee and Carter learn that Geneviève not only knows where the list is, she is the list. The names of the thirteen Triad leaders have been tattooed on the back of her head, as per tradition, and Genevieve explains that she will be decapitated and buried if the Triads capture her. When Lee and Carter bring Geneviève to Reynard, he asks Geneviève to show him the list. Lee points out that they never told him that she was the list. Reynard then reveals that he has been working with the Triads all along. Kenji calls and informs Lee that he has captured Soo Yung and that he would like to exchange Soo Yung for Geneviève.Lee arrives at the exchange point, the Jules Verne Restaurant in the Eiffel Tower, with Carter, disguised as Geneviève. During a sword fight, Lee and Kenji fall off the tower and get caught in a safety net. Kenji's sword cuts the safety net open and it collapses, leaving both men hanging on for dear life. Lee then grabs Kenji's arm, intending to save his life. Kenji then willingly lets go of Lee and presumably falls to his death, saving Lee's life, who then, with less weight, swung to a scaffolding. Meanwhile, Carter single-handedly defeats the rest of the Triad henchmen, unwittingly kills Jasmine, and saves Soo Yung. As they send Soo Yung down the elevator, more Triads arrive. In order to escape, Lee and Carter use a French flag as a makeshift parachute and float to safety. Unfortunately, they are confronted by Reynard, who is holding Geneviève hostage and threatening to kill her and frame Lee and Carter for her murder. However, George, having followed Lee and Carter, manages to shoot Reynard and declares "Case Closed". The police suddenly arrive, with the commissioner from earlier gloating and trying to get undeserved credit. After giving the commissioner a team punch to the face, Lee and Carter leave the scene dancing to War.

Review Summary

Not only that, but this movie seemed more rushed and the story wasn't as well developed as the first two Rush Hour films.In the beginning it seems like Lee and Carter are not on good terms, Carter seems to have broken off Lee's relationship to his ex girlfriend, Isabella. But I think if you loved the first two Rush Hour films, you should see this, it's still a fun film and has great comedy, there is a little less action, a warning in advance, but it's all good if you are looking for a fun film for the end of the summer.6/10. The first two were pretty good comedy movies staring both Jackie Chan and Chris Tucker as cop partners with a typical plot with good action mixed with comedy. There's quite a few decent action scenes and again Chris Tucker's character delivers a lot of the jokes and Jackie Chan's still got the awesome moves and stunts but is it just me or was the action a bit tamer compared to the other two? So anyway, you've got your B level action-comedy movie and it does it quite well.Jackie Chan (Who plays as Lee) acts well as usual (have some problem for pronouncing things but I didn't mind that) and Chris Tucker is still hilarious and he's still loud as ever. The action scene were always a thrill and the car chase was very fun (there was a bit of laughter in the theater).There's a lot more comedy (which some jokes were cheesy) in this movie than action, but in the end I didn't mind, I still felt entertained and happy to spend my 15$ in this movie.So this is the end of my simple review, go watch this movie with low expectation and in a mood for some good laughter and action and you'll enjoy it. Director Brett Ratner returns to his element, offering a third fun, funny, and violent slapstick installment in the Rush Hour series.Rush Hour 3 sees Inspector Lee and Detective Carter back together again, trying to save the lives of a Chinese ambassador who may be on the brink of cracking open a massive organized crime syndicate called the Triads, the ambassador's daughter, and a woman with a very dangerous secret. Chris Tucker gives his best performance in the series, delivering a lot of comic punch and playing a nice complement to Chan's sombre and serious Inspector Lee.Rush Hour 3 delivers exactly what fans of the series look for - a simple linear action-thriller liberally decorated with a lot of cleverly written comedy and the amazing physical performance of Jackie Chan. The original Rush Hour was a Jackie Chan vehicle of sorts to break into Hollywood, and it made a lot of money with the mis-pairing opposite Chris Tucker in a buddy cop movie formula filled with action and comedy. The action sequences in Rush Hour 3 look a bit tired, tame, and very uninspiring, and what Jackie Chan can probably still do, has been whittled down to sequences that are just a pale shadow of what could have been.Which leaves us with the comedy, thankfully still having its moments especially for those punchlines which deliver. If there's any hint of rudimentary character development after these years, is that his James Carter, besides having been relegated to traffic duties, managed to "half-chinese" himself, and no longer is that helpless cop who without his gun, can't kick a ball for nuts.The plot is no rocket science, and in fact, the previous two movies just had something which could coast along from scene to scene, providing a platform either to get our heroes Lee (Chan) and his brother-from-another-mother James (Tucker) into fisticuffs, or provide something for laughs. Some of the more totally insane moments involve those deliberate lost in translation moments, which are the more enjoyable moments in this movie.Rush Hour 3 is similar in structure with its predecessors, and it does seem a tad familiar at times in the way the story gets developed, with only a change in locale, now set in Paris. No prizes for guessing the other two.It's not that Rush Hour 3 is a particularly bad movie, but it's just a tired re-working of themes already heavily mined in the first two instalments. The only marginal difference here is that whereas in Episode 1 and 2 the "player-outside-his-turf" mantle was worn alternately by Lee (Jackie Chan) and Carter (Chris Tucker) respectively, here, they're both out of their comfort zone viz. Europe, and more specifically, Paris This plot point doesn't actually change the formula's outcome that much, because every other element is essentially unchanged.The coolest stuff in the movie is already showcased in the trailer, so if you're pressed for time, just watch that.PS: Roman Polanski did look like he was having fun though...so much fun, in fact, that he didn't bother to have his name added to the credits. And Chan, the straight-laced, 'good guy' Inspector Lee. The charisma is still there, just like it was since the first Rush Hour movie. OK, here are a few reasons why I disliked (note: NOT hated) this film.Chan looks bored and his action scenes simply do not impress.Tucker gets a few decent one-liners but surprisingly, his comic timing is off.Storyline is simultaneously boring and unbelievable, and the ending a massive letdown.Everyone seems to be in simply for the money, and there's clearly ZERO imagination or honesty visible. They both seem to be "just in it for the money"I really hope this will be the last Rush Hour film, the first and second was both really really enjoyable with fun comments, good comedy and good action scenes this third installment has nothing of it.For some good Jackie action stick with his older films and those made in Hong Kong, for Chris tucker films watch any other film he's in besides this one..The goofy antics of Chris Tucker mixed with the amazing martial arts moves of Jackie Chan made both of the previous Rush Hour films funny and entertaining. I admit it that it is funny and some jokes really make me laugh but now, we are focusing on the story plot which is straight-forward and its action scenes are not very impressive for a Jackie Chan movie. Okay, I've not seen either of the first two Rush Hour films, so don't have that direct yardstick to compare them to, but I have seen a good number of action comedies over the years and this one added absolutely nothing; in fact, it was damned close to reducing my enjoyment of the whole genre. It has so much going on but is understandable, no hard story lines to follow, it flows nicely and will make you think what a good film, this is sure to bring more rush hour's i hope, can't wait till the next installment! Here we have another example of a film franchise that is too successful for its own good, and in the year of threequels, this was one we didn't need.Set a few years after Rush Hour 2, James Carter (Chris Tucker) is no more then an LA traffic cop and Lee (Jackie Chan) is the head bodyguard for the Chinese Ambassador. James and Lee end up working together again, and take their investigation Paris and set out to break-up the Triad.The plot is skeleton thin, like they have been in the previous Rush Hour films; but this is a new low! A couple funny lines in a movie doesn't make it a funny movie.Second if you watch the movie close enough it copy's, takes or borrows plot devices and scenes from a lot of other movies that were way better.I want people to think about this $140 MILLION dollars(just let that sit there for a second) Third Since when did a Jackie Chan movie become so filled with special effects that the stunts don't even seem the least bit real therefore you can't even become engaged in the action. Very mixed, but these were the general thoughts..."Not enough action.", "A Chris Tucker movie.", "Same jokes used.", etc.I want to think that most of Rush Hour 3's problems are attributed to the fact that it was just a rushed film. The first two films are not that much longer, Rush Hour 2 is also 90 minutes, but they had good paces and weren't lazy productions.As for what some of the other reviews say, I say this: Jackie Chan is getting old, which may be the reason why the film didn't seem to have as much action. I think that Tucker may have gotten more screen time, however...and I will say he was still pretty damn funny.However, the true laughs are brought on by Yvan Attal, who, as their French cab driver, is inspired by the violence taking place around him to become an, "American who kills for no reason." I am an American and I thought that was hilarious.The bottom line is this: Rush Hour 3 is lazy, rushed, and not as good as the first two. Its a Mark of a quality film that makes you feel sad thats it ended and so quickly especially when it is 90 minutes in length.the chemistry between these two great stars in still there and the gags come thick and fast and have everybody in stitches.they both are putting some age and weight on but that does not stop the stars from delivering punch after punch whether thats as a joke or to the adversaries.my favourite gag was the one they have used throughout the series with chris tuckers confusion over the words and names me and you or who. Matters aren't helped by the fact that some jokes can be very hit or miss and the storyline is so obvious it unreal, I swear if you can't figure out who the villain is in the first few minutes then you are a blithering idiot.Part of the charm of the first two Rush Hour movies was the chemistry between Jackie Chan and Chris Tucker. Rush Hour 3 follows the adventure of detectives Carter and Lee (played by Chris Tucker and Jackie Chan) as they follow an important case into Paris. They battle impossible foes doing equally impossible feats of daring duo all while being sprite, charming and funny.In the end, they come out smelling like roses.The end.Rumors of filming a fourth Rush Hour film immediately after this third installment were apparently scrapped due to unknown reasons, but one could easily venture that failing interest in the series hamstrung such a project (but who knows ...maybe there will be a fourth).Tucker and Chan still have a unique chemistry on-screen, one a speed talking black man and the other a soft talking Chinese gentleman. Sure, there were some fun points here and there, Roman Polanski delivered a cute cameo and the Parisian settings were a nice change of scenery for the more adrenaline rushed aspects of the story - but as a whole, I felt this just wasn't enough for a franchise this big.I wanted to like it more, particularly after being pleasantly surprised by many of the other sequels this year (Pirates 3, Spider-Man 3, Evan Almighty, Live Free and Die Hard and Ocean's Thirteen to be precise), but it just didn't work for me in the end.I gave this a disappointed 5/10.. The problem with the 3rd of the series is that in every way it feels very forced, it also feels like they agreed to make the film so they could all work together again.Nothing in the movie feels fresh, or exciting, and nothing in the movie helps enhance the first two instalments.The Good.....Not much actually, Jackie Chan can still do some quite cool, quite difficult choreographed fight scenes, even though we have all seem much better now (Casino Royale anyone?) I actually can't think of anything else positive I will take away from this movie....The Bad.....Without contradiction, the fight scenes. Directed by Brett Ratner, who helmed the first two installments in the series, the film sends the pair to Paris in pursuit of the assassin, where they become involved with crime lords, the French police, a helpful taxi driver, Jackie's long lost brother, and some beautiful women.As expected in a Jackie Chan movie, the action is a non-stop series of martial arts fights, car chases, and explosions. While there is nothing ground-breaking here, the film has plenty of action for Jackie's fans, and some good lines from Tucker; when you throw in appearances by Max Von Sydow, Philip Baker Hall, and Roman Polanski, "Rush Hour 3" is pretty decent entertainment for the third film in a series.. Nonetheless, Rush Hour 3 provides just enough laughs and fun action to be an enjoyable watch.It follows the story of the attempted assassination of Ambassador Chan and the following chase of the Triads that did it, along with the protection of a woman with knowledge of the organisation's secrets by the Blackenese duo Lee and Carter. Chris Tucker is just as charismatically black as in the previous Rush Hour films and Jackie Chan is exactly the same as usual – we would expect no less and no more — and yes, charismatically is a new word, I'm basically Shakespeare. It still manages to be a pretty good action comedy flick with just enough Jackie Chan and Chris Tucker jokage to keep it at a relatively high quality among other films of its kind.. However, there are sequels that are not as good as the previous offering, and then there are God-awful, art-less, money-making piles of turd...very much like Rush Hour 3.As an audience, we've more or less had enough of Chris Tucker by the end of Rush Hour 2, but take a look at his CV, and you'll see that the poor guy couldn't get any work after the second movie, so along came Jackie Chan to help his mate out, allowing him to reprise his role as quite possibly the most annoying man on the planet.Brett Ratner too has effectively directed his own demise, with a distinct lack of vision, and what can only be described as sheer contempt for his audience.The film is set in France, yet French people speak English to one another, like it's an everyday occurrence, using Jewish insults like, "schmuck," to enhance the Gallic feel of the overall piece. This is the third film that director Rather worked with Tucker and Chan on the previous two "Rush Hour" movies. Imagine this movie without Chris Tucker and the jokes and you will have a dull Chinese movie with no artistic value.The acting is horrific, the story line is childish and almost cartoon like; the plot is so predictable they didn't bother thinking about making a change from the original 2 movies.Jacky Chan is clearly older and not capable to doing the same amazing stunts that brought him to fame in Rush Hour 1 & 2 (10 years ago), other than that I don't think he can act..the only saving grace for me is the Hilarious Carter who at times reminded me of American Dad the cartoon with his off the cuff impulsive comments.. I loved the first two films so i thought another sequel would just be 90 minutes more of action comedy enjoyment, i went to see the first showing in my local cinema and was stunned at how little fight scenes and unimpressive fights there were, which brought me to only a few conclusions why this was.1)American film makers don't let their stars do as much stuff as they used to.2)Brett Ratner decided Jackie C couldn't help choreograph fight scenes.Or god forbid age has finally caught up with Jackie which until he brings out another movie seems to be the logical explanation, now i will say Jackie Chan has done excellently in the past also bearing in mind Jackie is 55 years old so it has to happen eventually.I did find the script entertaining there were some funny moments and loud over the top remarks coming from Cris Tucker which i was expecting, i think as a family film it would be good but for classic Jackie Chan fans they'l be disappointed.over all i give Rush Hour 3, 5 out 0f 10 7 out of 10 for a funny script 2.5 out of 10 for action p.s I felt a similar disappointment with Die Hard 4.0 i just hope Stallone dosn't do the same with Rambo 4.. The subplot between Inspector Lee and his Brother was awkward and i thought it was very fake and un-believable.But we don't go to see a Rush Hour film for it's story, but rather for the comedy that Chris Tucker brings and the fighting that Jackie Chan brings. His scenes were great and easily the funniest scenes in the movie, in my opinion.I can't say i can recommend this film to anyone but die hard Rush Hour fans or fans of Chris/Jackie. The only people that are going to see it are going to be the fans of the first two Rush Hours, which, though they did get progressively worse, were still enjoyable action-comedy flicks with a healthy balance of Jackie Chan cracking ribs and Chris Tucker wise-cracking. Another sequel, of another movie that i was a fan off, and this this time with an actor who I've liked since when i can remember.Jackie Chan may not have delivered path breaking cinema or enjoy the iconic or cult status that Bruce Lee got, but what he has always delivered has been good fun, with the right blend of humour, action, and naughtiness. Six years after Rush Hour 2 comes this sequel which further chronicles the misadventures of mismatched cops Inspector Carter (Chris Tucker) and Inspector Lee (Jackie Chan).

August Rush

Plot Synopsis

In 1995, Lyla Novacek (Keri Russell) is a cellist studying at the Juilliard School and living under strict rule of her father (William Sadler). Louis Connelly (Jonathan Rhys Meyers) is the lead singer of ”The Connelly Brothers”, an Irish rock band. Lyla and Louis meet at a party after their respective concerts, and sleep together on the rooftop under a full moon, to the music of a street performer below. The day after, they separate in a hurry, and are unable to maintain contact as Lyla is ushered away by her father to Chicago. Later, Lyla realizes she is pregnant, and after an argument with her father, she is struck by a car. Due to the accident trauma, she gives birth prematurely, and her father secretly puts the baby boy up for adoption, allowing her to believe that her son died. Eleven years later, Evan Taylor (Freddie Highmore) is living in a boys' orphanage outside New York City, where he meets Richard Jeffries (Terrence Howard), a social worker with Child and Family Services. Evan has the savant-like ability to hear music wherever he is, making him a bullying target for the older orphans. Convinced that his parents will find him, Evan runs away to New York City, ”following the music” in the hope it will lead him to his family. He finds a boy named Arthur (Leon Thomas III) performing in Washington Square Park. Louis, who left the band the same night Lyla was struck, now lives in San Francisco as an agent, while Lyla has also given up performing and now lives in Chicago teaching music. Louis reconnects with his brothers at a birthday party for one of the other band members, and after an argument and fistfight over breaking up the band, he decides to reconnect with the woman he now knows is Lyla. Lyla is called to her father's deathbed, where he confesses that her son is alive and in New York, since her father believed that he was only doing it for both him and his daughter and that that her son could've destroy her future. Lyla abandons her father to his fate and heads to New York to look for him. Evan follows Arthur to his home in a condemned theater, and is taken in by Maxwell ”Wizard” Wallace (Robin Williams), a vagrant, arrogant, abusive and aggressive musician who teaches homeless children music and employs them as street performers. Evan tries playing Wizard's prize guitar, Roxanne, and is so good that Wizard gives him the guitar and his old spot in Washington Square Park (both of which were previously Arthur's). He gives Evan the stage name ”August Rush” and tries to market him to clubs. Seeing the posters that Jeffries has posted for the runaway Evan, Wizard destroys all the ones he finds, hoping to keep Evan and his gift for his own gain. On arriving at Lyla's apartment in Chicago, Louis talks to one of her neighbors, who mistakenly tells Louis she's on her honeymoon. Despairing, he ends up in New York, where he gets his band back together. After Jeffries meets Wizard and Arthur on the street and becomes suspicious, the police raid the derelict theatre in which Wizard and his ”children” are living. Wizard helps Evan evade the police, telling him never to reveal his real name to anyone. Evan (now ”August”) takes refuge in a church where a young girl, Hope (Jamia Simone Nash), introduces him to the piano and written music. He picks up both skills so quickly that Hope gets the attention of the parish pastor (Mykelti Williamson), who takes August to Juilliard where he once again impresses the faculty. A rhapsody takes shape from August's notes and homework. In New York, Lyla goes to Jeffries' office, and Jeffries identifies Evan as her son. While looking for him, she takes up the cello again and accepts an offer to perform with the Philharmonic at a series of concerts in Central Park. August is selected to perform the rhapsody he's been composing at the same concert. However, Wizard, who found out about August's performance by Arthur, interrupts the rehearsal and claims to be his father, and manages to pull August out of the school. On the day of the outdoor concert, August is back in his spot in Washington Square, while Wizard makes plans to smuggle him around the country to play. He meets Louis and, unaware of their blood relationship, they have an impromptu guitar duet. August tells him of his dilemma, and Louis encourages him to go. That evening, with help from Arthur, August escapes from Wizard through the subway and heads for his concert. Louis, after his own performance with his reunited band, sees Lyla's name on one of the concert banners and also heads for the park. Jeffries finds a misplaced flyer for ”August Rush” with a picture, and realizing August is Evan, also heads for the concert. August arrives in time to conduct his rhapsody, which attracts both Lyla and Louis to the audience, where they are reunited. August finishes his rhapsody and as he turns to discover his parents, he smiles knowing that he has been right all along.

Review Summary

I was abandoned a second time by one of my parents.The movie ”August Rush” was healing to my soul wounded since early childhood;and again, in my early twenties. Instead of music, I used my talent of writing to deal with the lost of my parents.”August Rush” made me fantasize during the movie that my yearning and searching for my parents were like this remarkable child.. The scenes have an appealing fantasy element, while at the same time, the plot manages to explore true-to-life human situations such as bullying of those who are different.The music is incredible, and mostly consists of original scores. It includes gospel, rock and classical, seamlessly integrated in a new way that works extremely well.The plot is somewhat predictable and possibly a little ”sappy”, but those elements are easily overcome by the moment-to-moment execution of the story. Think of a modernized ”Oliver” with Robin Williams as Fagin to a group of homeless, musically talented kids...plus extra elements of romance and intrigue, and you will have a bit of an idea about this movie.The three main characters are all physically ”beautiful” people who manage to convey the story with a minimum of dialog. In the end, this movie is at least an endorsement and celebration of the significance of music in our lives and at most a transcendent, fun experience to watch.I rarely like to see any movie more than once, but definitely want to see this again. There were some errors but for the most part I applaud the film makers for the attention to the musical details.Yes the movie was a bit bit corny, and a little over the top, but for the most part I loved it and suggested it to every one.. Although at times, there may seem like there are gaps in the story line/character development, the point of this is that the music is what communicates those hidden details of the movie.Overall, this film is a masterpiece that should be cherished by music-lovers everywhere.. Ridiculously laughable story, hammy, bad acting, sub par music, zero chemistry between the two romantic leads, sticky sweet, implausible plot are only a few of the ways I can describe this incredibly bad movie. I don't want to give anything away, in case for some insane reason you want to see it, so I'll only go into the story problems in the first 15 minutes.The actors were trying their hearts out–except Robin Williams, whom I normally love but found false and unsatisfying–and in some cases were able to overcome the material and give fairly good performances(Terence Howard, Kerri Russell). While the viewer knows what will eventually happen, there is still much film to go...during which you see Evan's amazing talents burst forth AND an evil manipulator, 'the Wizard' (Robin Williams, sees the boy's potential and takes him in and puts him to work. Robin Williams seems to be making a different movie than everyone else.Look, we're not cynics; we love ”Love, Actually,” ”About a Boy,” and all of Frank Capra, but the story has to seduce you in, not knock you to your knees; has to have a level of believability that doesn't require you to swallow logs when straining at gnats.This was a dud. With a star cast that consisted of Robin Williams, Terence Howard, Jonathan Rhys Meyers and one of the biggest star kids in Hollywood -Freddie Highmore, a story about a musical genius, it has to be a brilliant movie, hasn't it? And since the movie revolves around music and the fact that August is a ”prodigy”, more effort should have been put into teaching the kid to look like he knew anything about music or conducting. People who have never considered nor been exposed to the processes behind music might not notice a problem, but to those who have, the film's central character will more closely resemble a comic-book-superhero version of a musician than any musician, genius or no, who has ever lived.This young lad's extraordinary ability (to reach professionalism at any instrument, and even theory/notation, within seconds of coming into contact with it for the first time) is only a symptom of the problem. I don't remember the last time I saw a Hollywood film which genuinely felt like it was the vision of an artist who really had something to say.Perhaps this film actually was written by someone who loves and understands music and wanted to convey something about it, but the fact that you can't tell simply by watching the film is a testament to its failure.. The father says the kid died but really he had given the boy to child services.Meanwhile, the boy - now 11 and living in an orphanage - runs off to New York City somehow figuring that magically, through hearing music, he'll meet his parents. It weakly conveys that the main character (a boy named Evan Taylor) believes he has some kind of control over the field, but it falls short of the intended correlation to his sensation of ”music everywhere” which is better illustrated later in the film. Instead, my friends, I am going to tell you to please, use some of your time watching this movie, so you can come back here and rate it with this one little painful star, as I did. Com'on, ye people of sense and sensibility, join me and suffer this movie and be merry you found the strength and then give it the only rating it deserves....PS: I am not going to elaborate on the ”oh-you're-so-mean!” side characters and the sanctified trinity of the main characters and their ridiculously hollow ”deep” emotions within their hearts of jelly who have no backbone to ever efficiently stand up for themselves and all they do is cry and moan and dream under the moon and hope that their sorry lives will be solved by cosmical deliverance because they sure won't do a thing since they are made of childish fairy-jelly glow, ...nor on the plot and dialogue silliness, and such, ...because you can read all about it on other reviews.

The story is taken directly from Oliver Twist, but the actual events, it isn't even believable in the fairytale context that it is told.The central love story is based on a night of rooftop sex with strangers who have about 3 minutes of the corniest lines I could possibly come up with before going at it like guinea pigs in heat: Who are you Lyla?” She pauses, smiles then looks off in the distance, ”I'm just.. me.” And it just goes on and on like that.The rest of the movie is filled with similar vomit inducing dialogue; I don't know how many times ”You've got to believe in your music” was repeated.Most of the characters are cardboard cutouts: There's rich cellist girl with overbearing father, brooding punk rocker, inner city black kid who talks just like you'd expect, and perpetually dazed and confused skinny white kid who gets picked on but always follows his dream.The cinematography is mostly boring and standard, what you might see in a car commercial or something similarly mundane. A lighter touch in directing, and better musical direction would have turned this into a good film - the story is interesting, but it was painted with a jackhammer instead of a brush.. I rented August Rush a few days ago with good expectations, I just heard wonderful things about this film, so I was excited to see it. We also have the talented Jonathan Rhys Meyers from the Tudors, the incredible Terrence Howard, then a disturbing yet memorable performance from Robin Williams.Evan Taylor is an orphan who is just convinced that he can hear his parent's music, that they do want him and he goes out to find them. Evan is set to find his parents but come across a musical group of kids, who are making money for Wizzard, when Evan plays music, it's magical, Wizzard exposes Evan giving him a new name, August Rush and makes money off of him. But when Lyla finds out about her son being alive, she goes to New York to find him, Louis starts thinking about Lyla and finds out where she lives, Chicago, but when he finds out she's gone, he goes to New York to relive his band days, instead they find each other and the musical genius their love created.August Rush is one of the first films of the year that I'm rating a perfect 10, because there is nothing wrong with this film, to be honest, I think it deserves a higher rating than a 7.4. August Rush is a movie that I'm sure will work it's way into your heart, it's a magical film that is absolutely perfect.10/10. He believes that he will find his parents if they only hear his music, because they are truly bonded by their music.(My Comment) The movie is a human interest story about a young boy's unyielding faith and will power to never give up on his dream. Mozart would be an absolute imbecile compared to this little kid August Rush, and for those familiar with music, this aspect (the foundation, really) just kills the movie.It is impossible to play like Michael Hedges in your first few minutes with a guitar. However, I just finished watching August Rush and I am in no way exaggerating when I say that it is by far the best movie I have ever seen. It not only grabs your heart from the very first scene but it grabs your soul within the first thirty minutes and by the time the movie's climax arrives you're in it so deep that whether you're Mr. Macho who wouldn't cry at his own mother's funeral or just someone who's bored and wants to see something that will be worth watching you will undoubtedly be wiping your eyes with your shirt sleeve and not caring who sees because everyone around you will be wetting their sleeves as well. I know its a musical, but i think listening to ARR songs is a better resort to watching this incredibly stupid sappy cheesy movie.3/10. This is one of the most ridiculous movies I've watched in recent years.Essentially its the story of an orphan who is trying to find his parents and does so through music.It comes across like a fairytale, but even Alice In Wonderland was more realistic than this. Im not sure who would actually enjoy this movie, maybe if you're 70, or under 12 but for everyone else I'd save your time.The acting itself wasn't bad, though the more interesting characters were played by Terrence Howard and Robin Williams, and they were both severely under-developed as you wanted to know more about them and less about this kid with the stupid smile all the time.. However, while the movie has a modern setting, it shares many plot elements with OLIVER TWIST, ending even better.It begins with a young couple of musicians that meets and has a one-night stand, and when she becomes pregnant her dad does everything to make her believe that the child died at birth, although he just put the child for adoption.A decade later the boy, Evan, lives in a orphanage and is mocked by the other kids because of his talents in music, that makes him like a savant with powerful skills. In the meanwhile an inexplicable series of circumstances draw his mother and dad that search for their son (after they discovered he is NOT dead), but also Evan ends in New York, becoming a star for his talents in music while a evil man, Michael Wallace known as ”the Wizard” (Robin Williams in a rare villanious role) takes advantage of the boy and wants to make money with his talents. The story touched my heart that I nearly cried...I think that ”August Rush” should get Oscar's for at least music. Such a music I can listen for hours and days and it ever makes me bored off it.Seriously I can say that the first time I saw preview, I knew that it will be maybe the best movie during my life and actually it is. If you are a true music fan, musician, or even love soundtracks in the sense of Instrumentals, then this film will be a hit with you.No film, in years of my life have touched me the way this film has, how has this film gone under the radar for so long? The movie tells a story of a orphan boy who is a musical genius and who believes that his parents will find one day . Imagine a modern version of Oliver Twist, add beautiful classical and rock music and finish the mix with a somewhat predictable, but nevertheless intriguing love story and ”August Rush” is the best that you can possible make out of it.By watching the opening scene, showing Freddie Highmore in a corn field, I already suspected this could become something very special. I have never seen or heard anything like it and I sincerely hope that I'll one day watch a movie that does an even better job. Perhaps it's better to categorize this movie as being targeted at people of all ages, that love music and want to see a feel-good movie with beautiful music and top notch acting. I was hoping for him and moved by the music he felt in the world around him.Normally I don't watch movies of this genre, but August Rush captured my emotions. Howard is a fine actor as shown earlier this year in The Brave One (see my review) but he's not given one of the bigger and more important roles and not a lot to work with so he kind of gets out shined.I am not a musical expert nor a musician of any kind, much to my disappointment so they could have played those instruments in the film with their feet and it couldn't have mattered to me. You will either buy into this contrived tale of orphan who hears music then runs off New York to find his parents or you won't.I didn't.Cloyingly cute I had no patience for it and squirmed from the opening bits of the kid conducting the wind, through the flash back meeting of young rock star dad and rich girl cellist torn apart by her disapproving dad, on to the really annoying Robin ”Please put my head in a duck press to make me stop screaming” Williams and then to the oh gee ending. Although this film plays well to a broad audience, it is very mystical and based on simple, yet emotional themes that will play flat to some movie-goers.If you have strong parental feelings or enjoy movies centered on the power of human love and attraction, this story will move you like few films ever have. However, if you are easily bored with themes that are lacking in danger and suspense or prefer gritty true-to-life movies, this one may come off as a disappointment.The screenplay seems written as a spiritual message intimating that there is an energy field that connects all of life, and music is one of the domains available to any who care to experience it.The plot is simple but deep in implication- an orphaned boy wants to reunite with his parents and feels that his inherited musical genius can somehow guarantee their return. I was not impressed.The acting was unconvincing, the character development nonexistent: Russell, who spends most of the film gazing wistfully at various points on the horizon, evokes virtually no sympathy as a woman who loses her son and lapses into a decade-long depression; Rhys-Meyers is flat and uninspiring as August's tortured rock-musician-turned-bond-trader father (”I'm sad...I'm Irish...I'm sad”); and Williams is only mildly creepy as Wizard, the Fagin-like ringmaster of a coterie of musical ragamuffins who live in (of course!) an abandoned theater. August Rush is quite simply one of the best movies I have seen in years. This was one of the best movies I have seen in a very long time, maybe ever...The music, the dialogue, the story, it all speaks right to the heart and it leaves you glowing with happiness and admiration. I thought the premise of the story was a good one; A boy given up for adoption attempts to find his birth parents, because his love for music gives him the sense that his parents are still alive. I'm not a fan of musical movies; however, I thought I would give this film a try. Once I watched the kid Freddie Highmore tearing for the loss of his parents I was starting to get attached to the movie, and once I started tasting the music this film contains and with all beautiful emotions flying around I was amazed and could not take my eyes off the screen till the finish.. This movie has some great acting it makes you believe like it's an actual story. Overall this movie is great for both the family and also for anyone interested in Music, it was truly inspirational, I loved it, it was everything I expected and more, its definitely underrated.. If the story intrigues you, see it, I'm pretty sure you'll feel good too:-).August Rush is worth watching for us who still have some dreams inside of us and don't need to be reminded of the world we live in all the time!. 'Evan Taylor' AKA August Rush (Freddie Highmore) is placed in an orphanage, longing for parents he believes he can 'hear' in the music of the spheres. There's only a few movies a year that you watch and you just don't want it to end.. Amazing movie with an incredible story about a little boy who never gave up and kept faith.I watched this several times with my mom, she loves it, and it is an excellent family movie. August Rush is a must watch film because it's a very inspirational story.Remarkable movie filled with love, art, music, inspiration, and hope.

Table 9: Data from the human evaluation experiment. **B** represents the tags predicted by the baseline system, **N** represents the tags predicted by our new system, and **R** represents the open set tags extracted from the user reviews by our system. If a tag is followed by a number in superscript, the number indicates the number of annotators who selected the tag as relevant to the story. We consider a tag as relevant if it has at least two votes. ♠ indicates the instances where our system's predictions were more relevant compared to the baseline system, and ♣ indicates the opposite. For the rest of the instances, both systems had a tie. Annotators' feedback about the helpfulness of the tagsets (closed set tags and open set tags) are presented by emoticons (☺: Very helpful, 😐: Moderately helpful, ☹: Not helpful). First three emoticons are the feedback from all the annotators for the tags from the baseline system and our system. Rest of the three emoticons are the feedback for the tags extracted from the user reviews.

Mind Your Inflections! Improving NLP for Non-Standard Englishes with Base-Inflection Encoding

Abstract

Inflectional variation is a common feature of World Englishes such as Colloquial Singapore English and African American Vernacular English. Although comprehension by human readers is usually unimpaired by non-standard inflections, current NLP systems are not yet robust. We propose Base-Inflection Encoding (BITE), a method to tokenize English text by reducing inflected words to their base forms before reinjecting the grammatical information as special symbols. Fine-tuning pretrained NLP models for downstream tasks using our encoding defends against inflectional adversaries while maintaining performance on clean data. Models using BITE generalize better to dialects with non-standard inflections without explicit training and translation models converge faster when trained with BITE. Finally, we show that our encoding improves the vocabulary efficiency of popular data-driven subword tokenizers. Since there has been no prior work on quantitatively evaluating vocabulary efficiency, we propose metrics to do so.[1]

1 Introduction

Large-scale neural models have proven successful at a wide range of natural language processing (NLP) tasks but are susceptible to amplifying discrimination against minority linguistic communities (Hovy and Spruit, 2016; Tan et al., 2020) due to selection bias in the training data and model overamplification (Shah et al., 2019).

Most datasets implicitly assume a distribution of error-free Standard English speakers, but this does not accurately reflect the majority of the global English speaking population who are either second language (L2) or non-standard dialect speakers (Crystal, 2003; Eberhard et al., 2019). These World Englishes differ at lexical, morphological, and syntactic levels (Kachru et al., 2009); sensitivity to these variations predisposes English NLP systems to discriminate against speakers of World Englishes by either misunderstanding or misinterpreting them (Hern, 2017; Tatman, 2017). Left unchecked, these biases could inadvertently propagate to future models via metrics built around pretrained models, such as BERTScore (Zhang et al., 2020).

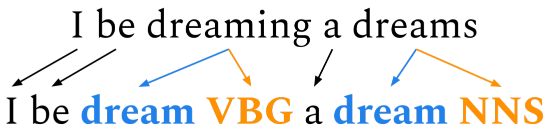

Figure 1: Base-Inflection Encoding reduces inflected words to their base forms, then reinjects the grammatical information into the sentence as inflection symbols.

In particular, Tan et al. (2020) show that current question answering and machine translation systems are overly sensitive to non-standard inflections—a common feature of dialects such as Colloquial Singapore English (CSE) and African American Vernacular English (AAVE).[2] Since people naturally correct for or ignore non-standard inflection use (Foster and Wigglesworth, 2016), we should expect NLP systems to be equally robust.

Existing work on adversarial robustness for NLP primarily focuses on adversarial training methods (Belinkov and Bisk, 2018; Ribeiro et al., 2018; Tan et al., 2020) or classifying and correcting adversarial examples (Zhou et al., 2019a). However, this effectively increases the size of the training dataset by including adversarial examples or training a new model to identify and correct perturbations, thereby significantly increasing the overall computational cost of creating robust models.

These approaches also only operate on either raw text or the model, ignoring tokenization—an operation that transforms raw text into a form that the neural network can learn from. We introduce a

November 16–20, 2020.

new representation for word tokens that separates base from inflection. This improves both model robustness and vocabulary efficiency by explicitly inducing linguistic structure in the input to the NLP system (Erdmann et al., 2019; Henderson, 2020).

Many extant NLP systems use a combination of a whitespace and punctuation tokenizer followed by a data-driven subword tokenizer such as byte pair encoding (BPE; Sennrich et al. (2016)). However, a purely data-driven approach may fail to find the optimal encoding, both in terms of vocabulary efficiency and cross-dialectal generalization. This could make the neural model more vulnerable to inflectional perturbations. Hence, we:

- Propose Base-InflecTion Encoding (BITE), which uses morphological information to help the data-driven tokenizer use its vocabulary efficiently and generate robust symbol[3] sequences. In contrast to morphological segmentors such as Linguistica (Goldsmith, 2000) and Morfessor (Creutz and Lagus, 2002), we reduce inflected forms to their base forms before reinjecting the inflection information into the encoded sequence as special symbols. This approach gracefully handles the canonicalization of words with non-concatenative morphology while generally allowing the original sentence to be reconstructed.
- Demonstrate BITE's effectiveness at making neural NLP systems robust to non-standard inflection use while preserving performance on Standard English examples. Crucially, simply fine-tuning the pretrained model for the downstream task after adding BITE is sufficient. Unlike adversarial training, BITE does not enlarge the dataset and is more computationally efficient.
- Show that BITE helps BERT (Devlin et al., 2019) generalize to dialects unseen during training and also helps Transformer-big (Ott et al., 2018) converge faster for the WMT'14 En-De task.
- Propose metrics like symbol complexity to operationalize and evaluate the vocabulary efficiency of an encoding scheme. Our metrics are generic and can be used to evaluate any tokenizer.

2 Related Work

Subword tokenization. Before neural models can learn, raw text must first be encoded into symbols with the help of a fixed-size vocabulary. Early models represented each word as a single symbol in the vocabulary (Bengio et al., 2001; Collobert et al., 2011) and uncommon words were represented by an `unknown` symbol. However, such a representation is unable to adequately deal with words absent in the training vocabulary. Therefore, subword representations like WordPiece (Schuster and Nakajima, 2012) and BPE (Sennrich et al., 2016) were proposed to encode out-of-vocabulary (OOV) words by segmenting them into subwords and encoding each subword as a separate symbol. This way, less information is lost in the encoding process since OOV words are approximated as a combination of subwords in the vocabulary. Wang et al. (2019) reduce vocabulary sizes by operating on bytes instead of characters (as in standard BPE).

To make subword regularization more tractable, Kudo (2018) proposed an alternative method of building a subword vocabulary by reducing an initially oversized vocabulary down to the required size with the aid of a unigram language model, as opposed to incrementally building a vocabulary as in WordPiece and BPE variants. However, machine translation systems operating on subwords still have trouble translating rare words from highly-inflected categories (Koehn and Knowles, 2017).

Sadat and Habash (2006),Koehn and Hoang (2007), and Kann and Schütze (2016) propose to improve machine translation and morphological reinflection by encoding morphological features separately while Sylak-Glassman et al. (2015) propose a schema for inflectional features. Avraham and Goldberg (2017) explore the effect of learning word embeddings from base forms and morphological tags for Hebrew, while Chaudhary et al. (2018) show that representing words as base forms, phonemes, and morphological tags improve cross-lingual transfer for low-resource languages.

Adversarial robustness in NLP. To harden NLP systems against adversarial examples, existing work largely uses adversarial training (Goodfellow et al., 2015; Jia and Liang, 2017; Ebrahimi et al., 2018; Belinkov and Bisk, 2018; Ribeiro et al., 2018; Iyyer et al., 2018; Cheng et al., 2019). However, this generally involves *retraining* the model with the adversarial data, which is computationally expensive and time-consuming. Tan et al. (2020) showed that simply fine-tuning a trained model for a single epoch on appropriately generated adversarial training data is sufficient to harden the model against inflectional adversaries. Instead of

---

[3] Following Sennrich et al. (2016), we use *symbol* instead of *token* to avoid confusion with the unencoded *word token*.

adversarial training, Piktus et al. (2019) train word embeddings to be robust to misspellings, while Zhou et al. (2019b) propose using a BERT-based model to detect adversaries and recover clean examples. Jia et al. (2019) and Huang et al. (2019) use Interval Bound Propagation to train provably robust pre-Transformer models, while Shi et al. (2020) propose an efficient algorithm for training certifiably robust Transformer architectures.

Summary. Popular subword tokenizers operate on surface forms in a purely data-driven manner. Existing adversarial robustness methods for large-scale Transformers are computationally expensive, while provably robust methods have only been shown to work for pre-Transformer architectures and small-scale Transformers.

Our work uses linguistic information (inflectional morphology) in conjunction with data-driven subword encoding schemes to make large-scale NLP models robust to non-standard inflections and generalize better to L2 and World Englishes, while preserving performance for Standard English. We also show that our method helps existing subword tokenizers use their vocabulary more efficiently.

3 Linguistically-Grounded Tokenization

Data-driven subword tokenizers like BPE improve a model's ability to approximate the semantics of unknown words by splitting them into subwords.

Although the fully data-driven nature of such methods make them language-agnostic, this forces them to rely only on the statistics of the surface forms when transforming words into subwords since they do not exploit any language-specific morphological regularities. To illustrate, the past tense of *go*, *take*, and *keep* have the inflected forms *went*, *took*, and *kept*, respectively, which have little to no overlap with their base forms[4] and each other even though they share the same tense. These six surface forms would likely have no subwords in common in the vocabulary. Consequently, the neural model would have the burden of learning both the relation between base forms and inflected forms and the relation between inflections for the same tense. Additionally, since vocabularies are fixed before model training, such an encoding does not optimally use a limited vocabulary.

Even when inflections do not orthographically alter the base form and there is a significant overlap between the base and inflected forms, e.g., the *-ed* and *-d* suffixes, the suffix may be encoded as a separate subword and base forms / suffixes may not be consistently represented. To illustrate, encoding *danced* as $[\textit{dance}, \textit{d}]$ and *dancing* as $[\textit{danc}, \textit{ing}]$ results in two different "base forms" for the same word, *dance*. This again burdens the model with learning the two "base forms" mean the same thing and makes inefficient use of a limited vocabulary.

Algorithm 1 Base-InflecTion Encoding (BITE)

```
Require: Input sentence $S = [w_1, \dots, w_N]$
Ensure: Encoded sequence $S'$
  $S' \leftarrow [\emptyset]$
  for all $i = 1, \dots, |N|$ do
      if POS$(w_i) \in$ {NOUN, VERB, ADJ} then
          base ← GETLEMMA$(w_i$, POS$(w_i))$
          inflection ← GETINFLECTION$(w_i)$
          $S' \leftarrow S' +$ [base, inflection]
      else
          $S' \leftarrow S' + [w_i]$
      end if
  end for
  return $S'$
```

When encoded in conjunction with another inflected form like *entered*, which should be encoded as $[\textit{enter}, \textit{ed}]$, this encoding scheme also produces two different subwords for the same type of inflection *-ed* vs *-d*. As in the first example, the burden of learning that the two suffixes correspond to the same tense is transferred to the learning model.

A possible solution is to instead encode *danced* as $[\textit{danc}, \textit{ed}]$ and *dancing* as $[\textit{danc}, \textit{ing}]$, but there is no guarantee that a data-driven encoding scheme will learn this pattern without some language-specific linguistic supervision. In addition, this unnecessarily splits up the base form into two subwords *danc* and *e*; the latter contains no extra semantic or grammatical information yet increases the encoded sequence length. Although individually minor, encoding many base words in this manner increases the computational cost for any encoder or decoder network.

Finally, although it is theoretically possible to force a data-driven tokenizer to segment inflected forms into morphologically logical subwords by limiting the vocabulary size, many inflected forms are represented as individual symbols at common vocabulary sizes (30–40k). We found that the BERT_{base} WordPiece tokenizer and BPE[5] encoded each of the above examples as single symbols.

---

[4] Base (no quotes) is synonymous with lemma in this paper.

[5] Trained on Wikipedia+BookCorpus (1M) with a vocabulary size of 30k symbols.

3.1 Base-Inflection Encoding

To address these issues, we propose the Base-InflecTion Encoding framework (or BITE), which encodes the base form and inflection of content words separately. Similar to how existing subword encoding schemes improve the model's ability to approximate the semantics of out-of-vocabulary words with in-vocabulary subwords, BITE helps the model better handle out-of-distribution inflection usage by keeping a content word's base form consistent even when its inflected form drastically changes. This distributional deviation could manifest as adversarial examples, such as those generated by MORPHEUS (Tan et al., 2020), or sentences produced by L2 or World Englishes speakers. By keeping the base forms consistent, BITE provides adversarial robustness to the model.

BITE (Fig. 1). Given an input sentence $S = [w_1, \ldots, w_N]$ where w_i is the i^{th} word, BITE generates a sequence of symbols $S' = [w'_1, \ldots, w'_N]$ such that $w'_i = [\textsc{Base}(w_i),\textsc{Inflect}(w_i)]$ where $\textsc{Base}(w_i)$ is the base form of the word and $\textsc{Inflect}(w_i)$ is the inflection (grammatical category) of the word (Algorithm 1). If w_i is not inflected, $\textsc{Inflect}(w_i)$ is NULL and excluded from the sequence of symbols to reduce the neural network's computational cost. In our implementation, we use Penn Treebank tags to represent inflections.

By lemmatizing each inflected word to obtain the base form instead of segmenting it like in most data-driven encoding schemes, BITE ensures this base form is consistent for all inflected forms of a word, unlike a subword produced by segmentation, which can only contain characters present in the original word. For example, $\textsc{Base}(took)$, $\textsc{Base}(taking)$, and $\textsc{Base}(taken)$ all correspond to the same base form, *take*, even though it is orthographically significantly different from *took*.

Similarly, encoding all inflections of the same grammatical category (e.g., verb-past-tense) in a canonical form should help the model to learn each inflection's grammatical role more quickly. This is because the model does not need to first learn that the same grammatical category can manifest in orthographically different forms.

Crucially, the original sentence can usually be reconstructed from the base forms and grammatical information preserved by the inflection symbols, except in cases of overabundance (Thornton, 2019).

Implementation details. We use the BertPreTokenizer from the `tokenizers`[6] library for whitespace and punctuation splitting. We use the NLTK (Bird et al., 2009) implementation of the averaged perceptron tagger (Collins, 2002) with greedy decoding to generate POS tags, which serve to improve lemmatization accuracy and as inflection symbols. For lemmatization and reinflection, we use `lemminflect`[7], which uses a dictionary look-up together with rules for lemmatizing and inflecting words. A benefit of this approach is that the neural network can now generate orthographically appropriate inflected forms by generating the base form and the corresponding inflection symbol.

3.2 Compatibility with Data-Driven Methods

Although BITE has the numerous advantages outlined above, it suffers from the same weakness as regular word-level tokenization schemes when used alone: a limited ability to handle out-of-vocabulary words. Hence, we designed BITE to be a general framework that seamlessly incorporates existing data-driven schemes to take advantage of their proven ability to handle OOV words.

To achieve this, a whitespace/punctuation-based pretokenizer is first used to transform the input into a sequence of words and punctuation characters, as is common in machine translation. Next, BITE is applied and the resulting sequence is converted into a sequence of integers by a data-driven encoding scheme (Fig. 6 in Appendix B). In our experiments, we use BITE in this manner and refer to the combined tokenizer as "BITE+D", where D refers to the data-driven encoding scheme.

4 Model-Based Experiments

We first demonstrate the effectiveness of BITE using the pretrained cased BERT$_{\text{base}}$ (Devlin et al., 2019) before training a full Transformer (Vaswani et al., 2017) from scratch. We do not replace WordPiece and BPE but instead incorporate them into the BITE framework as described in §3.2. The advantages and disadvantages to this approach will be discussed in the next section. We do not do any hyperparameter tuning but use the original models' in all experiments (detailed in Appendix B).

Table 1: $\text{BERT}_{\text{base}}$ results on the clean and adversarial MultiNLI and SQuAD 2.0 examples. We compare BITE+WordPiece to both WordPiece alone and with one epoch of adversarial fine-tuning. For fair comparison with adversarial fine-tuning, we trained the BITE+WordPiece model for an extra epoch (bottom) on clean data.

4.1 Adversarial Robustness (Classification)

We evaluate BITE's ability to improve model robustness for question answering and natural language understanding using SQuAD 2.0 (Rajpurkar et al., 2018) and MultiNLI (Williams et al., 2018), respectively. We use MORPHEUS (Tan et al., 2020), an adversarial attack targeting inflectional morphology, to test the overall system's robustness to non-standard inflections. They previously demonstrated MORPHEUS's ability to generate plausible and semantically equivalent adversarial examples resembling L2 English sentences. We attack each $\text{BERT}_{\text{base}}$ model separately and report F_1 scores on the answerable questions and the full SQuAD 2.0 dataset, following Tan et al. (2020). In addition, for MNLI, we report scores for both the in-domain (MNLI) and out-of-domain dev. set (MNLI-MM).

BITE+WordPiece vs. only WordPiece. First, we demonstrate the effectiveness of BITE at making the model robust to inflectional adversaries. After fine-tuning two separate $\text{BERT}_{\text{base}}$ models on SQuAD 2.0 and MultiNLI, we generate adversarial examples for them using MORPHEUS. From Table 1, we observe that the BITE+WordPiece model not only achieves similar performance (±0.5) on clean data, but is significantly more robust to inflectional adversaries (10-point difference for SQuAD 2.0, 17-point difference for MultiNLI).

BITE vs. adversarial fine-tuning. Next, we compare the BITE to adversarial fine-tuning (Tan et al., 2020), an economical variation of adversarial training (Goodfellow et al., 2015) for making models robust to inflectional variation. In adversarial fine-tuning, an adversarial training set is generated by randomly sampling inflectional adversaries k times from the adversarial distribution found by MORPHEUS and adding them to the original training set. Rather than retraining the model on this adversarial training set, the previously trained model is simply trained for one extra epoch. We follow the above methodology and adversarially fine-tune the WordPiece-only $\text{BERT}_{\text{base}}$ for one epoch with k set to 4. To ensure a fair comparison, we also train the BITE+WordPiece $\text{BERT}_{\text{base}}$ on the original training set for an extra epoch.

Condition	Encoding	BLEU	METEOR
Clean	BPE only	29.13	47.80
	BITE + BPE	**29.61**	**48.31**
MORPHEUS	BPE only	14.71	39.54
	BITE + BPE	**17.77**	**41.58**

Table 2: Results on newstest2014 for Transformer-big trained on WMT'16 English-German (En-De).

From Table 1, we observe that BITE is often more effective than adversarial fine-tuning at making the model more robust against inflectional adversaries and in some cases (SQuAD 2.0 All and MNLI-MM) even without needing the additional epoch of training. However, the adversarially fine-tuned model consistently achieves better performance on clean data. This is likely because even though adversarial fine-tuning requires only a single epoch of extra training, the process of generating the training set increases its size by a factor of k and hence the number of updates. In contrast, BITE requires no extra training and is more economical.

Adversarial fine-tuning is also less effective at inducing model robustness when the adversarial example is from an out-of-domain distribution (8 point difference between MNLI and MNLI-MM). This makes it less useful for practical scenarios, where this is often the case. In contrast, BITE performs equally well on both in- and out-of-domain data, demonstrating its applicability to practical scenarios where the training and testing domains may not match. This is the result of preserving the base forms, which we investigate further in §5.2.

4.2 Machine Translation

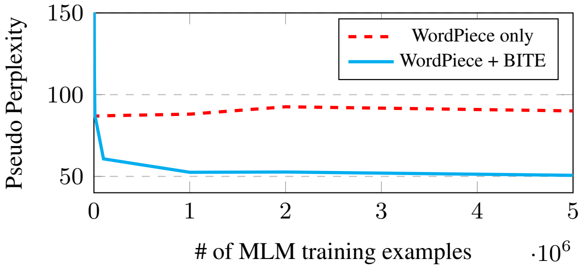
Next, we evaluate BITE's impact on machine translation using the Transformer-big architecture (Ott et al., 2018) and WMT'14 English–German (En–De) task. We apply BITE+BPE to the English examples and compare it to the BPE-only baseline. More details about our experimental setup can be found in Appendix B.3.

To obtain the final models, we perform early-stopping based on the validation perplexity and average the last ten checkpoints. We observe that the BITE+BPE model converges 28% faster (Fig. 7) than the baseline (20k vs. 28k updates) in addition to outperforming it by 0.48 BLEU on the standard data and 3.06 BLEU on the MORPHEUS adversarial examples (Table 2). This suggests that explicit encoding of morphological information helps models learn better and more robust representations faster.

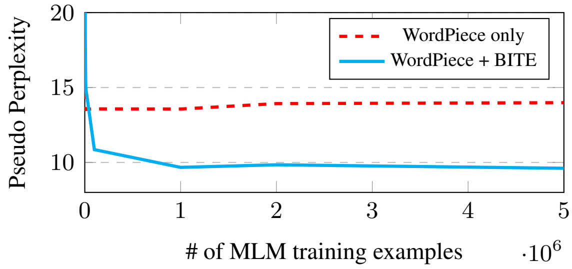
4.3 Dialectal Variation

Apart from second languages, dialects are another common source of non-standard inflections. However, there is a dearth of task-specific datasets in English dialects like AAVE and CSE. Therefore, in this section's experiments, we use the model's pseudo perplexity (pPPL) (Wang and Cho, 2019) on monodialectal corpora as a proxy for its performance on downstream tasks in the corresponding dialect. The pPPL measures how certain the pretrained model is about its prediction and reflects its generalization ability on the dialectal datasets. To ensure fair comparisons across different subword segmentations, we normalize the pseudo log-likelihoods by the number of *word tokens* fed into the WordPiece component of each tokenization pipeline (Mielke, 2019). This avoids unfairly penalizing BITE for inevitably generating longer sequences. Finally, we scale the pseudo log-likelihoods by the masking probability (0.15) so that the final pPPLs are within a reasonable range.

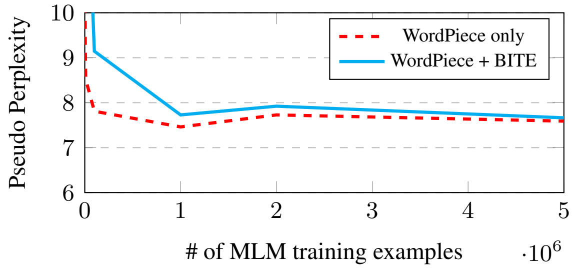
Corpora. For AAVE, we use the Corpus of Regional African American Language (CORAAL) (Kendall and Farrington, 2018), which comprises transcriptions of interviews with African Americans born between 1891 and 2005. For our evaluation, only the interviewee's speech was used. In addition, we strip all in-line glosses and annotations from the transcriptions before dropping all lines with less than three words. After preprocessing, this corpus consists of slightly under 50k lines of text (1,144,803 word tokens, 17,324 word types).



(a) Colloquial Singapore English (forum threads)



(b) African American Vernacular English (CORAAL)



(c) Standard English (Wikipedia+BookCorpus)

Figure 2: Pseudo perplexity of BERT$_{\text{base}}$ on CSE, AAVE, Standard English corpora. BITE$_{abl}$ refers to the ablated version without grammatical information.

To obtain a CSE corpus, we scrape the Infotech Clinics section of the Hardware Zone Forums[8], a forum frequented by Singaporeans and where CSE is commonly used. Similar preprocessing to the AAVE data yields a 2.2M line corpus (45,803,898 word tokens, 253,326 word types).

Setup. We take the same pretrained BERT$_{\text{base}}$ model and fine-tune two separate variants (with and without BITE) on English Wikipedia and BookCorpus (Zhu et al., 2015) using the masked language modeling (MLM) loss without the next sentence prediction (NSP) loss. We fine-tune for one epoch on increasingly large subsets of the dataset, since this has been shown to be more effective than doing the same number of gradient updates on a fixed subset (Raffel et al., 2019). Preprocessing steps are described in Appendix B.1.

Next, we evaluate model pPPLs on the AAVE

---

[8] forums.hardwarezone.com.sg

and CSE corpora, which we consider to be from dialectal distributions that differ from the training data which is considered to be Standard English. Since calculating the stochastic pPPL requires randomly masking a certain percentage of symbols for prediction, we also experiment with doing this for each sentence multiple times before averaging them. However, we find no significant difference between doing the calculation once or five times; the random effects likely canceled out due to the large sizes of our corpora.

Results. From Fig. 2, we observe that the BITE+WordPiece model initially has a much higher pPPL on the dialectal corpora, before converging to 50–65% of the standard model's pPPL as the model adapts to the presence of the new inflection symbols (e.g., `VBD`, `NNS`, etc.). Crucially, the models are not trained on dialectal corpora, which demonstrates the effectiveness of BITE at helping models better generalize to unseen dialects. For Standard English, WordPiece+BITE performs slightly worse than WordPiece, reflecting the results on QA and NLI in Table 1. However, it is important to note that the WordPiece vocabulary used was not optimized for BITE; results from §4.2 indicate that training the data-driven tokenizer from scratch with BITE might improve performance.

CSE vs. AAVE. Astute readers might notice that there is a large difference in pPPL between the two dialectal corpora, even for the same tokenizer combination. One possible explanation is that CSE differs significantly from Standard English in morphology and syntax due to its Austronesian and Sinitic influences (Tongue, 1974). In addition, loan words and discourse particles not found in Standard English like *lah*, *lor* and *hor* are commonplace in CSE (Leimgruber, 2009). AAVE, however, generally shares the same syntax as Standard English due to its largely English origins (Poplack, 2000) and is more similar linguistically. These differences are likely responsible for the significant increase in pPPL for CSE compared to AAVE.

Another possible explanation is that the BookCorpus may contain examples of AAVE since the BookCorpus' source, Smashwords, also publishes African American fiction. We believe the reason for the difference is a mixture of these two factors.

4.4 Ablation Study

To tease apart the effects of BITE's two components (lemmatization and inflection symbol) on task performance, we ablate the extra grammatical information from the encoding by replacing all inflection symbols with a dummy symbol (BITE_{abl}). As expected, BITE_{abl} is significantly more robust to adversarial inflections (Table 3) and the slight performance drop is likely due to the POS tagger being adversarially affected. However, different tasks likely require different levels of attention to inflections and BITE allows the network to learn this for each task. For example, NLI performance on clean data is only slightly affected by the absence of morphosyntactic information, while MT and QA performance is more significantly affected.

	Clean		**MORPHEUS**	
Dataset	BITE_{abl}	BITE	BITE_{abl}	BITE
SQuAD 2 (F_1)				
Ans. Qns.	68.85	**74.50**	70.68	**71.33**
All Qns.	**72.90**	72.71	**69.29**	69.23
MNLI (Acc.)				
Matched	82.28	**83.01**	**80.17**	76.11
Mismatched	83.18	**83.50**	**81.21**	76.64
WMT'14 (BLEU)	28.14	**29.61**	**20.91**	17.77

Table 3: Effect of reinjecting grammatical information via inflection symbols. BITE_{abl} refers to the ablation with the dummy symbol instead of inflection symbols.

In a similar ablation for the pPPL experiments, we find that both the canonicalizing effect of the base form and knowledge of each word's grammatical role contribute to the lower pPPL on dialectal data (Table 4 in the Appendix). We discuss this in greater detail in Appendix B.2 and also report the pseudo log-likelihoods and per-symbol pPPLs in the spirit of transparency and reproducibility.

5 Model-Independent Analyses

Finally, we analyze WordPiece, BPE, and unigram LM subword tokenizers that are trained with and without BITE. Implementation details can be found in Appendix B.4. Through our experiments, we explore how BITE improves adversarial robustness and helps the data-driven tokenizer use its vocabulary more efficiently. We use 1M examples from Wikipedia+BookCorpus for training.

5.1 Vocabulary Efficiency

We may operationalize the question of whether BITE improves vocabulary efficiency in numerous ways. We discuss two vocabulary-level measures here and a sequence-level measure in Appendix C.

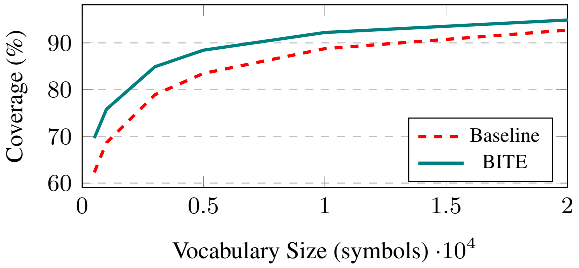


Figure 3: Comparison of coverage between BITE and a trivial baseline (word counts).

Vocabulary coverage. One measure of vocabulary efficiency is the coverage of a representative corpus by a vocabulary's symbols. We measure coverage by computing the total number of tokens (words and punctuation) in the corpus that are represented in the vocabulary divided by the total number of tokens in the corpus. We use the 1M subset of Wikipedia+BookCorpus as our representative corpus. Since BITE does not require a vocabulary size to be fixed before training, we set the N most frequent types (base forms and inflections) to be our vocabulary. We use the N most frequent types in the unencoded text as our baseline vocabulary.

From Fig. 3, we observe that the BITE vocabulary achieves a higher coverage of the corpus than the baseline, hence demonstrating the efficacy of BITE at improving vocabulary efficiency. Additionally, we note that this advantage is most significant (5–7%) when the vocabulary contains less than 10k symbols. This implies that inflected word forms comprise a large portion of frequently occurring types, which comports with intuition.

Symbol complexity. Another measure of vocabulary efficiency is the total number of symbols needed to encode a representative set of word types. We term this the *symbol complexity*. Formally, given N, the total number of word types in the evaluation corpus; S_i, the sequence of symbols obtained from encoding the ith type; and u, the number of unknown symbols in S_i, we define:

$$\text{SymbComp}(S_1, \ldots, S_N) = \sum_{i=1}^{N} f(S_i), \qquad (1)$$

$$f(S_i) = \begin{cases} |S_i| + u_i & |S_i| - u_i > 0 \\ 0 & \text{otherwise.} \end{cases} \qquad (2)$$

While not strictly necessary when comparing vocabularies on the same corpus, normalizing Eq. (1) by the number of word types in the corpus may be helpful for cross-corpus comparisons. For simplicity, we define $f(S_i) = 0$ when there are *only* unknown symbols in the encoded sequence and the penalty of each extra unknown symbol to be double that of a symbol in the vocabulary.[9] A general form of Eq. (2) is included in Appendix B.4.

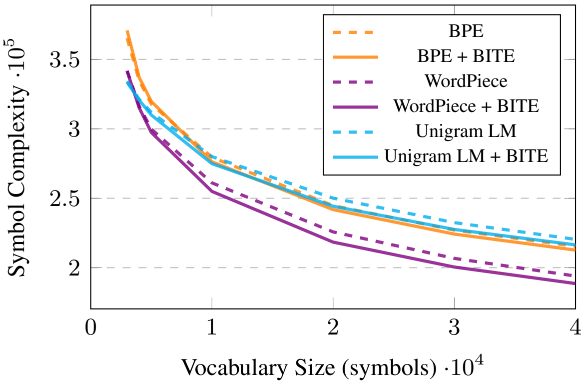

Figure 4: Symbol complexities of tokenizer vocabularies as computed in Eqs. (1) and (2). Lower is better.

To measure the symbol complexities of our vocabularies, we use WordNet's single-word lemmas (Miller, 1995) as our "corpus" ($N = 83118$). From Fig. 4, we see that training data-driven tokenizers with BITE produces vocabularies with lower symbol complexities. Additionally, we observe that tokenizer combinations incorporating WordPiece or unigram LM generally outperform the BPE ones. We believe this to be the result of using a language model to inform vocabulary creation. It is logical that a symbol that maximizes a language model's likelihood on the training data is also semantically "denser", hence prioritizing such symbols produces efficient vocabularies. We leave the in-depth investigation of this relationship to future work.

5.2 Adversarial Robustness

BITE's ability to make models more robust to inflectional variation can be directly attributed to its preservation of consistent, inflection-independent base forms. We demonstrate this by measuring the similarity between the encoded clean and adversarial sentences with the Ratcliff/Obershelp algorithm (Ratcliff and Metzener, 1988). We use the MultiNLI in-domain development set and the MORPHEUS adversaries generated in §4.1.

We find that clean and adversarial sequences encoded by the BITE+D tokenizers were more similar (1–2.5%) than those encoded without BITE

---

[9] $|S|$ contributes the extra count.

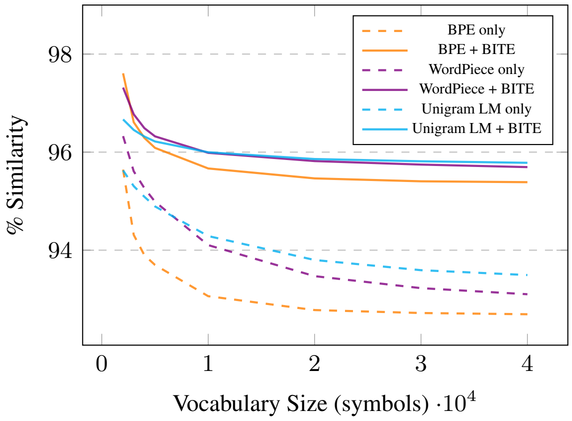

Figure 5: Mean percentage of symbols that are the same in the clean and adversarial encoded sequences.

(Fig. 5). The decrease in similarity with larger vocabularies is unsurprising; larger vocabularies result in shorter sequences, such that the same number of differing symbols will result in a larger relative change.

Hence, the improved robustness shown in §4.1 can be directly attributed to the separation of each content word's base forms from its inflection and keeping it consistent as the inflection varies, hence mitigating any significant symbol-level changes.

5.3 Micro and Error Analysis

Micro analysis. With a vocabulary of 20k symbols, BPE segments *climbs* as [*clim,bs*], *dreaming* as [*dre,aming*], and *tumbled* as [*t,umbled*]. WordPiece segments *tumbled* as [*tum,bled*] and encodes *dreaming* as a single symbol, but finds a morphologically accurate segmentation of *climbs*: [*climb,s*]. Unigram LM finds morphologically accurate segmentations for all three examples. When trained with BITE, all three tokenizers successfully find morphologically accurate segmentations of these examples and represent each corresponding base form as a single symbol.

Error analysis. Although the POS tagger is highly accurate[10], it may occasionally tag an inflected form as a base form. An example from the MultiNLI data is the word *turns* in *"..., it could turns out even better"* being tagged as `NN` instead of `VBZ`. Consequently, this word would not be split into base form and inflection. Orthographic errors like misspellings also contribute to the tagger's inaccuracy. Some of these errors can be easily fixed by using a robust POS tagger (Piktus et al., 2019).

6 Limitations

Our BITE implementation relies on an external POS tagger to assign inflection tags to each word. This tagger requires language-specific training data, which can be a challenge for low resource languages. However, this could be an advantage since the overall system can be improved by training the tagger on dialect-specific datasets, or readily extended to other languages given a suitable tagger. Another drawback of BITE is that it increases the length of the encoded sequence which may lead to extremely long sequences if used on morphologically rich languages. However, this is not an issue for English Transformer models since the increase in length will *always* be <2x, such that the increase in complexity is a constant factor.

7 Conclusion

The tokenization stage of the modern deep learning NLP pipeline has not received as much attention as the modeling stage, with researchers often defaulting to common subword tokenizers like BPE. We can do better. By encoding raw text into operable symbols, we can improve the generalization and adversarial robustness of resulting systems.

Hence, we guide the data-driven tokenizer by incorporating linguistic information to learn a more efficient vocabulary and generate symbol sequences that increase the network's robustness to inflectional variation. This improves its generalization to L2 and World Englishes without requiring explicit training on such data. Since dialectal data is often scarce or even nonexistent, an NLP system's ability to generalize across dialects in a zero-shot manner is crucial for it to work well for diverse linguistic communities. A more general, BITE-like algorithm should enable further gains on morphologically rich languages.

Finally, given the effectiveness of the common task framework for spurring progress in NLP (Varshney et al., 2019), we hope to do the same for tokenization. As a first step, we propose to evaluate an encoding scheme's efficacy by measuring its vocabulary coverage and symbol complexity (which may have interesting connections to information-theoretic limits (Ziv and Lempel, 1978)). We have already shown that Base-Inflection Encoding helps a data-driven tokenizer use its limited vocabulary more efficiently by reducing its symbol complexity when the combination is trained from scratch.

---

[10] Accuracy of 97.2% on the Wall Street Journal test set.

Acknowledgments

We are grateful to Michael Yoshitaka Erlewine from the NUS Dept. of English Language and Literature and our anonymous reviewers for their invaluable feedback. We also thank Xuan-Phi Nguyen for his help with reproducing the Transformer-big baseline. A Examples of Inflectional Variation in English Dialects

African American Vernacular English (Kendall and Farrington, 2018)

- I dreamed about we was over my uh, father mother house, and then we was moving.
- I be over with my friends.
- And this boy name `RD-NAME-3`, he was tryna be tricky, pretend like he don't do nothing all the time.

Colloquial Singapore English (Singlish) (Source: forums.hardwarezone.com.sg)

- Anyone face the problem after fresh installed the Win 10 Pro, under NetWork File sharing after you enable this function (Auto discovery), the computer still failed to detect our Users connected to the same NetWork?
- I have try it already, but no solutions appear.
- How do time machine works??

B Implementation/Experiment Details

All models are trained on 8 16GB Tesla V100s.

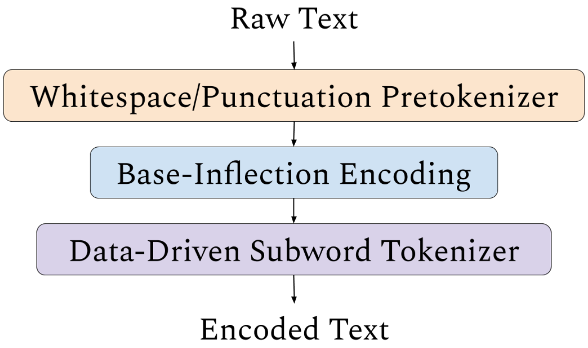

Figure 6: How BITE fits into the tokenization pipeline.

B.1 Classification Experiments

For our BERT experiments, we build BITE on top of the `BertTokenizer` class in Wolf et al. (2019) and use their BERT implementation and fine-tuning scripts[11]. $\text{BERT}_{\text{base}}$ has 110M parameters. We do not perform a hyperparameter search and instead use the example hyperparameters for the respective scripts.

Datasets and metrics. MultiNLI (Williams et al., 2018) is a natural language inference dataset of 392,702 training examples, 10k in-domain and 10k out-of-domain dev. examples, and 10k in-domain and 10k out-of-domain test examples spanning 10 domains. Each example comprises a premise, hypothesis, and a label indicating whether the premise entails, contradicts, or is irrelevant to the hypothesis. Models are evaluated using Accuracy $= \frac{\text{\# correct predictions}}{\text{\# predictions}}$.

SQuAD 2.0 (Rajpurkar et al., 2018) is an extractive question answering dataset comprising more than 100k answerable questions and 50k unanswerable questions (130,319 training examples, 11,873 development examples, and 8,862 test examples). Each example is composed of a question, a passage, and an answer. Answerable questions are questions that can be answered by a span in the passage and unanswerable questions are questions that cannot be answered by a span in the passage. Models are evaluated using the F_1 score.

Wikipedia+BookCorpus is a combination of English Wikipedia and BookCorpus. We use Lample and Conneau (2019)'s script to download and preprocess the Wikipedia dump before removing blank lines, overly short lines (less than three words or four characters), and lines with `doc` tags. We also remove blank and overly short lines from BookCorpus before concatenating and shuffling both datasets.

B.2 Discussion for Perplexity Experiments

Effect of lemmatization and inflection symbols. We conduct two ablations to investigate the effects of lemmatization and inflection symbols on the models' pseudo perplexities: the first simply lemmatizes the input before encoding it with WordPiece (WordPiece+LEMM) and the second replaces every inflection symbol generated by BITE with a dummy symbol (WordPiece+BITE_{abl}). The latter is the same ablation used in Table 3 and from Table 4, we see that this condition consistently achieved the lowest pPPL on all three corpora. However, we believe that the highly predictable dummy symbols likely account for the significant drops in pseudo perplexity.

To test this hypothesis, we perform another ablation, WordPiece+LEMM, where the the dummy symbols are removed entirely. If the dummy symbols were not truly responsible for the large drops in pPPL, we should observe similar results for

---

[11] github.com/huggingface/transformers/.../examples

Dataset	WordPiece (WP) —	WP + LEMM (Lemmatize)	WP + BITE (+Infl. Symbols)	WP + BITE$_{abl}$ (+Dummy Symbol)
Colloquial Singapore English				
Total word tokens before WP	45803898	45803898	51982873	51982873
Pseudo Negative Log-Likelihood	30910290	30558864	31110740	30292923
pPPL (per word token before WP)	92.58	85.43	**52.67**	48.66
pPPL (per symbol after WP)	49.10	46.39	**32.02**	30.20
African American Vernacular English				
Total word tokens before WP	1144803	1144803	1320730	1320730
Pseudo Negative Log-Likelihood	452269	444021	453031	434621
pPPL (per word token before WP)	13.92	13.27	**9.84**	8.96
pPPL (per symbol after WP)	12.90	12.41	**9.18**	8.43
Standard English				
Total word tokens before WP	252153	252153	290391	290391
Pseudo Negative Log-Likelihood	77339	78074	90148	75467
pPPL (per word token before WP)	**7.72**	7.87	7.92	5.65
pPPL (per symbol after WP)	6.34	6.36	**6.07**	4.86

Table 4: Effect of lemmatization, inflection symbols, and dummy symbol on pseudoperplexity (pPPL). We also show the effect of normalizing by the word token vs. subword symbol count. Lower is better. **Bolded** values indicate lowest row-wise pPPLs, *excluding* WP+BITE$_{abl}$ due to the confounding effect of the highly predictable dummy symbols.

both WordPiece+LEMM and WordPiece+BITE$_{abl}$. From Table 4 (pPPL per word token before WP), we see that the decrease in pPPL between WordPiece+LEMM and WordPiece is less drastic, thereby lending evidence for rejecting the null hypothesis.

Poorer performance on Standard English. We observe that lemmatizing all content words and reinjecting the grammatical information appears to have the opposite effect on Standard English data compared to the dialectal data. Intuitively, such an encoding *should* result in even more significant reductions in perplexity on Standard English since the POS tagger and lemmatizer were trained on Standard English data. A possible explanation for these results is that the WordPiece tokenizer and BERT model are overfitted on Standard English, since they were both (pre-)trained on Standard English data.

Normalizing log-likelihoods. In an earlier version of this paper, we computed pseudo perplexity by normalizing the pseudo log-likehoods with the number of masked subword symbols (the default). A reviewer pointed out that per subword symbol perplexities are not directly comparable across different subword segmentations/vocabularies, but per word perplexities are (Mielke, 2019; Salazar et al., 2020). However, using the same denominator would unfairly penalize models using BITE since it inevitably increases the symbol sequence length, which affects the predicted log-likelihoods. In addition, with the exception of the inflection/dummy symbols that replaced some unused tokens, the vocabularies of all the WordPiece tokenizers used in our pseudo perplexity experiments are exactly the same since we do not retrain them. Therefore, we attempt to balance these two factors by normalizing by the number of *word tokens* fed into the WordPiece component of each tokenization pipeline in Fig. 2. We also report the per subword pPPL and raw pseudo negative log-likelihood in Table 4.

B.3 Machine Translation Experiments

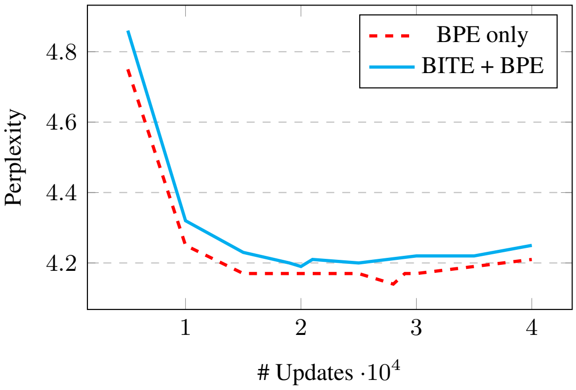

Figure 7: Validation perplexity over the course of training for Transformer-big.

For our Transformer-big experiments, we use the `fairseq` (Ott et al., 2019) implementation and the hyperparameters from Ott et al. (2018):

- Parameters: 210,000,000
- BPE operations: 32,000

- Learning rate: 0.001
- Per-GPU batch size: 3,584 tokens
- Warmup period: 4,000 updates
- Dropout: 0.3
- Gradient Accumulation: 16

Both models took 24.6 hours to complete 45k updates. We use a `fairseq` script[12] to average the selected checkpoint with the previous nine.

Dataset and metrics. We use the WMT'16 data[13] for training and newstest2013 for development and newstest2014 for testing. Although it is common practice to use the already encoded WMT'16 data released by Google, BITE requires raw or whitespace-tokenized text as input. Hence, we use the raw WMT data and the `fairseq` preprocessing script to preprocess our data. After preprocessing, we obtain a dataset of 4.3M training examples, 2,996 dev. examples, and 3,003 test examples. Models are evaluated using BLEU[14] (Papineni et al., 2002) and METEOR[15] (Denkowski and Lavie, 2014), standard MT evaluation metrics.

B.4 Model-Independent Analyses

We use the `tokenizers` implementation of WordPiece and BPE and the SentencePiece (Kudo and Richardson, 2018) implementation of unigram LM. For ease of comparison across the three encoding schemes, we pretokenize the raw text with `tokenizers` BertPreTokenizer before encoding them. For practical applications, users may use `sentencepiece`'s method of handling whitespace characters instead of the BertPreTokenizer.

General form of Eq. (2).

$$f(S_i, \lambda) = \begin{cases} (|S_i| - u_i) + \lambda u_i & |S_i| - u_i > 0 \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

where N is the total number of word types in the evaluation corpus, S_i is the sequence of symbols obtained from encoding the ith base form, u is the number of unknown symbols in S_i, and λ is the weight of the unknown symbol penalty.

Ratcliff/Obershelp algorithm. We use Python's `difflib` implementation.

C More Measures of Vocabulary Efficiency

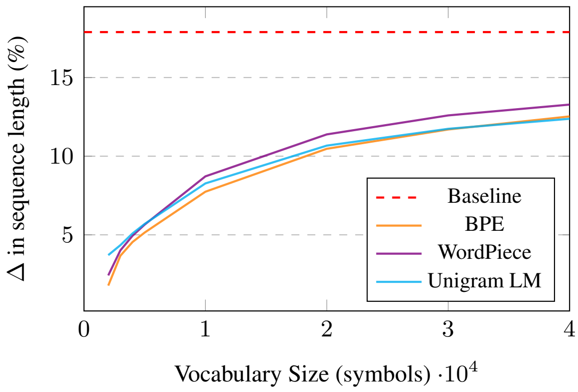

Figure 8: Relative increase in mean encoded sequence lengths (%) between BITE-less and BITE-equipped tokenizers after training the data-driven subword tokenizers with varying vocabulary sizes; lower is better. Baseline (dotted red line) denotes the percentage of inflected forms in an average sequence; this is equivalent to the increase in sequence length if BITE had no effect on the data-driven tokenizers' encoding efficiency.

Sequence lengths. A possible concern with BITE is that it may significantly increase the length of the encoded sequence, and hence the computational cost for sequence modeling, since it splits all inflected content words (nouns, verbs, and adjectives) into two symbols. We calculate the percentage of inflected words to be 17.89%.[16] Therefore, if BITE did not enhance WordPiece's and BPE's encoding efficiency, we should expect a 17.89% increase (i.e., upper bound) in their mean encoded sequence length. However, from Fig. 8, we see this is not the case as the relative increase (with and without BITE) in mean sequence length generally stays below 13%, 5% less than the baseline. This demonstrates that BITE helps the data-driven tokenizer make better use of its limited vocabulary.

In addition, we see that the gains are inversely proportional to the vocabulary size. This is likely due to the following reasons. For a given sentence, the corresponding encoded sequence's length usually decreases as the data-driven tokenizer's vocabulary size increases as it allows merging of more smaller subwords into longer subwords. On the other hand, BITE is vocabulary-independent, which means that the encoded sequence length is always the same for a given sentence. Hence, the same absolute difference contributes to a larger

---

[14] Calculated by `fairseq`.

[15] cs.cmu.edu/ alavie/METEOR/

[16] Note that only content words are subject to inflection.

relative increase as the vocabulary size increases. Additionally, more inflected forms are memorized as the vocabulary size increases, resulting in an average absolute increase of 0.4 symbols per sequence for every additional 10k vocabulary symbols. Together, these two factors explain the above phenomenon.

Measuring the Similarity of Grammatical Gender Systems by Comparing Partitions

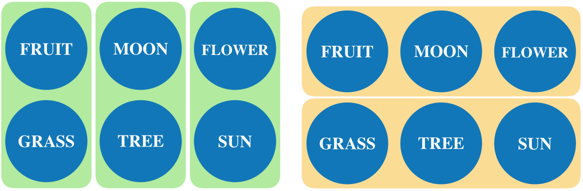
Abstract

A grammatical gender system divides a lexicon into a small number of relatively fixed grammatical categories. How similar are these gender systems across languages? To quantify the similarity, we define gender systems extensionally, thereby reducing the problem of comparisons between languages' gender systems to cluster evaluation. We borrow a rich inventory of statistical tools for cluster evaluation from the field of **community detection** (Driver and Kroeber, 1932; Cattell, 1945), that enable us to craft novel information-theoretic metrics for measuring similarity between gender systems. We first validate our metrics, then use them to measure gender system similarity in 20 languages. Finally, we ask whether our gender system similarities alone are sufficient to reconstruct historical relationships between languages. Towards this end, we make phylogenetic predictions on the popular, but thorny, problem from historical linguistics of inducing a phylogenetic tree over extant Indo-European languages. Languages on the same branch of our phylogenetic tree are notably similar, whereas languages from separate branches are no more similar than chance.

1 Introduction

As many as half the world's languages carve nouns up into classes (Corbett, 2013). In these languages, nouns are subdivided into **gender** categories, which together comprise the language's grammatical gender system. A gender system tends to use a small, fixed number of categories with fixed usage across speakers. Such categories, like 'feminine', can be defined extensionally,[1] and are reflected by agreement with other words within the noun phrase (i.e., **concord**). Gender exhaustively divides up the language's nouns; that is, the union of gender categories is the entire nominal lexicon. Taken this way, a gender system can be viewed as a **partition** of the lexicon into **communities** of same-gendered nouns. Given this, a lexical typologist might naturally wish to ask: how similar are two languages' gender systems?



(a) German, $K = 3$ (b) Spanish, $K = 2$

Figure 1: Two gender systems partitioning $N = 6$ concepts. German (a) has three communities: *Obst* (fruit) and *Gras* (grass) are neuter, *Mond* (moon) and *Baum* (tree) are masculine, *Blume* (flower) and *Sonne* (sun) are feminine. Spanish (b) has two communities: *fruta* (fruit), *luna* (moon), and *flor* are feminine, and *cesped* (grass), *arbol* (tree), and *sol* (sun) are masculine.

Using modern statistical and information-theoretic tools from the community detection literature, we offer the first cluster evaluation (Jardine et al., 1971) perspective on grammatical gender, and quantify the overlap of gender systems. We can compare the pairwise overlap of partitions of gender systems using a rich literature of measures, such as **mutual information** and several variants (Meilă, 2003; Vinh et al., 2010; McCarthy et al., 2019a), which we survey and contrast. Individual partitions of lexicons can also be framed as members of *distributions* over partitions—for instance, the distribution consisting of all partitions of N items, or of all partitions of N items into K gender clusters, as in Figure 1. For example, Spanish is bi-gendered (with masculine and feminine): a lexicon of Spanish nouns ($N = 1000$) and their genders would come from a distribution over partitions of $N = 1000$ items into $K = 2$ clusters.

---

[1] When we talk about the **extension** of a gender system, we refer to the set of nouns that belong to each gender. This stands in contrast to the **intension** of that gender system, which would be the governing dynamics that gave rise to the particular partitions observed. See §3.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5664–5675,
November 16–20, 2020.

The same lexicon translated into German, a tri-gendered language, would come from a distribution of $N = 1000$ items partitioned into $K = 3$ clusters. Indeed, languages needing different numbers of gender clusters makes this problem non-trivial. From this, we can compare the similarity to what we would expect for *the same lexica* if nouns were randomly supplied with gender specifications. That way, we can distinguish meaningful relationships from noise.

Armed with the first way to quantify community-wise similarity of gender systems, we ask: Do gender system similarities reflect linguistic phylogeny, or something else, like areal effects? Across 20 languages, we find that our pairwise overlap results measurably align with standard pairwise phylogenetic relationships. Zooming in on Indo-European, we find that we can recast pairwise similarities into an accurate phylogenetic tree, simply by measuring distance between gender systems and performing hierarchical agglomerative clustering (see §6.2).

The primary contribution of this work is *a novel metric for lexical typology* that measures the pairwise similarity of gender systems. We operationalize gender systems as partitions over a shared set of nouns (§3). We design and evaluate our measurements of gender system similarity under this formulation (§4), drawing on insights from community detection. Then we recover robust phylogenetic relationships between pairs of gender systems by applying these to 20 gendered languages (§6) and find that similarity between Slavic and Romance gender systems does not exceed chance levels. Finally, we show that our quantification of gender system similarity allows us to construct phylogenetic trees that closely resemble those posited for Indo-European in historical linguistics (e.g., Pagel et al. 2000; Gray and Atkinson 2003; Serva and Petroni 2008).

2 Background: Grammatical Gender

Grammatical gender is a highly fixed classification system for nouns. Native speakers rarely make errors in gender recall, which might tentatively argue against tremendous arbitrary variation (Corbett, 1991). Some regularity can surely be found in the associations between gender and various features of the noun, such as orthographic or phonological form, or semantics. With respect to form-based regularities, Cucerzan and Yarowsky (2003a) devise a system for inferring noun gender (masculine or feminine) from contextual clues and character representations, even in inflected forms of the noun. Nastase and Popescu (2009) also find that phonological form can lead to predictability of gender in two three-gender systems. With respect to word semantics, (Williams et al., 2019) quantify the relationship between the gender on inanimate nouns and their distributional word vectors.

We can't rely on form. Using phonological or orthographic form to derive gender is fraught with complications: particular to our study, **epicene** nouns (i.e., words that can appear in multiple genders) can pose issues. In German, only gender concord on the definite article and adjectives can disambiguate the gender of some nouns; the same word-form *Band* means "volume" when masculine, but "ribbon" when neuter and "band, musical group" in feminine. Another complication with determining gender from the phonological or orthographic form of the noun is that correspondences between are rarely absolute. For example, even though nouns ending in *-e* are usually 'feminine' in German, this is not universally the case; for example *Affe*, and *Löwe* etc. are masculine. To sidestep these complications, we abstract away from particular word forms and observe the objective consequences of gender over *sets of cross-lingual concepts*, i.e., indices not word forms, and instead compare those across gender systems (see Figure 1).

Which gender systems are likely to be similar? Several accounts highlight similarities between the gender systems of phylogenetically-related languages (Fodor, 1959; Ibrahim, 2014) and argue that they are likely to be at least partially due to historical relations between communities and socio-political factors governing language use. Given this, can we recover phylogenetic similarities across gender systems using our methods? If so, this should provide validation that we are indeed measuring at least some of the genuine similarity that exists between gender systems.

3 Gender Systems as Partitions

Any concept can be related to its referents either intensionally or extensionally. While linguistic research has historically sought to uncover the rules for associating a noun with gender in terms of surface features or semantics (see Corbett 1991 for an overview), we take an extensional approach. That is, we treat a gender category in a language solely as the *set of words it covers*. This maps directly to the notion of a **community** in the network science task of community detection: A community is defined by membership, not by other arbitrary properties, just as a gender here is defined by the union of all nouns it subsumes, not by its phonological realization or contributions to semantics. The disjoint set of communities forms a **partition** of the set of nouns: Each noun is a member of one and only one cluster.

Although some epicene nouns are present in our investigated languages (see §2), these are very rare. We thus make the simplifying modeling assumption of identifying each word with only a single gender (in our case, the most frequent). This assumption is necessary for our reduction of gender system comparison to clustering evaluation. Without it, we would be forced for words like German *der/die/das Band* to consider overlapping or "fuzzy" partitions, which although an intriguing option, will be left for future work.

Notation. A language's gender system is a partition, named in sans serif (e.g., A). A gender system A has K components called gender classes (i.e., communities, e.g., $\{A_{\text{MSC}}, A_{\text{FEM}}, \ldots\}$); these are in turn sets whose members are items drawn from a finite base set $\mathcal{A} \subseteq \mathcal{L}$, where $\mathcal{A}$ is a sub-lexicon selected from the full lexicon $\mathcal{L}$. In our case, $\mathcal{A}$ holds all inanimate concepts in our data (see §5). We use Ω to name the set of all partitions of $N = |\mathcal{A}|$ items (in our case, inanimate nouns) into K communities. When comparing two languages' respective gender systems, we will use the letters A and B.

4 Comparing Partitions

A partition groups items into a set of disjoint categories. We could compare any two gender systems (i.e., partitions) which organize the same nouns by determining how similar their gender labelings are. A first pass at quantifying the similarity of two gender partitions would be to measure simple overlap. We could ask: What fraction of $\mathcal{A}$ agrees in gender across languages? That is, for each noun in our multilingual vocabulary, do both languages lexicalize it with the same gender? This is an easily interpretable, accuracy-like measure, bounded by 0 and 1. Still, it has no capacity for comparing systems with *different numbers of categories*; the measure would be handicapped when comparing two-gender systems to three-gender ones.

Comparing systems with different numbers of categories, though, is a well known problem in the field of community detection. While this looks insurmountable from the gender perspective, where gender categories refer to something we recognize, in community detection, the labels themselves are meaningless—there's no notion of a so-called "Cluster 2". The field has circumvented issues arising from comparing systems differing in number of categories by introducing information-theoretic measures to compare partitions. Cluster evaluation functions in community detection are, by and large, based on information-theoretic concepts.

We define a gender system A's entropy as:

$$\mathrm{H}(\mathsf{A}) \overset{\text{def}}{=} -\sum_{A \in \mathsf{A}} \frac{|A|}{N} \log \frac{|A|}{N} \tag{1}$$

where we observe the standard convention that $0 \log 0 \overset{\text{def}}{=} 0$. How is this notion of entropy for partitions related to the entropy of a probability distribution? These are connected through maximum-likelihood estimation (MLE). In our case, the maximum-likelihood estimate that an inanimate noun a is located in a given partition turns out to be the size of that partition divided by N, e.g. we have $p_{\text{MLE}}(\text{MSC}) = {}^{|A_{\text{MSC}}|}/_{N}$. Recall that the Shannon entropy of a distribution p is defined as

$$\mathrm{H}(p) \overset{\text{def}}{=} -\sum_{a \in \mathcal{A}} p(a) \log p(a) \tag{2}$$

We have equality between Eq. 1 and Eq. 2 when we plug the definition of p_{MLE} into Eq. 2, which is why Eq. 1 is considered the entropy of a partition.

4.1 Mutual information (MI)

Mutual information is a workhorse of quantifying similarity between two probability distributions, measuring how much information (in bits) is shared between two random variables. Now we consider the case of the similarity between two partitions. If we have two partition A and B, we may generalize the entropy of a single partition to the mutual information between two partitions as follows:

$$\begin{aligned}\mathrm{I}(\mathsf{A};\mathsf{B}) &\overset{\text{def}}{=} \sum_{A \in \mathsf{A}} \sum_{B \in \mathsf{B}} \frac{|A \cap B|}{N} \log \frac{N\,|A \cap B|}{|A|\,|B|} \\ &= \sum_{a \in \mathcal{A}} \sum_{b \in \mathcal{B}} p_{\text{MLE}}(a,b) \log \frac{p_{\text{MLE}}(a,b)}{p_{\text{MLE}}(a)\,p_{\text{MLE}}(b)}\end{aligned} \tag{3}$$

As the equality above shows, we find, again, that Eq. 3 has an interpretation as the standard definition of probabilistic mutual information applied to the maximum-likelihood estimate of joint partition membership distribution. To foreshadow future discussion, we note the mutual information between any two clusterings on N items is bounded below by 0 and above by $\log N$. Beyond its interpretation as shared information, mutual information gives little in terms of interpretability: It has no consistent reference points, beyond that the minimum possible MI is zero. Therefore, several variants of MI are preferred in community detection.

Normalization. Furthermore, MI is often normalized to increase its interpretability, as:

$$\mathrm{NMI}(\mathsf{A}, \mathsf{B}) \overset{\mathrm{def}}{=} \frac{\mathrm{I}(\mathsf{A}; \mathsf{B})}{\sqrt{\mathrm{H}(\mathsf{A})\,\mathrm{H}(\mathsf{B})}} \tag{4}$$

While our denominator is the geometric mean, any generalized mean of the partitions' entropies can be used as a bound to normalize MI (Yang et al., 2016). As we divide bits by bits (or nats by nats), normalized mutual information (NMI) is unitless, unlike entropy and MI. It expresses the amount of revealed information as a percentage. Unfortunately, NMI has both theoretical and empirical flaws (Peel et al., 2017; McCarthy, 2017; McCarthy et al., 2019b); namely, it suffers from the *finite-size effect*: the baseline rises as N increases. (Recall that MI is bounded above by $\log N$.) High reward for guessing *even the trivial partition* into singleton clusters rises, making the measure—like vanilla mutual information (as in Eq. 3)—difficult to interpret. For its flaws, we exclude NMI in favor of the following MI-based measures that are both more interpretable and more pertinent.

4.2 Adjusted mutual information (AMI)

Spurious correlations between two gender systems can mislead the results, showing a higher-than-deserved agreement. We select a measure which adjusts for these chance clusterings: the adjusted mutual information (AMI; Vinh et al., 2010). We employ a recent variant (Gates and Ahn, 2017; McCarthy et al., 2019b):

$$\mathrm{AMI}(\mathsf{A},\mathsf{B}) \overset{\mathrm{def}}{=} \frac{\mathrm{I}(\mathsf{A}; \mathsf{B}) - \mathbb{E}\left[\mathrm{I}(\mathsf{A}'; \mathsf{B}')\right]}{\max \mathrm{I}(\mathsf{A}', \mathsf{B}') - \mathbb{E}\left[\mathrm{I}(\mathsf{A}'; \mathsf{B}')\right]} \tag{5}$$

where the expectation is taken under the uniform distribution over Ω, all clusterings on N items with K_{A} and K_{B} clusters (Gates and Ahn, 2017). The maximum is also taken over Ω. This distinguishes it from the textbook form of AMI, where the expectation is over a subset of Ω—only those partitions whose community sizes match those of the arguments. As we have subtracted the mean, the expected numerator is centered at 0; the denominator serves to re-normalize the measure. The measure thus compares the mutual information for the observed pair of gender systems to all others within their family. Using AMI also lends some beneficial properties in cluster evaluation:

Remark 1. *AMI has a fixed maximum score* 1.0 *for exactly matching gender systems.*

Remark 2. *The mathematical expectation of AMI is* 0 *so spurious correlations are not rewarded.*

4.3 Variation of Information (VI)

Unlike MI and AMI, Variation of Information (Meilă, 2003) is a **distance** (metric), meaning each language becomes a point in this metric space, whose set is all possible partitions of N items. VI is useful because it satisfies the **triangle inequality** (Meilă, 2007). Additionally, as a metric, it guarantees identity of indiscernibles: if two partitions are at a distance 0, then they are identical. VI is defined as

$$\mathrm{VI}(\mathsf{A}, \mathsf{B}) \overset{\mathrm{def}}{=} \mathrm{H}(\mathsf{A} \mid \mathsf{B}) + \mathrm{H}(\mathsf{B} \mid \mathsf{A}) \tag{6}$$

and is the summation of two conditional entropies. It can also be normalized by dividing by the joint entropy, $\mathrm{H}(\mathsf{A}, \mathsf{B})$. (This measure would be topologically equivalent to Eq. 6.) We do not adjust VI for chance. This would deprive it of its metric property, because of the subtraction in the numerator.

5 Data

Swadesh lists & NorthEuraLex. Our starting point is **Swadesh lists** (Buck, 1949; Swadesh, 1950, 1952, 1955, 1971/2006): concept-aligned minimal inventories of common, "core" or "basic" terminology thought to be "frequent, universal, and resistant to change over time" (Kaplan, 2017). For our purposes, concept-aligned sources are appealing, because they ensure a consistently present base set $\mathcal{A}$ across all our languages, maximizing comparability. We also use the NorthEuraLex dataset (Dellert and Jäger, 2017)—essentially, an extended Swadesh list covering 1016 concepts—to further validate our findings on the original Swadesh lists. Because grammatical gender on animate nouns has the added complication that it generally matches "natural" gender (or expressed preference) of living creatures across languages (Corbett, 1991; Romaine, 1997; Kramer, 2015), we omit animate nouns to remove semantic confounds from our investigation of cross-lingual gender assignments. We now take the base set $\mathcal{A}$ from the larger concept list in a broader swath of languages. We have 69 inanimate nouns in the Swadesh lists and 387 in NorthEuraLex.

Gender dictionaries. We choose a corpus-based approach to identifying a word's gender. We study the gendered languages available in Universal Dependencies v2.3[2] (Nivre et al., 2018), resulting in a sample of 20 (Hebrew, Greek, Hindi, Lithuanian, Latvian, Polish, Croatian, Slovak, Ukrainian, Russian, Slovenian, Bulgarian, Swedish, Danish, Romanian, French, Catalan, Italian, Spanish, Portuguese). This sample is somewhat skewed based on family, with all but one language (Hebrew) belonging to Indo-European. All are members of the Standard Average European Sprachbund (Whorf, 1997; Haspelmath, 2001), except Hebrew, Hindi, and Greek, which are the only representatives of their groups. Why the Indo-European focus? First, we needed aligned concept lists *with gender and animacy annotations* in languages which possess a gender system. Second, it is natural to test unsupervised methods on a sample with a known *ground truth*. Indo-European phylogeny, while not without its debates, is relatively well studied, making it a strong testbed for verifying our methods. Future work can enable greater linguistic diversity by scraping annotated dictionaries.

Gender labels are drawn from the MarMoT contextual morphological tagger (Müller et al., 2013) trained on Universal Dependencies corpora (Nivre et al., 2018) in each language and applied to Wikipedia in that language. In the case of epicene words and polysemy, we select the consensus gender (Cucerzan and Yarowsky, 2003b) for the character sequence—its most frequent gender label. We fill gaps manually using bilingual English-target language dictionaries. When multiple words are given to express a concept in a language, we select the most frequent.

6 Experiments

We apply each measure to the gender systems from our Swadesh lists, then validate our results on NorthEuraLex. We apply validation to ensure that they are picking up robust similarities as opposed to just reflecting properties of particular word lists. (See `github.com/aryamccarthy/gender-partitions`.) We then reconstruct phylogenetic trees of the languages involved. The trees show high agreement with ground truth, compared to random baselines.

6.1 Similarity measures

We apply the three evaluation measures (§4) to the partitions computed for our languages over the common conceptual lexicon. Figure 2 shows the pairwise scores for languages' gender systems (on the Swadesh list) as partitions. The rows and columns have been reordered according to a "ground truth" of pairwise distances (Serva and Petroni, 2008), for reasons we will explain in the next subsection.[3] Regardless of measure, a few clusters emerge along the diagonal. The (Balto-)Slavic branch (i.e., Polish, Croatian, Slovene, Ukrainian, Slovenian, Russian, and Bulgarian) is present at the top left, and the Romance branch (i.e., French, Catalan, Italian, Spanish, and Portuguese) appears at the bottom right. Outside of these blocks, AMI shows us that the similarity of gender systems is *no better than a chance relationship*; at the whole-lexicon level, influence from the common Indo-European root is absent.

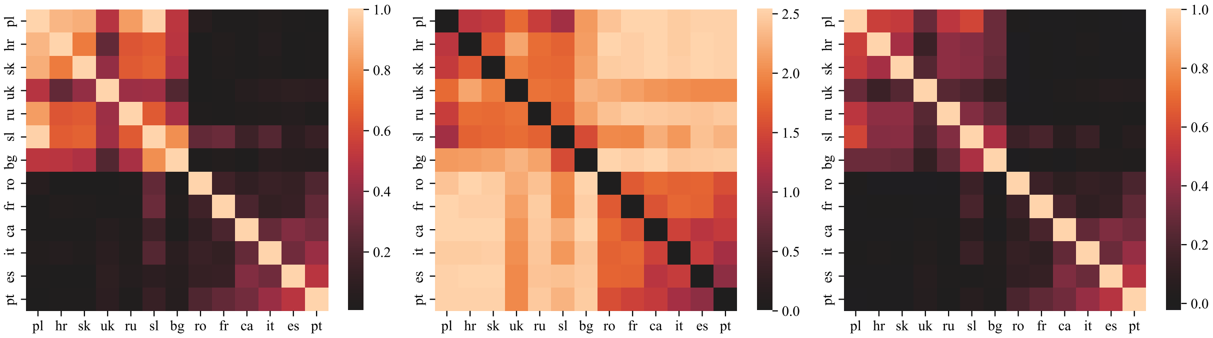
We also apply our measures to the wider swath of languages and larger aligned inventories of NorthEuraLex. The Romance languages again form a block, as do the Balto-Slavic languages. Figure 3 shows similar separation into families for both MI (a) and AMI (c), though this is less pronounced for Variation of Information (b). Variation of Information shows some surprising associations not present in AMI, such as associating Hebrew and Slovene highly with the Romance block.

Romanian deserves particular note: It is a Romance language but has been geographically isolated from its family for over a millennium, instead sharing membership in the Balkan Sprachbund with Greek and Bulgarian. As such, we may ask whether its phylogeny or its areal effects are reflected in the gender similarity metrics. While Romanian differs from other Romance languages in many ways (Dinu and Dinu, 2005;

---

[2] German and Arabic were excluded because of complications arising through alignment to annotated dictionaries.

[3] Selecting a ground truth hierarchy of languages is a contentious and sometimes political matter; even well-accepted trees suffer from criticism (Ringe et al., 2002; Gray and Atkinson, 2003; Greenhill, 2011; Pereltsvaig and Lewis, 2015).



(a) Mutual information (b) Variation of Information (c) Adjusted Mutual Information

(a) Mutual information (b) Variation of Information (c) Adjusted Mutual Information

Figure 3: Heatmaps uncovered in inanimate NorthEuraLex under each pairwise similarity measure, grouped by Levenshtein Distance ground-truth phylogenetic trees (Serva and Petroni, 2008).

Dobrovie-Sorin, 2011)—e.g., it possesses three genders instead of two[4]—it is still more similar to its phylogenetically related Romance relatives than to Balto-Slavic languages. This is easiest to discern in the Variation of Information plot: weak connections surface between Romanian and both Slovene and Ukrainian, but the majority of the Balto-Slavic languages are quite distant from it.

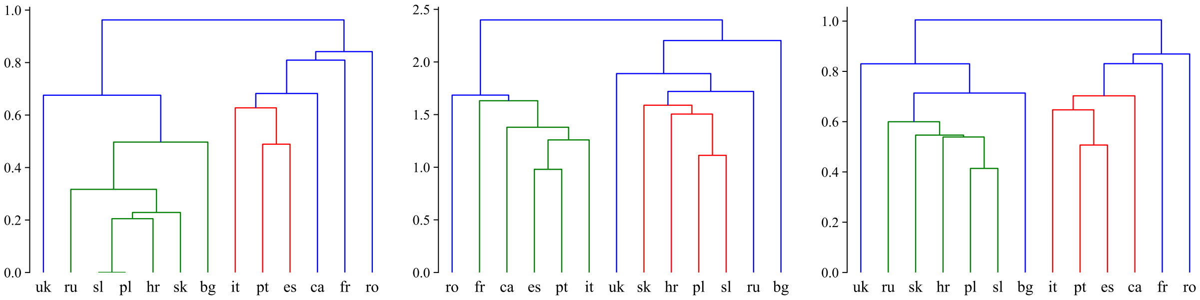
6.2 Phylogeny

Inspired by the findings in the previous section (especially the high similarity among Romance languages), we further validate our measure, asking whether the resulting similarities reflect known phylogenetic ground truth—namely, the developmental history of Indo-European languages. Obviously, there are many more facets to languages' relatedness than their gender systems, so it is interesting to find signal this strong from a single category. Rabinovich et al. (2017) cluster languages based on simple features of their translations into a common target language to craft phylogenetic trees. We take a similar approach, asking whether the pairwise similarities of gender systems are enough to reveal phylogenetic truth or some other relationship. We create phylogenetic trees through agglomerative hierarchical clustering, using both VI and one minus the AMI as distance measures. We use the weighted pair group method of averages (Sokal and Michener, 1958; Müllner, 2011) as implemented in the SciPy library (Jones et al., 2001).

The resulting trees ("dendrograms") can be visualized showing the sequence of cluster formations during hierarchical clustering (Figure 4 and Figure 5). In a dendrogram, any ordering of the leaves maintains fidelity to the computed tree structure, so long as the branching is still correct. We choose to improve upon this by optimally ordering the leaves, swapping subtrees to convey similarity *both within and across* subtrees (Bar-Joseph et al., 2001). On the whole, our dendrograms recover known phylogenetic relationships between the languages we consider; this serves to largely validate our measures as having uncovered some meaningful sim-

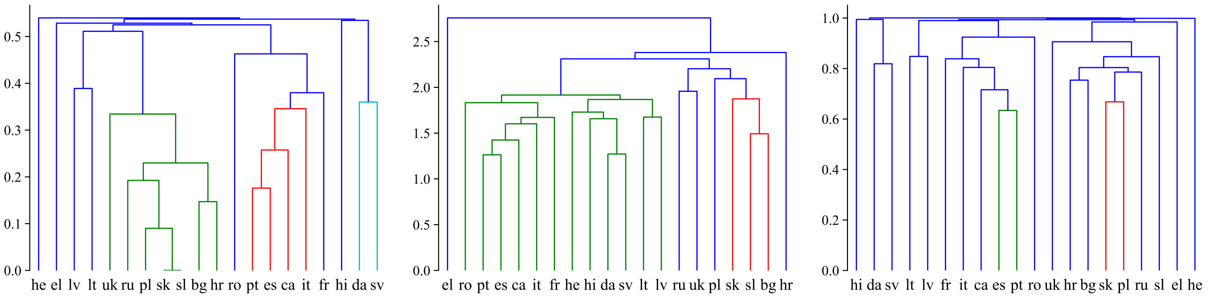
---

[4] This claim can be debated (Bateman and Polinsky, 2010): The neuter gender manifests as masculine when singular and feminine when plural (Corbett, 1991).



(a) Mutual information (b) Variation of Information (c) Adjusted Mutual Information

Figure 4: Phylogenies for inanimate Swadesh under each similarity measure. Colors label levels of similarity, with green being most similar, followed by red, then blue (e.g., blue is >70% of max value).



(a) Mutual information (b) Variation of Information (c) Adjusted Mutual Information

Figure 5: Phylogenies for inanimate NorthEuraLex under each similarity measure. Colors label levels of similarity, with green being most similar, followed by red, cyan, and dark blue (e.g., dark blue is >70% of max value).

ilarity between the languages' gender system. Indeed, in every case, we reconstruct the subtree of Romance languages with high fidelity. The only difference is that on NorthEuraLex, Catalan is more similar to Portuguese and Spanish than Italian is. In all trees, Romanian is always grouped with the Romance languages, matching its ancestry. The Balto-Slavic subtree is less perfect. MI and AMI recover similarities between Russian and Ukrainian (Eastern Slavic), Slovak and Polish (Western Slavic), and Croatian and Bulgarian (South Slavic) fairly well. Further, the Slavic and Baltic languages are properly joined to form a Balto-Slavic group. We take this as validation of our method.

When measuring with Variation of Information, though, things go awry. While it correctly pairs Russian and Ukrainian and recreates the same Romance subtree as the other measures, there are some major discrepancies. Hebrew, the only non–Indo-European language, is found to be closer to the Romance languages than to the Balto-Slavic cluster. Hindi's closeness to others is similarly exaggerated. In fact, everything seems to be close for VI, except Greek! As the other measures better capture the phylogeny, we suggest that similarity measured with Variation of Information is ill suited to our main task.

6.3 Quantitative Evaluation

Our proposals to measure similarity of gender systems give rise to dendrograms that resemble phylogenetic trees. But how much so? We answer this by measuring the similarity to the ground truth tree. To measure the similarity of two trees T_1 and T_2, we use Rabinovich et al. (2017)'s extension of the L_2 norm to leaf pair distance. Here, we sum the number of edges on a path between two nodes to get their distance d. We then compute the total distance as the sum of squared distances: $\sum_{i \neq j} \left(d_{T_1}(\ell_i, \ell_j) - d_{T_2}(\ell_i, \ell_j)\right)^2$, where each ℓ_i identifies one language (or leaf).

We show that the distance according to any of our three measures is significantly more like the ground truth (from Serva and Petroni, 2008) than chance by comparing the computed trees to 1000 randomly generated trees on the same set of languages. (We report mean and standard deviation of distance from the ground truth. We use Rabinovich et al. (2017)'s unweighted distance.) For each combination of dataset and measure, we use McNemar's test for significance and find $p < 0.0001$.

7 Related Work

There is a baffling dearth of work on quantifying similarity of gender systems. There is, however, ample work on characterizing intensional gender systems, i.e., sets of grammatical rules, that can be divided (Corbett, 1991) into sets of rules based on morphology (Tucker et al., 1977; Gregersen, 1967; Wald, 1975; Plank, 1986, i.a.) and on phonology (Bidot, 1925; Tucker et al., 1977; Newman, 1979; Hayward and Corbett, 1988; Marchese, 1988). Intensional approaches, particularly those with typological leanings, contribute very fine grained research on particular pairwise similarities for particular languages and dialects. Although we cannot survey these in detail here, we would love for our measures to contribute findings that can complement these approaches.

Relatedly, other recent works have investigated grammatical gender and other types of noun classification systems with information theoretic tools. For example, Williams et al. 2020b uses mutual information to quantify the strength of the relationships between declension class, grammatical gender, distributional semantics, and orthographic form respectively in several languages. Williams et al. 2020a, which is arguably closest to this work, measures the strength of semantic relationships between inanimate nouns and verbs or adjectives that takes those nouns as arguments, and that work can be seen as comparing the similarity of nouns clustered by their gender, with the same nouns clustered by the adjectives that modify them or the verbs that take them as arguments.

Although we adopt information theoretic measures, here there are two other major classes of cluster evaluation measures: set-matching measures, and pair-counting measures, which tally which pairs of items are in the same or different communities. One popular set-matching measure in information retrieval, *purity* (Manning et al., 2008), is asymmetric and biased by the size and number of communities (Danon et al., 2005). Its symmetric form, the F-measure (Artiles et al., 2007), has clear bounds but gives no indication of average-case performance.

The adjusted Rand index (ARI; Hubert and Arabie, 1985) is the preeminent pair-counting measure. It is related to AMI, adjusting the Rand index in the same way that AMI adjusts MI. ARI also computes an expectation, which can be computed over the proper distribution (Gates and Ahn, 2017), but it is empirically better suited to large, balanced clusters. In our case of small and uneven clusters, AMI should be preferred (Romano et al., 2016).

Dataset	Measure	Score	St. Dev.
Swadesh	MI	344	-
	VI	312	-
	AMI	344	-
	Random	1184	133.4
NorthEuraLex	MI	1231	-
	VI	1164	-
	AMI	1548	-
	Random	2531	209.6

Table 1: Distances of generated trees from gold tree.

We can only survey a representative handful of the numerous cluster evaluation measures in the limited space we have here. See McCarthy et al. (2019b) for an outline of desiderata for comparing partitions, as well as a general class of appropriate measures, and for further motivation for AMI using a different null model—languages have a fixed number of gender classes, so we select one over N items with K communities, rather than an arbitrary number of communities.

8 Conclusion

We have presented a clean method for comparing grammatical gender systems across languages: By defining gender classes extensionally, we reduced the problem to cluster evaluation from community detection. We validate three metrics by recovering known phylogenic relationships in our languages, with measurable success. Separate Indo-European branches are no more similar than chance.

We emphasize that our methods are not specifically tailored to gender systems. One could apply them more broadly other aspects of the lexicon, e.g. to Indo-European verb classes, Bantu noun classes, or diachronic time slices of a single language's gender system, data permitting. A related challenge is East and Southeast Asian numeral classifier systems, which associate nouns with classifiers based largely on the semantic properties of the nouns (Kuo and Sera, 2009; Zhan and Levy, 2018; Liu et al., 2019). They display more idiolectal variation, and often more than one classifier can accompany a given noun (Hu, 1993), unlike for gender (where this is rare). We note that we could further extend our measures to fuzzy partitions, which remain less explored in community detection, but are a promising avenue for future work.

Acknowledgments

We thank Tongfei Chen for comments on the Slavic languages, Jean-Gabriel Young for suggesting that we consider Variation of Information, and Johannes Bjerva for providing us with code to compute the tree distance. We also thank Tiago Pimentel for his help with proofreading. Finally, we would like to thank Eleanor Chodroff for providing useful insights during the formulation of the problem.

A Languages

While there are over 70 languages in the Universal Dependencies treebanks, only a select handful possess grammatical gender. We use 20 languages in the Universal Dependencies corpora that have gender and also present in our concept lists. Below find their ISO 639-1 codes (used in the paper to conserve space), ISO 639-3 codes (widely preferred), and their major family (in the case of Hebrew) or subfamily (in the case of our Indo-European languages), and the number of grammatical genders they have:

Language	ISO 639-1	ISO 639-3	(Sub-)Family	Genders
Bulgarian	`bg`	`bul`	Balto-Slavic	3
Catalan	`ca`	`cat`	Romance	2
Danish	`da`	`dan`	Germanic	2
Greek	`el`	`ell`	Hellenic	3
Spanish	`es`	`spa`	Romance	2
9 French	`fr`	`fra`	Romance	2
Hebrew	`he`	`heb`	Semitic	2
Hindi	`hi`	`hin`	Indo-Iranian	2
Croatian	`hr`	`hrv`	Balto-Slavic	3
Italian	`it`	`ita`	Romance	2
Lithuanian	`lt`	`lit`	Balto-Slavic	2
Latvian	`lv`	`lav`	Balto-Slavic	2
Polish	`pl`	`pol`	Balto-Slavic	3
Portuguese	`pt`	`por`	Romance	2
Romanian	`ro`	`ron`	Romance	3
Russian	`ru`	`rus`	Balto-Slavic	3
Slovak	`sk`	`slk`	Balto-Slavic	3
Slovene	`sl`	`slv`	Balto-Slavic	3
Swedish	`sv`	`swe`	Germanic	2
Ukrainian	`uk`	`ukr`	Balto-Slavic	3

Abstract

The performance of the Chinese Word Segmentation (CWS) systems has gradually reached a plateau with the rapid development of deep neural networks, especially the successful use of large pre-trained models. In this paper, we take stock of what we have achieved and rethink what's left in the CWS task. Methodologically, we propose a fine-grained evaluation for existing CWS systems, which not only allows us to *diagnose* the strengths and weaknesses of existing models (under the in-dataset setting), but enables us to *quantify* the discrepancy between different criterion and alleviate the negative transfer problem when doing multi-criteria learning. Strategically, despite not aiming to propose a novel model in this paper, our comprehensive experiments on eight models and seven datasets, as well as thorough analysis, could search for some promising direction for future research. We make all codes publicly available and release an interface that can quickly evaluate and diagnose user's models: https://github.com/neulab/InterpretEval.

1 Introduction

Chinese word segmentation (CWS), as a crucial first step in Chinese language processing, has drawn a large body of research (Sproat and Shih, 1990; Xue and Shen, 2003; Huang et al., 2007; Liu et al., 2014). Recent years have seen remarkable success in the use of deep neural networks on CWS (Zhou et al., 2017; Yang et al., 2017; Ma et al., 2018; Yang et al., 2019; Zheng et al., 2013; Chen et al., 2015b,a; Cai and Zhao, 2016; Pei et al., 2014), and the large unsupervised pre-trained models drive the state-of-the-art results to a new level (Huang et al., 2019).

However, the performance of CWS systems gradually reaches a plateau and the development of this field has slowed down. For example, the CWS systems on many existing datasets (e.g. `msr`, `ctb`) have achieved $F1$-score higher than 97.0 but with little further improvement. Naturally, a question would be raised: *is CWS a solved task*? When we rethink on what we have achieved so far, we find that there are still some important while rarely discussed unsolved questions for this task:

Q1: Does current excellent performance (e.g. more than 98.0 $F1$-score on the `msr` dataset) indicate a perfect CWS system, or are there still some limitations? Existing CWS systems are mainly evaluated by a corpus-level metric. The holistic measure fails to provide a fine-grained analysis. As a result, we are not clear about what the strengths and weaknesses of a specific model are.

To address this problem, we shift the traditional trend of holistic evaluation to fine-grained evaluation, in which the notion of the *attribute* (i.e., *word length*) has been introduced to describe a property of each word. Then test words will be partitioned into different buckets, in which we can observe the system's performances under different aspects based on word's attributes (e.g. *long words* will obtain lower $F1$-score).

Q2: Is there a one-size-fits-all system (i.e., best-performing systems on different datasets are the same)? If no, how can we make different choices of model architectures in different datasets? Insights are still missing for how the choices of different datasets influence architecture design.

To answer this question, we make use of our proposed fine-grained evaluation methodology and present two types of diagnostic methods for existing CWS systems, which not only helps us to identify the strengths and weaknesses of current approaches but provides us with more insight about how different choices of datasets influence the model design.

Q3: Now that existing works show CWS sys-

tems can benefit from multi-criteria learning at the cost of negative transfer (Chen et al., 2017; Qiu et al., 2019), can we design a measure to quantify the discrepancies among different criteria and use it to instruct the multi-criteria learning process (i.e., alleviate negative transfer)?

To answer this question, we extend the *in-dataset* evaluation (i.e., a system is trained and tested on the same dataset) to the setting of *cross-dataset*, in which a CWS model trained on one corpus would be evaluated on a range of out-of-domain corpora. On the other hand, it's the above in-dataset analysis (in Q1 & Q2) that helps us to design a measure to quantify the discrepancies of cross-dataset criterion. Empirical results not only show that the measure, calculated solely based on statistics of two datasets, has a higher correlation with cross-dataset performances but also helps us avoid the negative transfer (i.e., selecting the useful parts of source domains as training sets and achieve better results based on fewer training samples)

Our contributes can be summarized as follows: 1) Instead of using a holistic metric, we proposed an attribute-aided evaluation methodology for CWS systems. This allows us to diagnose the weakness of existing CWS systems (e.g., BERT-based models are not impeccable and limited in dealing with words with high label inconsistency). 2) We show that best-performing systems on different datasets are diverse. Based on some proposed quantified measures, we can make good choices of model architectures in different datasets. 3) We quantify the criterion discrepancy between different datasets, which can alleviate the negative transfer problem when performing multi-criteria learning for CWS.

2 Preliminaries

2.1 Task Description

Chinese word segmentation (CWS) was usually conceptualized as a character-based sequence labeling problem. Formally, let $X = \{x_1, x_2, \dots, x_T\}$ be a sequence of characters, and $Y = \{y_1, y_2, \dots, y_T\}$ be the output tags. The goal of the task is to estimate the conditional probability: $P(Y|X) = P(y_t|X, y_1, \cdots, y_{t-1})$. Here, y_t usually takes one value of $\{B, M, E, S\}$.

2.2 Attribute-aided Evaluation Methodology

The standard metric of CWS is becoming hard to distinguish the state-of-the-art word segmentation systems (Qian et al., 2016). Instead of evaluating CWS systems based on a holistic metric (F1 score), in this paper, we take a step towards the fine-grained evaluation of the current CWS systems by proposing an attribute-aided evaluation method. Specifically, we first introduce the notion of *attributes* to characterize the properties of the test words. Then, the test set will be divided into different subsets, and the overall performance could be broken down into several interpretable *buckets*. Below, we will introduce the *seven* attributes that we have explored to depict the word in diverse aspects. Fig. 1 gives an example for the test word "图书馆".

Aspect-I: Intrinsic nature We can characterize a word based on its (or the sentence it belongs to) constitute features. Here, we define three attributes: word length (`wLen`); sentence length (`sLen`); OOV density (`oDen`): the number of words outside the training set in a sentence divided by sentence length.

Aspect-II: Familiarity We introduce a notion of familiarity to quantify the degree to which a test word (or its constituents) has been seen in the training set. Specifically, the familiarity of a word can be calculated based on its *frequency* in the training set. For example, in Fig. 1, if the frequency in the training set of the test word 图书馆 (library) is `0.3`, the attribute of word frequency of 图书馆 will be `0.3`. In this paper, we consider two kinds of familiarity: word frequency (`wFre`); character frequency (`cFre`).

Aspect-III: Label consistency In this paper, we attempt to design a measure that can quantify the degree of label consistency phenomenon (Fu et al., 2020; Gong et al., 2017; Luo and Yang, 2016; Chen et al., 2017) for each test word (or character). Here, we investigate two attributes for label consistency: label consistency of word (`wCon`); label consistency of character (`cCon`). Following,

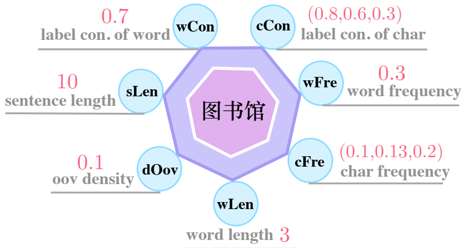

Figure 1: The attribute definition of the word “图书馆`(library)`” in the sentence: “图书馆在节假日会关闭(The `library` is closed on holidays”, and its ground truth label is `BME`. The text in the circle is the abbreviation of the attribute name, and the text in gray and in pink is the full name and the attribute value, respectively. *con.* in grey denotes *consistency*.

we give the definition of label consistency of word, and the label consistency of character can be defined in a similar way. Specifically, we refer to w_i^k as a test word with label k, whose label consistency $\psi(w_i^k)$ is defined as:

$$\psi(w_i^k, D^{tr}) = \begin{cases} 0 & |w_i^{tr}| = 0 \\ \frac{|w_i^{tr,k}|}{|w_i^{tr}|} & \text{otherwise} \end{cases} \tag{1}$$

where $|w_i^{tr,k}|$ represents the occurrence of word w_i with label k in the training set, and D^{tr} is the training set. For example, in Fig. 1, in the training set, “图书馆 (library)” is labeled as `BME` 7 times, and `BMM` 3 times, so ψ (“ 图书馆^{BME}”) $= 7/10 = 0.7$, and ψ (“图书馆^{BMM}”) $= 3/10 = 0.3$.

3 Investigation on In-dataset Setting

3.1 Setup

This section focuses on the *in-dataset* setting, in which each CWS model will be trained and test on the same dataset.

Datasets We choose seven mainstream datasets from SIGHAN2005 [1] and SIGHAN2008 [2], in which `cityu` and `ckip` are traditional Chinese, while `msr`, `pku`, `ctb`, `ncc` and `sxu` are simplified Chinese. We map traditional Chinese characters to simplified Chinese in our experiment. The details of the seven datasets used in this study are described in Chen et al. (2017).

Models We choose typical instances as analytical objects, which vary in terms of the following aspects: 1) character encoders: `ELMo` (Peters et al., 2018), `BERT` (Devlin et al., 2018); 2) bigram encoder: `Word2Vec` (Mikolov et al., 2013), averaging the embedding of two contiguous characters; 3) sentence encoders: `LSTM` (Hochreiter and Schmidhuber, 1997), `CNN` (Kalchbrenner et al., 2014); 4) decoders: `MLP`, `CRF` (Lample et al., 2016; Collobert et al., 2011). The name of combination of models in in a detailed setting in Tab.2.

3.2 Measures

Here, we refer to $M = \{m_1, \cdots, m_{N_m}\}$ as a set of **models** and $P = \{p_1, \cdots, p_{N_p}\}$ as a set of **attributes**. As described above, the test set could be split into different **buckets** $B = \{B_1^j, \cdots, B_{N_b}^j\}$ based on an attribute p_j. We introduce a performance table $\mathbf{V} \in \mathbb{R}^{N_m \times N_p \times N_b}$, in which $\mathbf{V}_{ijk}$ represents the performance of i-th model on the k-th sub-test set (bucket) generated by j-th attribute.

Model-wise The model-wise measure aims to investigate whether and how the attributes influence the performance of models with different choices of neural components. Formally, we characterize how the j-th attribute influences the i-th model based on two statistical variables: Spearman's rank correlation coefficient Spear (Mukaka, 2012) and standard deviation Std, which can be defined as:

$$\mathbf{S}_{i,j}^{\rho} = \mathrm{Spear}(\mathbf{V}[i, j:], R_j), \tag{2}$$

$$\mathbf{S}_{i,j}^{\sigma} = \mathrm{Std}(\mathbf{V}[i, j:]), \tag{3}$$

where R_j is the rank values of buckets based on j-th attribute. Intuitively, $\mathbf{S}_{i,j}^{\rho}$ reflects the degree to which the i-th model positively (negatively) correlates with j-th attribute while $\mathbf{S}_{i,j}^{\sigma}$ indicates the degree to which this attribute influences the model.

Dataset-wise The dataset-wise measures aim to characterize a dataset with different attributes quantitatively. We utilize two types of measures to build the connection between datasets and attributes: system-independent measure α^{μ}, and system-dependent measures α^{ρ} and α^{σ}.

1) *system-independent measure* reflects intrinsic statistics of the datasets, such as the average word length of the whole dataset. It can be formally defined as:

$$\alpha_j^{\mu} = \frac{1}{N_w} \sum_i^{N_w} \mathrm{Attr}(w_i, j), \tag{4}$$

where N_w is the number of test words and $\mathrm{Attr}(w_i, j)$ is the value of attribute j for word w_i.

2) *system-dependent measures* quantify the degree to which each attribute influences the CWS system on a given dataset. For example, “does the

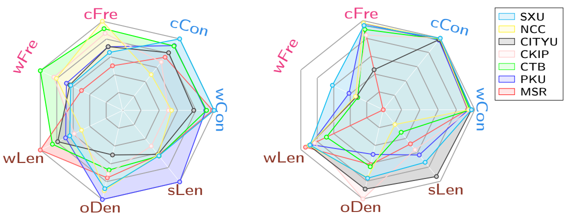
Table 2: Neural CWS systems with different architectures and pre-trained knowledge studied in this paper. We exclude systems based on joint training to make a fair comparison in the in-dataset setting. For the model name, "`C`" refers to "`Character`" and "`B`" refers to "`Bigram`". Intuitively, the models are named based on their constituents. For example, *Cw2vBw2vLstmCrf* denotes a model's character and the bigram feature is initialized by pre-trained embeddings using Word2Vec, and sentence encoder, as well as the decoder, are LSTM and CRF, respectively. We perform a Friedman test at p = 0.05 on model- (row-) wise and data- (column-)wise. The testing results are $p(\text{model} - \text{wise}) = 2.26 \times 10^{-6} < 0.05$ and $p(\text{data} - \text{wise}) = 8.42 \times 10^{-8}$. Therefore, the results of model-wise and data-wise have passed the significance testing.

attribute `word length` matter for the CWS system trained on `pku` dataset?". To achieve this, we design the following measures:

$$\alpha_j^\rho = \frac{1}{N_m} \sum_i^{N_m} |\mathbf{S}_{i,j}^\rho|, \tag{5}$$

where N_m is the number of evaluated models. Intuitively, a higher absolute value of $\alpha_j^\rho \in [-1, 1]$ suggests that attribute j is a crucial factor, greatly influencing the performance of CWS systems. For example, if $\alpha_{wLen}^\rho = 0.95$, it means `word length` is a major factor that influences the CWS performance.



(a) α^μ (b) α^ρ

Figure 2: Illustration of dataset biases characterized by task-independent measure α^μ and task-dependent measures α^ρ. We normalize α^μ on each attribute by divide the maximum α^μ on six datasets, and $\alpha^\rho \in [0, 1]$.

3.3 Analysis of Holistic Evaluation

Before giving a fine-grained analysis, we present the holistic results of different models on different datasets. As shown in Tab. 2, we can observe that **there is no one-size-fits-all model: best-performing systems on different datasets frequently consist of diverse components**. This naturally raises a question: how can pick up appropriate models for different datasets?

3.4 Analysis of Dataset Biases

Before the analysis, we conduct a statistical significance test with the Friedman test (Zimmerman and Zumbo, 1993) at $p = 0.05$, to examine whether the performance of different buckets partitioned by an attribute is significantly different for a given dataset. The results are shown in the Appendix. We find that the performance of different buckets partitioned by an attribute is significantly different ($p < 0.05$), which holds for all the datasets.

1) ***Label consistency* and *word length* have a more consistent impact on CWS performance.** The common parts of the radar charts Fig. 2 (b) illustrate that no matter which datasets are, label consistency attributes (`wCon`, `cCon`) and word length (`wLen`) are highly correlated with CWS performance (higher α^ρ). This suggests that the learning difficulty of CWS systems is commonly influenced by label consistency and word length.

2) ***Frequency* and *sentence length* matters but are minor factors** The outliers in the radar chart (Fig. 2 (b)) show the peculiarities of different corpora. On attributes: `sLen`, `wFre`, `oDen`, the extent to which different datasets are affected varies greatly. For example, the dataset `ckip` is distinctive with the highest value of α_{oDen}^ρ, which can explain why character pre-training shows no advantage while the CRF layer contributes a lot.

3.5 Analysis of Model Biases

Similar to the above section, we perform the Friedman test at $p = 0.05$. We give detailed significance testing results in the Appendix. Tab. 3 gives an illustration of model biases characterized by measures $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$. The values in grey denote the given model on the specific attribute does not pass the significance test ($p \geq 0.05$). Below, we will highlight some observations.

ELMo-based Models can make better use of the context information that long sentences carry. Regarding the attribute of `sLen` (sentence length), two models *CelmBnonLstmMlp* and *CbertBnonLstmMlp* pass the significance test. Additionally, we observe only ELMo (*CelmBnonLstmMlp*) shows a strong positive correlation with sentence length, referring to Tab. 3.

Contextualized models could reduce the negative effect of OOV density and remedy the deficiency of MLP decoder. a) The performances of non-contextualized models (i.e. word2vec) strongly correlate with the `oDen` (density of OOV words) attribute. When equipped with BERT or ELMo, the model still could provide each OOV word with a meaningful representation on the fly based on its context. b) We observe that the model *Cw2vBavgLstmMlp* is strong correlated with `wCon` and `wLen` with highest values of $\mathbf{S}^{\sigma}$ (referring to Tab. 3 with bolded value), suggesting that models with MLP layer are unstable when generalizing to the hard cases (words with lower value of `wCon` and higher value of `wLen`). However, once augmented with contextualized models, systems with MLP decoder also work well.

Table 3: Illustration of model biases characterized by model-wise measure (Percentage) $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$. Here, we average the F1, $\mathbf{S}^{\rho}_{i,j}$ and $\mathbf{S}^{\sigma}_{i,j}$ on seven datasets. The values in gray denotes the given model on the specific attribute does not pass the significance test ($p \geq 0.05$). The values in orange and in blue support observation 1 and observation 2, respectively.

3.6 Application: Model Diagnosis

Model diagnosis is the process of identifying where the model works well and where it worse (Vartak et al., 2018). We present two types of diagnostic methods: ***self-diagnosis*** and ***aided-diagnosis***. *self-diagnosis* aims to locate the bucket on which the input model has obtained the worst performance with respect to a given attribute. For *aided-diagnosis*, supposing that the holistic performance of two models satisfies: $A > B$. Then *Aided-diagnosis*(A,B) will first look for a bucket, on which the performance satisfies: $A < B$. If there is no qualified bucket, then the bucket, on which model A has achieved the best performance, will be returned.

Below, we will give a diagnostic analysis of some typical models shown in Tab. 4. The others are shown in the Appendix.

Self-diagnosis: BERT-based models are not impeccable. The first row in Tab. 4 shows the diagnosis of model *CbertBnonLstmMlp*, in which the x-ticklabel represents the bucket value of a specific attribute (e.g. `wLen`: word length) on which system has achieved worst performance. The blue bins represent the worst performance, while red bins denote the gap between worst and best performance. For example, the first histogram in the first row denotes that *CbertBnonLstmMlp* achieved the worst performance on attribute `wCon` with value `S`.

We observe that there is a huge performance drop on all the datasets when the test samples are with the attribute values: `wCon=S` (low label consistency of words), `cCon=S` (low label consistency of characters), `wLen=L` (long words). This suggests that contextualized information brought from BERT is not insufficient to deal with low label consistency and long words. To address this challenge, more efforts should be made on learning algorithms or data augmentation strategies.

Aided diagnosis: BERT v.s ELMo The second row in Tab. 4 shows the comparing between BERT and ELMo and we observed 1) BERT outperforms ELMo in the bucket of `wCon=S` (low label consistency of words) a lot on all datasets, suggesting that the benefit of BERT mainly comes from the processing of low label consistency of words. 2) When the OOV density of a sentence is high enough, BERT will lose its superiority. As shown in Tab. 4, BERT performs worse than ELMo in the bucket of `oDen=L` on the `pku` dataset whose average OOV density (α^{μ}_{oDen}) is the highest one

A: *CbertBnonLstmMlp* B: *CelmBnonLstmMlp* Aided-diagnosis							
Table 4: Diagnosis of different CWS systems. For ease of presentation, we attribute values are classified into three categories: **small**(S), **middle**(M), and **large**(L). Regarding *Self-diagnosis*, the x-ticklabel represents the bucket value of a specific attribute (e.g. `wLen`: word length) on which the system has achieved the worst performance. The blue bins represent the worst performance, while red bins denote the gap between worst and best performance. Regarding *Aided-diagnosis*, the bins below the line "$y = 0$" represent the largest gap that model A is less than model B. By contrast, the bins above the line "$y = 0$" denote the largest gap that model A is better than model B. x-ticklabels in red indicate that the corresponding bins will be used for analysis in Sec. 3.6.

(as shown in Fig. 2 (a)). To explain this, we take a closer look at the testing samples in the `pku` with high OOV density: "仰泳100米和400米" (backstroke 100m and 400m), "10月1日，北京 (October 1, Beijing)" . BERT, as multi-layer Transformers, is challenging to collect sufficient context to understand these cases. 3) BERT is inferior to ELMo in dealing with long sentences. As shown in Tab. 4, BERT obtain lower performance in the bucket of `sLen=L` on `pku` and `sxu` datasets, whose average lengths (α^{μ}_{sLen}) are the highest two.

4 Investigation on Cross-dataset Setting

The above in-dataset analysis aims to interpret model bias and dataset bias based on individual datasets. In many real-world scenarios, we need to transfer a trained model to a new dataset or domain, which requires us to understand the cross-dataset generalization behavior of current systems. In this section, our investigation on cross-dataset generalization is driven by two questions: 1) How different architectures (i.e. *Cw2vBavgLstmCrf*) of CWS systems influence their cross-dataset generalization ability? 2) Now that we have found the common factor (`label consistency`) that affects model performance across different datasets in the previous section, can we design a measure based on it and use it to interpret cross-data generalization? We will detail our exploration below.

4.1 Setup

This section focuses on the *zero-shot* setting: a model with specified architecture trained on one dataset (e.g. `pku`) will be evaluated on a range of other datasets (e.g. `ctb`). To better understand the generalization behavior of CWS systems and the relation between different datasets, we first define several measures to quantify our observations.

4.2 Measures

Similar to Sec.3.2, we refer to N_d as the number of all datasets and N_m as the number of architectures. The cross-dataset performance can be recorded by the following matrix:

$$\mathbf{U} \in \mathbb{R}^{N_d \times N_d \times N_m} \tag{6}$$

Quantifying System's Cross-dataset Generalization Intuitively, $\mathbf{U}_{ijk} = 0.65$ represents that we have adopted the architecture k (i.e. *Cw2vBavgLstmCrf*) to learn a model on the training set of i (e.g. `pku`), and the performance on test set of j (e.g., `msr`) is 0.65.

We do some simple numerical processing on matrix $\mathbf{U}$ to make the meaning of variables more intuitive: $\hat{\mathbf{U}}_{ijk} = (\mathbf{U}_{jjk} - \mathbf{U}_{ijk})/\mathbf{U}_{jjk}$. $\hat{\mathbf{U}}_{pku,msr,k} = 0.2$ suggests that, both tested on `msr`, the model with architecture k trained on `pku` is relatively lower than that trained on `msr` by 0.2. Usually, a lower value of $\hat{\mathbf{U}}$ is suggestive of better zero-shot generalization ability.

Quantifying Discrepancies of Cross-dataset Criterion To measure the discrepancy of segmentation criteria between any pair of training data D^{tr}_A and test data D^{te}_B, we extend the *label consistency of word* (defined in Sec. 2.2) to corpus-level by computing its expectation on a given training-test dataset pair. Base on Eq. 1, we defined the measure Ψ as:

$$\Psi(D^{tr}_A, D^{te}_B) = \sum_{i \in N_w} \psi(w^{te,k}_i, D^{tr}_A) * \mathrm{freq}(w^{te,k}_i) \tag{7}$$

in which $\psi(\cdot)$ (defined in Eq. 1) is a function to calculate the label consistency for a test word $w^{te,k}_i$.

N_w denotes the number of unique test words and $\text{freq}(w_i^{te,k})$ is the frequency of the test word.

A lower value of $\Psi(D_A^{tr}, D_B^{te})$ suggests a larger discrepancy between the two datasets. For example, $\Psi(D_{msr}^{tr}, D_{msr}^{te}) = 78.0$ and $\Psi(D_{msr}^{tr}, D_{pku}^{te}) = 75.5$, indicating that the discrepancy between `msr`'s training set and `msr`'s test set is smaller than the discrepancy between `msr`'s training set and `pku`'s test set.

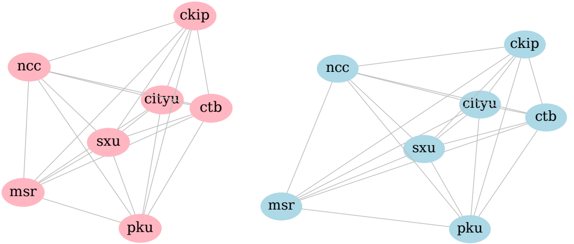
Table 5: The relationship between different pairs of datasets measured by data-wise Ψ and model-wise $\hat{U}_k$. Here k represents the model *Cw2vBavgLstmCrf*.

4.3 Analysis

Tab. 5 illustrate the relationship between different train-test pair using data-wise Ψ and model-wise $\hat{U}_k$. To test whether the expectation of label consistency is a factor that can be used to characterize cross-dataset generalization, we perform a Friedman test at $p = 0.05$. Each group of samples for significance testing is obtained by changing the test-set for a given train-set (we have 7 groups of testing samples corresponding to the 7 columns data of Ψ in Tab. 5). The testing result is $p = 0.011 < 0.05$, therefore, Ψ can be utilized to describe the feature of a cross-dataset pair.

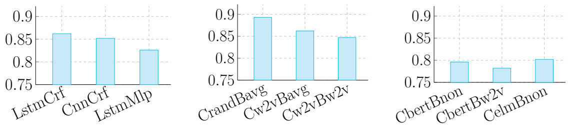
The distance between different datasets can be quantitatively characterized by Ψ. 1) As shown in Tab. 5, nearly all highest values are achieved on the diagonal except the row of `cityu`. Ψ(`cityu`, `cityu`) is slightly lower than Ψ(`ctb`, `cityu`), indicating the training sets of `ctb` and `cityu` are quite close. As shown in Fig. 3(a), we do find `cityu` is closet to `ctb`. 2) `ctb` achieves the highest value in the "avg"-column of Tab. 5 in red, which shows taking `ctb` as the source domain, the average distance to test sets of other corpora is the smallest. Similarly, if `cityu` is regarded as the target domain, then the average distance from other training sets to it is the smallest. 3) As shown in Fig. 3(a), `sxu`, `cityu`, and `ctb` cluster together, surrounded by other datasets `ckip`, `ncc`, and `pku` remotely, suggesting that these neighbor datasets have the similar distribution.



(a) Data-wise (Ψ)

(b) Model-wise (U)

Figure 3: 2D-visualization of the distances between datasets computed based on data-wise measure Ψ and model-wise U averaging on seven datasets, respectively. The weight of between dataset i and j is transformed into an undirected edge based on: $\frac{Z_{ij}}{Z_{jj}} + \frac{Z_{ji}}{Z_{ii}}$ and Z can be Ψ and U, in which the distance computed based on U is the average on eight models.



(a) Cw2vBavg

(b) LstmCrf

(c) LstmMlp

Figure 4: The Spearman's rank correlation coefficient between Ψ and the U_k.

The measure Ψ could be used to interpret the domain shift. As shown in Tab. 5, we find the value of Ψ could reflect the changing trends of $\hat{U}$. Similarly, as shown in Fig.3, impressively, these two graphs obtained in totally different ways are so close: Fig.3 (a) is computed purely based on intrinsic statistics of the dataset, while Fig.3 (b) is obtained based on model outputs. These qualitative results show our proposed measure Ψ could be used to explain the discrepancies across datasets.

To get a more convincing observation, we additionally conduct a quantitative analysis. Specifically, we calculate the Spearman's rank correlation coefficient between Ψ and the U_k. The results all shown in Fig. 4 (a-c). Encouragingly, we find that no matter which CWS system, the cross-dataset performances of them are highly correlated with our proposed measure of Ψ.

4.4 Application: Multi-source Transfer

Given a target domain D_t, the above quantitative and qualitative analysis shows that the measure Ψ can be used to quantify the importance of different source domains $D_{s_1}, \cdots, D_{s_N}$, therefore allowing us to select suitable ones for data augmentation.

Algorithm 1 Decoding Process for Dataset Order

```
Require: Target domain $D_t = \{D_t^{tr}, D_t^{dev}\}$; a sequence of source domains $\{D_{s_1}, D_{s_2}, \ldots, D_{s_N}\}$; indexes of source domains $K = \{1 \cdots N\}$;measure $\Phi$
Require: $\hat{K} \leftarrow \{\}$; $\hat{D} \leftarrow D_t^{tr}$
for $k \in K$ do
    if Max-select then
        $\hat{k} = \mathrm{argmax}_{k \in K \bigwedge k \notin \hat{K}} \Phi(\hat{D} + D_{s_k}, D_t^{dev})$
    else if Min-select then
        $\hat{k} = \mathrm{argmin}_{k \in K \bigwedge k \notin \hat{K}} \Phi(\hat{D} + D_{s_k}, D_t^{dev})$
    else if Rand-select then
        $\hat{k} = \mathrm{Random}_{k \in K \bigwedge k \notin \hat{K}} \Phi(\hat{D} + D_{s_k}, D_t^{dev})$
    end if
    $\hat{K} = \hat{K} + \{\hat{k}\}$                ▷ EnQueue
    $\hat{D} = \hat{D} + D_{s_{\hat{k}}}$
end for
    return $\hat{K}$
```

Next, we will show how to use the Ψ to make better choices of source domains from the other candidates. We take `ctb` as the tested object and continuously increase the training samples of above the seven datasets in three different ways: *Rand-*, *Max-*, and *Min-select*. Alg. 1 shows the decoding process for the dataset order. We choose the multi-criteria segmenter proposed by Chen et al. (2017) as our training framework for multiple datasets.

Result Fig. 5 illustrates the changes in F1-score as more source domains are introduced in three different orders. We do a Friedman test with the null hypothesis that the order of training set introduced had no influence on the performance of a given model. The significance testing result shows that the training set introduced with Max-, Min-, and Rand-select are significantly different ($p = 8.0 \times 10^{-3} < 0.05$). We can observe from Fig. 5 that: *More training samples are not a guarantee of better results for CWS models due to the criteria discrepancy between different datasets.*

Specifically, the *Max-select* operation helps us find an optimal set of source domains (`ctb`, `sxu`, `ncc`, `cityu`), on which the model could achieve the best results, outperforming Chen et al. (2017)'s result by a significant margin, which trained on nine datasets (two more than ours). Regarding the two baseline decoding strategies (*Min-select* and *Rand-select*), we find the best performance on `ctb` are both obtained when all seven training sets are used. The above observations indicate that, when we introduce multiple training sets for data augmentation, the order of the distance between training and development sets can help us select which parts of source domains are useful. And Ψ, we proposed in this paper, is an effective measure to quantify this order (without learning process), providing a novel solution for multi-source transfer learning.

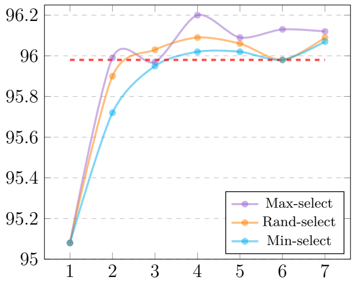


Figure 5: The changing of F1-score as more source domains are introduced in three different orders: *Max-*, *Min-*, and *Rand-select*. The red dotted line is the result reported by Chen et al. (2017) with the same model, trained on nine datasets.[1]

5 Discussion

We summarize the main observations from our experiments and try to give preliminary answers to our proposed research questions:

Does existing excellent performance imply a perfect CWS system? No. Beyond giving this unsurprising answer, we present an interpretable evaluation method to help us diagnose the weaknesses of existing top-performing systems and relative merits between two systems. For example, we find even top-scoring BERT-based models still cannot deal with the words with low label consistency or long words well, and BERT is inferior to ELMo as an encoder in dealing with long sentences.

Is there a one-size-fits-all system? No (Best-performing systems on different datasets frequently involve diverse neural architectures). Although this question can be answered relatively easily by simply looking at the overall results of different systems in diverse data sets (Sec.2), we take a step further to how to make choices of them (`BERT v.s ELMo`, `LSTM v.s CNN`)) by conducting dataset bias-aware *Aided-diagnosis* (Sec.3.6).

Can we design a measure to quantify the discrepancies among different criteria? Yes. We first verify that the *label consistency* of words and *word length* have a more consistent impact on CWS performance. Based on this, we design a measure to quantify the distance between different datasets, which correlates well with the cross-dataset performance and can be used for multi-source transfer learning, help us avoid the negative transfer.

---

[1] To make a fair comparison, all results are implemented based on their public code.

A Significance Testing

To conduct the fine-grained evaluation, we divide the words (characters) of the test set into several subsets, which are named buckets in this paper. We perform Friedman significance testing at $p = 0.05$ in dataset-dimension and model-dimension, and the results are shown in Tab. 6 and Tab. 7, respectively. For dataset-dimension (model-dimension), the null hypothesis is that the performance of buckets concerning an attribute has the same means for a given dataset (model).

B Application: Model Diagnosis

Model diagnosis is the process of identifying where the model works well and where it worse. Tab. 8 shows several model diagnoses of different CWS systems. Below, we will give several comparative-diagnostic analysis on some typical models.

LSTM v.s. CNN For the choice of CNN or LSTM, the main factors are `sLen` (sentence length) and `cCon` (label consistency of characters), referring to third row of Tab. 8. Besides shorter sentences, we're surprised to find that the *CNN encoder is better at handling ambiguous characters than LSTM*. Generally, we believe that LSTM could provide more long-term information, therefore, achieving disambiguation. However, the above results show that local information is more important to learn these highly ambiguous characters (such as “的”,“了”, “什”) for the CWS task. Based on this, we could explain why CNN outperforms LSTM on `ncc` (lowest value of α^{u}_{wCon}) while is significantly worse than LSTM on `ctb` and `sxu` (large values of α^{u}_{cAmb}).

CRF v.s. MLP CRF decoder has no advantage in dealing with unambiguous words compared with MLP, but is superior in processing long (`wLen=L`) and ambiguous (`wCon=S`) words, as observed in the fourth row of Tab. 8. Particularly, *Cw2vBavgLstmCrf* outperforms *Cw2vBavgLstmMlp* models by a large margin in the bucket of (`wCon=S`) on the `pku` dataset. Based on this, we could explain the difference in

Table 8: Diagnosis of different CWS systems. For ease of presentation, we attribute values are classified into three categories: **small**(S), **middle**(M), and **large**(L). Regarding *Aided-diagnosis*, the bins below the line "$x = 0$" represent the largest gap that model A is less than model B. By contrast, the bins above the line "$x = 0$" denote the largest gap that model A is better than model B. x-ticklabels in red indicate that the corresponding bins will be used for analysis in this section

the holistic F1 results between the above two models.

Cw2vBavg v.s. CrandBavg As shown in the last row of the Tab. 8, we find that pre-trained knowledge does not always help to improve the performance, especially when: 1) the characters or words are highly ambiguous; 2) the OOV density of a sentence is high. Above evidences will help us to explain why *CrandBavg* could achieve better performance measured on the holistic F1 on `ctb`, `sxu` and `pku`. They share a property of much higher value of α^{μ}_{wCon}, α^{μ}_{cCon}, α^{μ}_{oDen} as observed in the Fig. 2 (a).

Learning to Pronounce Chinese Without a Pronunciation Dictionary

Abstract

We demonstrate a program that learns to pronounce Chinese text in Mandarin, without a pronunciation dictionary. From non-parallel streams of Chinese characters and Chinese pinyin syllables, it establishes a many-to-many mapping between characters and pronunciations. Using unsupervised methods, the program effectively deciphers writing into speech. Its token-level character-to-syllable accuracy is 89%, which significantly exceeds the 22% accuracy of prior work.

1 Unsupervised Text-to-Pronunciation

Many papers address the construction of automatic grapheme-to-phoneme systems using rules or supervised learning, e.g. (Berndt et al., 1987; Zhang et al., 2002; Xu et al., 2004; Bisani and Ney, 2008; Peters et al., 2017).

The task of *unsupervised* grapheme-to-phoneme conversion is introduced by Knight and Yamada (1999). Given two non-parallel streams:

- A corpus of written language (characters).
- A corpus of spoken language (sounds).

the goal is to build:

- A mapping table between the character domain and the sound domain.
- A proposed pronunciation of the written character sequences.

Motivated by archaeological decipherment, Knight and Yamada (1999) view character sequences as "enciphered" phoneme sequences. Their evaluation compares the proposed pronunciations with actual pronunciations. With a noisy-channel expectation-maximization method, they obtain 96% phoneme accuracy on Spanish, 99% on Japanese kana, but only 22% syllable accuracy on Mandarin Chinese.

In this paper, we re-visit the task of deciphering Chinese text into standard Mandarin pronunciations (Figure 1). We obtain an improved 89% syllable accuracy. We further explore exposing the internals of characters and syllables to the analyzer, as Chinese characters sharing written components often sound similar.

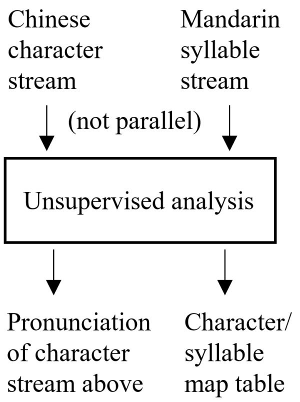

Figure 1: Learning to pronounce Chinese without a dictionary.

We find it compelling that pronunciation dictionaries are largely redundant with non-parallel text and speech corpora, even for writing systems as complex as Chinese. We also expect results may be of use in dealing with novel ways to write Chinese, such as Nüshu script (Zhang et al., 2016), with acoustic modeling of other Chinese languages and dialects, and with novel ways to phonetically encode and decode Chinese in online censorship applications (Zhang et al., 2014).

2 Chinese Writing

The most-popular modern Chinese writing system renders each spoken syllable token with a single character token (*hanzi*). There are over 400 syllable types in Mandarin[1] and several thousand character types. The mapping is many-to-many:

- Almost every syllable type can be written

---

[1] In this paper, we use standard *pinyin* syllable representation, and we refer strictly to Mandarin pronunciation.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5687–5693,
November 16–20, 2020. ©2020 Association for Computational Linguistics

with different characters (eg, *zhong* → {中, 重, 肿, ...}). The choice depends on context. For example, the word ***zhong**guo* (“China”) is written 中国, but ***zhong**yao* (“important”) is written 重要.

- Only a few character types are heteronyms, whose pronunciation depends on context and meaning (e.g., 了 → {*le*, *liao*}).

In addition, syllables have one of five tones, including the neutral tone (e.g., *dāng*, *dáng*, *dǎng*, *dàng*, *dang*). Tones increase pronunciation ambiguity. Most characters have single, unambiguous phonemic pronunciations (eg, 中 → *zhōng*), but a portion can be pronounced with different tones depending on context (eg, 当然 → ***dāng**rán*, but 适当 → *shì**dàng***).

While most Chinese words have two syllables, individual characters carry rough semantic meanings (eg, 中 = “middle”, 重 = “weighty”). So it is no accident that the same character is used to write semantically-similar words:

- 中国 (“China = middle kingdom”), 中学 (“middle school”), 市中心 (“city center”)
- 重要 (“important”), 重达 (“heavy”), 重点 (“focus”)
- Similarly, the second syllable of “website” is spelled “site”, not “sight”.

Finally, many characters have loosely informative internal structure. For example, 鸦 can be analyzed into two *character components*: 牙 and 鸟.[2] Character components are sometimes a clue to pronunciation and/or meaning. For example:

- The character 鸦 (“crow”, *yā*) is composed of 鸟 (meaning “bird”) and 牙 (sound *yá*).
- The 中 (*zhōng*) component of 肿 (“swollen”) is a clue to its pronunciation *zhǒng*, though the 月 (“moon”) component is more loosely suggestive of its meaning.
- For a character like 法 (“law”), the components “water” and “go” do not provide much of a phonetic or semantic clue. This is the case with many characters.

The vast majority of characters have two top-level components, arranged either side-by-side (as in the examples above), top-bottom, or outside-inside. It should be noted that a top-level character component may often be recursively divided into further sub-components.

Generally speaking, it is impossible for a student to correctly guess the pronunciation or meaning of a new character, though their guess may be better than chance.

3 Data Preparation

From a Chinese Wikipedia dump,[3] we remove all non-Chinese characters, then convert to simplified characters. This forms our character corpus.

For our pronunciation corpus, we could record and transcribe Mandarin speech into *pinyin* syllables. Instead, we simulate this. We take a large subset of the Baidu Baike encyclopedia,[4] but then immediately convert it to tone-marked *pinyin* syllables, by using a comprehensive dictionary[5] of 116,524 words and phrases. 99.97% of Baike character tokens are covered by this dictionary.

We substitute Baike character sequences with *pinyin* sequences in left-to-right, longest-match fashion. This strategy works well most of the time. For example, it correctly pronounces 睡觉 as *shui jiao*, and 觉得 as *jue de*, despite the ambiguity of 觉. However, it incorrectly pronounces 想睡觉 because a dictionary entry 想睡 matches the phrase before 睡觉 = *shui jiao* can be applied; it also has trouble with single-character words like 还.

Using character sequences from Chinese Wikipedia and pinyin sequences from Baidu Baike is important. If we alternatively divided Chinese Wikipedia into two parts, unsupervised analysis could easily exploit high-frequency boilerplate expressions like 英重定向：这是由英名，指向中文名的重定向。它引出英至遵循命名常的合名，能助者作。(“English Redirection: This is a redirect from the English name to the Chinese name. It guides the English title to a proper name that follows the naming convention and can assist the editor in writing.”)

We also *pinyin*-ize the first 100 lines (6059 characters) of our character corpus, as a gold-standard reference set, for later judging how well we phonetically decipher the character corpus. Unless stated otherwise, all results are for token accuracy on this reference set.

Table 1 gives statistics on our corpora. We release our data at *https://github.com/c2huc2hu/unsupervised-chinese-pronunciation-data*.

We also record internal structure of syllables

---

[2] Non-Chinese speakers may want to visually confirm that 牙 and 鸟, suitably thinned and placed side-by-side, do indeed form the composite character 鸦.

	Tokens	Types	Singletons
Characters (Wikipedia)	510m	17,442	3,444
Syllables (Baike)	264m	w/o tones: 412 w/ tones: 1506	1 5
Test set (characters)	6059	783	236

Table 1: Token and type statistics for our non-parallel character and syllable corpora. Singletons are one-count types.

and characters. For syllables, we separate onset and rime (eg, *zhang* → *zh* + *ang*).

For characters, we employ the thorough graphical decompositions given in Wikimedia Commons,[6] which divide each character into (at most) two parts. This allows us to find, for example, 44 characters that include the second component 包 (咆, 孢, 狍, 炮, etc). We only use top-level decompositions in this work, forgoing any further recursive decompositions.

4 Supervised Comparison Points

Before turning to unsupervised methods, we briefly present two supervised comparison points.

First, if we had a large *parallel* stream of character tokens and their *pinyin* pronunciations, we could train a simple pronouncer that memorizes the most-frequent *pinyin* for each character type. Using the Baike data as processed above as a putative parallel resource, we obtain 99.1% pronunciation accuracy on the test set.[7] The only errors involve ambiguous characters, showing that a deterministic character-to-pinyin mapping table—whether obtained by memorization or by unsupervised methods—is sufficient to solve the bulk of the problem.

Second, to investigate whether written character components predict pronunciation, we use gold pronunciations of the most common 2000 characters to predict pronunciations of the next 1000. If a test character X has second (e.g., rightmost) written component Y, then we use the pronunciation of Y as a guess for the pronunciation of X. We find this works 25% of the time if we do not consider tones, and 17% of the time if we do. Table 2 confirms that character components are only a loose guide to pronunciation, even with supervision.

Next we turn to unsupervised pronunciation, where we throw away pronunciation dictionaries and parallel data, working only from uncorrelated streams of characters and syllables.

5 Unsupervised Vector Method

Borrowing from unsupervised machine translation, which learns mappings between words in different languages (Lample et al., 2018a; Artetxe et al., 2018), we attempt to learn a mapping between embeddings for characters and embeddings for *pinyin* symbols. We train fastText (Bojanowski et al., 2017) vectors of dimension 300 and default settings on each of our corpora and use the MUSE system[8] to learn the relationship between the two vector spaces (Lample et al., 2018b).

There are two steps to this method: (1) map character vectors into *pinyin* space, (2) for each character type, find its nearest *pinyin* neighbor. This gives us a table that maps character types onto *pinyin* types. We apply this table to each character token of our 6059-character test set, obtaining token-level accuracy.

Unfortunately, this method does not work well. Only 0.5% of type mappings are correct, and token-level accuracy is similarly small. Reversing the mapping direction (*pinyin* embeddings into character embedding space) does not improve accuracy. It appears that the asymmetry of the mapping is difficult for the algorithm to capture. Each *pinyin* syllable should, in reality, be the nearest neighbor of many different characters. Moreover, the behavior of a *pinyin* syllable in running *pinyin* data may not be a good match for the behavior of any given character with that pronunciation.

Our next approach is to map words instead of characters. We break our long character sequence into a long word sequence, e.g., 竞争 很 激烈 by applying the Jieba tokenizer[9] to Wikipedia. We similarly break our long *pinyin* sequence into a long *pinyin*-word sequence, e.g., *wo xihuan chi jiaozi*, by applying the Stanford tokenizer[10] to pre-*pinyin*ized Baidu. We build embeddings for types on both sides, and we again map them into a shared space.

During the nearest-neighbor phase, we take each written-word and look for the closest *pinyin*-word, giving preference to *pinyin* words with the

	Exact *pinyin* match, with tone	Exact *pinyin* without tone	Partial *pinyin*
Majority-class Baseline (*yù*)	0.01	0.02	0.19
Supervised Match 1	0.17	0.25	0.39
Supervised Match 2	0.19	0.28	0.48

Table 2: Even with a partial pronunciation dictionary, it is difficult to predict exact pronunciation of a new written character from its components. This table records accuracy of pronunciation guesses for characters 2001-3000 (by frequency), given pronunciations of characters 1-2000; for these types, *yù* is most frequent. Match 1 uses a character's second component, e.g., guessing (incorrectly) that 耗 (*hào*) is pronounced the same as 毛 (*mào*). Match 2 uses either the first or second component, whichever is better. Partial match credits either onset or rime, e.g., counting *hào* for *mào* as correct.

Source	Target	Tone?	Accuracy
Character	Pinyin	no	0.20%
Character	Pinyin	yes	0.05%
Pinyin	Character	no	0.15%
Pinyin	Character	yes	0.12%
Character word	Pinyin word	yes	81.41%

Table 3: Accuracy of vector-mapping approaches, measuring % of character tokens we assign the correct (no tone) *pinyin* pronunciation to. Testing is on the first 6059 characters of the character corpus.

same number of syllables as the written-word. If we cannot find a near neighbor with the correct number of syllables, we map to a sequence of *de*, the most common Chinese *pinyin* token.

We find that matched word pairs are much more accurate than the individual character-*pinyin* mappings we previously obtained.[11] To get token-level pronunciation accuracy, we segment our 6059-token character test set, apply our learned mapping table, and count how many characters are pronounced correctly. Table 3 shows that the accuracy of this method is 81.4%.

6 Unsupervised Noisy Channel EM Method

We next turn to a noisy-channel approach, following Knight and Yamada (1999). We consider our character sequence $C = c_1...c_n$ as derived from a hidden (no tone) pinyin sequence $P = p_1...p_n$:

$$\begin{aligned}&\text{argmax}_\theta \Pr(C) = \\ &\text{argmax}_\theta \sum_P \Pr(P) \cdot \Pr(C|P) = \\ &\text{argmax}_\theta \sum_P \Pr(P) \cdot \prod_{i=1}^{n} \Pr_\theta(c_i|p_i)\end{aligned}$$

$\Pr(P)$ is a fixed language model over *pinyin* sequences. $\Pr_\theta(c|p)$ values are modified to maximize the value of the whole expression. Examples of $\Pr_\theta(c|p)$ parameters are Pr(中 | *zhong*), which we hope to be relatively high, and Pr(很 | *zhong*), which we hope to be zero.

6.1 Previous Noisy-Channel

We first faithfully re-implement Knight and Yamada (1999). They drive decipherment using a bigram $\Pr(P)$, pruning *pinyin* pairs that occur few than 5 times.

Unfortunately, they do not provide their training data or code, giving only the number of character types as 2113, and the number of observed *pinyin* pair types as 1177 (after pruning pairs occurring fewer than 5 times). Using our own data, we estimate their character corpus at ~30,000 tokens.

We applied this re-implementation to our data. Their *pinyin*-pair pruning has little effect, due to the size of our *pinyin* corpus (155,219 unique pairs). We ran their expectation-maximization (EM) algorithm for 170 iterations on a character corpus of 300,000 tokens, then applied their decoding algorithm to our 6059-token test, obtaining a token pronunciation accuracy of 8.6%. Because this accuracy is lower than their reported 22%, we confirmed our results with two separate implementations, and we took the best of 10 random restarts. Increasing the character corpus size to 10m yielded a worse 5.1% accuracy. We conjecture that Knight and Yamada (1999) used more homogeneous data.

6.2 Our Noisy-Channel

In this work, we use a *pinyin*-trigram model (rather than bigram), and we apply efficiency tricks that allow us to scale to our large data.

First, we reduce our character data C to a list of unique triples C_{tri}, recording count($c_1c_2c_3$) for each triple. A sample character triple is "的 人 口" (count = 43485).

Likewise, we reduce our *pinyin* training data to triples, sorted by unsmoothed probability $\Pr(p)$ =

---

[11] Similar to Marchisio et al. (2020) and Kim et al. (2020), we note that unsupervised translation techniques require certain types of data to work well.

```
Given:
  Character triples $c_1c_2c_3 \in C_{tri}$, with counts
  Pinyin triples $p_1p_2p_3$, with probabilities

Produce:
  Values for $\text{Pr}_\theta(c|p)$

Do:
  initialize $\text{Pr}_\theta(c|p)$ table (uniform, random)
  for k = 1 to max_iterations
    initialize $\text{Pr}_k(C_{tri})$ = 1.0
    count($c$, $p$) = 0   (whole table)
    for each of top N character triples $c_1c_2c_3$
      sum = 0
      for each of top M pinyin triples $p_1p_2p_3$
        score($p_1p_2p_3$) =
          $\text{Pr}(p_1p_2p_3)\ \text{Pr}_\theta(c_1|p_1)\ \text{Pr}_\theta(c_2|p_2)\ \text{Pr}_\theta(c_3|p_3)$
        sum += score($p_1p_2p_3$)
      $\text{Pr}_k(C_{tri}) = \text{Pr}_k(C_{tri}) \cdot \text{sum}^{\text{count}(c_1c_2c_3)}$
      for each of top M pinyin triples $p_1p_2p_3$
        $\text{Pr}(p_1p_2p_3|c_1c_2c_3)$ = score($p_1p_2p_3$) / sum
        for i = 1 to 3
          count($c_i$, $p_i$) +=
            $\text{Pr}(p_1p_2p_3|c_1c_2c_3) \cdot \text{count}(c_1c_2c_3)$
    normalize count($c$, $p$) into $\text{P}_\theta(c|p)$
  return final $\text{Pr}_\theta(c|p)$ table
```

Figure 2: EM algorithm for revising $\text{Pr}_\theta(c|p)$ parameters (*pinyin*-to-character substitution probabilities) to iteratively improve the probability of observed character triples C. EM guarantees $\text{Pr}_i(C_{tri}) \geq \text{Pr}_{i-1}(C_{tri})$.

```
Given:
  Test character string $c_1...c_n$

Do:
  Standard Viterbi algorithm (Viterbi, 1967)
```

Figure 3: Pronouncing a character sequence $c_1...c_n$, using a *pinyin* bigram model $\text{Pr}(p_2|p_1)$ and EM-optimized $\text{Pr}_\theta(c|p)$ values.

N=M	EM iterations	Test accuracy
10k	20	29 - 44 %
10k	100	50 %
20k	20	37 - 46 %
20k	100	58 - 62 %
100k	100	71 %

Table 4: Accuracy of noisy-channel decoding after EM training. N is the number of unique character triples shown to EM, and M is the number of unique pinyin triples available to "explain" each character triple. Accuracy ranges denote multiple random restarts.

normalized count($p_1p_2p_3$). A sample *pinyin* triple is "*de ren kou*" (probability = $8{\cdot}10^{-6}$).

Our training objective now becomes:

$$\begin{aligned}
&\text{argmax}_\theta\ \text{Pr}(C_{tri}) = \\
&\text{argmax}_\theta\ \textstyle\prod_{c_1c_2c_3 \in C_{tri}} \text{Pr}(c_1c_2c_3) = \\
&\text{argmax}_\theta\ \textstyle\prod_{c_1c_2c_3 \in C_{tri}} \\
&\qquad \textstyle\sum_{p_1p_2p_3} \text{Pr}(p_1p_2p_3) \cdot \text{Pr}(c_1c_2c_3|p_1p_2p_3) = \\
&\text{argmax}_\theta\ \textstyle\prod_{c_1c_2c_3 \in C_{tri}} \\
&\qquad \textstyle\sum_{p_1p_2p_3} \text{Pr}(p_1p_2p_3) \cdot \\
&\qquad\qquad \text{Pr}_\theta(c_1|p_1)\text{Pr}_\theta(c_2|p_2)\text{Pr}_\theta(c_3|p_3)
\end{aligned}$$

Figure 2 gives an expectation-maximization (EM) algorithm for choosing $\text{Pr}_\theta(c|p)$ to find a local maximum in $\text{Pr}(C_{tri})$.

After we have obtained $\text{Pr}_\theta(c|p)$ values, we decode our 6059-character-token test sequence ($C = c_1...c_n$) using the standard Viterbi algorithm (Viterbi, 1967) Our decoding criterion is:

$$\begin{aligned}
&\text{argmax}_P\ \text{Pr}(P|C) = \\
&\text{argmax}_P\ \text{Pr}(P) \cdot \text{Pr}(C|P) = \\
&\text{argmax}_P\ \text{Pr}(P) \cdot \textstyle\prod_{i=1}^{n} \text{Pr}_\theta(c_i|p_i) \approx \\
&\text{argmax}_P\ \text{Pr}(P) \cdot \textstyle\prod_{i=1}^{n} \text{Pr}_\theta(c_i|p_i)^3
\end{aligned}$$

where $\text{Pr}(P)$ is implemented with a smoothed bigram *pinyin* model $\text{Pr}(p_2|p_1)$. Figure 3 gives the outline. While EM only considers the top M *pinyin* triples, final decoding works on entire sentences and is free to create previously-unseen *pinyin* trigrams. Decoding is also free to pronounce the same character in different ways, depending on its context. We follow the prior work in cubing channel model values.

Because different random restarts yield different accuracy results, we report ranges. We are generally able to identify the best restart in an unsupervised way, due to the high correlation between EM's objective $\text{Pr}(C_{tri})$ and test-set accuracy.

Table 4 shows decoding accuracy results. We achieve 71%, substantially beating the 22% accuracy reported by Knight and Yamada (1999), as well as the 8.6% of a re-implementation applied to our data.

7 Exploiting Character Components

We next investigate whether character components can improve EM results. Instead of storing

N=M	EM iterations	Test accuracy w/o hints	Test accuracy w/ hints
20k	20	37 - 46 %	72 - 73 % (+27%)
20k	100	58 - 62 %	72 % (+10%)
100k	100	71 %	81 % (+10%)

Table 5: Improving EM results by assigning high initial weights to the 261 agreed-on mappings ("hints") from EM and vector-based methods. Accuracy ranges are due to multiple random restarts.

$\mathrm{Pr}_\theta(c|p)$ in a single lookup table, we compute it from five lookup tables ($\mathrm{Pr}_1..\mathrm{Pr}_5$):

$$\begin{aligned}
&\mathrm{Pr}_\theta(c|p) = \\
&\quad \lambda_1 \cdot \mathrm{Pr}_1(c|p) + \\
&\quad \lambda_2 \cdot \mathrm{Pr}_2(part1(c)|p) \cdot \mathrm{Pr}_3(c|part1(c)) \\
&\quad \lambda_3 \cdot \mathrm{Pr}_4(part2(c)|p) \cdot \mathrm{Pr}_5(c|part2(c))
\end{aligned}$$

As EM establishes a tentative high value for Pr_1(排 | *pai*), we hope to also create a high value for Pr_4(非 | *pai*), which will encourage *pai* to map to other characters with component 非 (such as 徘) in the following EM iterations.

Unfortunately, while we do see compelling Pr_4 entries, we do not see an overall improvement in test-set accuracy from this method.

8 Combining EM and Vector Methods

The EM method gives 71% accuracy, while the vector method gives 81% accuracy. We find that the two methods agree 47% of time, and are 98.7% accurate in agreement cases, so in an unsupervised way, we distill out 261 high-confidence character/pinyin mappings.

Improved EM results. We use the 261 high-confidence (c, p) mappings as our initial start point, by replacing each one's random initial $\mathrm{P}_\theta(c|p)$ value with a 1.0 weight. These weights bias the fractional counting in the first EM iteration. Table 5 shows that high-confidence mappings increase overall EM accuracy from 71% to 81%.

Improved vector-based results. We run the same initial procedure from Section 5, giving us a vector space inhabited by both written words and *pinyin* words. However, we modify the nearest-neighbor search that produces word/pronunciation mappings. Our modified nearest-neighbor search takes a written word's vector and returns the nearest pronunciation vector that is consistent with the 261 high-confidence (c, p) mappings. For example, given the word 重要, we prefer neighbors *dang yao* and *zhong yao* over *dang pin*, because (要, *yao*) is one of the high-confidence mappings originally proposed by both EM and vector-based approaches. We also use high-confidence mappings to improve *de* sequences (Section 5). This combination technique is also highly effective, raising accuracy from 81% to 89%.

9 Conclusion

We implement and evaluate techniques to pronounce Chinese text in Mandarin, without the use of a pronunciation dictionary or parallel resource. The EM method achieves a test-set accuracy of 71%, while the vector-based method achieves 81%. By combining the two methods, we obtain 89% accuracy, which significantly exceeds that of prior work.

We also demonstrate that current methods for unsupervised matching of vector spaces are sensitive to the structure of the spaces. In the presence of one-to-many mappings between *pinyin* and characters, the mapping accuracy is severely downgraded, leaving open an opportunity to design more robust unsupervised vector mapping systems.

Abstract

Multi-hop reasoning has been widely studied in recent years to seek an effective and interpretable method for knowledge graph (KG) completion. Most previous reasoning methods are designed for dense KGs with enough paths between entities, but cannot work well on those sparse KGs that only contain sparse paths for reasoning. On the one hand, sparse KGs contain less information, which makes it difficult for the model to choose correct paths. On the other hand, the lack of evidential paths to target entities also makes the reasoning process difficult. To solve these problems, we propose a multi-hop reasoning model named **DacKGR** over sparse KGs, by applying novel dynamic anticipation and completion strategies: (1) The anticipation strategy utilizes the latent prediction of embedding-based models to make our model perform more potential path search over sparse KGs. (2) Based on the anticipation information, the completion strategy dynamically adds edges as additional actions during the path search, which further alleviates the sparseness problem of KGs. The experimental results on five datasets sampled from Freebase, NELL and Wikidata show that our method outperforms state-of-the-art baselines. Our codes and datasets can be obtained from `https://github.com/THU-KEG/DacKGR`.

1 Introduction

Knowledge graphs (KGs) represent the world knowledge in a structured way, and have been proven to be helpful for many downstream NLP tasks like query answering (Guu et al., 2015), dialogue generation (He et al., 2017) and machine reading comprehension (Yang et al., 2019). Despite their wide applications, many KGs still face serious incompleteness (Bordes et al., 2013), which limits their further development and adaption for related downstream tasks.

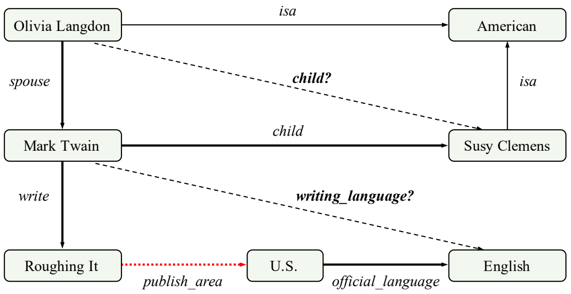

Figure 1: An illustration of multi-hop reasoning task over sparse KG. The missing relations (black dashed arrows) between entities can be inferred from existing triples (solid black arrows) through reasoning paths (bold arrows). However, some relations in the reasoning path are missing (red dashed arrows) in sparse KG, which makes multi-hop reasoning difficult.

To alleviate this issue, some embedding-based models (Bordes et al., 2013; Dettmers et al., 2018) are proposed, most of which embed entities and relations into a vector space and make link predictions to complete KGs. These models focus on efficiently predicting knowledge but lack necessary interpretability. In order to solve this problem, Das et al. (2018) and Lin et al. (2018) propose multi-hop reasoning models, which use the REINFORCE algorithm (Williams, 1992) to train an agent to search over KGs. These models can not only give the predicted result but also an interpretable path to indicate the reasoning process. As shown in the upper part of Figure 1, for a triple query (*Olivia Langdon*, *child*, ?), multi-hop reasoning models can predict the tail entity *Susy Clemens* through a reasoning path (bold arrows).

Although existing multi-hop reasoning models have achieved good results, they still suffer two problems on sparse KGs: (1) **Insufficient information**. Compared with normal KGs, sparse KGs

Table 1: The statistics of some benchmark KG datasets. #degree is the outgoing degree of every entity that can indicate the sparsity level.

contain less information, which makes it difficult for the agent to choose the correct search direction. (2) **Missing paths**. In sparse KGs, some entity pairs do not have enough paths between them as reasoning evidence, which makes it difficult for the agent to carry out the reasoning process. As shown in the lower part of Figure 1, there is no evidential path between *Mark Twain* and *English* since the relation *publish_area* is missing. From Table 1 we can learn that some sampled KG datasets are actually sparse. Besides, some domain-specific KGs (e.g., WD-singer) do not have abundant knowledge and also face the problem of sparsity.

As the performance of most existing multi-hop reasoning methods drops significantly on sparse KGs, some preliminary efforts, such as CPL (Fu et al., 2019), explore to introduce additional text information to ease the sparsity of KGs. Although these explorations have achieved promising results, they are still limited to those specific KGs whose entities have additional text information. Thus, reasoning over sparse KGs is still an important but not fully resolved problem, and requires a more generalized approach to this problem.

In this paper, we propose a multi-hop reasoning model named DacKGR, along with two dynamic strategies to solve the two problems mentioned above:

Dynamic Anticipation makes use of the limited information in a sparse KG to anticipate potential targets before the reasoning process. Compared with multi-hop reasoning models, embedding-based models are robust to sparse KGs, because they depend on every single triple rather than paths in KG. To this end, our anticipation strategy injects the pre-trained embedding-based model's predictions as anticipation information into the states of reinforcement learning. This information can guide the agent to avoid aimlessly searching paths.

Dynamic Completion temporarily expands the part of a KG to enrich the options of path expansion during the reasoning process. In sparse KGs, many entities only have few relations, which limits the choice spaces of the agent. Our completion strategy thus dynamically adds some additional relations (e.g., red dashed arrows in Figure 1) according to the state information of the current entity during searching reasoning paths. After that, for the current entity and an additional relation r, we use a pre-trained embedding-based model to predict tail entity e. Then, the additional relation r and the predicted tail entity e will form a potential action (r, e) and be added to the action space of the current entity for path expansion.

We conduct experiments on five datasets sampled from Freebase, NELL and Wikidata. The results show that our model DacKGR outperforms previous multi-hop reasoning models, which verifies the effectiveness of our model.

2 Problem Formulation

In this section, we first introduce some symbols and concepts related to normal multi-hop reasoning, and then formally define the task of multi-hop reasoning over sparse KGs.

Knowledge graph $\mathcal{KG}$ can be formulated as $\mathcal{KG} = \{\mathcal{E}, \mathcal{R}, \mathcal{T}\}$, where $\mathcal{E}$ and $\mathcal{R}$ denote entity set and relation set respectively. $\mathcal{T} = \{(e_s, r_q, e_o)\} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is triple set, where e_s and e_o are head and tail entities respectively, and r_q is the relation between them. For every KG, we can use the average out-degree D_{avg}^{out} of each entity (node) to define its sparsity. Specifically, if D_{avg}^{out} of a KG is larger than a threshold, we can say it is a dense or normal KG, otherwise, it is a sparse KG.

Given a graph $\mathcal{KG}$ and a triple query $(e_s, r_q, ?)$, where e_s is the source entity and r_q is the query relation, *multi-hop reasoning for knowledge graphs* aims to predict the tail entity e_o for $(e_s, r_q, ?)$. Different from previous KG embedding tasks, multi-hop reasoning also gives a supporting path $\{(e_s, r_1, e_1), (e_1, r_2, e_2) \ldots, (e_{n-1}, r_n, e_o)\}$ over $\mathcal{KG}$ as evidence. As mentioned above, we mainly focus on the multi-hop reasoning task over sparse KGs in this paper.

3 Methodology

In this section, we first introduce the whole reinforcement learning framework for multi-hop reasoning, and then detail our two strategies designed for the sparse KGs, i.e., dynamic anticipation and dynamic completion. The former strategy intro-

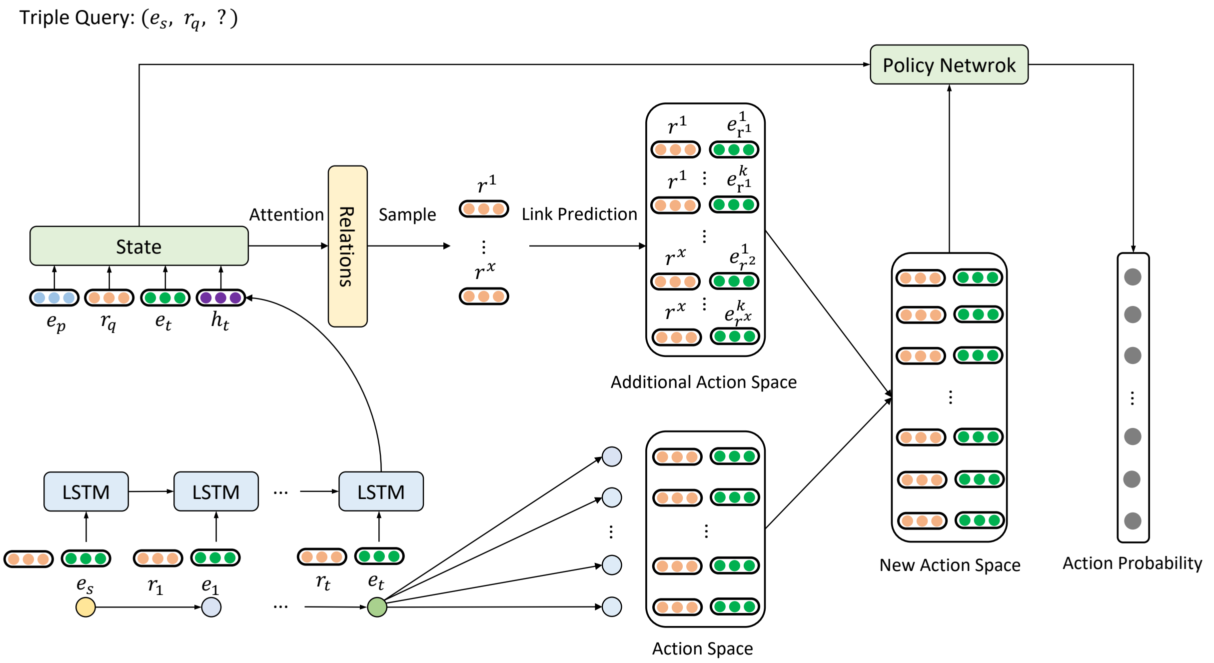

Figure 2: An illustration of our policy network with dynamic anticipation and dynamic completion strategies. The vector of e_p is the prediction information introduced in Section 3.3. We use the current state to dynamically select some relations, and use the pre-trained embedding-based model to perform link prediction to obtain additional action space. The original action space will be merged with the additional action space to form a new action space.

duces the guidance information from embedding-based models to help multi-hop models find the correct direction on sparse KGs. Based on this strategy, the dynamic completion strategy introduces some additional actions during the reasoning process to increase the number of paths, which can alleviate the sparsity of KGs. Following Lin et al. (2018), the overall framework of DacKGR is illustrated in Figure 2.

3.1 Reinforcement Learning Framework

In recent years, multi-hop reasoning for KGs has been formulated as a Markov Decision Process (MDP) over $\mathcal{KG}$ (Das et al., 2018): given a triple query $(e_s, r_q, ?)$, the agent needs to start from the head entity e_s, continuously select the edge (relation) corresponding to the current entity with maximum probability as the direction, and jump to the next entity until the maximum number of hops T. Following previous work (Lin et al., 2018), the MDP consists of the following components:

State In the process of multi-hop reasoning, which edge (relation) the agent chooses depends not only on the query relation r_q and the current entity e_t, but also on the previous historical searching path. Therefore, the state of the t-th hop can be defined as $s_t = (r_q, e_t, h_t)$, where h_t is the representation of the historical path. Specifically, we use an LSTM to encode the historical path information, h_t is the output of LSTM at the t-th step.

Action For a state $s_t = (r_q, e_t, h_t)$, if there is a triple (e_t, r_n, e_n) in the KG, (r_n, e_n) is an action of the state s_t. All actions of the state s_t make up its action space $\mathcal{A}_t = \{(r, e)|(e_t, r, e) \in \mathcal{T}\}$. Besides, for every state s_t, we also add an additional action (r_{LOOP}, e_t), where *LOOP* is a manually added self-loop relation. It allows the agent to stay at the current entity, which is similar to a "STOP" action.

Transition If the current state is $s_t = (r_q, e_t, h_t)$ and the agent chooses $(r_n, e_n) \in \mathcal{A}_t$ as the next action, then the current state s_t will be converted to $s_{t+1} = (r_q, e_n, h_{t+1})$. In this paper, we limit the maximum number of hops to T, and the transition will end at the state $s_T = (r_q, e_T, h_T)$.

Reward For a given query $(e_s, r_q, ?)$ with the golden tail entity e_o, if the agent finally stops at the correct entity, i.e., $e_T = e_o$, the reward is one, otherwise, the reward is a value between 0 and 1 given by the function $f(e_s, r_q, e_T)$, where the function f is given by a pre-trained knowledge graph embedding (KGE) model for evaluating the correctness of the triple (e_s, r_q, e_T).

3.2 Policy Network

For the above MDP, we need a policy network to guide the agent to choose the correct action in different states.

We represent entities and relations in $\mathcal{KG}$ as vectors in a semantic space, and then the action (r, e) at the step t can be represented as $\mathbf{a}_t = [\mathbf{r}; \mathbf{e}]$, where $\mathbf{r}$ and $\mathbf{e}$ are the vectors of r and e respectively. As we mentioned in Section 3.1, we use an LSTM to store the historical path information. Specifically, the representation of each action selected by the agent will be fed into the LSTM to generate historical path information so far,

$$\mathbf{h}_t = \text{LSTM}(\mathbf{h}_{t-1}, \mathbf{a}_{t-1}). \tag{1}$$

The representation of the t-th state $s_t = (r_q, e_t, h_t)$ can be formulated as

$$\mathbf{s}_t = [\mathbf{r}_q; \mathbf{e}_t; \mathbf{h}_t]. \tag{2}$$

After that, we represent the action space by stacking all actions in $\mathcal{A}_t$ as $\mathbf{A}_t \in \mathbb{R}^{|\mathcal{A}_t| \times 2d}$, where d is the dimension of the entity and relation vector. The policy network is defined as,

$$\pi_\theta(a_t|s_t) = \sigma(\mathbf{A}_t(\mathbf{W}_1 \text{ReLU}(\mathbf{W}_2 \mathbf{s}_t))), \tag{3}$$

where σ is the softmax operator, $\mathbf{W}_1$ and $\mathbf{W}_2$ are two linear neural networks, and $\pi_\theta(a_t|s_t)$ is the probability distribution over all actions in $\mathcal{A}_t$.

3.3 Dynamic Anticipation

As reported in previous work (Das et al., 2018; Lin et al., 2018), although the KGE models are not interpretable, they can achieve better results than the multi-hop reasoning models on most KGs. This phenomenon is more obvious on the sparse KG (refer to experimental results in Table 3) since KGE models are more robust as they do not rely on the connectivity of the KGs.

Inspired by the above phenomenon, we propose a new strategy named *dynamic anticipation*, which introduces the prediction information of the embedding-based models into the multi-hop reasoning models to guide the model learning. Specifically, for a triple query $(e_s, r_q, ?)$, we use the pretrained KGE models to get the probability vector of all entities being the tail entity. Formally, the probability vector can be formulated as $\mathbf{p} \in \mathbb{R}^{|\mathcal{E}|}$, where the value of the i-th dimension of $\mathbf{p}$ represents the probability that e_i is the correct tail entity.

For the dynamic anticipation strategy, we change the state representation in Equation 2 to:

$$\mathbf{s}_t = [\mathbf{e}_p; \mathbf{r}_q; \mathbf{e}_t; \mathbf{h}_t], \tag{4}$$

where $\mathbf{e}_p$ is prediction information given by KGE models. In this paper, we use the following three strategies to generate $\mathbf{e}_p$: (1) Sample strategy. We sample an entity based on probability distribution $\mathbf{p}$ and denote its vector as $\mathbf{e}_p$. (2) Top-one strategy. We select the entity with the highest probability in $\mathbf{p}$. (3) Average strategy. We take the weighted average of the vectors of all entities according to the probability distribution $\mathbf{p}$ as the prediction information $\mathbf{e}_p$. In experiments, we choose the strategy that performs best on the valid set.

3.4 Dynamic Completion

In sparse KGs, there are often insufficient evidential paths between head and tail entities, so that the performance of multi-hop reasoning models will drop significantly.

In order to solve the above problems, we propose a strategy named *dynamic completion* to dynamically augment the action space of each entity during reasoning process. Specifically, for the current state s_t, its candidate set of additional actions can be defined as $C_t = \{(r, e) | r \in \mathcal{R} \wedge e \in \mathcal{E} \wedge (e_t, r, e) \notin \mathcal{T}\}$. We need to select some actions with the highest probability from C_t as additional actions, where the probability can be defined as:

$$p((r, e)|s_t) = p(r|s_t) p(e|r, s_t). \tag{5}$$

However, the candidate set C_t is too large, it will be time-consuming to calculate the probability of all actions in C_t, so we adopt an approximate pruning strategy. Specifically, We first select some relations with the highest probability using $p(r|s_t)$, and then select entities with the highest probability for these relations using $p(e|r, s_t)$.

For the current state s_t, we calculate the attention value over all relations as $p(r|s_t)$,

$$\mathbf{w} = \text{Softmax}(\text{MLP}(\mathbf{s}_t) \cdot [\mathbf{r}_1, \cdots, \mathbf{r}_{|\mathcal{R}|}]). \tag{6}$$

We define a parameter α to control the proportion of actions that need to be added. Besides, we also have a parameter M which represents the maximum number of additional actions. Therefore, the number of additional actions can be defined as,

$$N_{add} = min(\lceil \alpha N \rceil, M), \tag{7}$$

where N is the action space size of the current state. After we have the attention vector $\mathbf{w}$, we select top x relations with the largest attention values in $\mathbf{w}$ to form a new relation set $\mathcal{R}_{add} = \{r^1, r^2, \cdots, r^x\}$.

Dataset	#Ent	#Rel	#Fact	#degree	
				mean	median
FB15K-237-10%	11,512	237	60,985	5.8	4
FB15K-237-20%	13,166	237	91,162	7.5	5
FB15K-237-50%	14,149	237	173,830	13.0	13
NELL23K	22,925	200	35,358	2.21	1
WD-singer	10,282	135	20,508	2.35	2

Table 2: Statistics of five datasets in experiments.

For every relation $r^i \in \mathcal{R}_{add}$ and the current entity e_t, we use the pre-trained KGE models to predict the probability distribution of the tail entity for triple query $(e_t, r^i, ?)$ as $p(e|r^i, s_t)$. We only keep the k entities with the highest probability, which form k additional actions $\{(r^i, e^1_{ri}), \cdots, (r^i, e^k_{ri})\}$ for triple query $(e_t, r^i, ?)$. Finally, all additional actions make up the additional action space $\mathcal{A}_t^{add}$ for s_t. Here, k is a parameter, and x can be calculated using previous parameters,

$$x = \lceil N_{add}/k \rceil. \tag{8}$$

During the multi-hop reasoning process, we dynamically generate the additional action space $\mathcal{A}_t^{add}$ for every state s_t. This additional action space will be added to the original action space $\mathcal{A}_t$ and make up a new larger action space,

$$\mathcal{A}_t = \mathcal{A}_t + \mathcal{A}_t^{add}. \tag{9}$$

Based on the previous dynamic anticipation strategy, the dynamic completion strategy can generate more accurate action space since the state contains more prediction information.

3.5 Policy Optimization

We use the typical REINFORCE (Williams, 1992) algorithm to train our agent and optimize the parameters of the policy network. Specifically, the training process is obtained by maximizing the expected reward for every triple query in the training set,

$$J(\theta) = \mathbb{E}_{(e_s,r,e_o)\in\mathcal{KG}}\mathbb{E}_{a_1,\ldots,a_{T-1}\in\pi_\theta}[R(s_T|e_s,r)]. \tag{10}$$

The parameters θ of the policy network are optimized as follow,

$$\begin{aligned} \nabla_\theta J(\theta) &\approx \nabla_\theta \sum_t R(s_T|e_s,r)\log \pi_\theta(a_t|s_t) \\ \theta &= \theta + \beta \nabla_\theta J(\theta), \end{aligned} \tag{11}$$

where β is the learning rate.

4 Experiments

4.1 Datasets

In this paper, we use five datasets sampled from Freebase (Bollacker et al., 2008), NELL (Carlson et al., 2010) and Wikidata (Vrandečić and Krötzsch, 2014) for experiments. Specifically, in order to study the performance of our method on KGs with different degrees of sparsity, we constructed three datasets based on FB15K-237 (Toutanova et al., 2015), i.e., FB15K-237-10%, FB15K-237-20% and FB15K-237-50%. These three datasets randomly retain 10%, 20% and 50% triples of FB15K-237 respectively.

In addition, we also construct two datasets NELL23K and WD-singer from NELL and Wikidata, where WD-singer is a dataset of singer domain from Wikidata. For NELL23K, we first randomly sample some entities from NELL and then sample triples containing these entities to form the dataset. For WD-singer, we first find all concepts related to singer in Wikidata, then use the entities corresponding to these concepts to build the entity list. After that, we expand the entity list appropriately, and finally use the triples containing entities in the entity list to form the final dataset. The statistics of our five datasets are listed in Table 2.

4.2 Experiment Setup

Baseline Models In our experiments, we select some KGE models and multi-hop reasoning models for comparison. For embedding-based models, we compared with TransE (Bordes et al., 2013), DistMult (Yang et al., 2015), ConvE (Dettmers et al., 2018) and TuckER (Balazevic et al., 2019). For multi-hop reasoning, we evaluate the following five models [1], Neural Logical Programming (NeuralLP) (Yang et al., 2017), Neural Theorem Prover (NTP) (Rocktäschel and Riedel, 2017), MINERVA (Das et al., 2018), MultiHopKG (Lin et al., 2018) and CPL [2] (Fu et al., 2019) . Besides, our model has three variations, DacKGR (sample), DacKGR (top) and DacKGR (avg), which use sample, top-one and average strategy (introduced in Section 3.3) respectively.

Evaluation Protocol For every triple (e_s, r_q, e_o) in the test set, we convert it to a triple query $(e_s, r_q, ?)$, and then use embedding-based models

---

[1] M-walk does not provide the necessary source codes and we do not compare with it.

[2] CPL can not run on NELL23K since its entities do not have additional text information.

Table 3: Link prediction results on five datasets from Freebase, NELL and Wikidata. @3 and @10 denote Hits@3 and Hits@10 metrics, respectively. All metrics are multiplied by 100. The best score of multi-hop reasoning models is in **bold**, and the best score of embedding-based models is underlined.

or multi-hop reasoning models to get the ranking list of the tail entity. Following the previous work (Bordes et al., 2013), we use the "filter" strategy in our experiments. We use two metrics: (1) the mean reciprocal rank of all correct tail entities (MRR), and (2) the proportion of correct tail entities ranking in the top K (Hits@K) for evaluation.

Implementation Details In our implementation, we set the dimension of the entity and relation vectors to 200, and use the ConvE model as the pre-trained KGE for both dynamic anticipation and dynamic completion strategies. In addition, we use a 3-layer LSTM and set its hidden dimension to 200. Following previous work (Das et al., 2018), we use Adam (Kingma and Ba, 2014) as the optimizer. For the parameters α, M and k in the dynamic completion strategy, we choose them from {0.5, 0.33, 0.25, 0.2}, {10, 20, 40, 60} and {1, 2, 3, 5} respectively. We select the best hyperparameters via grid search according to Hits@10 on the valid dataset. Besides, for every triple (e_s, r_q, e_o) in the training set, we also add a reverse triple (e_o, r_q^{inv}, e_s).

4.3 Link Prediction Results

The left part of Table 3 shows the link prediction results on FB15K-237-10%, FB15K-237-20% and FB15K-237-50%. From the table, we can learn that our model outperforms previous multi-hop reasoning models on these three datasets, especially on FB15K-237-10%, where our model gains significant improvements compared with the best multi-hop reasoning baseline MultiHopKG (which is about 56.0% relative improvement on Hits@10).

When we compare the experimental results on these three datasets horizontally (from right to left in Table 3), we can find that as the KG becomes sparser, the relative improvement of our model compared with the baseline models is more prominent. This phenomenon shows that our model is more robust to the sparsity of the KG compared to the previous multi-hop reasoning model.

As shown in previous work (Lin et al., 2018; Fu et al., 2019), KGE models often achieve better results than multi-hop reasoning models. This phenomenon is more evident on sparse KGs. The results of these embedding-based models are only used as reference because they are different types of models from multi-hop reasoning and are not interpretable.

The right part of Table 3 shows the link prediction results on NELL23K and WD-singer. From the table, we can find a phenomenon similar to that in the left part of Table 3. Our model performs better than previous multi-hop reasoning models, which indicates that our model can be adapted to many other knowledge graphs.

From the last three rows of Table 3, we can learn that the sample strategy in Section 3.3 performs better than top-one and average strategies in most cases. This is because these two strategies lose some information. The top-one strategy only retains the entity with the highest probability. The average strategy uses a weighted average of entity vectors, which may cause the features of different vectors to be canceled out.

4.4 Ablation Study

In this paper, we design two strategies for sparse KGs. In order to study the contributions of these two strategies to the performance of our model,

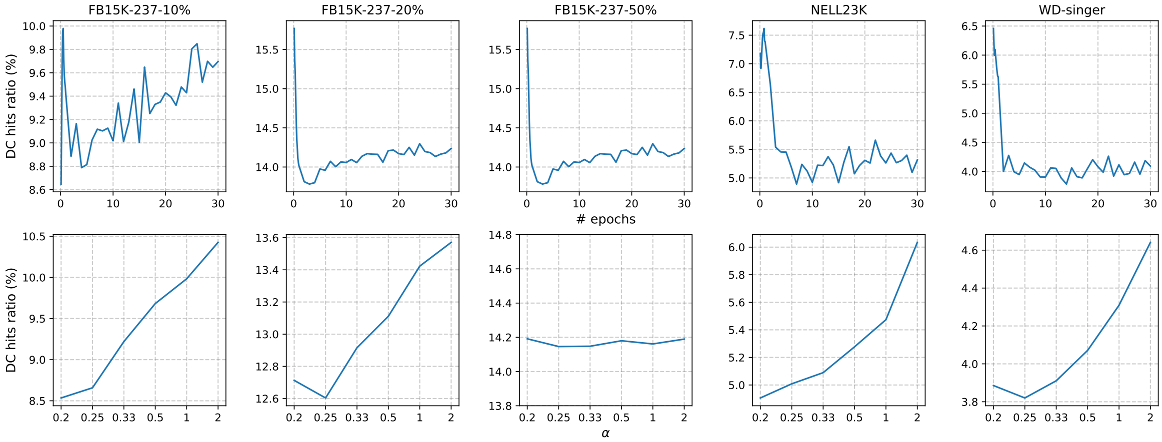

Figure 3: The top and bottom rows show the DC hits ratio change w.r.t. #epoch and α respectively.

Model	MRR	Hits@1	Hits@3	Hits@10
MultiHopKG	23.0	16.9	25.2	35.5
DacKGR (w/o DC)	23.5	17.2	25.8	36.5
DacKGR (w/o DA)	24.2	17.7	26.6	37.9
DacKGR	**24.7**	**17.8**	**27.2**	**39.1**

Table 4: Ablation study results on FB15K-237-20%. DC and DA denote dynamic completion and dynamic anticipation strategy respectively.

we conduct an ablation experiment by removing dynamic anticipation (DA) or dynamic completion (DC) strategy on FB15K-237-20% dataset.

As shown in Table 4, removing either the DA or DC strategy will reduce the effectiveness of the model, which demonstrates that both strategies contribute to our model. Moreover, we can learn that using either strategy individually will enable our model to achieve better results than the baseline model. Specifically, the model using the DC strategy alone performs better than the model using the DA strategy alone, which is predictable, since the DA strategy only allows the agent to make a correct choice, and will not substantially alleviate the sparsity of KGs.

4.5 Analysis

In the dynamic completion (DC) strategy, we dynamically provide some additional actions for every state, which enrich the selection space of the agent and ease the sparsity of KGs. However, will the agent choose these additional actions, or in other words, do these additional actions really work?

In this section, we analyze the results of the DC hits ratio, which indicates the proportion of the agent selecting additional actions (e.g., choosing actions in $\mathcal{A}_t^{add}$ for s_t). In the first step, we analyze the change of DC hits ratio as the training progresses, which is shown in the first row of Figure 3. From this figure, we can learn that for most KGs (except FB15K-237-10%), DC hits ratio is relatively high at the beginning of training, then it will drop sharply and tend to stabilize. This is reasonable because there is some noise in the additional actions. In the beginning, the agent cannot distinguish the noise part and choose them as the same as the original action. But as the training proceeds, the agent can identify the noise part, and gradually reduces the selection ratio of additional actions. For FB15K-237-10%, DC hits ratio will decrease first and then increase. This is because many triples have been removed in FB15K-237-10%, which exacerbates the incompleteness of the dataset. The additional actions work more effectively in this situation and increase the probability of correct reasoning.

In the second row of the Figure 3, we give the effect of parameter α (indicates the proportion of actions that need to be added) described in Section 3.4 on the DC hits ratio. Specifically, We use the average DC hits ratio results of the last five epochs as the final result. From this figure, we can find that for most datasets, DC hits ratio will gradually increase as α increases. This is as expected because a larger α means more additional actions, and the probability that they are selected will also increase. It is worth noting that on the FB15K-237-50%, DC hits ratio hardly changes with α. This is because the sparsity of FB15K-237-50% is not severe and does not rely on additional actions.

4.6 Case Study

In Table 5, we give an example of triple query and three reasoning paths with the top-3 scores given

	Triple query: *(Kirkby Lunn, country of citizenship, ?)*
1	$\textit{Kirkby Lunn} \xrightarrow{\textbf{\textit{place of burial}}} \textbf{\textit{London}} \xrightarrow{\textit{country}} \textit{United Kingdom} \xrightarrow{\textit{LOOP}} \underline{\textit{United Kingdom}}$
2	$\textit{Kirkby Lunn} \xrightarrow{\textit{student of}} \textit{Jacques Bouhy} \xrightarrow{\textit{country of citizenship}} \textit{Belgium} \xrightarrow{\textit{LOOP}} \textit{Belgium}$
3	$\textit{Kirkby Lunn} \xrightarrow{\textit{student of}} \textit{Albert Visetti} \xrightarrow{\textit{student}} \textit{Agnes Nicholls} \xrightarrow{\textit{country of citizenship}} \underline{\textit{United Kingdom}}$

Table 5: Case study of our model on link prediction experiment. For the triple query, we show the three reasoning paths with the top-3 scores via beam search. The relation and entity in **bold** are additional actions generated using dynamic completion strategy. The correct entities for the triple query are underline.

by our model DacKGR. From the first path, we can learn that our dynamic completion strategy can provide agents with some additional actions that are not in the dataset, and further form a reasoning path. Besides, as shown in the third path, DacKGR can also use the paths that exist in the KG to perform multi-hop reasoning.

5 Related Work

5.1 Knowledge Graph Embedding

Knowledge graph embedding (KGE) aims to represent entities and relations in KGs with their corresponding low-dimensional embeddings. It then defines a score function $f(e_s, r_q, e_t)$ with embeddings to measure the correct probability of each triple. Specifically, most KGE models can be divided into three categories (Wang et al., 2017): (1) Translation-based models (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015; Sun et al., 2018) formalize the relation as a translation from a head entity to a tail entity, and often use distance-based score functions derived from these translation operations. (2) Tensor-factorization based models (Nickel et al., 2011; Yang et al., 2015; Balazevic et al., 2019) formulate KGE as a three-way tensor decomposition task and define the score function according to the decomposition operations. (3) Neural network models (Socher et al., 2013; Dettmers et al., 2018; Nguyen et al., 2018; Shang et al., 2019) usually design neural network modules to enhance the expressive abilities. Generally, given a triple query $(e_s, r_q, ?)$, KGE models select the entity e_o, whose score function $f(e_s, r_q, e_o)$ has the highest score as the final prediction. Although KGE models are efficient, they lack interpretability of their predictions.

5.2 Multi-Hop Reasoning

Different from embedding-based models, multi-hop reasoning for KGs aims to predict the tail entity for every triple query $(e_s, r_q, ?)$ and meanwhile provide a reasoning path to support the prediction. Before multi-hop reasoning task is formalized, there are some models on relation path reasoning task, which aims to predict the relation between entities like $(e_s, ?, e_o)$ using path information. DeepPath (Xiong et al., 2017) first adopts reinforcement learning (RL) framework for relation path reasoning, which inspires much later work (e.g., DIVA (Chen et al., 2018) and AttnPath (Wang et al., 2019)).

MINERVA (Das et al., 2018) is the first model that uses REINFORCE algorithm to do the multi-hop reasoning task. To make the training process of RL models stable, Shen et al. propose M-Walk to solve the reward sparsity problem using off-policy learning. MultiHopKG (Lin et al., 2018) further improves MINERVA using action dropout and reward shaping. Lv et al. (2019) propose MetaKGR to address the new task that multi-hop reasoning on few-shot relations. In order to adapt RL models to a dynamically growing KG, Fu et al. (2019) propose CPL to do multi-hop reasoning and fact extraction jointly. In addition to the above RL-based reasoning models, there are some other neural symbolic models for multi-hop reasoning. NTP (Rocktäschel and Riedel, 2017) and NeuralLP (Yang et al., 2017) are two end-to-end reasoning models that can learn logic rules from KGs automatically.

Compared with KGE models, multi-hop reasoning models sacrifice some accuracy for interpretability, which is beneficial to fine-grained guidance for downstream tasks.

6 Conclusion

In this paper, we study the task that multi-hop reasoning over sparse knowledge graphs. The performance of previous multi-hop reasoning models on sparse KGs will drop significantly due to the lack of evidential paths. In order to solve this problem, we propose a reinforcement learning model named DacKGR with two strategies (i.e., dynamic anticipation and dynamic completion) designed for sparse KGs. These strategies can ease the sparsity of KGs. In experiments, we verify the effectiveness of DacKGR on five datasets. Experimental results show that our model can alleviate the sparsity of KGs and achieve better results than previous multi-hop reasoning models. However, there is still some noise in the additional actions given by our model. In future work, we plan to improve the quality of the additional actions.

Abstract

Capturing associations for knowledge graphs (KGs) through entity alignment, entity type inference and other related tasks benefits NLP applications with comprehensive knowledge representations. Recent related methods built on Euclidean embeddings are challenged by the hierarchical structures and different scales of KGs. They also depend on high embedding dimensions to realize enough expressiveness. Differently, we explore with low-dimensional hyperbolic embeddings for knowledge association. We propose a hyperbolic relational graph neural network for KG embedding and capture knowledge associations with a hyperbolic transformation. Extensive experiments on entity alignment and type inference demonstrate the effectiveness and efficiency of our method.

1 Introduction

Knowledge graphs (KGs) have emerged as the driving force of many NLP applications, e.g., KBQA (Hixon et al., 2015), dialogue generation (Moon et al., 2019) and narrative prediction (Chen et al., 2019). Different KGs are usually extracted from separate data sources or contributed by people with different expertise. Therefore, it is natural for these KGs to constitute complementary knowledge of the world that can be expressed in different languages, structures and levels of specificity (Lehmann et al., 2015; Speer et al., 2017). Associating multiple KGs via entity alignment (Chen et al., 2017) or type inference (Hao et al., 2019) particularly provides downstream applications with more comprehensive knowledge representations.

Entity alignment and type inference seek to find two kinds of knowledge associations, i.e., *sameAs* and *instanceOf*, respectively. An example showing such associations is given in Figure 1. Specifically, *entity alignment* is to find equivalent entities from different entity-level KGs, such as *United States* in DBpedia and *United States of America* in Wikidata. *Type inference*, on the other hand, associates a specific entity with a concept describing its type information, such as *United States* and *Country*. The main difference lies in whether such knowledge associations express the same level of specificity or not. Challenged by the diverse schemata, relational structures and granularities of knowledge representations in different KGs (Nikolov et al., 2009), traditional symbolic methods usually fall short of supporting heterogeneous knowledge association (Suchanek et al., 2011; Lacoste-Julien et al., 2013; Paulheim and Bizer, 2013). Recently, increasing efforts have been put into exploring embedding-based methods (Chen et al., 2017; Trivedi et al., 2018; Jin et al., 2019). Such methods capture the associations of entities or concepts in a vector space, which can help overcome the symbolic and schematic heterogeneity (Sun et al., 2017).

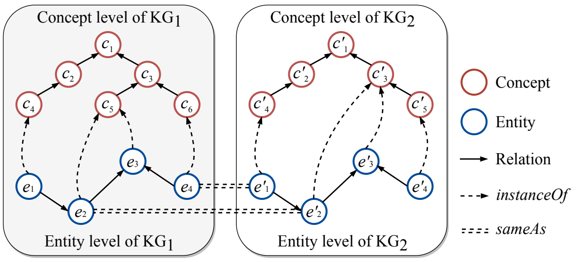

Figure 1: Illustration of two kinds of knowledge associations (i.e., *sameAs* and *instanceOf*) in KGs.

Embedding-based knowledge association methods still face challenges in the following aspects. (i) *Hierarchical structures.* A KG usually consists of many local hierarchical structures (Hu et al., 2015). Besides, a KG also usually comes with an ontology to manage the relations (e.g., *subClassOf*) of concepts (Hao et al., 2019), which typically forms hierarchical structures as illustrated in Figure 1. It is particularly difficult to preserve such hierarchical structures in a linear embedding space (Nickel et al., 2014). (ii) *High parameter complexity.* To enhance

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5704–5716,
November 16–20, 2020. ©2020 Association for Computational Linguistics

the expressiveness of KG embeddings, many methods require high embedding dimensions, which inevitably cause excessive memory consumption and intractable parameter complexity. For example, for the entity alignment method GCN-Align (Wang et al., 2018), the embedding dimension is selected to be as large as $1,000$. Reducing the dimensions can effectively decrease memory cost and training time. (iii) *Different scales.* The KGs that we manipulate may differ in scales. For example, while the English DBpedia contains $4,233,000$ entities, its ontology only contains less than a thousand concepts. Capturing the associations between entities and concepts has to deal with drastically different scales of structures and search spaces, while most existing methods do not consider such difference.

To tackle these challenges, we propose a novel hyperbolic knowledge association method, namely HyperKA, inspired by the recent success of hyperbolic representation learning (Nickel and Kiela, 2017; Dhingra et al., 2018; Tifrea et al., 2019). Unlike the Euclidean circle circumference that grows linearly w.r.t. the radius, the hyperbolic space grows exponentially with the radius. This property makes the hyperbolic geometry particularly suitable for embedding the hierarchical structures that drastically span their sizes along with their levels. It is also capable of achieving superior expressiveness at a low dimension. To leverage such merit, HyperKA employs a hyperbolic relational graph neural network (GNN) for KG embedding and captures multi-granular knowledge associations with a hyperbolic transformation between embedding spaces. For each KG, HyperKA first incorporates hyperbolic translational embeddings at the input layer of the GNN. Then, several hyperbolic graph convolution layers are stacked over the inputs to aggregate neighborhood information and obtain the final embeddings of entities or concepts. On top of the KG embeddings, a hyperbolic transformation is jointly trained to capture the associations. We conduct extensive experiments on entity alignment and type inference. HyperKA outperforms SOTA methods on both tasks at a moderate dimension (e.g., 50 or 75). Even with a small dimension (e.g., 10), our method still shows competitive performance.

2 Background

2.1 Knowledge Association

Knowledge association aims at capturing the correspondence between structured knowledge that is described under the same or different specificity. In this paper, we consider two knowledge association tasks, i.e., *entity alignment* between two entity-level KGs and *type inference* from an entity-level KG to an ontological one. We define a KG as a 3-tuple $\mathcal{K} = \{\mathcal{E}, \mathcal{R}, \mathcal{T}\}$, where $\mathcal{E}$ denotes the set of objects such as entities or concepts. $\mathcal{R}$ denotes the set of relations and $\mathcal{T} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ denotes the set of triples. Each triple $\tau = (h, r, t)$ records a relation r between the head and tail objects h and t. On top of this, the associations between two entity-level KGs (or between one entity-level and one ontological KGs) $\mathcal{K}_1 = \{\mathcal{E}_1, \mathcal{R}_1, \mathcal{T}_1\}$ and $\mathcal{K}_2 = \{\mathcal{E}_2, \mathcal{R}_2, \mathcal{T}_2\}$ are defined as $\mathcal{A} = \{(i, j) \in \mathcal{E}_1 \times \mathcal{E}_2 \,|\, i \rightarrow j\}$, where $\rightarrow$ denotes a kind of associations, such as the *sameAs* relationship for entity alignment or the *instanceOf* relationship in the case of type inference. A small subset of associations $\mathcal{A}^+ \subset \mathcal{A}$ are usually given as training data and we aim at finding the remaining.

2.2 Related Work

Knowledge association tasks and methods. Entity alignment or type inference between KGs can be viewed as a knowledge association task. A typical method of entity alignment is MTransE (Chen et al., 2017). It jointly conducts translational embedding learning (Bordes et al., 2013) and alignment learning to capture the matches of entities based on embedding distances or transformations. As for type inference, JOIE (Hao et al., 2019) deploys a similar framework to learn associations between entities and concepts. Later studies explore with three lines of techniques for improvement. (i) *KG embedding*. Besides translational embeddings, some studies employ other relational learning techniques such as circular correlations (Hao et al., 2019; Shi and Xiao, 2019), recurrent skipping networks (Guo et al., 2019), and adversarial learning (Pei et al., 2019a,b; Lin et al., 2019). Others employ various GNNs to seize the relatedness of entities based on neighborhood information, including GCN (Wang et al., 2018; Cao et al., 2019), GAT (Zhu et al., 2019; Li et al., 2019; Mao et al., 2020) and relational GCNs (Wu et al., 2019a,b; Sun et al., 2020a). These techniques seek to better induce embeddings with more comprehensive relational modeling. Other studies for ontology embeddings (Lv et al., 2018; Dong et al., 2019) consider relative positions between spheres as the hierarchical relationships of corresponding concepts. However, they are still limited to linear embeddings, hence may easily fall short of preserving the deep hierarchical structures of KGs. (ii) *Auxiliary information*. Besides relational structures, some studies characterize entities based on auxiliary information, including numerical attributes (Sun et al., 2017; Trisedya et al., 2019), literals (Gesese et al., 2019; Zhang et al., 2019) and descriptions (Yang et al., 2019; Chen et al., 2018; Jin et al., 2019). They capture associations based on alternative resources, but are also challenged by the less availability of auxiliary information in many KGs (Speer et al., 2017; Mitchell et al., 2018). (iii) *Semi-supervised learning*. Another group of studies seek to infer associations with limited supervision, including self-learning (Sun et al., 2018, 2019; Zhu et al., 2019) and co-training (Chen et al., 2018). These methods are competent in inferring one-to-one entity alignment, without consideration of associations between entities and concepts. A recent survey by Sun et al. (2020b) has systematically summarized all three lines of studies.

Hyperbolic representation learning. Different from Euclidean embeddings, some studies explore to characterize structures in hyperbolic embedding spaces, and use the non-linear hyperbolic distance to capture the relations between objects (Nickel and Kiela, 2017; Sala et al., 2018). This technique has shown promising performance in embedding hierarchical data, e.g., co-purchase records (Vinh et al., 2018), taxonomies (Le et al., 2019; Aly et al., 2019) and organizational charts (Chen and Quirk, 2019). Further work extends hyperbolic embeddings to capture relational hierarchies of sentences (Dhingra et al., 2018), neighborhood aggregation (Chami et al., 2019; Liu et al., 2019) and missing triples of a KG (Kolyvakis et al., 2020; Balazevic et al., 2019). These studies mainly focus on the scenario of a single independent structure. Learning associations across multiple KG structures with hyperbolic embeddings is still an unsolved issue, which is exactly the focus of this paper.

3 Hyperbolic Geometry

The hyperbolic space is one of the three kinds of isotropic spaces. Table 1 lists some key properties of the Euclidean (flat), spherical (positively curved) and hyperbolic (negatively curved) spaces. Compared with the Euclidean and spherical spaces, the amount of space covered by a hyperbolic geometry increases exponentially rather than polynomially w.r.t. the radius. This property allows us to capture KG structures at a very low dimension, and particularly suits those forming hierarchies. For the hyperbolic geometry, there are several important models including the hyperboloid model (Reynolds, 1993), Klein disk model (Nielsen and Nock, 2014) and Poincaré ball model (Cannon et al., 1997). In this paper, we choose the Poincaré ball model due to its feasibility for gradient optimization (Balazevic et al., 2019). Specifically, the n-dimensional Poincaré ball with a negative curvature $-c$ ($c > 0$) is defined by the manifold $\mathbb{D}^{n,c} = \{x \in \mathbb{R}^n \mid \|x\| < \frac{1}{c}\}$. For simplicity, we follow (Ganea et al., 2018) and let $c = 1$. We hereby introduce some basic operations of hyperbolic geometry, which we use extensively.

Property \ Geometry	Euclidean	Spherical	Hyperbolic
Curvature	0	> 0	< 0
Parallel lines	1	0	∞
Shape of triangles			Sum of triangle angles	π	$> \pi$	$< \pi$

Table 1: Characteristic properties of Euclidean, spherical and hyperbolic geometries (Krioukov et al., 2010).

Hyperbolic distance. The distance between vectors $\mathbf{u}$ and $\mathbf{v}$ in the Poincaré ball is given by:

$$d_{\mathbb{D}}(\mathbf{u}, \mathbf{v}) = \operatorname{arccosh}(1+2\frac{\|\mathbf{u}-\mathbf{v}\|^2}{(1-\|\mathbf{u}\|^2)(1-\|\mathbf{v}\|^2)}).$$

When points move from the origin towards the ball boundary, their distance would increase exponentially, offering a much larger volume of space for embedding learning.

Vector translation. The vector translation in the Poincaré ball is defined by the Möbius addition:

$$\mathbf{u} \oplus \mathbf{v} = \frac{(1 + 2\langle\mathbf{u}, \mathbf{v}\rangle + \|\mathbf{v}\|^2)\mathbf{u} + (1 - \|\mathbf{u}\|^2)\mathbf{v}}{1 + 2\langle\mathbf{u}, \mathbf{v}\rangle + \|\mathbf{u}\|^2\|\mathbf{v}\|^2}.$$

Transformation. A transformation is the backbone of both GNNs (Chami et al., 2019; Liu et al., 2019) and transformation-based associations (Chen et al., 2017; Hao et al., 2019). The work in (Ganea et al., 2018) defines the matrix-vector multiplication between Poincaré balls using the exponential and logarithmic maps. The hyperbolic vectors are first projected into the tangent space at $\mathbf{0}$ using the logarithmic map ($\log_{\mathbf{0}} : \mathbb{D}^{n,1} \rightarrow T_{\mathbf{0},n}\mathbb{D}^{n,1}$), then multiplied the transformation matrix like in the Euclidean space, and finally projected back on the manifold with the exponential map ($\exp_{\mathbf{0}}$:

$T_{\mathbf{0},n}\mathbb{D}^{n,1} \rightarrow \mathbb{D}^{n,1}$). Specifically, the two projections on vector $\mathbf{u} \in \mathbb{D}^{n,1}$ are defined as follows:

$$\exp_{\mathbf{0}}(\mathbf{u}) = \tanh(\|\mathbf{u}\|)\frac{\mathbf{u}}{\|\mathbf{u}\|}, \tag{1}$$

$$\log_{\mathbf{0}}(\mathbf{u}) = \tanh^{-1}(\|\mathbf{u}\|)\frac{\mathbf{u}}{\|\mathbf{u}\|}. \tag{2}$$

Through such inverse projections, theoretically, we can apply any Euclidean counterpart operations on hyperbolic vectors. The transformation that maps a vector $\mathbf{u} \in \mathbb{D}^{n,c}$ into $\mathbb{D}^{m,c}$ can be done using the Möbius version of matrix-vector multiplication:

$$\mathbf{M} \otimes \mathbf{u} = \exp_{\mathbf{0}}(\mathbf{M} \log_{\mathbf{0}}(\mathbf{u})). \tag{3}$$

4 Hyperbolic Knowledge Association

In this section, we introduce the technical details of HyperKA — the hyperbolic GNN-based representation learning method for knowledge association. Different from existing relational GNNs like R-GCN (Schlichtkrull et al., 2018), AVR-GCN (Ye et al., 2019) and CompGCN (Vashishth et al., 2020) that perform a relation-specific transformation on relational neighbors before aggregation, our method models relations as translations between entity vectors at the input layer, and performs neighborhood aggregation on top of them to derive the final entity embeddings. This allows our method to benefit from both relation translation and neighborhood aggregation without increasing computation complexity.

4.1 Hyperbolic Relation Translation

Given a triple from the KG, the translational technique (Bordes et al., 2013) models a relation as a translation vector between its head and tail entities. This technique has shown promising performance on many downstream tasks such as relation prediction, triple classification and entity alignment (Bordes et al., 2013; Chen et al., 2017; Sun et al., 2019). An apparent issue of such translations to embed hierarchies in the Euclidean space is that it would require a large space to preserve the successive relation translations in a hierarchical structure. The data in a hierarchy grows exponentially w.r.t. its levels, while the amount of space grows linearly in a Euclidean space. As a result, the Euclidean embeddings usually come with a high dimension so as to achieve enough expressiveness for the aforementioned hierarchical structures. However, such modeling can be easily done in the hyperbolic space with a low dimension, where the distance between two points increases exponentially as they move towards to the boundary of the hyper-sphere.

In our method, we seek to migrate the original translation operation to the hyperbolic space in a compact way. Accordingly, the following energy function is defined for a triple $\tau = (h, r, t)$:

$$f(\tau) = d_{\mathbb{D}}(\mathbf{u}_h^{(0)} \oplus \mathbf{u}_r^{(0)}, \mathbf{u}_t^{(0)}), \tag{4}$$

where $\mathbf{u}_h^{(0)}, \mathbf{u}_r^{(0)}, \mathbf{u}_t^{(0)} \in \mathbb{D}^{n,c}$ denote the embeddings for h, r and t at the input layer, respectively. Our method is different from some existing methods (Balazevic et al., 2019; Kolyvakis et al., 2020) that use hyperbolic relation-specific transformations on entity representations and may easily cause high complexity overhead. The parameter complexity of our translation operation remains the same as TransE. We prefer low energy for positive triples while high energy for negatives. Hence, we minimize the following contrastive learning loss:

$$\mathcal{L}_{\text{rel}} = \sum_{\tau \in \mathcal{T}_1 \cup \mathcal{T}_2} f(\tau) + \sum_{\tau' \in \mathcal{T}^-} [\lambda_1 - f(\tau')]_+, \tag{5}$$

where $\mathcal{T}^-$ denotes the set of negative triples generated by corrupting positive triples (Sun et al., 2018). λ_1 is the margin where we expect $f(\tau') > \lambda_1$.

4.2 Hyperbolic Neighborhood Aggregation

GNNs (Kipf and Welling, 2017) have recently become the paradigm for graph representation learning. Particularly, for the entity alignment task, the main merit of GNN-based methods lies in capturing the high-order proximity of entities based on their neighborhood information (Wang et al., 2018). Inspired by the recent proposal of hyperbolic GNNs (Liu et al., 2019; Chami et al., 2019), we seek to use the hyperbolic graph convolution to learn embeddings for knowledge association. The typical message passing process of GNNs consists of two phases, i.e., aggregating neighborhood features

$$\mathbf{u}_{\mathcal{N}(i)}^{(l)} = \text{agg}(\{\mathbf{u}_j^{(l-1)} | j \in \mathcal{N}(i)\}), \tag{6}$$

and combining node and neighborhood information

$$\mathbf{u}_i^{(l)} = \text{comb}(\mathbf{u}_i^{(l-1)}, \mathbf{u}_{\mathcal{N}(i)}^{(l)}), \tag{7}$$

where $\mathbf{u}_{\mathcal{N}(i)}^{(l)}$ denotes the representation of central object i by aggregating its neighborhood information $\mathcal{N}(i)$ at the l-th layer. $\mathbf{u}_i^{(l)}$ denotes the representation of object i by combining its representation from the last layer $\mathbf{u}_i^{(l-1)}$ and the aggregated representation of its neighborhood $\mathbf{u}_{\mathcal{N}(i)}^{(l)}$.

Different aggregation and combination functions lead to different variants of GNNs. We choose the message passing technique that highlights the representations of central objects, to benefit from the translational embeddings at the input layer. Specifically, the message passing process of our hyperbolic GNN from the $(l-1)$-th layer to the l-th layer is defined as follows:

$$\mathbf{u}_i^{(l)} = \mathbf{u}_i^{(l-1)} \oplus \sigma(\mathbf{W}^{(l)} \otimes \mathbf{u}_{\mathcal{N}'(i)}^{(l-1)} \oplus \mathbf{b}^{(l)}), \quad (8)$$

where $\mathbf{W}^{(l)}$ is the transformation matrix and $\mathbf{b}^{(l)}$ is the bias vector at the l-th layer. σ is an activation function. We adopt mean-pooling to compute $\mathbf{u}_{\mathcal{N}'(i)}^{(l-1)}$ based on the representations of entity i and its neighbors from the $(l-1)$-th layer. Generally, we can use the output representation of the final layer $\mathbf{u}_i = \mathbf{u}_i^{(L)}$ to represent object i, where L is the number of GNN layers. To further benefit from relation translation, we can also combine the input and output representations $\mathbf{u}_i = \mathbf{u}_i^{(0)} \oplus \mathbf{u}_i^{(L)}$ as the final embeddings for knowledge association.

4.3 Hyperbolic Knowledge Projection

Once each KG is embedded in a hyperbolic space, the next step is to capture the associations between different KGs. Many previous studies jointly embed different KGs into a unified space (Sun et al., 2017; Wang et al., 2018; Li et al., 2019), and infer the associations based on similarity of entity embeddings. However, pursing similar embeddings in a shared space is ill-posed for KGs with inconsistent structures, especially under the cases with different scales of knowledge representations. We hereby tackle the challenge with a knowledge projection technique in the hyperbolic space. Given a pair of seed knowledge association $(i, j) \in \mathcal{A}^+$, we use the Möbius multiplication to project $\mathbf{u}_i$ to find the target $\mathbf{u}_j$ in the other space. The transformation error is defined as the hyperbolic distance between projected embeddings:

$$\pi(i, j) = d_{\mathbb{D}}(\mathbf{M} \otimes \mathbf{u}_i, \mathbf{u}_j), \quad (9)$$

where $\mathbf{M} \in \mathbb{R}^{n \times m}$ serves as the linear transformation from the hyperbolic space $\mathbb{D}^{n,c}$ of $\mathcal{K}_1$ to $\mathbb{D}^{m,c}$ of $\mathcal{K}_2$. The two hyperbolic spaces are not necessarily of the same dimension, i.e., we usually have $n \neq m$. The projection loss is defined as follows:

$$\mathcal{L}_{\text{proj}} = \sum_{(i,j)\in\mathcal{A}^+} \pi(i, j) + \sum_{(i',j')\in\mathcal{A}^-} [\lambda_2 - \pi(i', j')]_+, \quad (10)$$

$\mathcal{A}^-$ thereof is the set of negative samples of knowledge associations, and $\lambda_2 > 0$ is a margin.

4.4 Training

The overall loss of the proposed method is the combination of relation translation learning and knowledge projection learning, which is given by:

$$\mathcal{L} = \mathcal{L}_{\text{rel}} + \mathcal{L}_{\text{proj}}. \quad (11)$$

The embedding vectors are initialized using the Xavier normal initializer. Then, we can use the exponential map to project vectors to the Poincaré ball. We adopt the Riemannian SGD algorithm (Bonnabel, 2013) to optimize the loss function. Let θ be the trainable parameters. The Riemannian gradient ∇_{H} at θ^t is computed as follows:

$$\nabla_{\text{H}} = \frac{(1 - \|\theta^t\|^2)^2}{4} \nabla_{\text{E}}, \quad (12)$$

where ∇_{E} denotes the Euclidean gradient. We use Adam (Kingma and Ba, 2015) as the optimizer.

5 Experiments

We evaluate the proposed method HyperKA on two tasks of knowledge association, i.e. entity alignment (Section 5.1) and entity type inference (Section 5.2). The source code is publicly available[1].

5.1 Entity Alignment

Entity alignment aims at matching the counterpart entities that describe the same real-world identity across two entity-level KGs. The inference of entity alignment is based on the embedding distances.

5.1.1 Experimental Setup

Datasets. We use the widely-adopted entity alignment dataset DBP15K (Sun et al., 2017) for evaluation. It is extracted from DBpedia (Lehmann et al., 2015) and consists of three settings, namely ZH-EN (Chinese-English), JA-EN (Japanese-English) and FR-EN (French-English). Each setting contains 15 thousand pairs of entity alignment. The dataset splits are consistent with those in previous studies (Sun et al., 2017, 2018), which result in 30% of entity alignment being used in training. The statistics of DBP15K are reported in Appendix A.

Baselines. We compare HyperKA with nine recent structure-based entity alignment methods, including five relation-based methods, i.e., MTransE (Chen et al., 2017), IPTransE (Zhu et al., 2017), AlignE (Sun et al., 2018), SEA (Pei et al., 2019a) and RSN4EA (Guo et al., 2019), as well as four

neighborhood-based methods, i.e., GCN-Align (Wang et al., 2018), MuGNN (Cao et al., 2019), KECG (Li et al., 2019) and AliNet (Sun et al., 2020a). We omit here several methods that require auxiliary entity information that are not used by others (see Section 2). We also do not involve two related methods MMEA (Shi and Xiao, 2019) and MRAEA (Mao et al., 2020) because their bidirectional alignment setting is different from ours and other baselines. For ablation study, we evaluate a variant of our method without relation translation, i.e., HyperKA (w/o relation). The main results are reported in Section 5.1.2. Besides, we further consider semi-supervised entity alignment methods BootEA (Sun et al., 2018), NAEA (Zhu et al., 2019) and TransEdge (Sun et al., 2019) as they achieve high performance by bootstrapping from unlabeled entity pairs. We describe the implementation of the semi-supervised HyperKA variant and experimental results shortly in Section 5.1.5.

Model configuration. In the main experiment, we use two GNN layers, and set the dimension of all layers in HyperKA to 75. The dimensions for the two KGs are the same, i.e., $n = m = 75$. This is the smallest dimension adopted by any baseline methods. Note that, we also evaluate our method with a range of dimensions from 10 to 150, to assess its robustness. We report in Appendix B the implementation details of HyperKA and the selected values for hyper-parameters, including the learning rate, the batch size, margin values λ_1 and λ_2, etc. Following convention, we report three metrics on entity alignment, i.e., H@1 (precision), H@10 (the proportion of correct alignment ranked within the top 10) and MRR (mean reciprocal rank). Higher scores of those metrics indicate better performance.

Datasets	Dimensions					
	10	25	35	50	75	150

JA-EN	0.391	0.510	0.551	0.563	0.564	0.583
FR-EN	0.368	0.528	0.574	0.585	0.597	0.611

Table 3: H@1 performance of HyperKA on DBP15K using different dimensions.

5.1.2 Main Results

We report the entity alignment results on DBP15K in Table 2. Note that the embedding dimension for HyperKA is set to 75 (the smallest setting among baseline methods). We can observe that HyperKA consistently outperforms all baseline methods on all three datasets, especially GNN-based methods. For example, on DBP15K FR-EN, the H@1 score of HyperKA reaches 0.597, surpassing MuGNN by 0.102 and AliNet by 0.045, even though HyperKA uses a smaller dimension than these methods. Compared against the baselines with dimension of 75, HyperKA also achieves much better performance. For instance, on the ZH-EN dataset, it surpasses AlignE by 0.1 in H@1. Overall, HyperKA significantly outperforms the SOTA Euclidean methods, while using the same or much smaller dimension settings. This shows that the hyperbolic embeddings have superior expressiveness than the linear embeddings. As for the comparison between two variants of HyperKA, we can see that the one with relation embedding performs notably better. This demonstrates the effectiveness of incorporating relation translation into GNNs.

5.1.3 Analysis on Dimensions

We further analyze the effect of different dimensions on performance and training efficiency. We

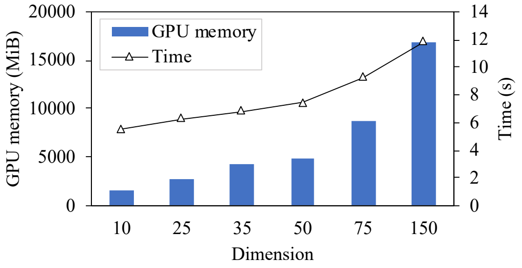

Figure 2: GPU memory cost and running time of each epoch w.r.t. different dimensions on DBP15K ZH-EN.

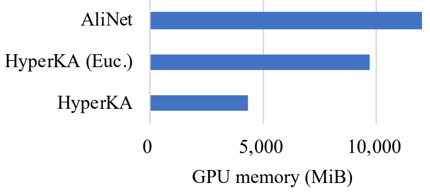

Figure 3: GPU memory cost of training HyperKA and its Euclidean counterpart HyperKA (Euc.) as well as AliNet (Sun et al., 2020a) on DBP15K ZH-EN when they achieve similar performance. The dimension settings that they need are respectively (35, 35, 35), (200, 200, 200) and (500, 400, 300), and their H@1 scores are 0.532, 0.549 and 0.539, respectively.

report the H@1 results of different dimensions in Table 3. We observe that the H@1 scores of HyperKA drop along with the decrease of embedding dimensions. This observation is generally in line with our expectations because a small dimension limits the expressiveness of KG embeddings. However, HyperKA still exhibits satisfying performance at very small dimensions in comparison to other methods, such as under the dimensions of 10 and 25. Specifically, HyperKA with 25 dimension even outperforms a number of methods in Table 2 with much higher dimensions, e.g., AlignE, GCN-Align and KECG. Note that, HyperKA with 35 dimension achieves very similar results to AliNet with layer dimensions of (500, 400, 300) and also outperforms other baseline methods. HyperKA with dimension of 150 establishes a new SOTA performance for structure-based entity alignment. Overall, the low-dimension hyperbolic representations of HyperKA demonstrate more precise and robust inference of counterpart entities across KGs.

Datasets	Dimensions	H@1	H@10	MRR
ZH-EN	200, 200, 200	0.549	0.827	0.650
JA-EN	200, 200, 200	0.527	0.813	0.631
FR-EN	200, 200, 200	0.567	0.864	0.675
ZH-EN	300, 300, 300	0.581	0.857	0.683
JA-EN	300, 300, 300	0.563	0.844	0.666
FR-EN	300, 300, 300	0.605	0.896	0.711

Table 4: Entity alignment results of HyperKA (Euc.).

Methods	ZH-EN		JA-EN		FR-EN	
	H@1	MRR	H@1	MRR	H@1	MRR
BootEA (Sun et al., 2018)	0.629	0.703	0.622	0.701	0.653	0.731
NAEA (Zhu et al., 2019)	0.650	0.720	0.641	0.718	0.673	0.752
TransEdge (Sun et al., 2019)	0.735	0.801	0.719	**0.795**	0.710	0.796
HyperKA (semi)	**0.743**	**0.805**	**0.727**	0.793	**0.741**	**0.813**

Table 5: H@1 and MRR results of semi-supervised entity alignment on DBP15K. Their dimension is 75.

We report in Figure 2 the GPU memory costs for training HyperKA in 64-bit precision settings w.r.t. various dimensions on ZH-EN, together with the average training time per epoch[2]. A larger dimension leads to more GPU memory costs and training time, although it also leads to better performance as shown in Table 3. HyperKA can achieve satisfying performance with limited GPU memory costs.

5.1.4 Analysis on Expressiveness

To further understand the expressiveness of our hyperbolic KG embeddings, we compare a small dimension along with their GPU memory costs of HyperKA and its Euclidean counterpart HyperKA (Euc.) with AliNet, when those three achieve similar performance. HyperKA (Euc.) is implemented by replacing hyperbolic operations with their corresponding Euclidean operations. For example, the Möbius addition $\oplus$ is replaced with vector addition $+$. We select the dimension of HyperKA (Euc.) in $\{75, 100, 150, 200, 300, 500\}$ and its best-performing model under the dimension of 200 can achieve similar performance to AliNet. By contrast, HyperKA only needs a dimension of 35 as shown in Table 3. Their GPU memory costs on ZH-EN are shown in Figure 3. We observe similar results on JA-EN and FR-EN. Specifically, HyperKA only costs about 45.09% memory of HyperKA (Euc.) and 29.97% of AliNet to achieve similar performance. This shows that hyperbolic embeddings can achieve satisfying expressiveness with a small dimension and efficient memory costs.

We report in Table 4 the entity alignment results of HyperKA (Euc.) on DBP15K. We can find that HyperKA (Euc.) with a high dimension (e.g., 300) can also achieve similar performance with HyperKA at a low dimension of 75. This is because the Euclidean embeddings also have enough expressiveness to represent hierarchical structures

---

if given a large dimension. However, hyperbolic embeddings only need a small dimension, bringing along the substantial advantage in saving memory.

5.1.5 Semi-supervised Entity Alignment

Semi-supervised entity alignment methods use self-training or co-training techniques to augment training data by iteratively finding new alignment labels (Sun et al., 2018; Zhu et al., 2019; Sun et al., 2019). Following BootEA (Sun et al., 2018), we use the self-training strategy to iteratively propose more aligned entity pairs to augment training data, denoted as $\mathcal{A}' = \{(i,j) \in \mathcal{E}_1 \times \mathcal{E}_2 \,|\, \pi(i,j) < \epsilon\}$, where ϵ is a distance threshold. As these pairs inevitably contains errors (Sun et al., 2018), we apply a small weight μ when using such proposed data for training, resulting in the following loss:

$$\mathcal{L}_{\text{semi}} = \mu \sum_{(i,j)\in\mathcal{A}'} \pi(i,j). \qquad (13)$$

Accordingly, the semi-supervised HyperKA variant minimizes the joint loss $\mathcal{L}+\mathcal{L}_{\text{semi}}$. The selected settings are $\epsilon = 0.25$, $\mu = 0.05$, and the training takes 800 epochs. Table 5 lists the H@1 and MRR results, where HyperKA shows drastic improvement over BootEA and NAEA. It also achieves noticeably better H@1 than the latest semi-supervised method TransEdge, especially on the FR-EN setting. The good performance of TransEdge comes with prohibitive memory overhead. Its parameter complexity is $O(2N_e n + N_r n)$ (Sun et al., 2019), where N_e and N_r denote the numbers of entities and relations in KGs, respectively. n is the dimension. By contrast, the complexity of our method is $O(N_e n + N_r n + Ln^2)$ and we have $N_e \gg Ln$ in practice, where L is the number of GNN layers. In this case, HyperKA outclasses TransEdge in both effectiveness and efficiency. Compared with our results in Table 2, we find that the self-training, being an optional and compatible technique, brings an improvement of more than 0.14 on H@1.

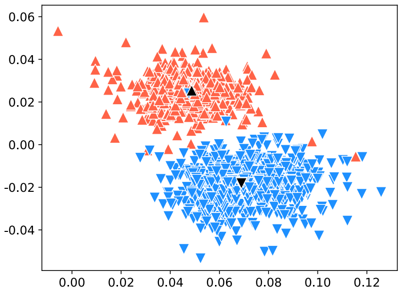

Figure 4: Visualization of the embeddings generated by HyperKA for two related concepts "*Film*" and "*Album*" along with their entities in DB111K-174. The black up triangle denotes "*Film*" and the surrounding red ones are its entities. The black down triangle denotes "*Album*" and the blue ones are its entities.

5.2 Type Inference

The main difference between type inference and entity alignment lies in that the knowledge to associate in the former scenario differs much in scales and specificity. This causes many related methods based on shared embedding spaces to fall short.

5.2.1 Experimental Setup

Datasets. The experiments for this task are conducted on datasets YAGO26K-906 and DB111K-174 (Hao et al., 2019), which are extracted from YAGO and DBpedia, respectively. Each dataset has an entity-level KG and an ontological KG for concepts (types). Their statistics are reported in Appendix A. To compare with the previous work (Hao et al., 2019), we use the original data splits, and report H@1, H@3 and MRR results. The hyperparameter settings are listed in Appendix B.

Baselines. So far, only a few methods have been applied to the type inference task in KGs. We compare with the SOTA method JOIE (Hao et al., 2019), and four other baseline methods TransE (Bordes et al., 2013), DistMult (Yang et al., 2015), HolE (Nickel et al., 2016) and MTransE (Chen et al., 2017) that are reported in the same paper. For JOIE, we choose its best-performing variant based on the translational encoder with cross-view transformation. A related method (Jin et al., 2019) is not taken into comparison as it requires entity attributes that are unavailable in our problem setting.

5.2.2 Main Results

In this task, the embedding dimensions for entities and concepts are different, i.e., $n > m$, as an entity-level KG usually contains much more entities than concepts in a related ontological (or concept-level) KG. For HyperKA, we evaluate two dimension settings: $n = 75, m = 15$ and $n = 150, m = 30$. Both are much smaller than the dimensions of baseline methods. The results are reported in Table 6. We can observe that HyperKA (75, 15) outperforms JOIE in terms of H@1 on both datasets, especially on DBP111K-174, although HyperKA uses a much smaller dimension. For example, the H@1 score of HyperKA (75, 15) on DB111K-174 reaches 0.778, with a gain of 0.022 over JOIE in its best setting. HyperKA (150, 30) achieves the best performance over H@1 and MRR. We also try the dimension setting of (300, 50), but no longer observe further improvement. We believe this is because the dimension setting (150, 30) is enough for type inference as the concept-level KG is small. Meanwhile, once we apply the same small-dimension setting (75, 15) as HyperKA to baseline methods, the performance of those methods become much worse. For example, MTransE achieves no more than 0.357 in H@1 using this small dimension.

5.2.3 Case Study

For case study, we visualize the embeddings of two related concepts "*Film*" and "*Album*" in DBP111K-174 along with their associated entities in the PCA-projected space in Figure 4. Despite these two groups of entities are closely relevant, the embeddings learned by HyperKA are able to clearly distinguish between these two. We can see that the entities of the same type are embedded closely after transformation, while the two clusters are generally well differentiated by a clear margin (with only a few exceptions). This displays how the hyperbolic transformation is able to capture the multi-granular associations, while preserves the gap between the entities associated with different concepts.

6 Conclusion and Future Work

We propose a method to capture knowledge associations with a new hyperbolic GNN-based representation learning model. The proposed HyperKA method extends translational and GNN-based techniques to hyperbolic spaces, and captures associations by a hyperbolic transformation. Our method outperforms SOTA baselines using lower embedding dimensions on both entity alignment and type inference. For future work, we plan to incorporate hyperbolic RNNs (Ganea et al., 2018) to encode auxiliary information for zero-shot entity and concept representations. Another meaningful direction is to use HyperKA to infer the associations between snapshots in temporally dynamic KGs (Xu et al., 2020). We also seek to investigate the use of HyperKA for cross-domain representations of biological and medical knowledge (Hao et al., 2020).

Acknowledgments. We thank the anonymous reviewers for their insightful comments. This work is supported by the National Natural Science Foundation of China (Nos. 61872172 and 61772264), and the Collaborative Innovation Center of Novel Software Technology and Industrialization.

A Dataset Statistics

Table 7 lists the statistics of the entity alignment dataset DBP15K[3] (Sun et al., 2017), as well as two type inference datasets YAGO26K-906 and DB111K-174[4] (Hao et al., 2019). For a fair comparison, we reuse the original splits of associations in these datasets for training and evaluation, i.e., 30% alignment in DBP15K as well as around 60% associations in YAGO26K-906 and DB111K-174 as training data. We can see that the two KGs of type inference datasets differs much more in terms of the scales of objects and triples than those in entity alignment datasets, which also bring along more challenges to knowledge association.

Datasets			#Objects	#Rel.	#Triples	#Assoc.
DBP15K	ZH-EN	ZH	66,469	2,830	153,929	15,000
		EN	98,125	2,317	237,674

		Ont.	174	20	763	

Table 7: Statistics of the datasets used in this paper.

B Hyper-parameter Settings

In this section, we report the implementation details and hyper-parameter settings of HyperKA on the two knowledge association tasks. We select each hyper-parameter setting within a wide range of values as follows:

- Learning rate: $\{0.0001, 0.0002, 0.0005, 0.001\}$
- Batch size: $\{2000, 5000, 10000, 20000, 50000\}$
- # GNN layers: $\{1, 2, 3, 4, 5\}$
- # Negative samples: $\{1, 10, 20, 30, 40, 50, 100\}$
- λ_1: $\{0.01, 0.02, 0.05, 0.1, 0.15, 0.2, 0.3, 0.4\}$
- λ_2: $\{0.01, 0.02, 0.05, 0.1, 0.15, 0.2, 0.3, 0.4\}$

Table 8 lists the selected hyper-parameter settings for the best-performing models (measured by H@1 scores) of HyperKA with 75 dimension for entity alignment on DBP15K, as well as (75, 15) dimensions for type inference on YAGO26K-906 and DB111K-174. We use truncated negative sampling and cross-domain similarity local scaling for the entity alignment task. The training takes 800 epochs on DBP15K, 60 epochs on YAGO26K-906 and 100 epochs on DB111K-174. The activation function used in our method is $\tanh$.

Parameters	DBP15K	YAGO26K-906	DB111K-174
Learning rate	0.0002	0.0005	0.0005
Batch size	20,000	2,000	20,000
# GNN layers	2	3	3
# Neg. samples	40	40	30
λ_1	0.1	0.2	0.2
λ_2	0.4	0.1	0.1

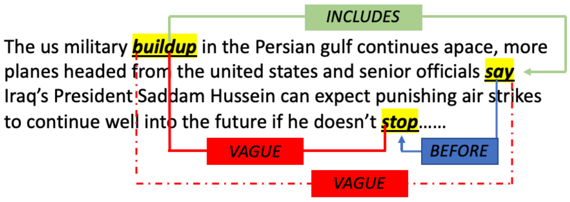
Abstract

Extracting event temporal relations is a critical task for information extraction and plays an important role in natural language understanding. Prior systems leverage deep learning and pre-trained language models to improve the performance of the task. However, these systems often suffer from two shortcomings: 1) when performing maximum a posteriori (MAP) inference based on neural models, previous systems only used structured knowledge that is assumed to be absolutely correct, i.e., *hard constraints*; 2) biased predictions on dominant temporal relations when training with a limited amount of data. To address these issues, we propose a framework that enhances deep neural network with *distributional constraints* constructed by probabilistic domain knowledge. We solve the constrained inference problem via Lagrangian Relaxation and apply it to end-to-end event temporal relation extraction tasks. Experimental results show our framework is able to improve the baseline neural network models with strong statistical significance on two widely used datasets in news and clinical domains.

1 Introduction



The us military **buildup** in the Persian gulf continues apace, more planes headed from the united states and senior officials **say** Iraq's President Saddam Hussein can expect punishing air strikes to continue well into the future if he doesn't **stop**......

	Overall	Type Pair (P)	Type Pair (G)
VAGUE	49.9%	55.1%	39.9%
INCLUDES	5.1%	0.0%	12.3%
Others	45.0%	44.9%	47.8%

Figure 1: An example of the event temporal ordering task. Text input is taken from the news dataset in our experiments. Solid lines / arrows between two highlighted events show their gold temporal relations, e.g. **say** *BEFORE* **stop** and **buildup** *INCLUDES* **say**, and the dash line shows a wrong prediction, i.e., the *VAGUE* relation between **buildup** and **say**. In the table, Column Overall shows the relation distribution over the entire training corpus; Column Type Pair (P) shows the *predicted* relation distribution condition on the event pairs having types `occurrence` and `reporting` (such as **buildup** and **say**); Column Type Pair (G) shows the *gold* relation distribution condition on event pairs having the same types. Biased predictions of *VAGUE* relation between **buildup** and **say** can be partially corrected by using the gold event type-relation statistics in Column Type Pair (G).

Extracting event temporal relations from raw text data has attracted surging attention in the NLP research community in recent years as it is a fundamental task for commonsense reasoning and natural language understanding. It facilitates various downstream applications, such as forecasting social events and tracking patients' medical history. Figure 1 shows an example of this task where an event extractor first needs to identify events (**buildup**, **say** and **stop**) in the input and then a relation classifier predicts all pairwise relations among them, resulting in a temporal ordering as illustrated in the figure. For example, **say** is *BEFORE* **stop**; **buildup** *INCLUDES* **say**; the temporal ordering between **buildup** and **stop** cannot be decided from the context, so the relation should be *VAGUE*.

Predicting event temporal relations is inherently challenging as it requires the system to understand each event's beginning and end times. However, these time anchors are often hard to specify within a complicated context, even for humans. As a result, there is usually a large amount of *VAGUE* pairs (nearly 50% in the table of Figure 1) in an expert-annotated dataset, resulting in heavily class-imbalanced datasets. Moreover, expert annotations are often time-consuming to gather, so the sizes of existing datasets are relatively small. To cope

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5717–5729,
November 16–20, 2020. ©2020 Association for Computational Linguistics

with the class-imbalance problem and the small dataset issues, recent research efforts adopt *hard constraint*-enhanced deep learning methods and leverage pre-trained language models (Ning et al., 2018c; Han et al., 2019b) and are able to establish reasonable baselines for the task.

The *hard-constraints* used in the SOTA systems can only be constructed when they are nearly 100% correct and hence make the knowledge adoption restrictive. Temporal relation transitivity is a frequently used *hard constraint* that requires *if* **A** *BEFORE* **B** and **B** *BEFORE* **C**, it *must be* that **A** *BEFORE* **C**. However, constraints are usually not deterministic in real-world applications. For example, a clinical `treatment` and `test` are more *likely* to happen *AFTER* a medical `problem`, but not *always*. Such probabilistic constraints cannot be encoded with the *hard-constraints* as in the previous systems.

Furthermore, deep neural models have biased predictions on dominant classes, which is particularly concerning given the small and biased datasets in event temporal extraction. For example, in Figure 1, an event pair **headed** and **say** (with relation *INCLUDES*) is incorrectly predicted as *VAGUE* (Column Type Pair (P)) by our baseline neural model, partially due to dominant percentage of *VAGUE* label (Column Overall), and partially due to the complexity of the context. Using the domain knowledge that **headed** and **say** have event types of `occurrence` and `reporting`, respectively, we can find a new label probability distribution (Type Pair (G)) for this pair. The probability mass allocated to *VAGUE* would decrease by 10% and increase by 7.2% for *INCLUDES*, which significantly increases the chance for a correct label prediction.

We propose to improve deep structured neural networks by incorporating domain knowledge such as corpus statistics in the model inference, and by solving the constrained inference problem using Lagrangian Relaxation. This framework allows us to benefit from the strong contextual understanding of pre-trained language models while optimizing model outputs based on probabilistic structured knowledge that previous deep models fail to consider. Experimental results demonstrate the effectiveness of this framework.

We summarize our contributions below:

- We formulate the incorporation of probabilistic knowledge as a constrained inference problem and use it to optimize the outcomes from strong neural models.
- Novel applications of Lagrangian Relaxation on end-to-end temporal relation extraction task with event-type and relation constraints.
- Our framework significantly outperforms baseline systems without knowledge adoption and achieves new SOTA results on two datasets in news and clinical domains.

2 Problem Formulation

The problem we focus on is end-to-end event temporal relation extraction, which takes a raw text as input, first identifies all events, and then classifies temporal relations for all predicted event pairs. The left column of Figure 2 shows an example. An end-to-end system is practical in a real-world setting where events are not annotated in the input and challenging because temporal relations are harder to predict after noise is introduced during event extraction.

3 Method

In this section, we first describe the details of our deep neural networks for an end-to-end event temporal relation extraction system, then show how to formulate *domain-knowledge* between event types and relations as *distributional constraints* in Integer Linear Programming (ILP), and finally apply Lagrangian Relaxation to solve the constrained inference problem. Our base model is trained end-to-end with cross-entropy loss and multitask learning to obtain relation scores. We need to perform an additional inference step in order to incorporate *domain-knowledge* as *distributional constraints*.

3.1 End-to-end Event Relation Extraction

As illustrated in the left column in Figure 2, our end-to-end model shares a similar work-flow as the pipeline model in Han et al. (2019b), where multi-task learning with a shared feature extractor is used to train the pipeline model. Let $\mathcal{E}$, $\mathcal{EE}$ and $\mathcal{R}$ denote event, candidate event pairs and the feasible relations, respectively, in an input instance $\boldsymbol{x}^n$, where n is the instance index. The combined training loss is $\mathcal{L} = c_\mathcal{E}\mathcal{L}_\mathcal{E} + \mathcal{L}_\mathcal{R}$, where $\mathcal{L}_\mathcal{E}$ and $\mathcal{L}_\mathcal{R}$ are the losses for the event extractor and the relation module, respectively, and $c_\mathcal{E}$ is a hyper-parameter balancing the two losses.

Feature Encoder. Input instances are first sent to pre-trained language models such as BERT (Devlin

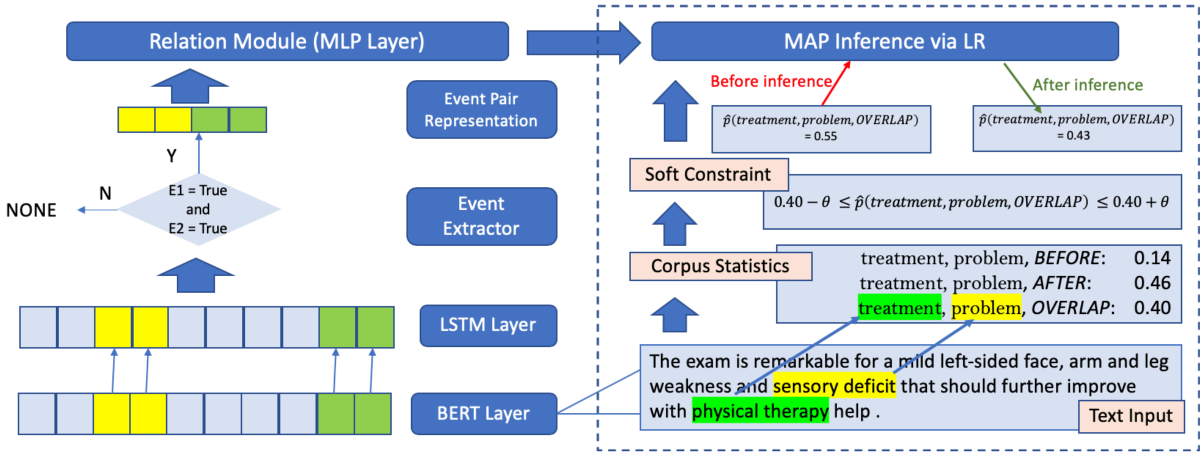


Figure 2: An overview of the proposed framework. The left column shows the end-to-end event temporal relation extraction workflow. The right column (in the dashed box) illustrates how we propose to enhance the end-to-end extraction system. The final MAP inference contains two components: scores from the relation module and *distributional constraints* constructed using domain knowledge and corpus statistics. The text input is a real example taken from the I2B2-TEMPORAL dataset. The MAP inference is able to push the predicted probability of the event type-relation triplet closer to the ground-truth (corpus statistics).

et al., 2018) and RoBERTa (Liu et al., 2019), then to a Bi-LSTM layer as in previous event temporal relation extraction work (Han et al., 2019a).

Encoded features will be used as inputs to the event extractor and the relation module below.

Event Extractor. The event extractor first predicts scores over event classes for each input token and then detects event spans based on these scores. If an event has over more than one tokens, its beginning and ending vectors are concatenated as the final event representation. The event score is defined as the predicted probability distribution over event classes. Pairs predicted to include non-events are automatically labeled as *NONE*, whereas valid candidate event pairs are fed into the relation module to obtain their relation scores.

Relation Module. The relation module's input is a pair of events, which share the same encoded features as the event extractor. We simply concatenate them before feeding them into the relation module to produce relation scores $S(y^r_{i,j}, \boldsymbol{x}^n)$, which are computed using the Softmax function where $y^r_{i,j}$ is a binary indicator of whether an event pair $(i, j) \in \mathcal{EE}$ has relation $r \in \mathcal{R}$.

3.2 Constrained Inference for Knowledge Incorporation

As shown in Figure 2, once the relation scores are computed via the relation module, a MAP inference is performed to incorporate *distributional constraints* so that the structured knowledge can be used to adjust neural baseline model scores and optimize the final model outputs. We formulate our MAP inference with *distributional constraints* as an LR problem and solve it with an iterative algorithm.

Next, we explain the details of each component in our MAP inference.

3.2.1 Distributional constraints

Much of the *domain-knowledge* required for real-world problems are probabilistic in nature. In the task of event relation extraction, *domain-knowledge* can be the prior probability of a specific event-pair's occurrence acquired from large corpora or knowledge base (Ning et al., 2018b); *domain-knowledge* can also be event-property and relation distribution obtained using corpus statistics, as we study in this work. Previous work mostly leverage *hard constraints* for inference (Yoshikawa et al., 2009; Ning et al., 2017; Leeuwenberg and Moens, 2017; Ning et al., 2018a; Han et al., 2019a,b), where constraints such as transitivity and event-relation consistency are assumed to be absolutely correct. As we discuss in Section 1, *hard constraints* are rigid and thus cannot be used to model probabilistic *domain-knowledge*.

The right column in Figure 2 illustrates how our work leverages corpus statistics to construct *distributional constraints*. Let P be a set of event properties such as clinical types (e.g. `treatment` or `problem`).

For the pair (P^m, P^n) and the triplet (P^m, P^n, r), where $P^n, P^m \in P$ and $r \in \mathcal{R}$, we can retrieve their counts in the training corpus as

$$C(P^m, P^n, r) = \sum_{i,j \in \mathcal{EE}} c(P_i = P^m; P_j = P^n; r_{i,j} = r)$$

and

$$C(P^m, P^n) = \sum_{i,j \in \mathcal{EE}} c(P_i = P^m; P_j = P^n).$$

Let $t = (P^m, P^n, r)$. The prior triplet probability can thus be defined as

$$p_t^* = \frac{C(P^m, P^n, r)}{C(P^m, P^n)}.$$

Let $\hat{p}_t$ denote the predicted triplet probability, *distributional constraints* require that,

$$p_t^* - \theta \leq \hat{p}_t \leq p_t^* + \theta \qquad (1)$$

where θ is the tolerance margin between the prior and predicted probabilities.

3.2.2 Integer Linear Programming with Distributional Constraints

We formulate our MAP inference as an ILP problem. Let $\mathcal{T}$ be a set of triplets whose predicted probabilities need to satisfy Equation 1. We can define our full ILP as

$$\mathcal{L} = \sum_{(i,j) \in \mathcal{EE}} \sum_{r \in \mathcal{R}} y_{i,j}^r S(y_{i,j}^r, \boldsymbol{x}) \qquad (2)$$

$$\textbf{s.t. } p_t^* - \theta \leq \hat{p}_t \leq p_t^* + \theta,\ \forall t \in \mathcal{T}, \text{ and}$$

$$y_{i,j}^r \in \{0, 1\}\,,\ \sum_{r \in \mathcal{R}} y_{i,j}^r = 1,$$

where $S(y_{i,j}^r, \boldsymbol{x}), \forall r \in \mathcal{R}$ is the scoring function obtained from the relation module. For $t = (P^m, P^n, r)$, we have $\hat{p}_t = \frac{\sum_{(i:P^m, j:P^n)}^{\mathcal{EE}} y_{i,j}^r}{\sum_{(i:P^m, j:P^n)}^{\mathcal{EE}} \sum_{r'}^{\mathcal{R}} y_{i,j}^{r'}}$. The output of the MAP inference, $\hat{\mathbf{y}}$, is a collection of optimal label assignments for all relation candidates in an input instance $\boldsymbol{x}^n$. $\sum_{r \in \mathcal{R}} y_{i,j}^r = 1$ ensures that each event pair gets one label assignment and this is the only *hard constraint* we use.

To improve computational efficiency, we apply the heuristic to optimize only the equality constraints $p_t^* = \hat{p}_t, \forall t \in \mathcal{T}$. Our optimization algorithm terminates when $|p_t^* - \hat{p}_t| \leq \theta$. This heuristic has been shown to work efficiently without hurting inference performance (Meng et al., 2019). For each triplet t, its equality constraint can be rewritten as

$$F(t) = (1 - p_t^*) \sum_{(i:P^m, j:P^n)}^{\mathcal{EE}} y_{i,j}^r, \qquad (3)$$

$$-p_t^* \sum_{(i:P^m, j:P^n)}^{\mathcal{EE}} \sum_{r' \neq r}^{\mathcal{R}} y_{i,j}^{r'} = 0.$$

The goal is to maximize the objective function defined by Eq. (2) while satisfying the equality constraints.

Algorithm 1 Gradient Ascent for LR

```
procedure
    for $t \in \mathcal{T}$ do
        $\lambda_t^0 = 0$
    $k = 0$
    while $k < K$ do                                ▷ $K$: max iteration
        $\hat{y}^{k+1} \leftarrow \arg\max \mathcal{L}(\boldsymbol{\lambda}^k)$
        for $t \in \mathcal{T}$ do
            $\Delta_t = p_t^* - \hat{p}_t$
            if $|\Delta_t| > \theta$ then
                $\lambda_t^{k+1} = \lambda_t^k + \alpha\Delta_t$
        if $\Delta_t \leq \theta, \forall t$ then
            break
        $k = k + 1$
        $\alpha = \gamma\alpha$                     ▷ $\gamma$: decay rate
```

3.2.3 Lagrangian Relaxation

Solving Eq. (2) is NP-hard. Thus, we reformulate it as a Lagrangian Relaxation problem by introducing Lagrangian multipliers λ_t for each *distributional constraint*. Lagrangian Relaxation has been applied in a variety NLP tasks, as described by Rush and Collins (2011, 2012) and Zhao et al. (2017).

The Lagrangian Relaxation problem can be written as

$$\mathcal{L}(\mathbf{y}, \boldsymbol{\lambda}) = \sum_{(i,j) \in \mathcal{EE}} \sum_{r \in \mathcal{R}} y_{i,j}^r S(y_{i,j}^r, \boldsymbol{x}) + \sum_{t \in \mathcal{T}} \lambda_t F(t). \qquad (4)$$

Initialize $\lambda_t = 0$. Eq. (4) can be solved with the following iterative algorithm (Algorithm 1).

1. At each iteration k, obtain the best relation assignments per MAP inference, $\hat{y}^k = \arg\max \mathcal{L}(\mathbf{y}, \boldsymbol{\lambda})$
2. Update the Lagrangian multiplier in order to bring the predicted probability closer to the prior. Specifically, for each $t \in \mathcal{T}$,
    - If $|p_t^* - \hat{p}_t| \leq \theta$, $\lambda_t^{k+1} = \lambda_t^k$
    - Otherwise, $\lambda_t^{k+1} = \lambda_t^k + \alpha(p_t^* - \hat{p}_t)$

α is the step size. We are solving a min-max problem: the first step chooses the maximum likelihood assignments by fixing $\boldsymbol{\lambda}$; the second step searches for $\boldsymbol{\lambda}$ values that minimize the objective function.

4 Constrained Inference Implementation

This section explains how to construct our *distributional constraints* and the implementation details for inference with LR.

Constraint Triplets	Count	%
`occurrence`, `occurrence`, *	124	19.7
`occurrence`, `reporting`, *	50	7.9
`occurrence`, `action`, *	44	7.0
`reporting`, `occurrence`, *	41	6.5
`action`, `occurrence`, *	40	6.4
`action`, `action`, *	20	3.2
`reporting`, `reporting`, *	18	2.9
`action`, `reporting`, *	18	2.9
`reporting`, `action`, *	17	2.7

Table 1: TimeBank-Dense: triplet prediction count and percentage in the development set (sample size = 629).

4.1 Distributional Constraint Selection

The selection of *distributional constraints* is crucial for our algorithm. If the probability of an event-type and relation triplet is unstable across different splits of data, we may over-correct the predicted probability. We use the following search algorithm with heuristic rules to ensure constraint stability.

4.1.1 TimeBank-Dense

For TimeBank-Dense, we first sort candidate constraints by their corresponding values of $C(P^m, P^n) = \sum_{\hat{r}\in\mathcal{R}} C(P^m, P^n, \hat{r})$. We list $C(P^m, P^n)$ with the largest prediction numbers and their percentages in the development set in Table 1.

Next, we set 3% as our threshold to include constraints for our main experimental results. We found this number to work relatively well for both TimeBank-Dense and I2B2-TEMPORAL. We will show the impact of relaxing this threshold in the discussion section. In Table 1, the constraints in the bottom block are filtered out. Moreover, Eq. 3 implies that a constraint defined on one triplet (P^m, P^n, r) has impact on all (P^m, P^n, r') for $r' \in \mathcal{R}\backslash r$. In other words, decreasing $\hat{p}_{(P^m,P^n,r)}$ is equivalent to increasing $\hat{p}_{(P^m,P^n,r')}$ and vice versa. Thus, we heuristically pick $(P^m, P^n, \mathit{VAGUE})$ as our default constraint triplets.

Finally, we adopt a greedy search rule to select the final set of constraints. We start with the top constraint triplet in Table 1 and then keep adding the next one as long as it doesn't hurt the grid search[1] F_1 score on the development set. Eventually, four constraints triplets are selected, and they can be found in Table 3.

4.1.2 I2B2-TEMPORAL

Similar to TimeBank-Dense, we use the 3% threshold to select candidate constraints. However, it is computationally expensive to use the greedy search rule above by conducting grid search as the number of constraints that pass this threshold is large (15 of them), development set sample size is more than 3 times of TimeBank-Dense, and a large transformer is used for modeling, Therefore, we incorporate another two heuristic rules to directly select constraints,

1. We randomly split the train data into five subsets of equal size $\{s_1, s_2, s_3, s_4, s_5\}$. For triplet t to be selected, we must have $\frac{1}{5}\sum_{k=1}^{5} |p_{t,s_k} - p_t^*| < 0.001$.
2. $|\hat{p}_t - p_t^*| > 0.1$, where $\hat{p}_t$ is the predicted probability of t on the development set.

The first rule ensures that a constraint triplet is stable over a randomly split of data; the second one ensures that the probability gaps between the predicted and gold are large so that we will not over-correct them. Eventually, four constraints satisfy these rules, and they can be found in Table 9, and we run only one final grid search for these constraints.

4.2 Inference

The ILP component in Sec. 3.2.2 is implemented using an off-the-shelf solver provided by Gurobi optimizer. Hyper-parameters choices can be found in Table 6 in the Appendix.

5 Experimental Setup

This section describes the two event temporal relation datasets used in this paper and then explains the evaluation metrics.

5.1 Data

TimeBank-Dense. Temporal relation corpora such as TimeBank (Pustejovsky et al., 2003) and RED (O'Gorman et al., 2016) consist of expert annotations of news articles. The common issue of these corpora is missing annotations. Collecting densely annotated temporal relation corpora with all events and relations fully annotated is a challenging task as annotators could easily overlook some facts (Bethard et al., 2007; Cassidy et al., 2014; Chambers et al., 2014; Ning et al., 2017).

---

[1] Recall that our LR algorithm in Section 3.2.3 has three hyper-parameters: initial step size α, decay rate γ, and tolerance θ. We perform a grid search on the development set and use the best hyper-parameters on the test set.

	TimeBank-Dense				**2012 i2b2 Challenge** (I2B2-TEMPORAL)				
	Event	Relation			Event		Relation (TempEval Metrics)		
	F_1	R	P	F_1	Span F_1	Type Accuracy	R	P	F_1
Feature-based Benchmark	87.4	43.8	35.7	39.4	**90.1**	86.0	37.8	51.8	43.0
Han et al. (2019b)	**90.9**	52.6	46.5	49.4	-	-	73.4	76.3	74.8
End-to-end Baseline	90.3	51.5	45.9	48.5	87.8	**87.8**	73.3	79.9	76.5
End-to-end + Inference	90.3	**53.4**	**47.9**	**50.5**	87.8	**87.8**	**74.0**	**80.8**	**77.3**

Table 2: Overall experiment results: per MacNemar's test, the improvements against the end-to-end baseline models by adding inference with *distributional constraints* are both statistically significant for TimeBank-Dense (p-value < 0.005) and I2B2-TEMPORAL (p-value < 0.0005). For I2B2-TEMPORAL, our end-to-end system is optimized for the F_1 score of the gold pairs.

The TimeBank-Dense dataset mitigates this issue by forcing annotators to examine all pairs of events within the same or neighboring sentences, and this dataset has been widely evaluated on this task (Chambers et al., 2014; Ning et al., 2017; Cheng and Miyao, 2017; Meng and Rumshisky, 2018). Temporal relations consist of *BEFORE*, *AFTER*, *INCLUDES*, *INCLUDED*, *SIMULTANEOUS*, and *VAGUE*. Moreover, each event has several properties, e.g., **type**, **tense**, and **polarity**. Event types include `occurrence`, `action`, `reporting`, `state`, etc. Event pairs that are more than 2 sentences away are not annotated.

I2B2-TEMPORAL. In the clinical domain, one of the earliest event temporal datasets was provided in the 2012 Informatics for Integrating Biology and the Bedside (i2b2) Challenge on NLP for Clinical Records (Sun et al., 2013). Clinical events are categorized into 6 types: `treatment`, `problem`, `test`, `clinical-dept`, `occurrence`, and `evidential`. The final data used in the challenge contains three temporal relations: *BEFORE*, *AFTER*, and *OVERLAP*. The 2012 i2b2 challenge also had an end-to-end track, which we use as our feature-based system baseline. To mimic the input structure of TimeBank-Dense, we only consider event pairs that are within 3 consecutive sentences. Overall, 13% of the long-distance relations are excluded.[2]

5.2 Evaluation Metrics

To be consistent with previous work, we adopt two different evaluation metrics. For TimeBank-Dense, we use standard **micro-average** scores that are also used in the baseline system (Han et al., 2019b). Since the end-to-end system can predict the gold pair as *NONE*, we follow the convention of IE tasks and exclude them from the evaluation. For I2B2-TEMPORAL, we adopt the **TempEval** evaluation metrics used in the 2012 i2b2 challenge. These evaluation metrics differ from the standard F_1 in a way that it computes the graph closure for both gold and predictions labels. Since I2B2-TEMPORAL contains roughly six times more missing annotations than the gold pairs, we only evaluate the performance of the gold pairs.

Both datasets contain three types of entities: events, time expressions, and document time. In this work, we focus on **event-event** relations and exclude all other relations from the evaluation.

5.3 Baselines

Feature-based Systems. We use CAEVO[3] (Chambers et al., 2014), a hybrid system of rules and linguistic feature-based MaxEnt classifier, as our feature-based benchmark for TimeBank-Dense. Model implementation and performance are both provided by Han et al. (2019b). As for I2B2-TEMPORAL, we retrieve the predictions from the top end-to-end system provided by Yan et al. (2013) and report the performance according to the evaluation metrics specified in Section 5.2.

Neural Model Baselines. We use the end-to-end systems described by Han et al. (2019b) as our neural network model benchmarks (Row 2 of Table 2). For TimeBank-Dense, the best global structured model's performance is reported by Han et al. (2019b). For I2B2-TEMPORAL, we re-implement the pipeline joint model. [4] Note that this end-to-end model only predicts whether each token is an event as well as each pair of token's relation. Event

---

[2] Over 80% of these long-distance pairs are event coreference, i.e., simply predicting them as *OVERLAP* will achieve high performance.

[3] `https://www.usna.edu/Users/cs/nchamber/caevo/`

[4] `https://github.com/PlusLabNLP/JointEventTempRel`

spans are not predicted, so head-tokens are used to represent events; event types are also not predicted. Therefore, we do not report Span F_1 and Type Accuracy in this benchmark.

End-to-end Baseline. For the *TimeBank-Dense* dataset, we use the pipeline joint (local) model with no global constraints as presented by Han et al. (2019b). In contrast to the aforementioned neural baseline provided in the same paper, this end-to-end model does not use any inference techniques. Hence, it serves as a fair baseline for our method (with inference). For *TimeBank-Dense*, we build our framework based on this model[5].

For the I2B2-TEMPORAL dataset to be more comparable with the 2012 i2b2 challenge, we augment the event extractor illustrated in Figure 2 by allowing event type predictions; that is, for each input token, we not only predict whether it is an event or not, but also predict its event type. We follow the convention in the IE field by adding a "BIO" label to each token in the data. For example, the two tokens in "physical therapy" in Figure 2 will be labeled as B-`treatment` and I-`treatment`, respectively. To be consistent with the partial match method used in the 2012 i2b2 challenge, the event span detector looks for token predictions that start with either "B-" or "I-" and ensures that all tokens predicted within the same event span have only one event type.

RoBERTa-large is used as the base model, and cross-entropy loss is used to train the model. We fine-tune the base model and conduct a grid search on the random hold-out set to pick the best hyper-parameters such as $c_{\mathcal{E}}$ in the multitask learning loss and the weight, $w_{\mathcal{E}_{pos}}$ for positive event types (i.e. B- and I-). The best hyper-parameter choices can be found in Table 6 in the Appendix.

6 Results and Analysis

Table 2 contains our main results. We discuss model performances on TimeBank-Dense and I2B2-TEMPORAL in this section.

6.1 TimeBank-Dense

All neural models outperform the feature-based system by more than 10% per relation F_1 score. Our structured model outperforms the previous SOTA systems with *hard constraints* and **joint event and relation training** by 1.1%. Compared with the end-to-end baseline model with no constraints, our system achieves 2% absolute improvement, which is statistically significant with a p-value < 0.005 per MacNemar's test. This is strong evidence that leveraging Lagrangian Relaxation to incorporate domain knowledge can be extremely beneficial even for strong neural network models.

The ablation study in Table 3 shows how *distributional constraints* work and the constraints' individual contributions. The predicted probability gaps shrink by 0.15, 0.24, and 0.13 respectively for the three constraints chosen, while providing 0.91%, 0.65%, and 0.44% improvements to the final F_1 score for relation extraction. We also show the breakdown of the performance for each relation class in Table 4. The overall F_1 improvement is mainly driven by the recall scores in the positive relation classes (*BEFORE*, *AFTER*, and *INCLUDES*) that have much smaller sample size than *VAGUE*. These results are consistent with the ablation study in Table 3, where the end-to-end baseline model over-predicts on *VAGUE*, and the LR algorithm corrects it by assigning less confident predictions on *VAGUE* to positive and minority classes according to their relation scores.

6.2 I2B2-TEMPORAL

All neural models outperform the feature-based system by more than 30% per relation F_1 score. Our structured model with *distributional constraints* outperforms the neural pipeline joint models of Han et al. (2019b) by 2.5% per absolute scale. Compared with our end-to-end baseline model, our system achieves 0.77% absolute improvement on F_1 measure, which is statistically significant with a p-value < 0.0005 per MacNemar's test. This result also shows that adding inference with *distributional constraints* can be helpful for strong neural baseline models.

Table 9 in the Appendix Section C shows how *distributional constraints* work and their individual contributions. Predicted probability gaps shrink by 0.17, 0.16, 0.11, and 0.14, respectively, for the four constraints chosen, providing 0.19%, 0.25%, 0.22%, and 0.12% improvements to the final F_1 scores for relation extraction. We also have the breakdown performance for each relation class in Table 8. The performance gain is caused mostly by the increase of recall scores in *BEFORE* and *AFTER*. This is consistent with the results in Table 9 where the model over-predicts on the *OVERLAP*

---

[5] Code and data for TimeBank-Dense are published here: `https://github.com/rujunhan/EMNLP-2020`

Constraint Triplets	Prob. Gap	F_1
`occur.`, `occur.`, *VAGUE*	-0.15	+0.91%
`occur.`, `reporting`, *VAGUE*	-0.24	+0.65%
`action`, `occur.`, *VAGUE*	-0.13	+0.44%
`reporting`, `occur.`, *VAGUE**	0.0	0%
Combined F1 Improvement		2.0%

Table 3: TimeBank-Dense ablation study: gap shrinkage of predicted probability and F_1 contribution per constraint. * is selected per Sec. 4, but the probability gap is smaller than the tolerance in the test set, hence no impact to the F_1 score.

	End-to-end Baseline			**End-to-end Inference**		
	P	**R**	**F_1**	**P**	**R**	**F_1**
B	59.0	46.9	52.3	58.6	55.7	57.1
A	69.3	45.3	54.8	67.8	51.5	58.5
I	-	-	-	8.3	1.8	2.9
II	-	-	-	-	-	-
S	-	-	-	-	-	-
V	45.1	55.0	49.5	47.6	51.4	49.4
Avg	51.5	45.9	48.5	53.4	47.9	50.5

Table 4: Model performance breakdown for TimeBank-Dense. "-" indicates no predictions were made for that particular label, probably due to the small size of the training sample. *BEFORE* (**B**), *AFTER* (**A**), *INCLUDES* (**I**), *IS_INCLUDED* (**II**), *SIMULTANEOUS* (**S**), *VAGUE* (**V**)

class, possibly because of label imbalance. Inference is able to partially correct this mistake by leveraging *distributional constraints* constructed with event type and relation corpus statistics.

6.3 Qualitative Error Analysis

We can use the errors made by our structured neural model on TimeBank-Dense to guide potential directions for future research. There are 26 errors made by the structured model that are correctly predicted by the baseline model. In Table 5, we show the error breakdown by constraints. Our method works by leveraging corpus statistics to correct borderline errors made by the baseline model; however, when the baseline model makes borderline correct predictions, the inference could mistakenly change them to the wrong labels. This situation can happen when the context is complicated or when the event time interval is confusing.

For the constraint (`occur.`, `occur.`, *VAGUE*), nearly all errors are cross-sentence event pairs with long context information. In **ex.1**, the gold relation between **responded** and **use** is *VAGUE* because of the negation of **use**, but one could also argue that if **use** were to happen, **responded** is *BEFORE* **use**. This inherent annotation confusion can cause the baseline model to predict *VAGUE* marginally over *BEFORE*. When informed by the constraint statistics that **vague** is over-predicted, the inference algorithm revises the baseline prediction to *BEFORE*. Similarly, in **ex.2** and **ex.3**, one could make strong cases that both the relations between **delving** and **acknowledged**, and **opposed** and **expansion** are *BEFORE* rather than *VAGUE* from the context. This annotation ambiguity can contribute to the errors made by the proposed method.

`occurrence`, `occurrence`, *VAGUE* (57.7%)
ex.1 In a bit of television diplomacy, Iraq's deputy foreign minister responded from Baghdad in less than one hour, saying Washington would break international law by attacking without UN approval. The United States is not authorized to use force before going to the council.
`occurrence`, `reporting`, *VAGUE* (26.9%)
ex.2 A new Essex County task force began delving Thursday into the slayings of 14 black women over the last five years in the Newark area, as law-enforcement officials acknowledged that they needed to work harder...
`action`, `occurrence`, *VAGUE* (15.4%)
ex.3 The Russian leadership has staunchly opposed the western alliance's expansion into Eastern Europe.

Table 5: Error examples and breakdown by constraints.

Our analysis shows that besides the necessity to create high-quality data for event temporal relation extraction, it could be useful to incorporate additional information such as discourse relation (particularly for (`occur.`, `occur.`, *VAGUE*)) and other prior knowledge on event properties to resolve the ambiguity in event temporal reasoning.

7 Discussion

7.1 Constraint Selection

In Sec. 4, we use a 3% threshold when selecting candidate constraints. In this section, we show the impact of relaxing this threshold on TimeBank-Dense. Table 1 shows three constraints that miss the 3% bar by 0.1-0.3%. In Figure 3, we show F_1 scores on the development and test sets by including these constraints. Recall that only constraints that do not hurt development F_1 score are used. Therefore, **Top5** and **Top6** on the chart both correspond to the results in Table 2. **Top7** includes (`reporting`, `reporting`, *VAGUE*), **Top8** includes (`actioin`, `reporting`, *VAGUE*), and **Top9** includes (`reporting`, `actioin`, *VAGUE*).

We observe that F_1 score continues to improve over the development set, but on the test set, F_1 score eventually falls. This appears to support our hypothesis that when the triplet count is small, the ratio calculated based on that count is not so reliable as the ratio could vary drastically between development and test sets. Optimizing over the

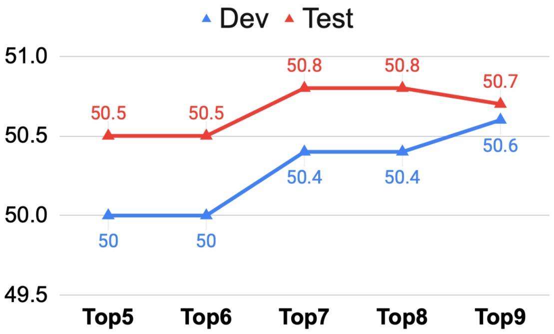

Figure 3: Dev v.s. Test sets performance (F_1 score) after relaxing the threshold of triplet count for selecting constraints. All numbers are percentages.

development set can be an over-correction for the test set, and hence results in a performance drop.

7.2 Event Type Prediction

As described in Sec 5.3, to ensure fair comparison with the previous SOTA system (Han et al., 2019b), our baseline model for TimeBank-Dense does not predict event types. That is, when counting the triplet $(P^m, P^n, \hat{r})$, we assume there is an oracle model that provides event types P^m, P^n for the predicted relation $\hat{r}$. One could potentially extend our work by training a similar multi-task learning model to predict both types and relations as our model does for the I2B2-TEMPORAL dataset. We leave this as a future research direction.

8 Related Work

News Domain. Early work on **temporal relation extraction** use local pair-wise classification with hand-engineered features (Mani et al., 2006; Verhagen et al., 2007; Chambers et al., 2007; Verhagen and Pustejovsky, 2008). Later efforts, such as ClearTK (Bethard, 2013), UTTime (Laokulrat et al., 2013), NavyTime (Chambers, 2013), and CAEVO (Chambers et al., 2014), improve earlier work with better linguistic and syntactic rules. Yoshikawa et al. (2009); Ning et al. (2017); Leeuwenberg and Moens (2017) explore structured learning for this task, and more recently, neural methods have also been shown effective (Tourille et al., 2017; Cheng and Miyao, 2017; Meng et al., 2017; Meng and Rumshisky, 2018). Ning et al. (2018c) and Han et al. (2019b) are the most recent work leveraging neural network and pre-trained language models to build an end-to-end system. Our work differs from these prior work in that we build a structured neural model with *distributional constraints* that combines both the benefits of both deep learning and *domain knowledge*.

Clinical Domain. The 2012 i2b2 Challenge ((Sun et al., 2013)) is one of the earliest efforts to advance event temporal relation extraction of clinical data. The challenge hosted three tasks on event (and event property) classification, temporal relation extraction, and the end-to-end track. Following this early effort, a series of clinical event temporal relation challenges were created in the following years ((Bethard et al., 2015, 2016, 2017)). However, data in these challenges are relatively hard to acquire, and therefore they are not used in this paper. As in the news data, traditional machine learning approaches (Lee et al., 2016; Chikka, 2016; Xu et al., 2013; Tang et al., 2013; Savova et al., 2010) that tackle the end-to-end event and temporal relation extraction problem require time-consuming feature engineering such as collecting lexical and syntax features. Some recent work (Dligach et al., 2017; Leeuwenberg and Moens, 2017; Galvan et al., 2018) apply neural network-based methods to model the temporal relations, but are not capable of incorporating prior knowledge about clinical events and temporal relations as proposed by our framework.

9 Conclusion

In conclusion, we propose a general framework that augments deep neural networks with *distributional constraints* constructed using probabilistic *domain knowledge*. We apply it in the setting of end-to-end temporal relation extraction task with event-type and relation constraints and show that the MAP inference with *distributional constraints* can significantly improve the final results.

We plan to apply the proposed framework on various event reasoning tasks and construct novel *distributional constraints* that could leverage *domain knowledge* beyond corpus statistics, such as the larger unlabeled data and rich information contained in knowledge bases.

B Data Summary

C I2B2-TEMPORAL Results

We show the breakdown performance and contributions of individual constraints for I2B2-TEMPORAL in Table 8 and Table 9 respectively.

	TimeBank-Dense	I2B2-TEMPORAL
$c_{\mathcal{E}}$	-	1.0
$w_{\mathcal{E}_{pos}}$	-	5.0
lr	-	$2e^{-5}$
α	5.0	5.0
θ	0.05	0.02
γ	0.7	0.8

Table 6: Hyper-parameters chosen using development data. For TimeBank-Dense, end-to-end baseline model is provided by the Han et al. (2019b), so we do not train it from scratch.

	TimeBank-Dense	I2B2-TEMPORAL
# of Documents		
Train	22	190
Dev	5	-
Test	9	120
# of Pairs		
Train	4032	11253
Dev	629	-
Test	1427	8794

Table 7: Data overview. Note that we exclude event pairs whose sentence distance longer than 3 in I2B2-TEMPORAL, and there are 6 times more missing relations than the gold annotated ones in, which explains why number of pairs per documents are smaller in I2B2-TEMPORAL than in TimeBank-Dense.

D Reproducibility List

- Data and code used for TimeBank-Dense can be found in project code base. However, due to user confidentiality agreement, we are not able to provide data and and data analysis code for I2B2-TEMPORAL. Modeling code will be added to the project code base upon obtaining permission from the data owner.

- We use BERT-base-uncased and Roberta-large models implemented in Huggingface transformers. Additional parameters (such as LSTM and MLP) are negligible compared to those used in the pre-trained LMs;

- ILP is solved by an off-the-shelf solver provided by Gurobi optimizer;

- Range of grid-search. $c_{\mathcal{E}}$: (1.0, 2.0); $w_{\mathcal{E}_{pos}}$: (1.0, 2.0, 5.0, 10.0); lr: ($1e^{-5}$, $2e^{-5}$, $5e^{-5}$), α: (1.0, 2.0, 5.0, 10.0); θ: (0.2, 0.3, 0.5); γ: (0.7, 0.8, 0.9).

Abstract

Inferring missing facts in temporal knowledge graphs (TKGs) is a fundamental and challenging task. Previous works have approached this problem by augmenting methods for static knowledge graphs to leverage time-dependent representations. However, these methods do not explicitly leverage multi-hop structural information and temporal facts from recent time steps to enhance their predictions. Additionally, prior work does not explicitly address the temporal *sparsity* and *variability* of entity distributions in TKGs. We propose the **Te**mporal **M**essage **P**assing (TeMP) framework to address these challenges by combining graph neural networks, temporal dynamics models, data imputation and frequency-based gating techniques. Experiments[1] on standard TKG tasks show that our approach provides substantial gains compared to the previous state of the art, achieving a 10.7% average relative improvement in Hits@10 across three standard benchmarks. Our analysis also reveals important sources of variability both within and across TKG datasets, and we introduce several simple but strong baselines that outperform the prior state of the art in certain settings.

1 Introduction

The ability to infer missing facts in temporal knowledge graphs is essential for applications such as event prediction (Leblay and Chekol, 2018; De Winter et al., 2018), question answering (Jia et al., 2018), social network analysis (Zhou et al., 2018; Trivedi et al., 2019) and recommendation systems (Kumar et al., 2018).

Whereas static knowledge graphs (KGs) represent facts as triples (e.g., *(Obama, visit, China)*), temporal knowledge graphs (TKGs) additionally associate each triple with a timestamp (e.g., *(Obama, visit, China, 2014)*). Figure 1 shows a subgraph of such TKG. Usually, TKGs are assumed to consist of discrete timestamps (Jiang et al., 2016), meaning that they can be represented as a sequence of static KG snapshots, and the task of inferring missing facts across these snapshots is referred to as temporal knowledge graph completion (TKGC).

Recent works on TKGC have largely focused on developing time-dependent scoring functions, which score the likelihood of missing facts and build closely upon popular representation learning methods for static KGs (Dasgupta et al., 2018; Jiang et al., 2016; Goel et al., 2019; Xu et al., 2019; Lacroix et al., 2020). However, while powerful, these existing methods do not properly account for multi-hop structural information in TKGs, and they lack the ability to explicitly leverage temporal facts in nearby KG snapshots to answer queries. Knowing facts like *(Obama, make agreement with, China, 2013)* or *(Obama, visit, China, 2012)* is useful for answering the query *(Obama, visit, ?, 2014)*.

Moreover—and perhaps more importantly—there are also serious challenges regarding *temporal variability* and *temporal sparsity*, which previous works fail to address. In real-world TKGs, models have access to *variable* amounts of reference temporal information in near KG snapshots when answering different queries (Figure 2 and Figure 6 in the Appendix). For example, in a political event dataset, there are likely to be more quadruples with subject-relation pair *(Obama, visit)* than *(Trump, visit)* from 2008 to 2013.[2] Hence the model could access more reference information to answer *where Obama visited in 2014*.

The *temporal sparsity* problem reveals that only a small fraction of entities are *active*[3] at each time

---

[1] Code and data are published at `https://github.com/JiapengWu/TeMP`

[2] Obama was the president of US during the period.

[3] An entity is *active* at a time step if it has at least one neighboring entity in the same KG snapshot.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5730–5746,
November 16–20, 2020.

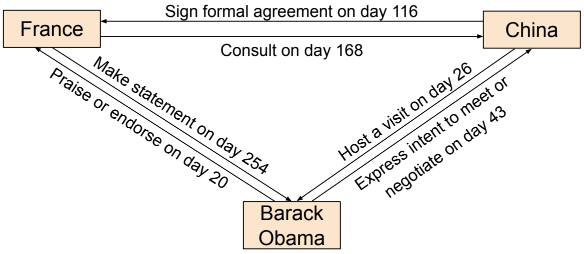

Figure 1: A sample temporal knowledge subgraph involving France, China and Barack Obama.

step (Figure 7 in the Appendix). Previous methods usually assign the same embedding for *inactive* entities at different time steps, which is not fully representative of the time-sensitive features.

Present work. To address these issues, we introduce the **Te**mporal **M**essage **P**assing (TeMP) framework, which combines neural message passing and temporal dynamic models. We then propose frequency-based gating and data imputation techniques to counter the temporal sparsity and variability issues.

We achieve state-of-the-art performance on standard TKGC benchmarks. In particular, on the standard ICEWS14, ICEWS05-15, and GDELT datasets, TeMP is able to provide an 7.3% average relative improvement in Hits@10 compared to the next-best model. Fine-grained error analysis on these three datasets demonstrates the unique contributions made by each of the different components of TeMP. Our analysis also highlights important sources of variability, in particular variations in temporal sparsity both within and across TKG datasets, and how effects of different components are affected by such variability.

2 Related Work

Static KG representation learning Much research exists on representation learning methods for static KGs, in which entities and relations are represented as low-dimensional embeddings (Nickel et al., 2011; Yang et al., 2014; Trouillon et al., 2016; Nickel et al., 2016). Generally, these methods involve a *decoding* method, which scores candidate facts based on entity and relation embeddings, and the models are optimized so that valid triples receive higher scores than random *negative examples*. While these methods typically rely on shallow encoders to generate the embeddings—i.e., single embedding-lookup layers (Hamilton et al., 2017)—message passing (or graph neural network; GNN) approaches have also been proposed (Schlichtkrull et al., 2018; Vashishth et al., 2019; Busbridge et al., 2019) to leverage multi-hop information around entities.

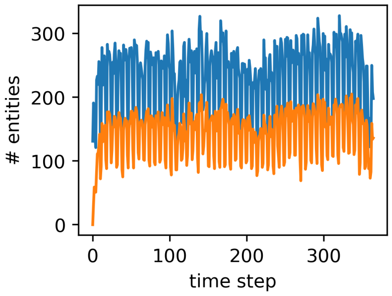

Figure 2: Dataset statistics of the ICEWS14 dataset. The blue (top) curve shows the number of active entities at each time step, while the orange (bottom) curve represents the number of active entities at each time step that are also active at least once in the past 15 time steps. While the total number of entities is 7,128, only 2% – 4% of these entities are active at each time step. (See Appendix A.5 for further examples and discussion).

Temporal KG representation learning Recent works endeavor to extend static KGC models to the temporal domain. Typically, such approaches employ embedding methods with a shallow encoder and design time-sensitive quadruple decoding functions (Dasgupta et al., 2018; Jiang et al., 2016; Goel et al., 2019; Xu et al., 2019; Lacroix et al., 2020). While time-specific information is considered by these methods, entity-level temporal patterns such as event periodicity are not explicitly captured.

Another line of work on temporal (knowledge) graph reasoning uses message passing networks to capture intra-graph neighborhood information, which is sometimes combined with temporal recurrence or attention mechanisms (Manessi et al., 2020; Kumar et al., 2018; Pareja et al., 2019; Chen et al., 2018; Jin et al., 2019; Sankar et al., 2020; Hajiramezanali et al., 2019). Orthogonal to our work, Trivedi et al. (2017, 2019); Han et al. (2020) explore using temporal point processes. However, their focus is on continuous TKGC. The prior works that most resemble our framework are Recurrent Event Networks (RE-NET) (Jin et al., 2019) and DySAT (Sankar et al., 2020). RE-NET uses multi-level RNNs to model entity interactions, while DySAT uses self-attention to learn latent node representations on dynamic graphs. However, both these works were proposed for the task of graph extrapolation (i.e., inferring the next time-step in a sequence), so they are not directly compatible with the TKGC setting.

3 Proposed Approach

We first define our key notation and provide an overview of our TeMP framework, before describing the individual components in detail in the following sections.

Notation and task definition. Our goal is to predict missing facts in a temporal knowledge graph (TKG) $\mathcal{G} = \{G^{(1)}, G^{(2)}, ..., G^{(T)}\}$, where $G^{(t)} = (E, R, D^{(t)})$. Here, E and R stand for the union of sets of entities and relations across all time steps and are known in advance. $D^{(t)}$ denotes the set of all *observed* triples (s, r, o) at time t, with subjects $s \in E$, objects $o \in E$ and relations $r \in R$. Let $\overline{D}^{(t)}$ denote the set of *true* triples at time t such that $D^{(t)} \subseteq \overline{D}^{(t)}, \forall t$, the temporal knowledge graph completion (TKGC) problem is defined as ranking the subject and object entities given object queries $(s, r, ?\,, t)$ and subject queries $(?\,, r, o, t)$ where $(s, r, o) \in \overline{D}^{(t)}$ but $(s, r, o) \notin D^{(t)}, t \in \{0, ..., T\}$.

Overview of TeMP.

Following common practice, we structure our TeMP framework around the notion of an *encoder* and *decoder*. The encoder maps each entity $e_i \in E$ to time-dependent low-dimensional embedding $\boldsymbol{z}_{i,t}$ at each time-step t, while the decoder uses these entities' embeddings to score the likelihood of a temporal fact.

Figure 3 depicts the architecture of our model. A key insight in TeMP is that we use an encoder that combines a *structural* entity representation and *temporal* representations. The structural encoder (SE) based on a multi-relational message passing network produces entity representation $\boldsymbol{x}_{i,t} = \text{SE}(e_i, D^{(t)})$ while the temporal encoder (TE) integrates the output of SE at previous time steps to induce $\boldsymbol{z}_{i,t} = \text{TE}(\boldsymbol{x}_{i,t-\tau}, ..., \boldsymbol{x}_{i,t})$. Here τ stands for the number of temporal input KG snapshots to the model.

In addition, in Section 3.3, we propose a series of augmentations to TeMP that are designed to address the temporal sparsity and variability issues of real-world TKGs. Finally, in Section 3.4, we discuss how TeMP can leverage existing decoders from the static KG setting in order to train a model.

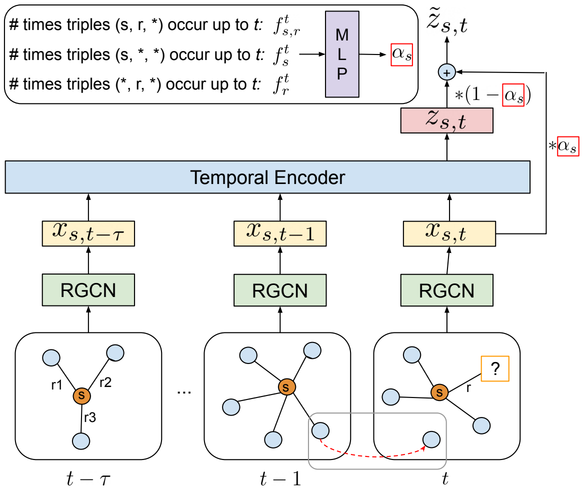

Figure 3: Architecture of TeMP Framework. TeMP combines structural graph encoder and temporal encoder to induce entity representations. Given query $(s, r, ?\,, t)$ at time t, TeMP takes graphs from time step $t-\tau$ to t as input to compute structural embedding $\boldsymbol{x}_{s,t}$ and temporal embedding $\boldsymbol{z}_{s,t}$ for the centering entity s. The final representation $\tilde{\boldsymbol{z}}_{s,t}$ is obtained by further applying frequency-based gating, as illustrated in the upper rectangle. The red dotted arrow at the bottom indicates the imputation process for an inactive entity at time step t.

3.1 Structural Encoder

The first key component of TeMP is the structural encoder, which generates entity embeddings based on the graph $G^{(t)}$ within each time-step. We build our structural encoder by adapting existing techniques for message passing on static knowledge graphs (Schlichtkrull et al., 2018).

$$\boldsymbol{h}^{(0)}_{i,t} = \boldsymbol{W}_0 \boldsymbol{u}_i, \forall t \in 0, ..., T,$$
$$\boldsymbol{h}^{(l+1)}_{i,t} = \sigma\Big(\sum_{r \in R} \sum_{j \in N^r_i} \frac{1}{|N^r_i|} \boldsymbol{W}^{(l)}_r \boldsymbol{h}^{(l)}_{j,t} + \boldsymbol{W}^{(l)}_s \boldsymbol{h}^{(l)}_{i,t}\Big)$$

Here, $\boldsymbol{u}_i$ denotes a one-hot embedding indicating entity e_i, $\boldsymbol{W}_0$ is an entity embedding matrix, and $\boldsymbol{W}^{(l)}_r$ and $\boldsymbol{W}^{(l)}_s$ are transformation matrices specific to each layer of the model. These matrices are shared across all discrete time stamps. We use N^r_i to denote the set of neighboring entities of e_i connected by relation r, whose size acts as a normalizing constant for averaging the neighborhood information. After running L layers of this message-passing approach on a snapshot $G^{(t)}$, we use $\boldsymbol{x}_{i,t} = \boldsymbol{h}^{(L)}_{i,t}$ to denote the resulting structural embedding of entity e_i, which summarizes its L-hop neighborhood within $G^{(t)}$.

While we focus on RGCN as the structural encoder, our framework is not tied to any specific multi-relational message passing network. One can swap RGCN with any multi-relational graph encoder, e.g. CompGCN (Vashishth et al., 2019) and EdgeGAT (Busbridge et al., 2019).

3.2 Temporal Encoder

The second key component of TeMP is the temporal encoder, which seeks to integrate information *across* time in the entity representations. We investigate two approaches to compute entity representation $\boldsymbol{z}_{i,t}$ leveraging temporal information: a recurrent architecture (inspired by Jin et al. (2019)) and a self-attention approach (inspired by Sankar et al. (2020)).

Temporal recurrence model (TeMP-GRU). We propose to couple a traditional recurrence mechanism with weight decay, in order to account the diminishing effect of historical facts. Let t^- denote the last time step at which entity e_i was *active* before t, the down-weighted entity representation $\hat{\boldsymbol{z}}_{i,t^-}$ is defined as follows:

$$\hat{\boldsymbol{z}}_{i,t^-} = \gamma^z_{i,t^-}\boldsymbol{z}_{i,t^-} \tag{1}$$

$$\gamma^z_{i,t^-} = \exp\{-\max(0, \lambda_z|t-t^-|+b_z)\}, \tag{2}$$

where γ^z denotes the decay rate with λ_z and b_z as learnable parameters. This design is inspired by Che et al. (2018) and ensures that γ^z is monotonically decreasing with respect to the temporal difference and ranges from 0 to 1. We ensure that $\hat{\boldsymbol{z}}_{i,t^-}$ is only nonzero if $t^- \in \{t-\tau, .., t-1\}$, otherwise it will be assigned a zero vector. Finally, we use a gated recurrent unit (GRU) to obtain the entity embedding $\boldsymbol{z}_{i,t}$ based on $\hat{\boldsymbol{z}}_{i,t^-}$ and the static representation $\boldsymbol{x}_{i,t}$:

$$\boldsymbol{z}_{i,t} = \mathrm{GRU}(\boldsymbol{x}_{i,t}, \hat{\boldsymbol{z}}_{i,t^-}), \tag{3}$$

where GRU denotes the standard cell defined by Cho et al. (2014).

Temporal self attention model (TeMP-SA). Another way to incorporate historical information is to selectively attend to the sequence of active temporal entity representations. We use the following equations—inspired by the transformer architecture (Vaswani et al., 2017)—to perform attentive pooling over the entity embeddings $\boldsymbol{x}_{i,t'}$ at each time step $t' \in \{t-\tau, .., t\}$, in order to generate time-dependent embeddings $\boldsymbol{z}_{i,t}$:

$$\boldsymbol{q}_{ij} = \frac{(\boldsymbol{x}_{i,t}\boldsymbol{W}_q)(\boldsymbol{x}_{i,t-j}\boldsymbol{W}_k)^T}{\sqrt{d}} \tag{4}$$

$$\boldsymbol{e}_{ij} = \boldsymbol{q}_{ij} - \max(0, \lambda_z j + b_z) + \boldsymbol{M}_{ij} \tag{5}$$

$$\boldsymbol{\beta}_{ij} = \frac{\exp(\boldsymbol{e}_{ij})}{\sum_{k=0}^{\tau}\exp(\boldsymbol{e}_{ik})} \tag{6}$$

$$\boldsymbol{z}_{i,t} = \sum_{j=0}^{\tau}\boldsymbol{\beta}_{ij}(\boldsymbol{x}_{i,t-j}\boldsymbol{W}_v), \tag{7}$$

where $\boldsymbol{W}_q, \boldsymbol{W}_k, \boldsymbol{W}_v \in \mathbb{R}^{d\times d}$ denote linear projection matrices, as in a transformer layer (Vaswani et al., 2017), $\boldsymbol{\beta} \in \mathbb{R}^{|E|\times\tau}$ denotes the attention weight matrix obtained by multiplicative attention function and $\{\lambda_z, b_z\}$ denotes the learnable parameters of the down-weighting function. The $\boldsymbol{M} \in \mathbb{R}^{|E|\times\tau}$ matrix is a mask defined as

$$\boldsymbol{M}_{ij} = \begin{cases} 0, & \text{if } e_i \text{ is active at time } t-j, \\ -\infty, & \text{otherwise.} \end{cases} \tag{8}$$

As $\boldsymbol{M}_{ij} \rightarrow -\infty$, the attention weights $\boldsymbol{\beta}_{ij} \rightarrow 0$, which ensures that only active temporal entity representations are assigned non-zero weights. Finally, note that the full self-attention model can be generalized to use multiple attention heads, as in Vaswani et al. (2017).

Incorporating future information. Note that in the TKGC setting, we assume that the model has access to all the time steps during training. In particular, we assume there is missing data within each time step but that all the (incomplete) snapshots information $D^{(t)}$ are available during training. Thus, in both the attention and recurrence-based approaches, it is worthwhile to integrate temporal information from both the past and future. We do so by employing a bi-directional GRU in the recurrent approach, and by attending over both past and future time steps in the attention-based approach.

3.3 Tackling Temporal Heterogeneities

Although TeMP jointly models structural and temporal information, the encoder alone is insufficient to deal with the *temporal heterogeneity* in real-world TKGs, namely *sparsity* and *variability* of entity occurrences. We explore data imputation and frequency-based gating techniques to address these temporal heterogeneities. Because the degrees of temporal heterogeneities vary drastically across datasets (Appendix A.5), our proposed techniques are optional model variations that may improve model performance depending on the dataset characteristics.

Imputation of inactive entities. Recall that structural encoder only encodes neighboring entities within the same KG snapshot. For entity e_i that is inactive at time step t, the static representation $\boldsymbol{x}_{\boldsymbol{i},\boldsymbol{t}}$ is hence not informed by any structural neighbors, resulting in stale representations shared across multiple time steps. We propose an imputation (IM) approach that integrates stale representations with temporal representations for inactive entities, i.e., $\hat{\boldsymbol{x}}_{i,t} = \mathrm{IM}(\boldsymbol{x}_{i,t}, \boldsymbol{x}_{i,t-})$, where $\hat{\boldsymbol{x}}_{i,t}$ represents imputed structural representation.

Without loss of generality, we define the imputation for a uni-directional model and refer the bidirectional case to Appendix A.2. We defined IM to be the weighted sum function, with the similar exponential decay mechanism used in Equation (1):

$$\gamma^x_{i,t^-} = \exp\{-\max(0, \lambda_x|t - t^-|+b_x)\}. \quad (9)$$

The imputed representation is defined as follows:

$$\hat{\boldsymbol{x}}_{i,t} = \gamma^x_{i,t^-}\boldsymbol{x}_{i,t^-} + (1 - \gamma^x_{i,t^-})\boldsymbol{x}_{i,t}. \quad (10)$$

This model-agnostic approach is applicable by replacing $\boldsymbol{x}_{i,t}$ in the temporal models with $\hat{\boldsymbol{x}}_{i,t}$.

Frequency-based gating. In addition to imputation, we also implement an approach to perform frequency-based gating (FG). The encoded representation of an entity is modulated depending on how many recent temporal facts it participates in. In particular, we propose to learn a gating term in order to fuse the embeddings $\boldsymbol{x}_{i,t}$ from output of the structural encoder (Section 3.1) with the temporal embeddings $\boldsymbol{z}_{i,t}$ (Section 3.2) in a frequency-dependent way. We differentiate the weights by the query types (subject or object query) and entity position (whether e_i is subject or object in the queried fact) in order to contextualize the entities into their role within a quadruple.

In what follows, we use the term *pattern* to denote a non-empty subset of the quadruple (s, r, o, t) (not containing time t). The *temporal frequency* of a pattern is defined as the number of facts with such pattern in the defined time window. Consider the quadruple *(Obama, visit, China, 2014)*, the temporal frequency of the pattern *(Obama, visit)* is the number of quadruples *(Obama, visit, $*$, t')* with t' in the time window (e.g., from 2000 to 2014).

We define the following *temporal pattern frequencies* (TPFs) associated with the quadruple (s, r, o, t): (1) subject frequency f^t_s, (2) object frequency f^t_o, (3) relation frequency f^t_r, (4) subject-relation frequency $f^t_{s,r}$, (5) relation-object frequency $f^t_{r,o}$.

Without loss of generality, we define our gating mechanism from the perspective of object queries $(s, r, ?\,, t)$, where the goal is to predict the missing object in a quadruple. The definition for subject queries is analogous and detailed in Appendix A.3.

When answering the object query $(s, r, ?\,, t)$ the model has only the access to frequencies $F_s = [f^t_s, f^t_r, f^t_{s,r}]$. Thus, we use the frequency vector F_s to define a gating term over the embeddings in the query:

$$\tilde{\boldsymbol{z}}_{s,t} = \alpha_{os}\boldsymbol{x}_{s,t} + (1 - \alpha_{os})\boldsymbol{z}_{s,t} \quad (11)$$

$$\tilde{\boldsymbol{z}}_{o,t} = \alpha_{oo}\boldsymbol{x}_{o,t} + (1 - \alpha_{oo})\boldsymbol{z}_{o,t}, \quad (12)$$

where $\alpha_{os} = \mathrm{MLP}_{os}(F_s), \alpha_{oo} = \mathrm{MLP}_{oo}(F_s)$ are weights in the range $[0, 1]$ learned via a two-layer dense neural network. Here the calculation for object embedding $\tilde{\boldsymbol{z}}_{o,t}$ covers all entities.

3.4 Decoder and Training

Let $\phi(.)$ denote the score for a tuple and let DEC denote any proper decoding function for static KGs, e.g., the TransE decoder (Bordes et al., 2013). The score for the quadruple is defined as follows:

$$\phi(s, r, o, t) = \mathrm{DEC}(\tilde{\boldsymbol{z}}_{s,t}, \boldsymbol{z}_r, \tilde{\boldsymbol{z}}_{o,t}). \quad (13)$$

Here, $\tilde{\boldsymbol{z}}_{s,t}$ and $\tilde{\boldsymbol{z}}_{o,t}$ are the subject and object embeddings (as defined in Sections 3.1-3.3) while $\boldsymbol{z}_r$ is a learned embedding of the relation r. To train a model using this score function, the model parameters are learned using gradient-based optimization in mini-batches. For each triple $\eta = (s, r, o) \in D^{(t)}$, we sample a negative set of entities $D^-_\eta = \{o'|(s, r, o') \notin D^{(t)}\}$ and define the cross-entropy loss as follows:

$$L = -\sum_{t=1}^{T}\sum_{\eta\in D^{(t)}} \frac{\exp(\phi(s, r, o, t))}{\sum_{o'\in D^-_\eta}\exp(\phi(s, r, o', t))}.$$

Note that without loss of generality, we defined the above loss over object queries (as in Section 3.3), with an analogous loss and negative sampling used for subject queries defined in Appendix A.3.

4 Experiments

We evaluate the performances of TeMP models on three standard TKGC benchmark datasets and analyze the strengths and shortcomings when answering queries with different characteristics. Code to

4.1 Datasets

We evaluate our model on Global Database of Events, Language and Tone (GDELT) (Leetaru and Schrodt, 2013) and Integrated Crisis Early Warning System (ICEWS) (Boschee et al., 2015) datasets. For ICEWS, we use the two subsets generated by García-Durán et al. (2018): ICEWS14, corresponding to the facts in 2014 and ICEWS 05-15, containing all facts from 2005 to 2015. For GDELT, we use the subset provided by Trivedi et al. (2017) corresponding to facts from April 1, 2015 to March 31, 2016. We utilize the same partitioning of train, validation and test set as specified by Goel et al. (2019). More dataset statistics are summarized in Appendix A.5.

4.2 Evaluation Metrics

For each quadruple (s, r, o, t) in the test set, we evaluate two queries $(s, r, ?, t)$ and $(?, r, o, t)$. For the first query we calculate scores for $(s', r, o, t), \forall s' \in E$ using Equation (13). Similar procedure applies to the second query. We then calculate the metrics based on the rank of (s, r, o, t) in each query. Evaluation is performed under filtered settings defined by Bordes et al. (2013). We report the Hits@1,@3, @10 scores and MRR (mean reciprocal rank). Please see Appendix A.6 for detailed definitions.

4.3 Baseline Methods

We compare TeMP against a broad spectrum of existing approaches, including a novel rule-based baseline, static embedding methods, and existing state-of-the-art approaches for TKGC.

TED model. We propose a rule-based baseline by directly copying facts from quadruples in the recent past and future, denoted as temporal exponential decay (TED) model. The basic idea in this approach is that we predict missing facts by simply copying facts from nearby time steps. The probability of copying each fact is dependent on (1) number of elements overlapping with the queried quadruple and (2) temporal distance to the current time step. For a detailed description of this baseline, please refer to Appendix A.4.

Static KGC methods. We include TransE (Nguyen et al., 2016), DistMult (Yang et al., 2014), ComplEx (Trouillon et al., 2016) and SimplE (Kazemi and Poole, 2018) in the realm of static KG embedding methods. We also include a Static RGCN baseline (denoted as SRGCN), which implements the RGCN message-passing approach proposed by Schlichtkrull et al. (2018). Note that all these static baseline methods are employed without considering the time information in the input.

Temporal KGC methods. We also compare with state-of-the arts models designed for TKGC including TTransE (Leblay and Chekol, 2018), TADistMult (García-Durán et al., 2018), HyTe (Dasgupta et al., 2018), Diachronic Embedding (DE) (Goel et al., 2019), AtisEE, AtisER (Xu et al., 2019) and TNTComplEx (Lacroix et al., 2020). We don't compare with RE-NET, GHN (Han et al., 2020), DartNet (Garg et al., 2020) and Know-Evolve since these work focus on graph extrapolation task.

4.4 Implementation and Hyperparameters

All the models except TED are implemented in PyTorch, making use of the PyTorch lightning module and the Deep Graph Library (Wang et al., 2019). We set the negative sampling ratio to 500, i.e. 500 negative samples per positive triple. Because we corrupt subjects and objects separately, there are in total 1000 negative samples collected to estimate the probability of a factual triple. For full details on all the model hyperparameters for TeMP and the baselines, refer to Appendix A.7.

4.5 Results and Analysis

4.5.1 Comparative Study

We compare the baseline models with two instantiations of the TeMP framework: *TeMP-GRU*, *TeMP-SA*, corresponding to the GRU and self-attention variants discussed in Section 3.2. Incorporating imputation or frequency-based gating is treated optional and we explore different model variants in Section 4.5.2. Results on each dataset are given by the model variant that achieves the best validation set performance. The core experimental results are summarized in Table 1.

TeMP achieves a new state of the art. We find that TeMP-SA and TeMP-GRU achieve state-of-the-art results on all three datasets in terms of Hits@10. Compared to the most recent work (Lacroix et al., 2020)—which achieves the best performance to-date on the ICEWS datasets—our results are 8.0% and 10.7% higher on the Hits@10 evaluation, though they are slightly worse on Hits@1. Additionally, our model achieves a 3.7% improvement on GDELT compared with DE, the prior state-of-the-art on that dataset. The results of the AtiSEE and TNTComplEx methods on the GDELT dataset are not available.

Strong baseline performance. Interestingly, we find that two of our proposed baseline models also achieve surprisingly strong performance, even outperforming the prior state of the art in some settings. For example, our rule-based TED baseline achieves relatively strong performance on all three datasets, in particular on GDELT, where it is better than all existing neural models by all measures. This highlights the power of simply copying temporal facts with the same patterns as the queried quadruples. Similarly, our static RGCN baseline (*SRGCN*) also achieves very strong performance, with the next-best Hits@10 results behind the TeMP framework. We hypothesize that the message-passing procedure in SRGCN allows the model to leverage multi-hop structural information that is specific to each time-step, enabling strong performance.

4.5.2 Exploration of Model Variations

We study the effect of the imputation and frequency-based gating approaches proposed in Section 3.3 by running model variants on three datasets. We highlight the performance comparison as well as the implication of dataset characteristics on the performance variations.

Our results are reported on the corresponding validation sets of these benchmarks. The results regarding the incorporation of imputation (IM) and frequency-based gating (FG) are shown in Table 2. We use a ✓ to indicate a certain component being used in the experiment, and blank for the absence of the corresponding component. [4]

ICEWS14. On the ICEWS14 dataset, we find that combining both TeMP-GRU and TeMP-SA models with both imputation and gating achieves the best results on validation set (3.3% improvement). Additionally, each individual component helps improve the overall model performance by about 1%.

ICEWS05-15. On ICEWS05-15, models with gating improved the performance by more than 1% compared to those without gating. However, the additional incorporation of imputation does not result in improvement in the results.

GDELT. As for GDELT dataset, we find neither imputation nor gating is significant for model performance. However, it is evident from dataset characteristics that GDELT does not exhibit the same temporal variability and sparsity as the ICEWS datasets. Discussion in Appendix A.5 shows that all entities are active at every time step in GDELT

---

[4] Imputation is an intrinsic part of TeMP-SA thus it is used in all experiments. See Appendix A.2 for details.

Table 2: MRR results for different model variations on ICEWS14, ICEWS05-15 and GDELT

Model	IM	FG	ICEWS14	ICEWS05-15	GDELT
TeMP-GRU	✓	✓	**0.610**	0.680	0.269
TeMP-GRU		✓	0.599	**0.689**	0.270
TeMP-GRU	✓		0.593	0.670	**0.275**
TeMP-GRU			0.577	0.673	0.274
TeMP-SA	✓	✓	**0.623**	**0.676**	0.233
TeMP-SA	✓		0.619	0.670	**0.235**

(unlike the ICEWS datasets). Additionally, on average each active entity has roughly 150 reference temporal facts in the last 15 time steps, suggesting that each entity involved in TKGC queries are sufficiently informed by the nearby KG snapshots. Data imputation and gating methods are thus unnecessary complexities in GDELT.

4.5.3 Fine-grained Error Analysis

To assess how models perform on TKGC queries with different temporal pattern frequencies (TPFs; see Section 3.3), we group queried quadruples based on different TPFs and calculate the Hits@10 metrics in each group.

We plot the temporal subject-relation frequency $f^t_{s,r}$ (defined in Section 3.3) versus the model performances on subject and object queries to study the *replication* and *reference* effects of temporal facts, respectively. Here, we use the term *replication effect* to denote the situation where the model can make predictions by copying the exact correct answer to a query from temporal facts. For example, copying *China* from *(Biden, visit, China, 2013)* to answer the query *(Obama, visit, ?, 2014)*. We use the term *reference effect* to denote the effect of having facts that are related (but do not not contain answer entity) to the query fact in the temporal context. For example, selecting *China* from a set countries where Obama visited in the year 2013.

We compare the performances of static models (DE and SRGCN) and temporal models (TeMP-GRU models) on different TPFs. *TeMP-GRU-Vanilla* represents the vanilla version of the model and *TeMP-GRU-Gating* refers to TeMP-GRU model combined with gating technique. Detailed analysis regarding TKGC performance versus other TPFs are discussed in Appendix A.8.

Replication effect analysis Here, we examine how the subject-relation TPF correlates with model performance on subject queries. Figure 4 illustrates that temporal models exhibit positive correlation between subject-relation TPF and subject query performance, while static models show relatively negative correlation between the two quantities. This suggests that the replication effect is stronger in TeMP, indicating that the TeMP model is better at utilizing temporal information for TKGC queries. Additionally, gating helps improve over the vanilla version by a slight margin on all subject-relation frequency values. On the other hand, SRGCN achieves better performance on low-TPF queries than temporal models. However, coupling the TeMP model with gating helps close the gap, sometimes surpassing SRGCN on such queries.

Reference effect analysis. Here, we examine how the occurrence of related facts (not containing the answer) in the temporal context impacts performance. We find that the temporal models exhibit non-linear correlations between object query performance and subject-relation TPF (Figure 5). In particular, on the ICEWS datasets the performance increases as the log-frequencies grows from $-\infty$ to 2 and drops at higher frequency values. We hypothesize that it is harder for temporal model to select the answer from a very large set of object candidates, e.g,. choosing *China* from more than 100 countries that Obama visited from 2008 to 2013. In terms of model comparisons, we find that gating helps TeMP-GRU to surpass its vanilla version and SRGCN on most TPF values. The margin of improvement is especially significant on queries of high TPF in ICEWS05-15.

The null effect of frequency-based gating on GDELT can be attributed to the same reason as discussed in Section 4.5.2.

5 Conclusion

In this work, we present a novel framework named TeMP for temporal knowledge graph completion (TKGC). TeMP computes entity representation by jointly modelling multi-hop structural information and temporal facts from nearby time-steps.

Additionally, we introduce novel frequency-based gating and data imputation techniques to address the temporal variability and sparsity problems in TKGC. We show that our model is able to achieve superior performance (10.7% relative improvement) over the state-of-the-arts on three benchmark datasets. Our work is potentially beneficial to other tasks such as temporal information extraction and temporal question answering, by providing beliefs about the likelihood of facts at particular points in time.

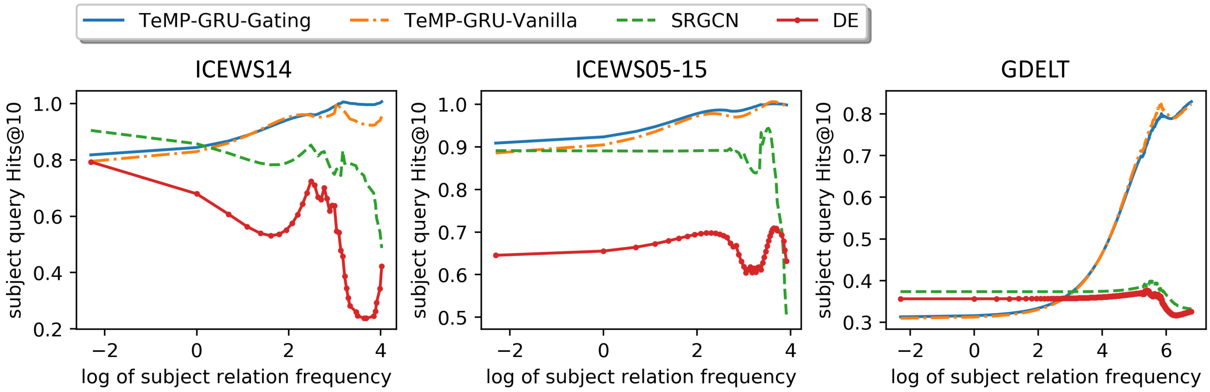

Figure 4: Subject query hit@10 performance comparison of TeMP with different variations and baseline methods.

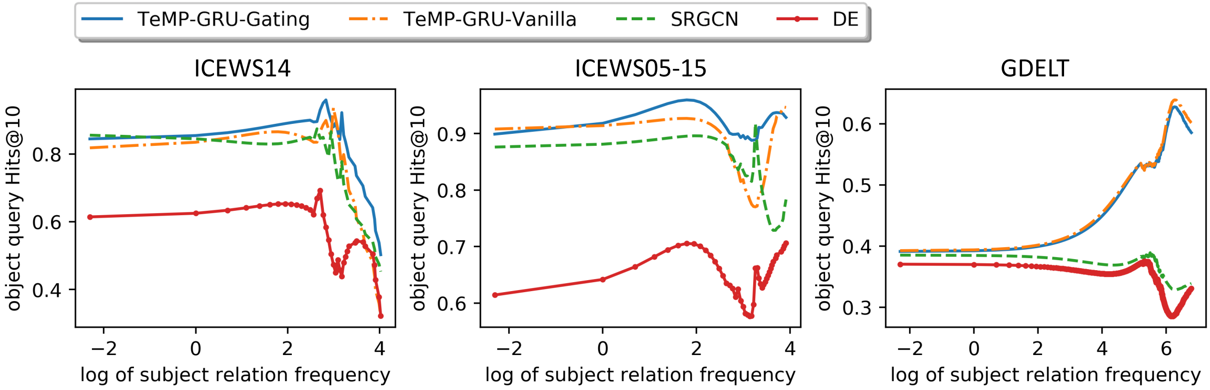

Figure 5: Object query hit@10 performance comparison of TeMP with different variations and baseline methods.

Future work involves exploring the generalization of TeMP to continuous TKGC and better imputation techniques to induce representations for infrequent and inactive entities.

A Appendix

A.1 Architecture Details

Temporal Edge Dropout.

The replication effect illustrated in Figure 4 and 8 shows that TeMP is increasingly better capable at copying from temporal facts when TPFs also increase. We refer to this as ”overfitting” to the temporal facts. In order to alleviate such problem, we propose temporal edge dropout: randomly dropping facts occurred in the defined time window used to induce the entity representation.

Rong et al. (2019) propose dropping a proportion in the local graph context to combat over-fitting and over-smoothing. We extend this technique to TKG by either (1) randomly dropping a certain percentage of quadruples in each temporal snapshot and (2) drop quadruples with different probabilities based on certain quadruple characteristics. Details of the second method is omitted since we find the two methods working equally well. We use 0.2 as temporal edge dropout rate in all experiments.

Positional Embedding. We capture the time-sensitive information in the TKG by combining the entity representation with positional embedding. The positional embedding is denoted as $\{\boldsymbol{p}_1, \boldsymbol{p}_2, ..., \boldsymbol{p}_T\}$, which embeds absolute positional information of each time step. The set of representations for entity e_i at all time steps is $\{\boldsymbol{p}_1 + \boldsymbol{z}_{i,1}, \boldsymbol{p}_2 + \boldsymbol{z}_{i,2}, ..., \boldsymbol{p}_T + \boldsymbol{z}_{i,T}\}$, which are used as input entity representation to the decoding function.

A.2 Extended Imputation Formulation

For bidirectional temporal recurrent model, we defined the imputed representation analogous to Equation (9) and 10. We use t^+ to denote the very next time step at which entity e_i is active after t. The decay rate for imputing from future representations as follows:

$$\gamma^x_{i,t^+} = \exp\{-\max(0, \lambda_x|t - t^+|+b_x)\}.$$

To calculate the imputed representation of the e_i at time t, we divide both exponential decay rates by two and renormalize:

$$\begin{aligned}\gamma^x_{i,t} &= 1 - \frac{\gamma^x_{i,t^-}}{2} - \frac{\gamma^x_{i,t^+}}{2}\\ \hat{\boldsymbol{x}}_{i,t} &= \frac{\gamma^x_{i,t^-}}{2}\boldsymbol{x}_{i,t^-} + \frac{\gamma^x_{i,t^+}}{2}\boldsymbol{x}_{i,t^+} + \gamma^x_{i,t}\boldsymbol{x}_{i,t}\ .\end{aligned}$$

Intrinsic imputation for TeMP-SA. We use Equation (4) - (7) to derive entity representations for both active and inactive entities and view it as an intrinsic way of imputation. Hence imputation is tagged with all TeMP-SA results in Table 2.

A.3 Analogous Definition of Frequency Based Gating and Training Loss

We define the process for deriving entity representation for subject queries $(?\,, r, o, t)$ analogous to Equation (11) and (12). The model is only allowed the access to frequencies $F_o = [f_o^t, f_r^t, f_{o,r}^t]$, we use it to define a similar gating over static and temporal entity representations:

$$\begin{aligned}\boldsymbol{z}_{s,t} &:= \alpha_{ss}\boldsymbol{x}_{s,t} + (1-\alpha_{ss})\boldsymbol{z}_{s,t}\\ \boldsymbol{z}_{o,t} &:= \alpha_{so}\boldsymbol{x}_{o,t} + (1-\alpha_{so})\boldsymbol{z}_{o,t},\end{aligned}$$

where $\alpha_{ss} = \mathrm{MLP}_{ss}(F_o)$, $\alpha_{so} = \mathrm{MLP}_{ss}(F_o)$, $\alpha_{ss}, \alpha_{so} \in [0,1]$. With the negative subject entity set being $D^{-}_{\eta,s} = \{s' | (s', r, o) \notin D^{(t)}\}$, the training loss for subject queries is defined as follows:

$$L_{sub} = -\sum_{t=1}^{T}\sum_{\eta\in D^{(t)}} \frac{\exp(\phi(s,r,o,t))}{\sum_{s'\in D^{-}_{\eta,s}}\exp(\phi(s',r,o,t))}.$$

The final training loss is the sum of losses for two types of queries: $L = L_{sub} + L_{obj}$.

A.4 Detailed TED Formulation and Analysis

TED Model Definition. We hypothesize that certain quadruples with *more frequent* occurrence in *more recent* time steps are informative for the current-step KGC. For each query, we construct a set of reference entities from training data. Similar to the down-weighting mechanism of temporal encoder (Section 3.2), we score each entity based on exponential decaying mechanism with respect to the temporal distance to the current time step. We then rank the entities in the reference set according to such scores.

For each queried quadruple (s, r, o, t), we collect reference entity sets consisting of tuples $\{(e, t'), t' \neq t\}$ where e is the subject or object entity and t' is the corresponding time of occurrence. The tuples are extracted from the temporal facts sharing at least one element with (s, r, o, t). We divide them into subject and object reference sets two types of queries. The subject reference set consists of:

(1) subjects with shared relation-object pair, i.e., $\{(s', t') | \exists t' \neq t, (s', r, o) \in D^{(t')}_{train}\}$,

(2) subjects with shared object, i.e., $\{(s', t') | \exists t' \neq t \wedge r' \in R, (s', r', o) \in D^{(t')}_{train}\}$,

(3) subjects with shared relation, i.e., $\{(s', t') | \exists t' \neq t \wedge o' \in E, (s', r, o') \in D^{(t')}_{train}\}$.

Symmetrically, object reference set consists of:

(1) objects with shared subject-relation pair, i.e., $\{(o', t') | \exists t' \neq t, (s, r, o') \in D^{(t')}_{train}\}$,

(2) objects with shared subject, i.e., $\{(o', t') | \exists t' \neq t \wedge r' \in R, (s, r', o') \in D^{(t')}_{train}\}$,

(3) objects with shared relation, i.e., $\{(o', t') | \exists t' \neq t \wedge s' \in E, (s', r, o') \in D^{(t')}_{train}\}$.

We don't collect triples in the current time step t as we assume $D^{(t)}_{train} \cap D^{(t)}_{test} = \emptyset, \forall t$.

Note that (1) is a subset of (2) and (3), also (2) and (3) contain overlapping tuples. We define the priority to be (1) > (2) > (3), such that if some tuple is present in (1), then it will be removed from both (2) and (3). This is based on the assumption that objects with the same subject-relation pair as the current triple are the most ideal candidates. For example, because of the characteristics of *police*, the fact *(police, arrest, citizen)* occurred multiple times across in the dataset. Objects with same shared subject and different relation comes second, e.g. *(Obama, visit, China, 2013)*, *(Obama, visit, Russia, 2014)* are important information for predicting *(Obama, make_announcement_to, ?, 2015)*.

Let S be some set of tuple defined above. The score for e is the sum over all tuples containing e,

$$\sum_{t',(e,t')\in S} \exp(-\sigma|t-t'|), \sigma > 0. \qquad (14)$$

TED Results and Analysis. Table 3 shows the sensitivity analysis for parameter σ on validation set. We notice that the performances are low when σ is either extremely large or small, while peaks when $\sigma = 0.1$ on ICEWS datasets and $\sigma = 1$ on GDELT dataset. This suggests an existing trade-off between *recency* and *frequency* heuristics.

TED model results also expose the bias of recurring events in political event datasets, particularly in GDELT. However, TED should be considered by future work as an important baseline to gauge the relative model performance. Additionally, the results suggests the potential for pointer-style TKGC – deciding between coping an entity from historical facts and selecting an entity in the current snapshot to answer a query.

A.5 Dataset Statistics and Characteristics

The dataset statistics are summarized in Table 4. The numbers of entities are 7,128, 10,488 and 500 respectively in three datasets, indicating that temporal sparsity issue is severe on ICEWS datasets but trivial on GDELT dataset. The temporal variability of three datasets is demonstrated in Figure 7. The average number of associated temporal facts for each entity is much lower in ICEWS datasets compared to GDELT. The difference can be attributed to the fact that GDELT dataset is constructed by extracting facts among the most frequent 500 entities in the entire dataset. This intrinsically eliminates the sparsity and variability bias in the original datasets.

A.6 Definitions for Evaluation Metrics

We use MRR, Hits@1, Hits@3 and Hits@10 to evaluate the model performance. MRR is defined as:

$$\frac{1}{2 * |D_{test}|} \sum_{t=1}^{T} \sum_{\eta=(s,r,o) \in D_{test}^{(t)}} \Big(\frac{1}{\text{rank}(o|s,r,t)} + \frac{1}{\text{rank}(s|r,o,t)} \Big) \quad (15)$$

The Hit@1, Hit@3, Hit@10 are the percentages of test facts for which the k highest ranked predictions contain the correct prediction, $k = 1, 3, 10$. That is,

$$\frac{1}{2 * |D_{test}|} \sum_{t=1}^{T} \sum_{\eta=(s,r,o) \in D_{test}^{(t)}} (I(\text{rank}(o|s,r,t) \leq k) + I(\text{rank}(s|r,o,t) \leq k)) \quad (16)$$

where $k = 1, 3, 10$, I is the indicator function.

A.7 Detailed Implementation and Hyperparameters

We use the Adam optimizer and set the learning rate to 0.001. The batch size is set to 8 for ICEWS14 and ICEWS05-15, i.e. each batch contains facts in 8 snapshots. We additionally sample 3,000 quadruples in each snapshot to avoid out-of-memory issue. Embedding size and hidden sizes for both recurrent and self-attentive models are both set to 128. We use 8 attention heads in TeMP-SA to model the multi-faced evolution of TKG. As required by reproducibility checklist, the complete hyperparameter setting and run-time information for TeMP-GRU model on all benchmark datasets are summarized in Table 5.

Suggested by ablation study in (Jin et al., 2019) we set the number of relational convolution layers to 2 to encode two-hop neighbors. We apply temporal edge dropout technique to TKG, in each training epoch we randomly drop 50% of the quadruples in current KG and 20% triples in each temporal reference KG to combat over-fitting and over-smoothing. We experimented with TransE, DistMult and ComplEx on validation set and found that ComplEx (Trouillon et al., 2016) yields the best performance overall. Hence ComplEx is used as decoding function to score head or tail entities given queries. During inference on $D_{valid}^{(t)}$ and $D_{test}^{(t)}$, our models take $D_{train}^{(t-\tau)}, ..., D_{train}^{(t)}$ as input and compute the scores to compute the entity representations.

The parameter τ stands for the number of KG snapshots available for answering query. This is applied to temporal models as a *budget*. Single-direction models take temporal entity embedding from the past τ graphs while bidirectional models focus on $\frac{\tau}{2}$ historical and future snapshots.

We use early stopping with patience 10 with respect to the average MRR on the validation set. All ablation studies are conducted on the validation set. For the best model variants, we use the model checkpoint that achieves the best MRR score on validation set to perform final evaluation on test set.

A.8 Detailed Analysis of Performances versus TPFs

We studied the correlation between subject-relation TPF and query answering performances in Section 4.5.3. Here, we first define a complete set of TPFs that covers all possible subsets of a quadruple. In Section 3.3 we defined (1) subject frequency f_s^t, (2) object frequency f_o^t, (3) relation frequency f_r^t, (4) subject-relation frequency $f_{s,r}^t$, (5) relation-object frequency $f_{r,o}^t$ related to quadruple (s, r, o, t). We additionally define (6) subject-object frequency $f_{s,o}^t$ and (7) triple frequency $f_{s,r,o}^t$. We use the following combinations of TPFs and query types to study replication and reference effects respectively.

σ	ICEWS14				ICEWS05-15				GDELT			
	MRR	Hit@1	Hit@3	Hit@10	MRR	Hit@1	Hit@3	Hit@10	MRR	Hit@1	Hit@3	Hit@10
10^{-5}	0.434	36.2	48.9	60.5	0.466	36.2	52.4	66.6	0.179	10.1	18.7	33.1
10^{-2}	0.445	35.5	49.9	61.2	0.498	39.7	55.9	**68.8**	0.192	11.0	20.3	35.6
10^{-1}	**0.455**	**36.7**	**50.7**	**61.6**	**0.505**	**40.8**	**56.3**	68.7	0.226	13.7	24.7	40.4
1	0.449	35.9	50.3	61.4	0.500	40.1	55.9	68.5	**0.238**	**15.0**	**26.3**	**40.8**
10^{1}	0.449	35.9	50.3	61.5	0.496	39.8	55.4	68.1	0.237	14.9	26.2	40.7
10^{2}	0.446	35.5	50.0	61.2	0.482	38.3	53.9	66.8	0.232	14.4	25.8	40.2
10^{5}	0.359	24.9	41.7	57.2	0.362	23.8	42.8	60.6	0.091	3.0	8.0	20.2

Table 3: TKGC evaluation results(filtered setting) using TED model under various σ values. The Hit@1, Hit@3, and Hit@10 metrics are multiplied by 100.

Dataset	# entities	# relations	# time steps	N˙train	N˙valid	N˙test	N˙total
ICEWS14	7,128	230	365	72,826	8,941	8,963	90,730
ICEWS05-15	10,488	251	4017	386,962	46,275	46,092	479,329
GDELT	500	20	366	2,735,685	341,961	341,961	3,419,607

Table 4: Statistics of ICEWS14, ICEWS05-15 and GDELT datasets.

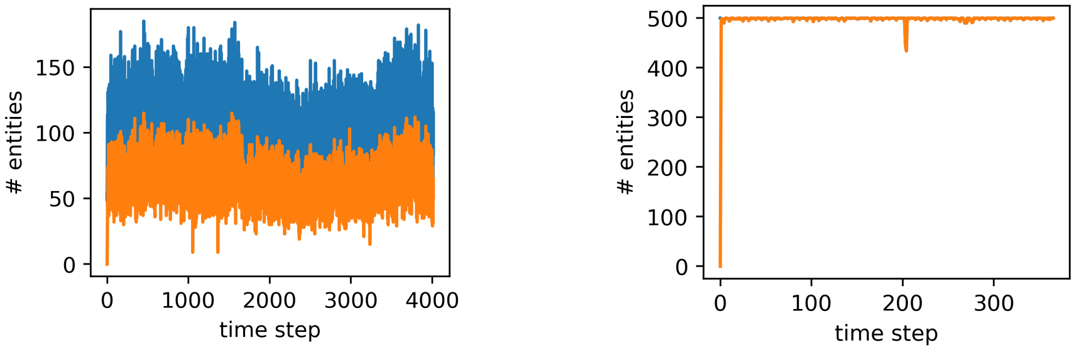

Figure 6: Dataset statistics of ICEWS05-15 (left) and GDELT (right) as a supplement of Figure 2.

Table 5: Hyperparameters setting for TeMP-GRU model on three benchmark datasets

Dataset	batch size	# temporal snapshots	GPU type	# GPU	Time limit	runtime per epoch	# parameters
ICEWS14	8	15	GeForce GTX TiTan	1	24h	8m	885K
ICEWS05-15	8	10	Nvidia V100	1	60h	70m	2856K
GDELT	4	15	Nvidia V100	2	60h	13m	878K

For replication effect, we compare subject query results against (1), then compare object query results against (2) and (5). Values of (6) and (7) are compared with the results of both subject and object queries. For reference effect, we compare object query results against (1), and subject query results against (2) and (5). Results are summarized in Figure 8 and Figure 9 respectively.

The general observation is similar to the discussion in Section 4.5.3. In the replication analysis , TeMP-GRU models show significantly more positive trends than the static models (SRGCN and DE). However, we witness drops in performances when TPFs become large in the reference effect analysis. Performance of TeMP-GRU-Vanilla model improves with the help of gating on ICEWS datasets on TPFs. The benefit is less obvious on GDELT dataset due to the observation that GDELT is less affected by temporal sparsity and variability problem (Appendix A.5).

We conclude that TeMP models are significant more advantageous in utilizing temporal facts for TKGC task. In addition, frequency-based gating improves the overall performance with respect to all different TFPs.

Abstract

Transformers have proved effective in many NLP tasks. However, their training requires non-trivial efforts regarding carefully designing cutting-edge optimizers and learning rate schedulers (*e.g.*, conventional SGD fails to train Transformers effectively). Our objective here is to understand *what complicates Transformer training* from both empirical and theoretical perspectives. Our analysis reveals that unbalanced gradients are not the root cause of the instability of training. Instead, we identify an *amplification effect* that influences training substantially–for each layer in a multi-layer Transformer model, heavy dependency on its residual branch makes training unstable, since it amplifies small parameter perturbations (*e.g.*, parameter updates) and results in significant disturbances in the model output. Yet we observe that a light dependency limits the model potential and leads to inferior trained models. Inspired by our analysis, we propose *Admin* (**Ad**aptive **m**odel **in**itialization) to stabilize the early stage's training and unleash its full potential in the late stage. Extensive experiments show that Admin is more stable, converges faster, and leads to better performance[1].

1 Introduction

Transformers (Vaswani et al., 2017) have led to a series of breakthroughs in various deep learning tasks (Devlin et al., 2019; Velickovic et al., 2018). They do not contain recurrent connections and can parallelize all computations in the same layer, thus improving effectiveness, efficiency, and scalability. Training Transformers, however, requires extra efforts. For example, although stochastic gradient descent (SGD) is the standard algorithm for conventional RNNs and CNNs, it converges to bad/suspicious local optima for Transformers (Zhang et al., 2019b). Moreover, comparing to other neural architectures, removing the warmup stage in Transformer training results in more severe consequences such as model divergence (Popel and Bojar, 2018; Liu et al., 2020a). Here, we conduct comprehensive analyses in empirical and theoretical manners to answer the question: *what complicates Transformer training*.

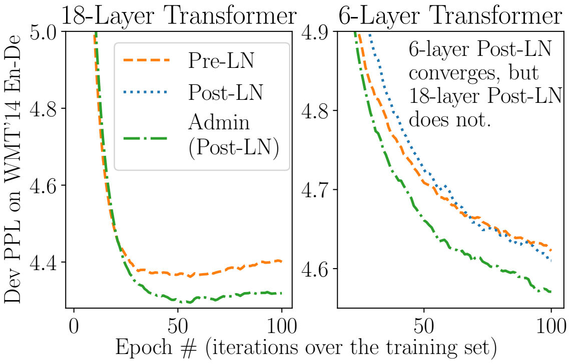

Figure 1: Lacking enough robustness and stability, the 18-Layer Post-LN Transformer training (*i.e.*the original architecture) diverges and is omitted in the left graph. Admin not only stabilizes model training but unleashes the model potential for better performance.

Our analysis starts from the observation: the original Transformer (referred to as Post-LN) is less robust than its Pre-LN variant[2] (Baevski and Auli, 2019; Xiong et al., 2019; Nguyen and Salazar, 2019). We recognize that gradient vanishing issue is not the direct reason causing such difference, since fixing this issue alone cannot stabilize Post-LN training. It implies that, besides unbalanced gradients, there exist other factors influencing model training greatly.

With further analysis, we recognize that for each Transformer residual block, the dependency

---

[1] Implementations are released at: `https://github.com/LiyuanLucasLiu/Transforemr-Clinic`

[2] As in Figure 2, Post-LN places layer norm outside of residual blocks, and Pre-LN moves them to the inside.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5747–5763,
November 16–20, 2020.

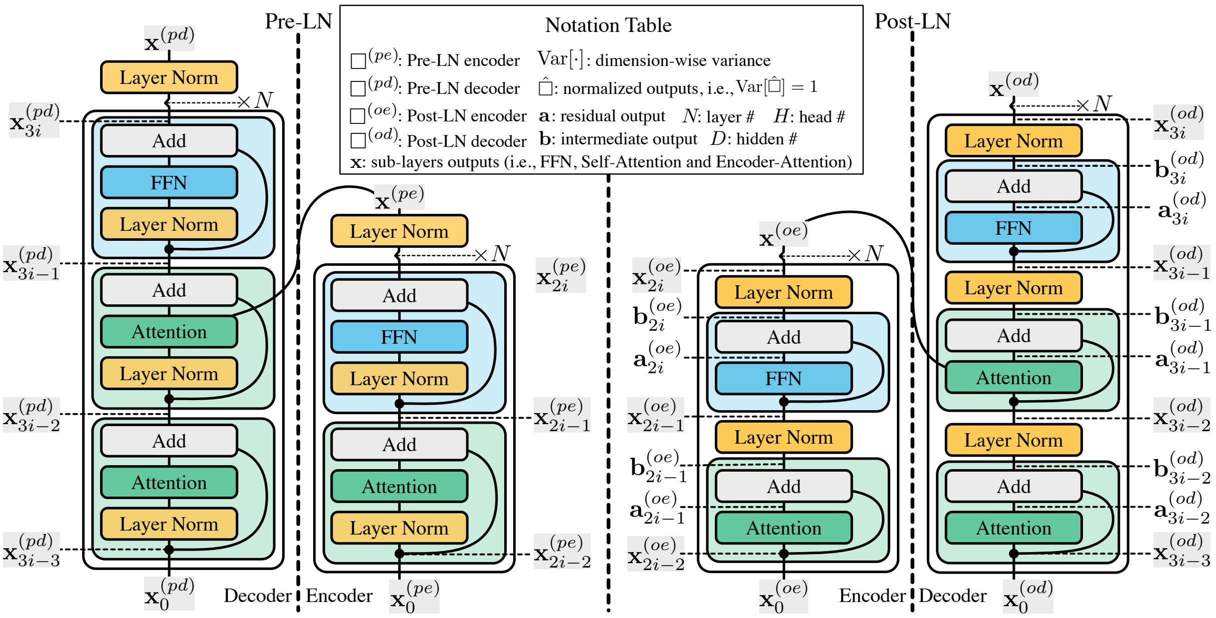

Figure 2: The Architecture and notations of Pre-LN Transformers (Left) and Post-LN Transformers (Right).

on its residual branch[3] plays an essential role in training stability. First, we find that a Post-LN layer has a heavier dependency on its residual branch than a Pre-LN layer. As in Figure 7, at initialization, a Pre-LN layer has roughly the same dependency on its residual branch and any previous layer, whereas a Post-LN layer has a stronger dependency on its residual branch (more discussions are elaborated in Section 4.1). We find that strong dependencies of Post-LN amplify fluctuations brought by parameter changes and destabilize the training (as in Theorem 2 and Figure 4). Besides, the loose reliance on residual branches in Pre-LN generally limits the algorithm's potential and often produces inferior models.

In light of our analysis, we propose Admin, an adaptive initialization method which retains the merits of Pre-LN stability without hurting the performance. It restricts the layer dependency on its residual branches in the early stage and unleashes the model potential in the late stage. We conduct experiments on IWSLT'14 De-En, WMT'14 En-De, and WMT'14 En-Fr; Admin is more stable, converges faster, and achieves better performance. For example, without introducing any additional hyper-parameters, Admin successfully stabilizes 72-layer Transformer training on WMT'14 En-Fr and achieves a 43.80 BLEU score.

2 Preliminaries

Transformer Architectures and Notations. The Transformer architecture contains two types of sub-layers, *i.e.*, Attention sub-layers and Feedforward (FFN) sub-layers. They are composed of mainly three basic modules (Vaswani et al., 2017), *i.e.*, Layer Norm (f_{LN}), Multi-head Attention (f_{ATT}), and Feedforward Network (f_{FFN}).

As illustrated in Figure 2, the Pre-LN Transformer and the Post-LN Transformer organize these modules differently. For example, a Pre-LN encoder organizes the Self-Attention sub-layer as $\mathbf{x}^{(pe)}_{2i-1} = \mathbf{x}^{(pe)}_{2i-2} + f_{\text{S-ATT}}(f_{\text{LN}}(\mathbf{x}^{(pe)}_{2i-2}))$ and a Post-LN encoder as $\mathbf{x}^{(oe)}_{2i-1} = f_{\text{LN}}(\mathbf{x}^{(oe)}_{2i-2} + f_{\text{S-ATT}}(\mathbf{x}^{(oe)}_{2i-2}))$, where $\mathbf{x}^{(\cdot)}_{2i-2}$ is the input of the i-th Transformer layer and $\mathbf{x}^{(\cdot)}_{2i-1}$ is the output of the i-th Self-Attention sub-layer. Here, we refer $f_{\text{S-ATT}}(f_{\text{LN}}(\mathbf{x}^{(pe)}_{2i-2}))$ and $f_{\text{S-ATT}}(\mathbf{x}^{(oe)}_{2i-2})$ as the residual branches and their outputs as the residual outputs, in contrast to layer/sub-layer outputs, which integrates residual outputs and shortcut outputs.

Notation elaborations are shown in Figure 2. In particular, we use superscripts to indicate network architectures (*i.e.*, the Pre-LN Encoder), use subscripts to indicate layer indexes (top layers have larger indexes), all inputs and outputs are formulated as Sequence-Len × Hidden-Dim.

Layer Norm. Layer norm (Ba et al., 2016) plays a vital role in Transformer architecture. It is defined

---

[3] For a residual block $x + f(x)$, its shortcut output refers to x, its residual branch output refers to $f(x)$, and the dependency on its residual branch refers to $\frac{\text{Var}[f(x)]}{\text{Var}[x+f(x)]}$.

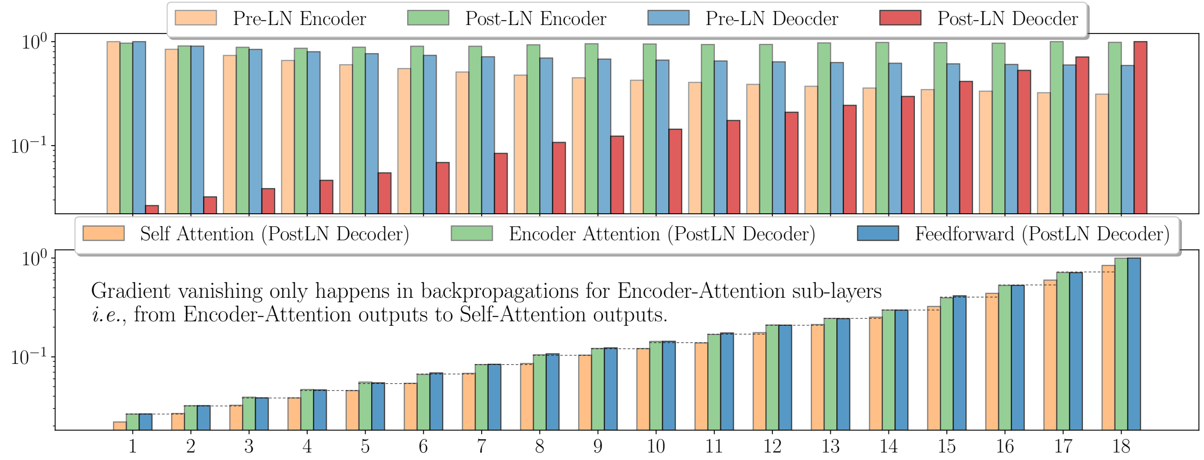

Figure 3: Relative gradient norm histogram (on a log scale) of 18-layer Transformers on the WMT'14 En-De dataset, *i.e.*, the gradient norm of sub-layer outputs, scaled by the largest gradient norm in the same network.

as $f_{\text{LN}}(\mathbf{x}) = \boldsymbol{\gamma}\frac{\mathbf{x}-\mu}{\sigma} + \boldsymbol{\nu}$, where μ and σ are the mean and standard deviation of $\mathbf{x}$.

Feedforward Network. Transformers use two-layer perceptrons as feedforward networks, *i.e.*, $f_{\text{FFN}}(\mathbf{x}) = \phi(\mathbf{x}W^{(1)})W^{(2)}$, where $\phi(\cdot)$ is the non-linear function[4], and $W^{(\cdot)}$ are parameters.

Multi-head Attention. Multi-head Attentions allows the network to have multiple focuses in a single layer and plays a crucial role in many tasks (Chen et al., 2018). It is defined as (with H heads): $f_{\text{ATT}}(\mathbf{q}, \mathbf{k}, \mathbf{v}) = \sum_{h=1}^{H} f_s(\mathbf{q}W_h^{(Q)}W_h^{(K)}\mathbf{k}^T)\mathbf{v}W_h^{(V_1)}W_h^{(V_2)}$, where f_s is the row-wise softmax function and $W_h^{(\cdot)}$ are parameters. $W_h^{(Q)}$ and $W_h^{(V_1)}$ are $D \times \frac{D}{H}$ matrices, $W_h^{(K)}$ and $W_h^{(V_2)}$ are $\frac{D}{H} \times D$ matrices, where D is the hidden state dimension. Parameters without subscript refer the concatenation of all H-head parameters, *e.g.*, $W^{(Q)} = [W_1^{(Q)}, \cdots, W_H^{(Q)}]$. In Transformer, this module is used in two different settings: Encoder-Attention ($f_{\text{E-ATT}}(\mathbf{x}) = f_{\text{ATT}}(\mathbf{x}, \mathbf{x}^{(\cdot e)}, \mathbf{x}^{(\cdot e)})$ and $\mathbf{x}^{(\cdot e)}$ is the encoder output), and Self-Attention ($f_{\text{S-ATT}}(\mathbf{x}) = f_{\text{ATT}}(\mathbf{x}, \mathbf{x}, \mathbf{x})$).

3 Unbalanced Gradients

In this study, we strive to answer the question: *what complicates Transformer training*. Our analysis starts from the observation: Pre-LN training is more robust than Post-LN, while Post-LN is more likely to reach a better performance than Pre-LN. In a parameter grid search (as in Figure 10), Pre-LN converges in all 15 settings, and Post-LN diverges in 7 out of 15 settings; when Post-LN converges, it outperforms Pre-LN in 7 out of 8 settings. We seek to reveal the underlying factor that destabilizes Post-LN training and restricts the performance of Pre-LN.

In this section, we focus on the unbalanced gradients (*e.g.*, gradient vanishing). We find that, although Post-LN suffers from gradient vanishing and Pre-LN does not, gradient vanishing is not the direct reason causing the instability of Post-LN. Specifically, we first theoretically and empirically establish that only Post-LN decoders suffer from gradient vanishing and Post-LN encoders do not. We then observe that fixing the gradient vanishing issue alone cannot stabilize training.

3.1 Gradients at Initialization

As gradient vanishing can hamper convergence from the beginning, it has been regarded as the major issue causing unstable training. Also, recent studies show that this issue exists in the Post-LN Transformer, even after using residual connections (Xiong et al., 2019). Below, we establish that only Post-LN decoders suffer from the gradient vanishing, and neither Post-LN encoders, Pre-LN encoders, nor Pre-LN decoders.

We use $\Delta\mathbf{x}$ to denote gradients, *i.e.*, $\Delta\mathbf{x} = \frac{\partial\mathcal{L}}{\partial\mathbf{x}}$ where $\mathcal{L}$ is the training objective. Following previous studies (Glorot and Bengio, 2010), we analyze the gradient distribution at the very beginning of training and find only Encoder-Attention sub-layers in Post-LN suffers from gradient vanishing.

---

[4] Our analysis uses ReLU as the activation function, while Admin can be applied to other non-linear functions.

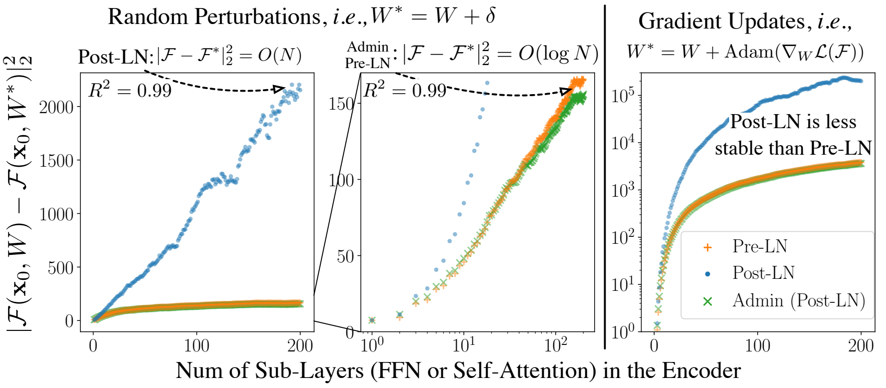

Figure 4: Encoder output changes for parameter changes, *i.e.*, $|\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)|_2^2$ where $W^* - W$ is random perturbations (left) or gradient updates (right). Intuitively, very large $|\mathcal{F} - \mathcal{F}^*|$ indicates the training to be ill-conditioned.

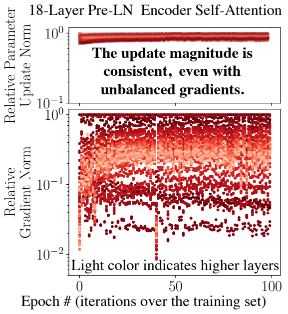

Figure 5: Histogram of relative norm of gradient and $|W_{i+1} - W_i|$ where W_i is the checkpoint saved after training for i epochs.

Encoder	**Decoder**	**Gradient**	**Training**
Post-LN	Post-LN	Varnishing	Diverged
Post-LN	Pre-LN	~~Varnishing~~	Diverged
Pre-LN	Pre-LN	~~Varnishing~~	Converged

Table 1: Changing decoders from Post-LN to Pre-LN fixes gradient vanishing, but does not stabilize model training successfully. Encoder/Decoder have 18 layers.

First, we conduct analysis from a theoretical perspective. Similar to Xiong et al. (2019), we establish that Pre-LN networks do not suffer from gradient vanishing (as elaborated in Appendix A.1). Unlike Xiong et al. (2019), we recognize that not all Post-LN networks suffer from gradient vanishing. As in Theorem 1, we establish that Post-LN Encoder networks do not suffer from gradient vanishing. Detailed derivations are elaborated in Appendix A.2.

THEOREM 1. — For Post-LN Encoders, if γ and $\boldsymbol{\nu}$ in the Layer Norm are initialized as 1 and 0 respectively; all other parameters are initialized by symmetric distributions with zero mean; $\mathbf{x}_i^{(oe)}$ and $\Delta\mathbf{x}_i^{(oe)}$ are subject to symmetric distributions with zero mean; the variance of $\mathbf{x}_i^{(oe)}$ is 1 (*i.e.*, normalized by Layer Norm); $\Delta\mathbf{x}_i^{(oe)}$ and the derivatives of modules in i-th sub-layer are independent, we have $\text{Var}[\Delta\mathbf{x}_{i-1}] \geq \text{Var}[\Delta\mathbf{x}_i]$.

To make sure that the assumptions of Theorem 2 match the real-world situation, we further conduct empirical verification. At initialization, we calculate $||\Delta\mathbf{x}_i^{(\cdot)}||_2$ for 18-layer Transformers[5] and visualize $\frac{||\Delta\mathbf{x}_i^{(\cdot)}||_2}{\max_j ||\Delta\mathbf{x}_j^{(\cdot)}||_2}$ in Figure 3. It verifies that only Post-LN decoders suffer from the gradient vanishing. Besides, we can observe that the dropping of gradient norms mostly happens in the backpropagation from encoder-attention outputs (encoder-attention bars) to its inputs (self-attention bars, since the output of self-attention is the input of encoder-attention). This pattern is further explained in Appendix A.3.

3.2 Impact of the Gradient Vanishing

Now, we explore whether gradient vanishing is the direct cause of training instability.

First, we design a controlled experiment to show the relationship between gradient vanishing and training stability. We construct a hybrid Transformer by combining a Post-LN encoder and a Pre-LN decoder. As in Section 3.1, only Post-LN decoders suffer from gradient vanishing, but not Post-LN encoders. Therefore, this hybrid Transformer does not suffer from gradient vanishing. As shown in Table 1, fixing gradient vanishing alone (*i.e.*, changing Post-LN decoders to Pre-LN decoders) fails to stabilize model training. This observation provides evidence supporting that the gradient vanishing issue is not the direct cause of unstable Post-LN training.

Moreover, we observe that gradients of all attention modules are unbalanced, while adaptive optimizers mostly address this issue. As in Figure 5, adaptive optimizers successfully assign different learning rates to different parameters and lead to consistent update magnitudes even with unbalanced gradients. It explains why the standard SGD fails in training Transformers (*i.e.*, lacking

---

[5] Note if $\mathbb{E}[\Delta\mathbf{x}_{i-1}^{(p\cdot)}] = 0$, $\text{Var}[\Delta\mathbf{x}_{i-1}^{(p\cdot)}] \approx |\Delta\mathbf{x}_{i-1}^{(p\cdot)}|_2^2$.

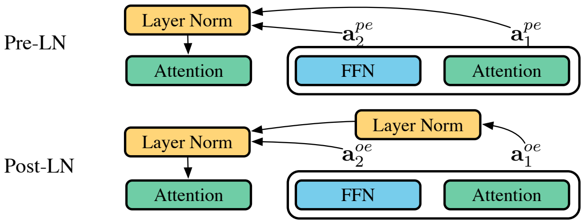

Figure 6: The major difference between Pre-LN and Post-LN is the position of layer norms.

the ability to handle unbalanced gradients) and necessitates using adaptive optimizers. More discussions are included in Appendix A.4.

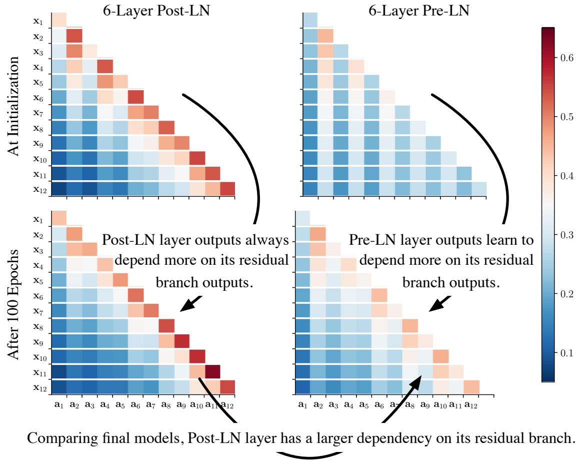
4 Instability from Amplification Effect

We find that unbalanced gradients are not the root cause of the instability of Post-LN, which implies the existence of other factors influencing model training. Now, we go beyond gradient vanishing and introduce the *amplification effect*. Specifically, we first examine the difference between Pre-LN and Post-LN, including their early-stage and late-stage training. Then, we show that Post-LN's training instability is attributed to layer dependency's amplification effect, which intensifies gradient updates and destabilizes training.

4.1 Impact of Layer Norms Positions

As described in Section 2, both Pre-LN and Post-LN employ layer norm to regularize inputs and outputs. Different residual outputs are aggregated and normalized in residual networks before serving as inputs of other layers (*i.e.*, residual outputs will be scaled to ensure the integrated input to have a consistent variance). To some extend, layer norm treats the variance of residual outputs as weights to average them. For example, for Post-LN Self-Attention, we have $\mathbf{x}_{2i-1}^{(o\cdot)} = \frac{\mathbf{x}_{2i-2}^{(o\cdot)}+\mathbf{a}_{2i-1}^{(o\cdot)}}{\sqrt{\mathrm{Var}[\mathbf{x}_{2i-2}^{(o\cdot)}]+\mathrm{Var}[\mathbf{a}_{2i-1}^{(o\cdot)}]}}$ at initialization. Larger $\mathrm{Var}[\mathbf{a}_{2i-2}^{(o\cdot)}]$ not only increases the proportion of $\mathbf{a}_{2i-2}^{(o\cdot)}$ in $\mathbf{x}_{2i-2}^{(o\cdot)}$ but decreases the proportion of other residual outputs. Intuitively, this is similar to the weight mechanism of the weighted average.

The position of layer norms is the major difference between Pre-LN and Post-LN and makes them aggregate residual outputs differently (*i.e.*, using different weights). As in Figure 6, all residual outputs in Pre-LN are only normalized once before feeding into other layers (thus only treating residual output variances as weights); in Post-LN, most residual outputs are normalized more than once, and different residual outputs are normalized for different times. For example, if all layers are initialized in the same way, output variances of different Pre-LN residual branches would be similar, and the aggregation would be similar to the simple average. Similarly, for Post-LN, nearby residual outputs are normalized by fewer times than others, thus having relatively larger weights. We proceed to calculate and analyze these weights to understand the impact of layer norm positions.



Post-LN layer outputs always depend more on its residual branch outputs.

Pre-LN layer outputs learn to depend more on its residual branch outputs.

Comparing final models, Post-LN layer has a larger dependency on its residual branch.

Figure 7: $\beta_{i,j}$ in 6-Layer Post-LN and Pre-LN on the WMT-14 En-De dataset (contains 12 sub-layers).

First, we use $\widehat{\mathbf{a}}_i$ to refer $\frac{\mathbf{a}_i}{\sqrt{\mathrm{Var}\,\mathbf{a}_i}}$ (*i.e.*, normalized outputs of i-th residual branch) and $\widehat{\mathbf{x}}_i$ to refer $\frac{\mathbf{x}_i}{\sqrt{\mathrm{Var}\,\mathbf{x}_i}}$ (*i.e.*, normalized outputs of i-th layer or normalized inputs of (i+1)-th residual branch). Then, we describe their relationships as $\widehat{\mathbf{x}}_i = \sum_{j\leq i} \beta_{i,j}\widehat{\mathbf{a}}_j$, where $\beta_{i,j}$ integrates scaling operations of all layer norms (including $\sqrt{\mathrm{Var}[\mathbf{a}_i]}$). For example, Pre-LN sets $\beta_{i,j} = \frac{\sqrt{\mathrm{Var}[\mathbf{a}_j]}}{\sqrt{\mathrm{Var}[\sum_{k\leq i}\mathbf{a}_k]}}$. Intuitively, $\beta_{i,j}$ describes the proportion of j-th residual branch outputs in i-th layer outputs, thus reflects the dependency among layers.

We visualize $\beta_{i,j}$ in Figure 7. For a Post-LN layer, its outputs rely more on its residual branch from the initialization to the end. At initialization, Pre-LN layer outputs have roughly the same reliance on all previous residual branches. As the training advances, each layer starts to rely more on its own residual outputs. However, comparing to Post-LN, Pre-LN layer outputs in the final model still has less reliance on their residual branches.

Intuitively, it is harder for Pre-LN layers to depend too much on their own residual branches. In

Pre-LN, layer outputs (*i.e.*, $\mathbf{x}_i^{(p\cdot)}$) are not normalized, and their variances are likely to be larger for higher layers[6]. Since $\beta_{i,i} = \frac{\sqrt{\mathrm{Var}[\mathbf{a}_i]}}{\sqrt{\mathrm{Var}[\mathbf{x}_{i-1}^{(p\cdot)}+\mathbf{a}_i]}}$, $\beta_{i,i}$ is likely to be smaller for higher layers, which restricts i-th layer outputs from depending too much on its residual branch and inhibits the network from reaching its full potential. In other words, Pre-LN restricts the network from being too deep (*i.e.*, if it is hard to distinguish $\mathbf{x}_i^{(p\cdot)}$ and $\mathbf{x}_{i+1}^{(p\cdot)}$, appending one layer would be similar to doubling the width of the last layer), while Post-LN gives the network the choice of being wider or deeper.

4.2 Amplification Effect at Initialization

Although depending more on residual branches allows the model to have a larger potential, it amplifies the fluctuation brought by parameter changes. For a network $\widehat{\mathbf{x}} = \mathcal{F}(\mathbf{x}_0, W)$ where $\mathbf{x}_0$ is the model input and W is the parameter, the output change caused by parameter perturbations is $\mathrm{Var}[\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)]$, where $W^* = W + \delta$. Its relationship with N is described in Theorem 2, and the derivation is elaborated in Appendix B.

THEOREM 2. — Consider a N-layer Transformer $\widehat{\mathbf{x}} = \mathcal{F}(\widehat{\mathbf{x}}_0, W)$ at initialization, where $\widehat{\mathbf{x}}_0$ is the input and W is the parameter. If the layer dependency stays the same after a parameter change (*i.e.*, $\beta_{i,j}$ has the same value after changing W to W^*, where W is randomly initialized and $\delta = W^* - W$ is independent to W), the output change (*i.e.*, $\mathrm{Var}[\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)]$) can be estimated as $\sum_{i=1}^{N} \beta_{i,i}^2 C$ where C is a constant.

If $\mathrm{Var}[\mathbf{a}_i]$ is the same for all layers, Pre-LN sets $\beta_{i,i}^2$ as $1/i$, and Post-LN sets $\beta_{i,i}^2$ as a constant. Thus, we have Corollary 1 and 2 as below.

COROLLARY 1. — For a N-layer Pre-LN $\mathcal{F}$, we have $\mathrm{Var}[\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)] = O(\log N)$.

COROLLARY 2. — For a N-layer Post-LN $\mathcal{F}$, we have $\mathrm{Var}[\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)] = O(N)$.

They show that, since Post-LN relies more on residual branches than Pre-LN (*i.e.*, has a larger $\beta_{i,i}^2$), the perturbation is amplified to a larger magnitude. To empirically verify these relationships, we calculate $|\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)|_2^2$ for Pre-LN and Post-LN and visualize the results in Figure 4. In Corollary 2, N is linearly associated with $|\mathcal{F} - \mathcal{F}^*|_2^2$ for Post-LN; and in Corollary 1, $\log N$ is linearly associated with $|\mathcal{F} - \mathcal{F}^*|_2^2$ for Pre-LN. These relationships match the observation in our experiments (as in Figure 4). For further verification, we measure their correlation magnitudes by R^2 and find $R^2 = 0.99$ in both cases.

Moreover, we replace the random noise δ with optimization updates (*i.e.*, setting $W^* = W + \mathrm{Adam}(\Delta W)$, where opt$(\cdot)$ is update calculated by the Adam optimizer) and visualize output shifts. This replacement makes the correlation between $|\mathcal{F} - \mathcal{F}^*|_2^2$ and N (for Post-LN) or $\log N$ (for Pre-LN) to be weaker (*i.e.*, $R^2 = 0.75$). Still, as in Figure 4, the output shift $|\mathcal{F} - \mathcal{F}^*|_2^2$ for Post-LN is larger than Pre-LN by multiple magnitudes.

Intuitively, large output shifts would destabilize the training (Li et al., 2018). Also, as elaborated in Appendix B, the constant C in Theorem 2 is related to network derivatives and would be smaller as training advances, which explains why warmup is also helpful for the standard SGD. Therefore, we conjecture it is the large output shift of Post-LN results in unstable training. We proceed to stabilize Post-LN by controlling the dependency on residual branches in the early stage of training.

4.3 *Admin* – Adaptive Model Initialization

In light of our analysis, we add additional parameters (*i.e.*, $\boldsymbol{\omega}$) to control residual dependencies of Post-LN and stabilize training by adaptively initializing $\boldsymbol{\omega}$ to ensure an $O(\log N)$ output change.

Due to different training configurations and model specificities (*e.g.*, different models may use different activation functions and dropout ratios), it is hard to derive a universal initialization method. Instead, we decompose model initialization into two phrases: *Profiling* and *Initialization*. Specifically, Admin adds new parameters $\boldsymbol{\omega}$ and constructs its i-th sub-layer as $\mathbf{x}_i = f_{\mathrm{LN}}(\mathbf{b}_i)$, where $\mathbf{b}_i = \mathbf{x}_{i-1} \cdot \boldsymbol{\omega}_i + f_i(\mathbf{x}_{i-1})$, $\boldsymbol{\omega}_i$ is a D-dimension vector and $\cdot$ is element-wise product. Then the *Profiling* phrase and *Initialization* phrase are:

Profiling. After initializing the network with a standard method (initializing $\boldsymbol{\omega}_i$ as $\mathbf{1}$), conduct forward propagation without parameter updating and record the output variance of residual branches (*i.e.*, calculate $\mathrm{Var}[f_i(\mathbf{x}_{i-1})]$). Since all elements in the same parameter/output matrix are independent to each other and are subject to the same distribution, it is sufficient to use a small number of

---

[6] If $\mathbf{a}_0$ and $\mathbf{a}_1$ are independent, $\mathrm{Var}[\mathbf{a}_0 + \mathbf{a}_1] = \mathrm{Var}[\mathbf{a}_0] + \mathrm{Var}[\mathbf{a}_1]$; also, in our experiments $\mathrm{Var}[\mathbf{x}_i^{(p\cdot)}]$ increases as i becomes larger

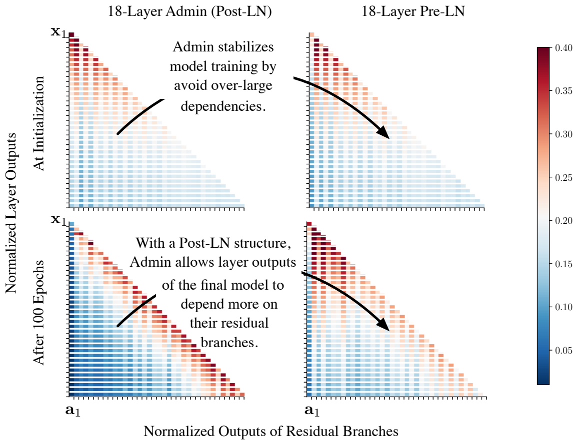


Figure 8: $\beta_{i,j}$ of 18-Layer Admin (Post-LN) and Pre-LN on the WMT-14 En-De dataset.

instances in this phrase. In our experiments, the first batch (no more than 8192 tokens) is used.

Initialization. Set $\omega_i = \sqrt{\sum_{j<i} \operatorname{Var}[f_j(\mathbf{x}_{j-1})]}$ and initialize all other parameters with the same method used in the *Profiling* phrase.

In the early stage, Admin sets $\beta^2_{i,i}$ to approximately $\frac{1}{i}$ and ensures an $O(\log N)$ output change, thus stabilizing training. Model training would become more stable in the late stage (the constant C in Theorem 2 is related to parameter gradients), and each layer has the flexibility to adjust $\boldsymbol{\omega}$ and depends more on its residual branch to calculate the layer outputs. After training finishes, Admin can be reparameterized as the conventional Post-LN structure (*i.e.*, removing $\boldsymbol{\omega}$). More implementation details are elaborated in Appendix C.

To verify our intuition, we calculate the layer dependency of 18-Layer models and visualize the result in Figure 8. Figures 7 and 8 show that Admin avoids over-large dependencies at initialization and unleashes the potential to make the layer outputs depend more on their residual outputs in the final model. Moreover, we visualize the output change of Admin in Figure 4. Benefiting from the adaptive initialization, the output change of Admin gets roughly the same increase speed as Pre-LN, even constructed in the Post-LN manner. Also, although Admin is formulated in a Post-LN manner and suffers from gradient vanishing, 18-layer Admin successfully converges and outperforms 18-layer Pre-LN (as in Table 2). This evidence supports our intuition that the large dependency on residual branches amplifies the output fluctuation and destabilizes training.

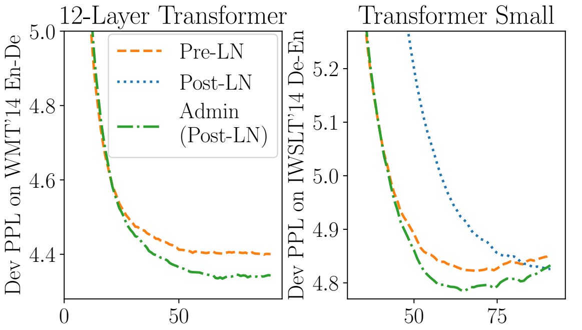

Figure 9: Development PPL on the WMT'14 En-De dataset and the IWLST'14 De-En dataset.

5 Experiments

We conduct experiments on IWSLT'14 De-En, WMT'14 En-De, and WMT'14 En-Fr. More details are elaborated in Appendix D.

5.1 Performance Comparison

We use BLEU as the evaluation matric and summarize the model performance in Table 2. On the WMT'14 dataset, we use Transformer-base models with 6, 12, or 18 layers. Admin achieves a better performance than Post-LN and Pre-LN in all three settings. Specifically, 12-Layer and 18-Layer Post-LN diverges without the adaptive initialization. Pre-LN converges in all settings, but it results in sub-optimal performance. Admin not only stabilizes the training of deeper models but benefits more from the increased model capacity then Pre-LN, which verifies our intuition that the Pre-LN structure limits the model potential. As in Figure 1 and Figure 9, although the 6-layer Pre-LN converges faster than Post-LN, its final performance is worse than Post-LN. In contrast, Admin not only achieves the same convergence speed with Pre-LN in the early stage but reaches a good performance in the late stage.

We use 6-layer Transformer-small (its hidden dimension is smaller than the base model) on the IWSLT'14 dataset, and all methods perform similarly. Still, as in Figure 10, Admin outperforms the other two by a small margin. Together with WMT'14 results, it implies the training stability is related to layer number. For shallow networks, the stability difference between Post-LN and Pre-LN is not significant (as in Figure 4), and all methods reach reasonable performance. It is worth mentioning that attention and activation dropouts have an enormous impact on IWSLT'14, which is smaller than WMT'14 datasets.

Table 2: BLEU on IWSLT’14 De-En and WMT’14 En-Fr/De (AL-BL refers A-layer encoder & B-layer decoder).

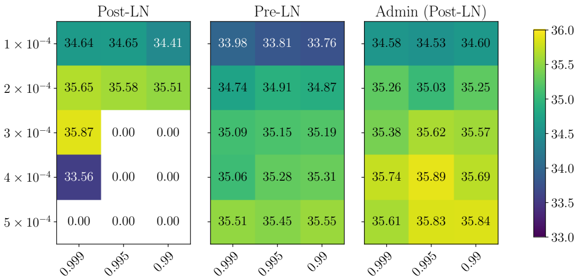
Dataset	IWSLT’14 De-En	WMT’14 En-Fr		WMT’14 En-De		
Enc #–Dec #	6L–6L (small)	6L–6L	60L–12L	6L–6L	12L–12L	18L–18L
Post-LN	35.64±0.23	41.29	failed	27.80	failed	failed
Pre-LN	35.50±0.04	40.74	43.10	27.27	28.26	28.38
Admin	**35.67±0.15**	**41.47**	**43.80**	**27.90**	**28.58**	**29.03**

To further explore the potential of Admin, we train Transformers with a larger size. Specifically, we expand the Transformer-base configuration to have a 60-layer encoder and a 12-layer decoder. As in Table 2, our method achieves a BLEU score of 43.8 on the WMT’14 En-Fr dataset, the new state-of-the-art without using additional annotations (*e.g.*, back-translation). More discussions are conducted in Appendix F to compare this model with the current state of the art. Furthermore, in-depth analyses are summarized in Liu et al. (2020b), including systematic evaluations on the model performance (with TER, METEOR, and BLEU), comprehensive discussions on model dimensions (*i.e.*, depth, head number, and hidden dimension), and fine-grained error analysis. It is worth mentioning that the 60L-12L Admin model achieves a 30.1 BLEU score on WMT’14 En-De (Liu et al., 2020b).

5.2 Connection to Warmup

Our previous work (Liu et al., 2020a) establishes that the need for warmup comes from the unstable adaptive learning rates in the early stage. Still, removing the warmup phrase results in more severe consequences for Transformers than other architectures. Also, warmup has been found to be useful for the vanilla SGD (Xiong et al., 2019).

Theorem 1 establishes that $\mathrm{Var}[\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)] \approx \sum_{i=1}^{N} \beta_{i,i}^2 C$ where $C = \mathrm{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*)]$. In the early stage of training, the network has larger parameter gradients and thus larger C. Therefore, using a small learning rate at initialization helps to alleviate the massive output shift of Post-LN. We further conduct experiments to explore whether more prolonged warmups can make up the stability difference between Post-LN and Pre-LN. We observe that 18-layer Post-LN training still fails after extending the warmup phrase from 8 thousand updates to 16, 24, and 32 thousand. It shows that learning rate warmup alone cannot neutralize the instability of Post-LN. Intuitively, massive output shifts not only require a small learning rate but also unsmoothes the loss surface (Li et al., 2018) and make the training ill-conditioned.



Post-LN

	0.999	0.995	0.99

Figure 10: BLEU score of Post-LN, Pre-LN and Admin on the IWSLT’14 De-En dataset (x-axis is the β_2 for adaptive optimizers and y-axis is the learning rate). Pre-LN converges in all settings while Post-LN diverges in 7 out of 15 settings. When Post-LN converges, it outperforms Pre-LN in 7 out of 8 settings. Admin stabilizes Post-LN training and outperforms Pre-LN (its best performance is comparable with Post-LN).

Admin regularizes the model behavior at initialization and stabilizes the training. To explore whether Admin is able to stabilize the training alone, we remove the warmup phase and conduct a grid search on optimizer hyper-parameters. The results are visualized in Figure 10. It shows that as Post-LN is more sensitive to the choice of hyper-parameters, Admin successfully stabilizes the training without hurting its potential.

5.3 Comparing to Other Initializations

We compare our methods with three initialization methods, *i.e.*, ReZero (Bachlechner et al., 2020), FixUp (Zhang et al., 2019a), and LookLinear (Balduzzi et al., 2017a). Specifically, we first conduct experiments with 18-layer Transformers on the WMT’14 De-En dataset. In our experiments, we observe that all of ReZero (which does not contain layer normalization), FixUp (which also does not contain layer normalization), and LookLinear (which is incorporated with Post-LN) leads to divergent training. With further analysis, we find that the half-precision training and dropout could destabilize FixUp and ReZero, due to the lack of layer normalization. Simultaneously, we find that even for shadow networks, having an over small reliance on residual branches hurts the model performance, which also supports our intuition. For example, as elaborated in Appendix E, applying ReZero to Transformer-small leads to a 1-2 BLEU score drop on the IWSLT'14 De-En dataset.

6 Related Work

Transformer. Transformer (Vaswani et al., 2017) has led to a series of breakthroughs in various domains (Devlin et al., 2019; Velickovic et al., 2018; Huang et al., 2019; Parmar et al., 2018; Ramachandran et al., 2019). Liu et al. (2020a) show that compared to other architectures, removing the warmup phase is more damaging for Transformers, especially Post-LN. Similarly, it has been found that the original Transformer (referred to as Post-LN) is less robust than its Pre-LN variant (Baevski and Auli, 2019; Nguyen and Salazar, 2019; Wang et al., 2019). Our studies go beyond the existing literature on gradient vanishing (Xiong et al., 2019) and identify an essential factor influencing Transformer training greatly.

Deep Network Initialization. It has been observed that deeper networks can lead to better performance. For example, Dong et al. (2020) find that the network depth players a similar role with the sample number in numerical ODE solvers, which hinders the system from getting more precise results. Many attempts have been made to clear obstacles for training deep networks, including various initialization methods. Based on the independence among initialized parameters, one method is derived and found to be useful to handle the gradient vanishing (Glorot and Bengio, 2010). Similar methods are further developed for ReLU networks (He et al., 2015). He et al. (2016) find that deep network training is still hard even after addressing the gradient vanishing issue and propose residual networks. Balduzzi et al. (2017b) identifies the shattered gradient issue and proposes LookLinear initialization.

On the other hand, although it is observed that scaling residual outputs to smaller values helps to stabilize training (Hanin and Rolnick, 2018; Mishkin and Matas, 2015; Zhang et al., 2019a; Bachlechner et al., 2020; Goyal et al., 2017), there is no systematic analysis on what complicates Transformer training or its underlying connection to the dependency on residual branches. Here, we identify that unbalanced gradients are not the direct cause of the Post-LN instability, recognize the amplification effect, and propose a novel adaptive initialization method.

7 Conclusion

In this paper, we study the difficulties of training Transformers in theoretical and empirical manners. Our study in Section 3 suggests that the gradient vanishing problem is not the root cause of unstable Transformer training. Also, the unbalanced gradient distribution issue is mostly addressed by adaptive optimizers. In Section 4, we reveal the root cause of the instability to be the strong dependency on residual branches, which amplifies the fluctuation caused by parameter changes and destabilizes model training. In light of our analysis, we propose Admin, an adaptive initialization method to stabilize Transformers training. It controls the dependency at the beginning of training and maintains the flexibility to capture those dependencies once training stabilizes. Extensive experiments verify our intuitions and show that, without introducing additional hyper-parameters, Admin achieves more stable training, faster convergence, and better performance.

Our work opens up new possibilities to not only further push the state-of-the-art but understand deep network training better. It leads to many interesting future works, including generalizing Theorem 2 to other models, designing new algorithms to automatically adapt deep networks to different training configurations, upgrading the Transformer architecture, and applying our proposed Admin to conduct training in a larger scale.

A Gradients at Initialization

Here, we first reveal that Pre-LN does not suffer from the gradient vanishing. Then we establish that only the Post-LN decoder suffers from the gradient vanishing, but not the Post-LN encoder. For simplicity, we use $\Delta\mathbf{x}$ to denote gradients, *i.e.*, $\Delta\mathbf{x} = \frac{\partial\mathcal{L}}{\partial\mathbf{x}}$ where $\mathcal{L}$ is the training objective. Following the previous study (Bengio et al., 1994; Glorot and Bengio, 2010; He et al., 2015; Saxe et al., 2013), we analyze the gradient distribution at the very beginning of training, assume that the randomly initialized parameters and the partial derivative with regard to module inputs are independent.

A.1 Pre-LN Analysis

For Pre-LN encoders, we have $\mathbf{x}_{2i}^{(pe)} = \mathbf{x}_{2i-1}^{(pe)} + f_{\text{FFN}}(f_{\text{LN}}(\mathbf{x}_{2i-1}^{(pe)}))$ and $\Delta\mathbf{x}_{2i-1}^{(pe)} = \Delta\mathbf{x}_{2i}^{(pe)}(1 + \frac{\partial f_{\text{FFN}}(f_{\text{LN}}(\mathbf{x}_{2i-1}^{(pe)}))}{\partial\mathbf{x}_{2i}^{(pe)}})$. At initialization, the two terms on the right part are approximately independent and $E[\frac{\partial f_{\text{FFN}}(f_{\text{LN}}(\mathbf{z}_{2i-1}^{(pe)}))}{\partial\mathbf{x}_{2i}^{(pe)}}] = 0$. Therefore we have $\text{Var}[\Delta\mathbf{x}_{2i-1}^{(pe)}] \geq \text{Var}[\Delta\mathbf{x}_{2i}^{(pe)}]$. Similarly, we can get $\text{Var}[\Delta\mathbf{x}_{2i-2}^{(pe)}] \geq \text{Var}[\Delta\mathbf{x}_{2i-1}^{(pe)}]$ thus $\forall i \leq j, \text{Var}[\Delta\mathbf{x}_{i}^{(pe)}] \geq \text{Var}[\Delta\mathbf{x}_{j}^{(pe)}]$. Applying the same analysis to Pre-LN decoders, we can get $\forall i \leq j, \text{Var}[\Delta\mathbf{x}_{i}^{(pd)}] \geq \text{Var}[\Delta\mathbf{x}_{j}^{(pd)}]$. Thus, lower layers have larger gradients than higher layers, and gradients do not vanish in the backpropagation.

REMARK 1. — For Pre-LN, if $\forall i, \Delta\mathbf{x}_{i}^{(p\cdot)}$ and the derivatives of modules in the i-th sub-layer are independent, then $\forall i \leq j, \text{Var}[\Delta\mathbf{x}_{i}^{(p\cdot)}] \geq \text{Var}[\Delta\mathbf{x}_{j}^{(p\cdot)}]$.

A.2 Post-LN Encoder Analysis

Different from Pre-LN, $\mathbf{x}_{i}^{(oe)}$ and $\mathbf{x}_{i-1}^{(oe)}$ are associated with not only the residual connection but the layer normalization, which makes it harder to establish the connection on their gradients. After making assumptions on the model initialization, we find that lower layers in Post-LN encoder also have larger gradients than higher layers, and gradients do not vanish in their backpropagations.

THEOREM 1. — For Post-LN Encoders, if $\boldsymbol{\gamma}$ and $\boldsymbol{\nu}$ in the Layer Norm are initialized as 1 and 0 respectively; all other parameters are initialized by symmetric distributions with zero mean; $\mathbf{x}_{i}^{(oe)}$ and $\Delta\mathbf{x}_{i}^{(oe)}$ are subject to symmetric distributions with zero mean; the variance of $\mathbf{x}_{i}^{(oe)}$ is 1 (*i.e.*, normalized by Layer Norm); $\Delta\mathbf{x}_{i}^{(oe)}$ and the derivatives of modules in i-th sub-layer are independent, we have $\text{Var}[\Delta\mathbf{x}_{i-1}] \geq \text{Var}[\Delta\mathbf{x}_{i}]$.

Proof. We first prove $\mathrm{Var}[\Delta \mathbf{x}_{2i-1}^{(oe)}] \geq \mathrm{Var}[\Delta \mathbf{x}_{2i}^{(oe)}]$, *i.e.*, the backpropagation through FFN sublayers does not suffer from gradient vanishing. In Post-LN encoders, the output of FFN sublayers is calculated as $\mathbf{x}_{2i}^{(oe)} = f_{\mathrm{LN}}(\mathbf{b}_{2i}^{(oe)})$ where $\mathbf{b}_{2i}^{(oe)} = \mathbf{x}_{2i-1}^{(oe)} + \max(0, \mathbf{x}_{2i-1}^{(oe)} W^{(1)}) W^{(2)}$. Since at initialization, $W^{(1)}$ and $W^{(2)}$ are independently randomized by symmetric distributions, we have $\mathbb{E}[\mathbf{b}_{2i}^{(oe)}] = 0$ and

$$\mathbf{x}_{2i}^{(oe)} = \frac{\mathbf{x}_{2i-1}^{(oe)} + \max(\mathbf{x}_{2i-1}^{(oe)} W^{(1)}, 0) W^{(2)}}{\sigma_{b,2i}}$$

where $\sigma_{b,2i}^2 = \mathrm{Var}[\mathbf{b}_{2i}^{(oe)}]$. Referring to the dimension of $W^{(1)}$ as $D \times D_f$, He et al. (2015) establishes that

$$\mathrm{Var}[\max(\mathbf{x}_{2i-1}^{(oe)} W^{(1)}, 0) W^{(2)}] = \frac{1}{2} D D_f \,\mathrm{Var}[w^{(1)}] \,\mathrm{Var}[w^{(2)}] \,\mathrm{Var}[\mathbf{x}_{2i-1}^{(oe)}].$$

Since in Post-LN, $\mathbf{x}_{2i-1}^{(oe)}$ is the output of layer norm, we have $\mathrm{Var}[\mathbf{x}_{2i-1}^{(oe)}] = 1$. Thus,

$$\begin{aligned} \sigma_{b,2i}^2 &= \mathrm{Var}[\mathbf{b}_{2i}^{(oe)}] = \mathrm{Var}[\mathbf{x}_{2i-1}^{(oe)}] + \mathrm{Var}[\max(\mathbf{x}_{2i-1}^{(oe)} W^{(1)}, 0) W^{(2)}] \\ &= 1 + \frac{1}{2} D D_f \,\mathrm{Var}[w^{(1)}] \,\mathrm{Var}[w^{(2)}]. \end{aligned} \tag{1}$$

Assuming different terms are also independent in the backpropagation, we have

$$\mathrm{Var}[\Delta \mathbf{x}_{2i-1}^{(oe)}] \geq \mathrm{Var}[\frac{1}{\sigma_{b,2i}} (\Delta \mathbf{x}_{2i}^{(oe)} + \Delta \mathbf{x}_{2i}^{(oe)} \frac{\partial \max(\mathbf{x}_{2i-1}^{(oe)} W^{(1)}, 0) W^{(2)}}{\partial \mathbf{x}_{2i-1}^{(oe)}})].$$

At initialization, He et al. (2015) establishes that

$$\mathrm{Var}[\Delta \mathbf{x}_{2i}^{(oe)} \frac{\partial \max(\mathbf{x}_{2i-1}^{(oe)} W^{(1)}, 0) W^{(2)}}{\partial \mathbf{x}_{2i-1}^{(oe)}}] = \frac{1}{2} D D_f \,\mathrm{Var}[w^{(1)}] \,\mathrm{Var}[w^{(2)}] \,\mathrm{Var}[\Delta \mathbf{x}_{2i}^{(oe)}].$$

Therefore, we have

$$\mathrm{Var}[\Delta \mathbf{x}_{2i-1}^{(oe)}] \geq \frac{1}{\sigma_{b,2i}^2} (1 + \frac{1}{2} D D_f \,\mathrm{Var}[w^{(1)}] \,\mathrm{Var}[w^{(2)}]) \,\mathrm{Var}[\Delta \mathbf{x}_{2i}^{(oe)}]. \tag{2}$$

Combining Equation 1 with Equation 2, we have

$$\mathrm{Var}[\Delta \mathbf{x}_{2i-1}^{(oe)}] \geq \mathrm{Var}[\Delta \mathbf{x}_{2i}^{(oe)}] \tag{3}$$

which shows the backpropagation through FFN sublayers does not suffer from gradient vanishing.

Now we proceed to prove that, $\mathrm{Var}[\Delta \mathbf{x}_{2i-2}^{(oe)}] \geq \mathrm{Var}[\Delta \mathbf{x}_{2i-1}^{(oe)}]$, *i.e.*, the backpropagation through Self-Attention sublayers do not suffer from gradient vanishing. In Post-LN encoders, the output of Self-Attention sublayers are calculated as $\mathbf{x}_{2i-1}^{(oe)} = f_{\mathrm{LN}}(\mathbf{b}_{2i-1}^{(oe)})$ where $\mathbf{b}_{2i-1}^{(oe)} = \mathbf{x}_{2i-2}^{(oe)} + \mathbf{a}_{2i-1}^{(oe)}$ and $\mathbf{a}_{2i-1}^{(od)} = \sum_h f_s(\mathbf{x}_{2i-2}^{(oe)} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{T}{}_{2i-2}^{(oe)}) \mathbf{x}_{2i-2}^{(oe)} W_h^{(V_1)} W_h^{(V_2)}$. At initialization, since $W^{(Q)}$, $W^{(K)}$, $W^{(V_1)}$, and $W^{(V_2)}$ are independently randomized by symmetric distributions, we have $\mathbb{E}[\mathbf{b}_{2i-1}^{(od)}] = 0$, thus $\mathbf{x}_{2i-1}^{(oe)} = \frac{\mathbf{b}_{2i-1}^{(oe)}}{\sigma_{b,2i-1}}$, where $\sigma_{b,2i-1}^2 = \mathrm{Var}[\mathbf{b}_{2i-1}^{(oe)}] = \mathrm{Var}[\mathbf{x}_{2i-2}^{(oe)}] + \mathrm{Var}[\mathbf{a}_{2i-1}^{(oe)}]$.

Referring $\mathbb{E}[{f_s}^2(\mathbf{x}_{2i-2}^{(oe)} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{T}{}_{2i-2}^{(oe)})]$ as P_h, we have

$$\mathrm{Var}[\mathbf{a}_{2i-1}^{(od)}] = \mathrm{Var}[\mathbf{x}_{2i-2}^{(oe)} W_h^{(V_1)} W_h^{(V_2)}] H P_h.$$

Similar to He et al. (2015), we have

$$\mathrm{Var}[\mathbf{x}_{2i-2}^{(oe)} W_h^{(V_1)} W_h^{(V_2)}] = \frac{D^2}{H} \mathrm{Var}[\mathbf{x}_{2i-2}^{(oe)}] \,\mathrm{Var}[w^{(V_1)}] \,\mathrm{Var}[w^{(V_2)}].$$

Since $\mathbf{x}^{(oe)}_{2i-2}$ is the output of layer norm, we have $\mathrm{Var}[\mathbf{x}^{(oe)}_{2i-2}] = 1$. Thus,

$$\sigma^2_{b,2i-1} = 1 + D^2 P_h \,\mathrm{Var}[\mathbf{x}^{(oe)}_{2i-2}]\,\mathrm{Var}[w^{(V_1)}]\,\mathrm{Var}[w^{(V_2)}]. \tag{4}$$

In the backpropagation, we have

$$\begin{aligned}
&\mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-2}] \geq \mathrm{Var}[\frac{1}{\sigma_{b,2i-1}}(\Delta\mathbf{x}^{(oe)}_{2i-1} + \Delta\mathbf{x}^{(oe)}_{2i-1}\sum_h \frac{\partial f_s(\mathbf{x}^{(oe)}_{2i-2} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{T(oe)}_{2i-2})\mathbf{x}^{(oe)}_{2i-2} W_h^{(V_1)} W_h^{(V_2)}}{\partial \mathbf{x}^{(oe)}_{2i-2}})] \\
&\geq \frac{1}{\sigma^2_{b,2i-1}}(\mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-1}] + \mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-1}\sum_h f_s(\mathbf{x}^{(oe)}_{2i-2} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{T(oe)}_{2i-2})\frac{\partial \mathbf{x}^{(oe)}_{2i-2} W_h^{(V_1)} W_h^{(V_2)}}{\partial \mathbf{x}^{(oe)}_{2i-2}}])
\end{aligned}$$

At initialization, we assume $\Delta\mathbf{x}^{(oe)}_{2i-1}$ and model parameters are independent (He et al., 2015), thus

$$\begin{aligned}
&\mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-1}\sum_h f_s(\mathbf{x}^{(oe)}_{2i-2} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{T(oe)}_{2i-2})\frac{\partial \mathbf{x}^{(oe)}_{2i-2} W_h^{(V_1)} W_h^{(V_2)}}{\partial \mathbf{x}^{(oe)}_{2i-2}}] \\
=&D^2 P_h \,\mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-1}]\,\mathrm{Var}[w^{(V_1)}]\,\mathrm{Var}[w^{(V_2)}]
\end{aligned}$$

Therefore, we have

$$\mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-2}] \geq \frac{1}{\sigma^2_{b,2i-1}}(1 + D^2 P_h \,\mathrm{Var}[w^{(V_1)}]\,\mathrm{Var}[w^{(V_2)}])\,\mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-1}]. \tag{5}$$

Integrating Equation 4 with Equation 5, we have

$$\mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-2}] \geq \mathrm{Var}[\Delta\mathbf{x}^{(oe)}_{2i-1}]. \tag{6}$$

Combining Equation 3 and Equation 6, we have $\mathrm{Var}[\Delta\mathbf{x}_{i-1}] \geq \mathrm{Var}[\Delta\mathbf{x}_i]$. ☐

A.3 Post-LN Decoder Analysis

In Post-LN, the Encoder-Attention sub-layer suffers from gradient vanishing. The Encoder-Attention sub-layer calculates outputs as $\mathbf{x}^{(od)}_{3i-1} = f_{\mathrm{LN}}(\mathbf{b}^{(od)}_{3i-1})$ where $\mathbf{b}^{(od)}_{3i-1} = \mathbf{x}^{(od)}_{3i-2} + \mathbf{a}^{(od)}_{3i-1}$ and $\mathbf{a}^{(od)}_{3i-1} = \sum_h f_s(\mathbf{x}^{(od)}_{3i-2} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{T(oe)})\mathbf{x}^{(oe)} W_h^{(V_1)} W_h^{(V_2)}$. Here $\mathbf{x}^{(oe)}$ is encoder outputs and f_s is the row-wise softmax function. In the backpropagation, $\Delta\mathbf{x}^{(od)}_{3i-2} \approx \frac{\Delta\mathbf{x}^{(od)}_{3i-1}}{\sigma_{b,3i-1}}(1 + \frac{\partial \mathbf{a}^{(od)}_{3i-1}}{\mathbf{x}^{(od)}_{3i-2}})$. All of the backpropagations from $\mathbf{a}^{(od)}_{3i-1}$ to $\mathbf{x}^{(od)}_{3i-2}$ went through the softmax function, we have $\mathrm{Var}[\frac{\partial \mathbf{a}^{(od)}_{3i-1}}{\mathbf{x}^{(od)}_{3i-2}}] + 1 \leq \sigma^2_{b,3i-1}$. Thus, those backpropagations suffer from gradient vanishing. This observation is further verified in Figure 3, as the encoder attention bars (gradients of encoder-attention outputs) are always shorter than self-attention bars (gradients of encoder-attention inputs), while adjacent self-attention bars and fully connected bars usually have the same length.

A.4 Distributes of Unbalanced Gradients

As in Figure 5 and Figure 11, the gradient distribution of Attention modules is unbalanced even for Pre-LN. Specifically, parameters within the softmax function (*i.e.*, $W^{(K)}$ and $W^{(V_1)}$) suffer from gradient vanishing (*i.e.*, $\frac{\partial f_s(x_0,\cdots,x_i,\cdots)}{\partial x_i} \leq 1$) and have smaller gradients than other parameters.

With further analysis, we find it is hard to neutralize the gradient vanishing of softmax. Unlike conventional non-linear functions like ReLU or sigmoid, softmax has a dynamic input length (*i.e.*, for the sentences with different lengths, inputs of softmax have different dimensions). Although this setting allows Attention modules to handle sequential inputs, it restricts them from having stable and consistent backpropagation. Specifically, let us consider the comparison between softmax and sigmoid. For the sigmoid function, although its derivation is smaller than 1, this damping effect is consistent for all inputs. Thus, sigmoid can be neutralized by a larger initialization (Glorot and

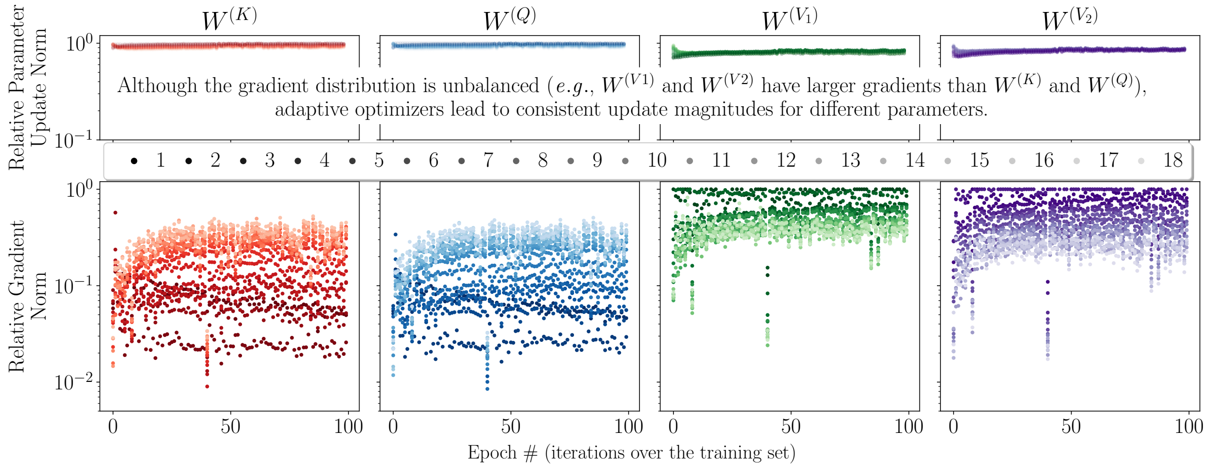

Figure 11: Relative Norm of Gradient (ΔW_i, where W_i is the checkpoint of i-th epoch) and Update ($|W_{i+1} - W_i|$) of Self-Attention Parameters in 12-Layer Pre-LN.

Table 3: ReZero Performance on IWSLT'14 De-En. Models are Transformer-small w. 6-layer encoder & decoder.

Models	Admin	Post-LN	Pre-LN	ReZero	ReZero+Post-LN
BLEU	35.67±0.15	35.64±0.23	35.50±0.04	33.67±0.14	34.67±0.08

Bengio, 2010). For softmax, its damping effect is different for different inputs and cannot be neutralized by a static initialization.

Also, we observe that adaptive optimizers largely address this issue. Specifically, we calculate the norm of parameter change in consequent epochs (*e.g.*, $|W_{t+1}^{(K)} - W_t^{(K)}|$ where $W_t^{(K)}$ is the checkpoint saved after t epochs) and visualize the relative norm (scaled by the largest value in the same network) in Figure 11. Comparing the relative norm of parameter gradients and parameter updates, we notice that: although the gradient distribution is unbalanced, adaptive optimizers successfully assign different learning rates to different parameters and lead to consistent update magnitudes. This result explains why the vanilla SGD fails for training Transformer (*i.e.*, lacking the ability to handle unbalanced gradient distributions). Besides, it implies that the unbalanced gradient distribution (*e.g.*, gradient vanishing) has been mostly addressed by adaptive optimizers and may not significantly impact the training instability.

B Proof of Theorem 2

Here, we elaborate the derivation of Theorem 2, which the relationship between layer number and output fluctuation caused by parameter change.

THEOREM 2. — Consider a N-layer Transformer $\widehat{\mathbf{x}} = \mathcal{F}(\widehat{\mathbf{x}}_0, W)$, where $\widehat{\mathbf{x}}_0$ is the input and W is the parameter. If the layer dependency stays the same after a parameter change (*i.e.*, $\beta_{i,j}$ has the same value after changing W to W^*, where W is randomly initialized and $\delta = W^* - W$ is independent to W), the output change (*i.e.*, $\mathrm{Var}[\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)]$) can be estimated as $\sum_{i=1}^{N} \beta_{i,i}^2 C$ where C is a constant.

Proof. We refer the module in i sub-layer as $\mathbf{a}_i = \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}, W_i)$, where $\widehat{\mathbf{x}}_i = \sum_{j \le i} \beta_{i,j} \widehat{\mathbf{a}}_j$ is the normalized residual output and $\widehat{\mathbf{a}}_i = \frac{\mathbf{a}_i}{\sqrt{\mathrm{Var}\,\mathbf{a}_i}}$ is the normalized module output. The final output is marked as $\widehat{\mathbf{x}} = \mathcal{F}(\mathbf{x}_0, W) = \sum_{j \le N} \beta_{N,j} \widehat{\mathbf{a}}_j$. To simplify the notation, we use the superscript $*$ to indicate variables related to W^*, *e.g.*, $\widehat{\mathbf{x}}^* = \mathcal{F}(\mathbf{x}_0, W^*)$ and $\mathbf{a}_i^* = \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*)$.

At initialization, all parameters are initialized independently. Thus $\forall i \ne j$, $\widehat{\mathbf{a}}_i$ and $\widehat{\mathbf{a}}_j$ are independent and $1 = \mathrm{Var}[\sum_{j \le i} \beta_{i,j} \widehat{\mathbf{a}}_j] = \sum_{j \le i} \beta_{i,j}^2$. Also, since k-layer and $(k+1)$-layer share the residual connection to previous layers, $\forall i, j \le k$ we have $\frac{\beta_{i,k}}{\beta_{j,k}} = \frac{\beta_{i,k+1}}{\beta_{j,k+1}}$. Thus $\forall i \le k, \beta_{i,k+1}^2 = (1 - \beta_{k,k}^2)\beta_{i,k}^2$ and

$$\mathrm{Var}[\widehat{\mathbf{x}}_i - \widehat{\mathbf{x}}_i^*] = \mathrm{Var}[\sum_{j \le i} \beta_{i,j} (\widehat{\mathbf{a}}_j - \widehat{\mathbf{a}}_j^*)]$$

$$= \sum_{j \le i} \beta_{i,j}^2 \,\mathrm{Var}[\widehat{\mathbf{a}}_j - \widehat{\mathbf{a}}_j^*] \tag{7}$$

$$= \beta_{i,i}^2 \,\mathrm{Var}[\widehat{\mathbf{a}}_i - \widehat{\mathbf{a}}_i^*] + (1 - \beta_{i,i}^2)\,\mathrm{Var}[\widehat{\mathbf{x}}_i - \widehat{\mathbf{x}}_i^*].$$

Now, we proceed to analyze $\mathrm{Var}[\widehat{\mathbf{a}}_i - \widehat{\mathbf{a}}_i^*]$.

Specifically, we have

$$
\begin{aligned}
&\operatorname{Var}[\widehat{\mathbf{a}}_i - \widehat{\mathbf{a}}_i^*] \\
&= \operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*)] \\
&= \operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i) + \\
&\qquad \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*)] \\
&= \operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i)] + \\
&\quad \operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*)]. \qquad (8)
\end{aligned}
$$

Since W is randomly initialized, $\operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*)]$ should have the same value for all layers, thus we use a constant C to refer its value ($C = \operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i^*)]$ and $C \approx |\delta| \cdot |\nabla \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i)|$).

As to $\operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i)]$, since the sub-layer of Transformers are mostly using linear weights with ReLU nonlinearity and $1 = \operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}, W_i)] = \operatorname{Var}[\widehat{\mathbf{x}}_{i-1}]$, we have $\operatorname{Var}[\mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}, W_i) - \mathcal{G}_i(\widehat{\mathbf{x}}_{i-1}^*, W_i)] \approx \operatorname{Var}[\widehat{\mathbf{x}}_{i-1} - \widehat{\mathbf{x}}_{i-1}^*]$. Thus, we can rewrite Equation 8 and get

$$
\operatorname{Var}[\widehat{\mathbf{a}}_i - \widehat{\mathbf{a}}_i^*] \approx \operatorname{Var}[\widehat{\mathbf{x}}_{i-1} - \widehat{\mathbf{x}}_{i-1}^*] + C
$$

With Equation 7, we have

$$
\begin{aligned}
&\operatorname{Var}[\widehat{\mathbf{x}}_i - \widehat{\mathbf{x}}_i^*] \\
=&\beta_{i,i}^2 \operatorname{Var}[\widehat{\mathbf{a}}_i - \widehat{\mathbf{a}}_i^*] + (1 - \beta_{i,i}^2) \operatorname{Var}[\widehat{\mathbf{x}}_i - \widehat{\mathbf{x}}_i^*] \\
\approx&\beta_{i,i}^2 (\operatorname{Var}[\widehat{\mathbf{x}}_{i-1} - \widehat{\mathbf{x}}_{i-1}^*] + C) \\
&+ (1 - \beta_{i,i}^2) \operatorname{Var}[\widehat{\mathbf{x}}_i - \widehat{\mathbf{x}}_i^*] \\
=&\operatorname{Var}[\widehat{\mathbf{x}}_i - \widehat{\mathbf{x}}_i^*] + \beta_{i,i}^2 C
\end{aligned}
$$

Thus, $\operatorname{Var}[\mathcal{F}(\mathbf{x}_0, W) - \mathcal{F}(\mathbf{x}_0, W^*)] \approx \sum_{i=1}^{N} \beta_{i,i}^2 C$. □

C Admin Implementation Details

As introduced in Section 4.3, we introduce a new set of parameters to rescale the module outputs. Specifically, we refer these new parameters as ω and construct the Post-LN sub-layer as:

$$
\mathbf{x}_i = f_{\text{LN}}(\mathbf{b}_i), \text{where } \mathbf{b}_i = \mathbf{x}_{i-1} \cdot \boldsymbol{\omega}_i + f_i(\mathbf{x}_{i-1})
$$

where $\cdot$ is the element-wise product.

After training, Admin can be reparameterized as the conventional Post-LN structure (*i.e.*, removing $\boldsymbol{\omega}_i$). Specifically, we consider $\mathbf{x}_i = \frac{\mathbf{b}_i}{\sigma_b}\boldsymbol{\gamma} + \boldsymbol{\nu}$. Then, for feedforward sub-layers, we have

$$
\mathbf{b}_i = \mathbf{x}_{i-1} \cdot \omega + \max(0, \mathbf{x}_{i-1} W^{(1)}) W^{(2)}, \text{where } \mathbf{x}_i = \frac{\mathbf{b}_{i-1}}{\sigma_b}\boldsymbol{\gamma} + \boldsymbol{\nu}.
$$

It can be reparameterized by changing $\boldsymbol{\gamma}$, $\boldsymbol{\nu}$, $W^{(1)}$ to $\boldsymbol{\gamma}\boldsymbol{\omega}_i$, $\boldsymbol{\nu}\boldsymbol{\omega}_i$, $\frac{1}{\boldsymbol{\omega}_i} W^{(1)}$ respectively, *i.e.*,

$$
\mathbf{b}_i' = \mathbf{x}_{i-1}' + \max(0, \mathbf{x}_{i-1}' \frac{1}{\boldsymbol{\omega}_i} W^{(1)}) W^{(2)}, \text{where } \mathbf{x}_{i-1}' = \frac{\mathbf{b}_{i-1}'}{\sigma_b}\boldsymbol{\gamma}\boldsymbol{\omega}_i + \boldsymbol{\nu}\boldsymbol{\omega}_i.
$$

For Self-Attention sub-layers, we have

$$
\mathbf{b}_i = \mathbf{x}_{i-1} + \sum_h f_s(\mathbf{x}_{i-1} W_h^{(Q)} W_h^{(K)} \mathbf{x}_{i-1}) \mathbf{x}_{i-1} W_h^{(V_1)} W_h^{(V_2)}, \text{where } \mathbf{x}_i = \frac{\mathbf{b}_{i-1}}{\sigma_b}\boldsymbol{\gamma} + \boldsymbol{\nu}.
$$

It can be reparameterized by changing $\boldsymbol{\gamma}$, $\boldsymbol{\nu}$, $W_h^{(Q)}$, $W_h^{(K)}$, $W_h^{(V_1)}$ to $\boldsymbol{\gamma}\boldsymbol{\omega}_i$, $\boldsymbol{\nu}\boldsymbol{\omega}_i$, $\frac{1}{\boldsymbol{\omega}_i} W_h^{(Q)}$, $\frac{1}{\boldsymbol{\omega}_i} W_h^{(K)}$ $\frac{1}{\boldsymbol{\omega}_i} W_h^{(V_1)}$ respectively, *i.e.*,

$$
\mathbf{b}_i' = \mathbf{x}_{i-1}' + \sum_h f_s(\mathbf{x}_{i-1}' \frac{1}{\boldsymbol{\omega}_i} W_h^{(Q)} W_h^{(K)} \frac{1}{\boldsymbol{\omega}_i} \mathbf{x}_{i-1}') \mathbf{x}_{i-1}' \frac{1}{\boldsymbol{\omega}_i} W_h^{(V_1)} W_h^{(V_2)}, \text{where } \mathbf{x}_{i-1}' = \frac{\mathbf{b}_{i-1}'}{\sigma_b}\boldsymbol{\gamma}\boldsymbol{\omega}_i + \boldsymbol{\nu}\boldsymbol{\omega}_i.
$$

For Encoder-Attention sub-layers, we have

$$
\mathbf{b}_i = \mathbf{x}_{i-1} + \sum_h f_s(\mathbf{x}_{i-1} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{\cdot e}) \mathbf{x}^{\cdot e} W_h^{(V_1)} W_h^{(V_2)}, \text{where } \mathbf{x}_i = \frac{\mathbf{b}_{i-1}}{\sigma_b}\boldsymbol{\gamma} + \boldsymbol{\nu}.
$$

It can be reparameterized by changing $\boldsymbol{\gamma}$, $\boldsymbol{\nu}$, $W_h^{(Q)}$ to $\boldsymbol{\gamma}\boldsymbol{\omega}_i$, $\boldsymbol{\nu}\boldsymbol{\omega}_i$, $\frac{1}{\boldsymbol{\omega}_i} W_h^{(Q)}$ respectively, *i.e.*,

$$
\mathbf{b}_i' = \mathbf{x}_{i-1}' + \sum_h f_s(\mathbf{x}_{i-1}' \frac{1}{\boldsymbol{\omega}_i} W_h^{(Q)} W_h^{(K)} \mathbf{x}^{\cdot e}) \mathbf{x}^{\cdot e} \frac{1}{\boldsymbol{\omega}_i} W_h^{(V_1)} W_h^{(V_2)}, \text{where } \mathbf{x}_{i-1}' = \frac{\mathbf{b}_{i-1}'}{\sigma_b}\boldsymbol{\gamma}\boldsymbol{\omega}_i + \boldsymbol{\nu}\boldsymbol{\omega}_i.
$$

It is easy to find $\mathbf{b}_i' = \mathbf{b}_i$ in all three situations.

From the previous analysis, it is easy to find that introducing the additional parameter $\boldsymbol{\omega}_i$ is equivalent to rescale some model parameters. In our experiments on IWSLT14 De-En, we find that directly rescaling initialization parameters can get roughly the same performance with introducing $\boldsymbol{\omega}_i$. However, it is not very stable when conducting training in a half-precision manner. Accordingly, we choose to add new parameters $\boldsymbol{\omega}_i$ instead of rescaling parameters.

D Experimental Setup

Our experiments are based on the implementation from the fairseq package (Ott et al., 2019). As to pre-processing, we follow the public released script from previous work (Ott et al., 2019; Lu et al., 2020). For WMT'14 datasets, evaluations are conducted on the provided 'newstest14' file, and more details about them can be found in Bojar et al. (2014). For the IWSLT'14 De-En dataset, more analysis and details can be found in Cettolo et al. (2014).

As to model specifics, we directly adopt Transformer-small configurations on the IWSLT'14 De-En dataset and stacks more layers over the Transformer-base model on the WMT'14 En-De and WMT'14 En-Fr datasets. Specifically, on the IWSLT'14 De-En dataset, we use word embedding with 512 dimensions and 6-layer encoder/decoder with 4 heads and 1024 feedforward dimensions; on the WMT'14 En-De and WMT'14 En-Fr datasets, we use word embedding with 512 dimension and 8-head encoder/decoder with 2048 hidden dimensions. Label smoothed cross entropy is used as the objective function with an uncertainty $= 0.1$ (Szegedy et al., 2016).

For Model training, we use RAdam as the optimizer (Liu et al., 2020a) and adopt almost all hyper-parameter settings from Lu et al. (2020). Specifically, for the WMT'14 En-De and WMT'14 En-Fr dataset, all dropout ratios (including (activation dropout and attention dropout) are set to 0.1. For the IWSLT'14 De-En dataset, after-layer dropout is set to 0.3, and a weight decay of 0.0001 is used. As to optimizer, we set $(\beta_1, \beta_2) = (0.9, 0.98)$, use inverse sqrt learning rate scheduler with a warmup phrase (8000 steps on the WMT'14 En-De/Fr dataset, and 6000 steps on the IWSLT'14 De-En dataset). The maximum learning rate is set to $1e^{-3}$ on the WMT'14 En-De dataset and $7e^{-4}$ on the IWSLT'14 De-En and WMT'14 En-Fr datasets. We conduct training for 100 epochs on the WMT'14 En-De dataset, 90 epochs on the IWSLT'14 De-En dataset and 50 epochs on the WMT'14 En-Fr dataset, while the last 10 checkpoints are averaged before inference.

On the IWSLT'14 De-En dataset, we conduct training on one NVIDIA GeForce GTX 1080 Ti GPU and set the maximum batch size to be 4096. On the WMT'14 En-De dataset, we conduct training on four NVIDIA Quadro R8000 GPUs and set maximum batch size (per GPU) as 8196. On the WMT'14 En-Fr dataset, we conduct training with the Nvidia DGX-2 server (6L-6L uses 4 NVIDIA TESLA V100 GPUs and 60L-16L uses 16 NVIDIA TESLA V100 GPUs) and set the maximum batch size (per GPU) as 8000 for 6L-6L and 5000 for 60L-16L. On the IWSLT'14 De-En dataset, Transformer-small models (w. 37 M Param.) take a few hours to train. On the WMT'14 En-De dataset, 6L-6L models (w. 63 M Param.) take $\sim$ 1 day to train, 12L-12L (w. 107M Param.) models take $\sim$ 2 days to train, and 18L-18L (w. 151M Param.) models take $\sim$ 3 days to train. On the WMT'14 En-Fr dataset, 6L-6L models (w. 67 M Param.) takes $\sim$ 2 days to train, and 60L-12L models (w. 262M Param.) takes $\sim$ 2.5 days to train. All training is conducted in half-precision with dynamic scaling (with a 256-update scaling window and a 0.03125 minimal scale). All our implementations and pre-trained models would be released publicly.

E Comparison to ReZero

Here, we first conduct comparisons with ReZero (Bachlechner et al., 2020) under two configurations–the first employs the original ReZero model, and the second adds layer normalizations in a Post-LN manner. As summarized in Table 3, the ReZero initialization leads to a performance drop, no matter layer normalization is used or not. It verifies our intuition that over small dependency restricts the model potential. At the same time, we find that adding layer normalization to ReZero helps to improve the performance. Intuitively, as dropout plays a vital role in regularizing Transformers, layer normalization helps to not only stabilize training but alleviate the impact of turning off dropouts during the inference.

Table 4: Performance and model size on WMT'14 En-Fr (AL-BL refers A-layer encoder & B-layer decoder).

Methods	Param. #	dim($W^{(1)}$) in FFN	Enc#-Dec#	BLEU
T5-Base (Raffel et al., 2019)	220 M	512 × 2048	6L-6L	41.2
T5-Large (Raffel et al., 2019)	770 M	1024 × 4096	12L-12L	41.5
T5-3B (Raffel et al., 2019)	3 B	1024 × 16384	24L-24L	42.6
T5-11B (Raffel et al., 2019)	11 B	1024 × 65536	24L-24L	43.4
Trans.Big-RNMT+ (Chen et al., 2018)	377 M	1024 × 8192	6L-6L	41.12
DynamicConv (Wu et al., 2019a)	213 M	1024 × 4096	7L-7L	43.2
DG-Transformer (Wu et al., 2019b)	264 M	1024 × 4096	8L-8L	43.27
Prime (Zhao et al., 2019)	252 M	1024 × 4096	6L-6L	43.48
Pre-LN (60L–12L)	262 M	512 × 2048	60L-12L	43.10
Admin (60L–12L)	262 M	512 × 2048	60L-12L	43.80

F Performance on the WMT'14 En-Fr

To explore the potential of Admin, we conduct experiments with 72-layer Transformers on the WMT'14 En-Fr dataset (with a 60-layer encoder and 12-layer decoder, we add less layers to decoder to encourage the model to rely more on the source context).

As in Table 4, Admin (60L–12L) achieves a BLEU score of 43.80, the new state-of-the-art on this long-standing benchmark. This model has a 60-layer encoder and a 12-layer decoder, which is significantly deeper than other baselines. Still, since the number of parameters increases in a quadratic speed with regard to hidden dimensions and a linear speed with regard to layer numbers, our model has roughly the same number of parameters with other baselines. It is worth mentioning that Admin even achieves better performance than all variants of pre-trained T5 models, which demonstrates the great potential of our proposed method. Also, Admin achieves a better performance than Pre-LN (60L–12L), which further verifies that the Pre-LN architecture restricts deep models' potential.

An Empirical Study of Generation Order for Machine Translation

Abstract

In this work, we present an empirical study of generation order for machine translation. Building on recent advances in insertion-based modeling, we first introduce a soft order-reward framework that enables us to train models to follow arbitrary oracle generation policies. We then make use of this framework to explore a large variety of generation orders, including uninformed orders, location-based orders, frequency-based orders, content-based orders, and model-based orders. Curiously, we find that for the WMT'14 English → German and WMT'18 English → Chinese translation tasks, order does not have a substantial impact on output quality. Moreover, for English → German, we even discover that unintuitive orderings such as alphabetical and shortest-first can match the performance of a standard Transformer, suggesting that traditional left-to-right generation may not be necessary to achieve high performance.

1 Introduction

Neural sequence models (Sutskever et al., 2014; Cho et al., 2014) have been successfully applied to a broad range of tasks in recent years. While these models typically generate their outputs using a fixed left-to-right order, there has also been some investigation into non-left-to-right and order-independent generation in pursuit of quality or speed. For example, Vinyals et al. (2015) explored the problem of predicting sets using sequence models. While this is a domain where generation order should intuitively be unimportant, they nevertheless found it to make a substantial difference in practice. Ford et al. (2018) explored treating language modeling as a two-pass process, where words from certain classes are generated first, and the remaining words are filled in during the second pass. They found that generating function words first followed by content words second yielded the best results. Separately, Gu et al. (2018) and Lee et al. (2018) developed non-autoregressive approaches to machine translation where the entire output can be generated in parallel in constant time. These models do away with order selection altogether but typically lag behind their autoregressive counterparts in translation quality.

More recently, a number of novel insertion-based architectures have been developed for sequence generation (Gu et al., 2019; Stern et al., 2019; Welleck et al., 2019). These frameworks license a diverse set of generation orders, including uniform (Welleck et al., 2019), random (Gu et al., 2019), or balanced binary trees (Stern et al., 2019). Some of them also match the quality of state-of-the-art left-to-right models (Stern et al., 2019). In this paper, we utilize one such framework to explore an extensive collection of generation orders, evaluating them on the WMT'14 English-German and WMT'18 English-Chinese translation tasks. We find that a number of non-standard choices achieve BLEU scores comparable to those obtained with the classical approach, suggesting that left-to-right generation might not be a necessary ingredient for high-quality translation. Our contributions are as follows:

- We introduce a general soft order-reward framework that can be used to teach insertion-based models to follow any specified ordering.
- We perform a large empirical study on various orders, including: uniform, random, left-to-right, right-to-left, common-first, rare-first, shortest-first, longest-first, alphabetical, and model-adaptive.
- We show that there is little variation in BLEU regardless of generation order. On the competitive WMT 2014 English → German task, we

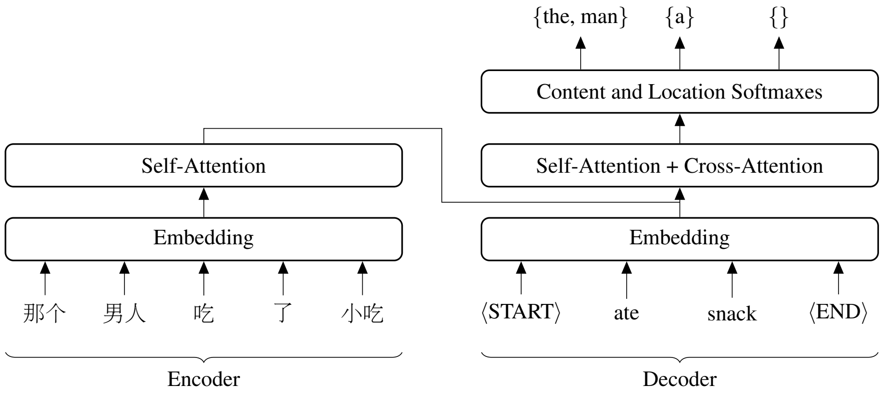

Figure 1: A schematic of the Insertion Transformer model for a Chinese-English translation pair. The model is encouraged to predict the correct set of remaining words within each slot. Using our order-reward framework (Section 3), we can derive the necessary weight distribution to apply to the set of correct actions in order to train the model to follow any oracle generation policy of interest.

Serial generation:

Hypothesis	Insertion
[]	(ate, 0)
[ate]	(snack, 1)
[ate, snack]	(man, 0)
[man, ate, snack]	(the, 0)
[the, man, ate, snack]	(a, 3)
[the, man, ate, a, snack]	(⟨EOS⟩, 5)

Parallel generation:

Hypothesis	Insertions
[]	(ate, 0)
[ate]	(man, 0), (snack, 1)
[man, ate, snack]	(the, 0), (a, 2)
[the, man, ate, a, snack]	(⟨EOS⟩, 5)

Figure 2: Example decoding paths for serial and parallel generation using the Insertion Transformer.

further find that most orders are able to match the performance of a standard base Transformer.

2 Background

Neural sequence models have traditionally been designed with left-to-right prediction in mind. In the classical setting, output sequences are produced by repeatedly appending tokens to the rightmost end of the hypothesis until an end-of-sequence token is generated. Though high-performing across a wide range of application areas, this approach lacks the flexibility to accommodate other types of inference such as parallel generation, constrained decoding, infilling, etc. Moreover, it also leaves open the possibility that a non-left-to-right factorization of the joint distribution over output sequences could outperform the usual monotonic ordering.

To address these concerns, several recent approaches have been proposed for insertion-based sequence modeling, in which sequences are constructed by repeatedly inserting tokens at arbitrary locations in the output rather than only at the rightmost position. We use one such insertion-based model, the Insertion Transformer (Stern et al., 2019), for our empirical study. We give a brief overview of the model in this section before moving on to the details of our investigation.

2.1 Insertion Transformer

The Insertion Transformer (Stern et al., 2019) is a sequence-to-sequence model in which the output is formed by successively inserting one or more tokens at arbitrary locations into a partial hypothesis. This type of generation is made possible through the use of a joint distribution over tokens and slots. More formally, given an input x and a partial output $\hat{y}_t$ at time t, the Insertion Transformer gives the joint distribution

$$p(c, l \mid x, \hat{y}_t) = \mathrm{InsertionTransformer}(x, \hat{y}_t),$$

where $c \in V$ is the content being selected from the vocabulary V and $0 \le l \le |\hat{y}_t|$ is the insertion location.

As its name suggests, the Insertion Transformer extends the Transformer model (Vaswani et al.,

2017) with a few key modifications to generalize from ordinary next-token modeling to joint token-and-slot modeling. First, the Insertion Transformer removes the causal attention mask from the decoder, allowing for fully contextualized output representations to be derived after each insertion. Second, the Insertion Transformer pads the length-n decoder input on both ends so that $n + 2$ output vectors are produced. It then concatenates adjacent pairs of output vectors to obtain $n + 1$ slot representations, which in turn inform the conditional distributions over tokens within each slot, $p(c \mid l)$. Lastly, it performs an additional attention step over the slot representations to obtain a location distribution $p(l)$, which is multiplied with the conditional content distributions to obtain the full joint distribution: $p(c, l) = p(c \mid l)p(l)$. A schematic of the architecture is given in Figure 1 for reference.

We note that Stern et al. (2019) also experimented with a number of other architectural variants, but we use the baseline version of the model described above in our experiments for simplicity.

2.2 Decoding

Once the model has been trained, it can be used for greedy autoregressive sequence generation as follows. At each step of decoding, we compute the joint argmax

$$(\hat{c}_t, \hat{l}_t) = \operatorname*{argmax}_{c,l} p(c, l \mid x, \hat{y}_t)$$

to determine what content $\hat{c}_t$ should be inserted at which location $\hat{l}_t$. We then apply this insertion, increasing the sequence length by one, and repeat this process until an end-of-sequence token is produced. This is the serial decoding procedure shown in the left half of Figure 2.

The model can also be used for parallel partially-autoregressive decoding. Instead of computing the joint argmax across all locations, we instead compute the best content for each location:

$$\hat{c}_{l,t} = \operatorname*{argmax}_{c} p(c \mid l, x, \hat{y}_t).$$

We then insert the highest-scoring tokens in parallel for all slots that are not yet finished, increasing the sequence length by anywhere between one and $n + 1$ tokens. This strategy visualized in the right half of Figure 2.

Order	**Order Function** $O(a)$
Uniform	0
Balanced Binary Tree	$\lvert s - (i + j)/2 \rvert$
Random	$\mathrm{rank}(\mathrm{hash}(w))$
Sequential (L2R vs. R2L)	$\pm s$
Frequency (Common vs. Rare)	$\pm\mathrm{rank}(\mathrm{frequency}(w))$
Length (Short vs. Long)	$\pm\mathrm{rank}(\mathrm{length}(w))$
Alphabetical (A → z vs. z → A)	$\pm\mathrm{rank}(w)$
Adaptive (Easy vs. Hard)	$\pm \log p(a)$

Table 1: Order functions for an action a corresponding to the insertion of word w into slot s within span (i, j). The rank terms are computed with respect to the set of words from the valid action set A^*.

3 Soft Order-Reward Framework

Having presented our model of interest, we now describe a general soft order-reward framework that can be used to train the model to follow any oracle ordering for sequence generation. Let $O(a)$ be an order function mapping insertion actions to real numbers, where lower values correspond to better actions, and let $p(a)$ be the probability assigned by the model to action a. From these, we construct a reward function $R(a)$, an oracle policy q_{oracle}, and a per-slot loss $\mathcal{L}$:

$$R(a) = \begin{cases} -O(a) & \forall a \in A^* \\ -\infty & \forall a \notin A^* \end{cases}$$

$$q_{\text{oracle}}(a) = \frac{\exp(R(a)/\tau)}{\sum_{a' \in A^*} \exp(R(a')/\tau)}$$

$$\mathcal{L} = \mathrm{KL}(q_{\text{oracle}} \,\|\, p)$$

Here, A^* is the set of all valid actions. The temperature $\tau \in (0, \infty)$ controls the sharpness of the distribution, where $\tau \to 0$ results in a one-hot distribution with all mass on the best-scoring action under the order function $O(a)$, and $\tau \to \infty$ results in a uniform distribution over all valid actions. Intermediate values of τ result in distributions which are biased towards better-scoring actions but allow for other valid actions to be taken some of the time.

Having defined the target distribution, we take the slot loss $\mathcal{L}$ for insertions within a particular slot to be the KL-divergence between the oracle distribution q_{oracle} and the model distribution p. Substituting $\mathcal{L}$ in for the slot loss within the training framework of Stern et al. (2019) then gives the full sequence generation loss, which we can use to train an Insertion Transformer under any oracle policy rather than just the specific one they propose. We describe a wide variety of generation orders which can be characterized by different order functions $O(a)$ in the subsections that follow. A summary is given in Table 1.

3.1 Uninformed Orders

We evaluate two uninformed orders, uniform and random. The uniform order $O(a) = 0$ gives equal reward or equivalently probability mass to any valid action. Consequently, this means we give each order a uniform probability treatment. We also experiment with random order $O(a) = \mathrm{rank}(\mathrm{hash}(w))$, wherein we hash each word and use the sorted hash ID as the generation order. The random order forces the model to follow a specific random path, whereas the uniform order gives equal probability mass to any order.

3.2 Location-based Orders

We explore two types of location-based orders, balanced binary tree and monotonic orders. The balanced binary tree order $O(a) = |s - (i + j)/2|$ encourages the model to place most of its probability mass towards the middle tokens in a missing span. Consequently, this encourages the model to generate text in a balanced binary tree order. We also experiment with soft monotonic orders $O(a) = \pm s$, or soft left-to-right and soft right-to-left, which differ slightly from the left-to-right teacher forcing traditionally used in seq2seq. First, we still maintain a uniform roll-in policy (see Section 3.6), which increases diversity during training and helps avoid label bias. Additionally, this endows the model with the ability to "look back" and insert missing tokens in the middle of the sequence during inference, as opposed to always being forced to append only at one end of the sequence. The order reward is also soft (as described by the τ term above), wherein we do not place all the probability mass on the next monotonic token, but merely encourage it to generate in a monotonic fashion.

3.3 Frequency-based Orders

We evaluate two frequency-based orders: rare words first via $O(a) = \mathrm{rank}(\mathrm{frequency}(w))$ and common words first via $O(a) = -\mathrm{rank}(\mathrm{frequency}(w))$. For these orders, we simply sort the words based on their frequencies and used their rank as the order. We note the most frequent words tend to be punctuation and stop words, such as commas, periods, and "the" in English.

3.4 Content-based Orders

We also explore content-based orders. One class of orders is based on the word length: $O(a) = \pm\mathrm{rank}(\mathrm{length}(w))$. This encourages the model to either emit all the shortest words first or all the longest words first.

We also explore alphabetical orderings $O(a) = \pm\mathrm{rank}(w)$, where sorting is based on Unicode order. We note that in Unicode, uppercase letters occur before lower case letters. This biases the model to produce words which are capitalized first (or last), typically corresponding to nouns in German. Additionally, for Chinese, the characters are roughly sorted by radical and stroke count, which bears a loose relation to the complexity and frequency of the character.

3.5 Model-based Orders

The orders presented thus far are static, meaning they are independent of the model. We also explore orders which are adaptive based on the model's posterior. We also introduce "easy" and "hard" adaptive orders induced by $O(a) = \pm \log p(a)$. The adaptive orders look at the model's posterior to determine the oracle policy. Consequently the loss is adaptive, as when the model updates after each gradient step, the order adapts to the model's posterior.

In the "easy" version, we use $O(a) = + \log p(a)$, which is similar to a local greedy soft EM loss. We renormalize our current model's posterior over valid actions and optimize towards that distribution. This pushes the model's posterior to what is correct and where it has already placed probability mass. Intuitively, this reinforces the model to select what it thinks are the easiest actions first. Conversely, the "hard" variant uses $O(a) = - \log p(a)$ which encourages the model to place probability mass on what it thinks are the hardest valid actions. This is akin to a negative feedback system whose stationary condition is the uniform distribution.

3.6 Roll-in Policy

We follow Stern et al. (2019) and use a uniform roll-in policy when sampling partial outputs at training time in which we first select a subset size uniformly at random, then select a random subset of the output of that size. Repeated tokens are handled via greedy left or right alignment to the true output.

Input: It would of course be a little simpler for the Germans if there were a coherent and standardised European policy, which is currently not the case.

Output: Es wäre für die Deutschen natürlich ein wenig einfacher, wenn es eine kohärente und einheitliche europäische Politik gäbe, was derzeit nicht der Fall ist.

Parallel decode (alphabetical):

4 Experiments

For our experiments, we train and evaluate models for each order on two standard machine translation datasets: WMT14 En-De and WMT18 En-Zh. For WMT14 En-De, we follow the standard setup with newstest2013 as our development set and newstest2014 as our test set. For WMT18 En-Zh, we use the official preprocessed data[1] with no additional data normalization or filtering, taking newstest2017 to be our development set and newstest2018 our test set. En-Zh evaluation is carried out using sacreBLEU[2] (Post, 2018). In both cases, we train all models for 1M steps using sequence-level knowledge distillation (Hinton et al., 2015; Kim and Rush, 2016) from a base Transformer (Vaswani et al., 2017). We perform a sweep over temperatures $\tau \in \{0.5, 1, 2\}$ and EOS penalties $\in \{0, 0.5, 1, 1.5, \ldots, 8\}$ (Stern et al., 2019) on the development set, but otherwise perform no additional hyperparameter tuning, borrowing all other model and optimization settings from the base Transformer.

Table 2: Percentage of insertions that follow the target order exactly, averaged over the development set.

4.1 Ability to Learn Different Orders

By and large, we find that the Insertion Transformer is remarkably capable of learning to generate according to whichever order it was trained for. We give example decodes for three different generation orders in Figures 3, 4, and 5. In the first example, we see that the alphabetical En-De model adheres to the Unicode ordering for Latin characters (punctuation → uppercase → lowercase), and that the En-Zh model similarly adheres to the Unicode order for Chinese (punctuation → CJK characters sorted by radical and stroke count). In the second example, the longest-first En-De model generates subwords in decreasing order of length as expected. Finally, in the third example, the common-first En-Zh model begins with common particles and punctuation before generating the main content words.

We give a quantitative measurement of the success of each model in Table 2, computing the percentage of insertions across the development set that adhered to the best-scoring action under the desired ordering. Most models exhibit similar trends, with the majority of En-De models achieving accuracies in excess of 90% when a low temperature is used, and with corresponding results in the mid-to-upper 80% range for En-Zh. Even the random order based on token hashes has accuracies exceeding 80% for both languages, demonstrating that the model has a strong capacity to adapt to any oracle policy.

4.2 Test Results

Next, we measure the quality of our models by evaluating their performance on their respective test sets. The resulting BLEU scores are reported in Table 3. The uniform loss proposed by Stern et al. (2019) serves as a strong baseline for both language pairs, coming within 0.6 points of the original Transformer for En-De at 26.72 BLEU, and attaining a respectable score of 33.1 BLEU on En-Zh. We note that there is a slightly larger gap between the normal Transformer and the Insertion Transformer for the latter of 2.7 points, which we hypothesize is a result of the larger discrepancy between word orders in the two languages combined with the more difficult nature of the Insertion Transformer training objective.

Most of the content-based orderings (frequency-based, length-based, alphabetical) perform comparably to the uniform loss, and even the random order is not far behind. The adaptive orders perform similarly well, with easy-first attaining one of the highest scores on En-De. Curiously, in our model adaptive easy-order, we were unable to identify any strong patterns in the generation order. The model did have a slight preference towards functional words (i.e., "," and "der"), but the preference was weak. As for location-based losses, the binary tree loss is notable in that it achieves the highest score across all losses for both languages. On the other hand, we note that while the soft left-to-right and right-to-left losses perform substantially better than the hard loss employed in the original work by Stern et al. (2019), performance does suffer when using parallel decoding for those models, which is generally untrue of the other orderings. We believe this is due in part to exposure bias issues arising from the monotonic ordering as

Order	En → De		En → Zh

compared with the uniform roll-in policy that are not shared by the other losses.

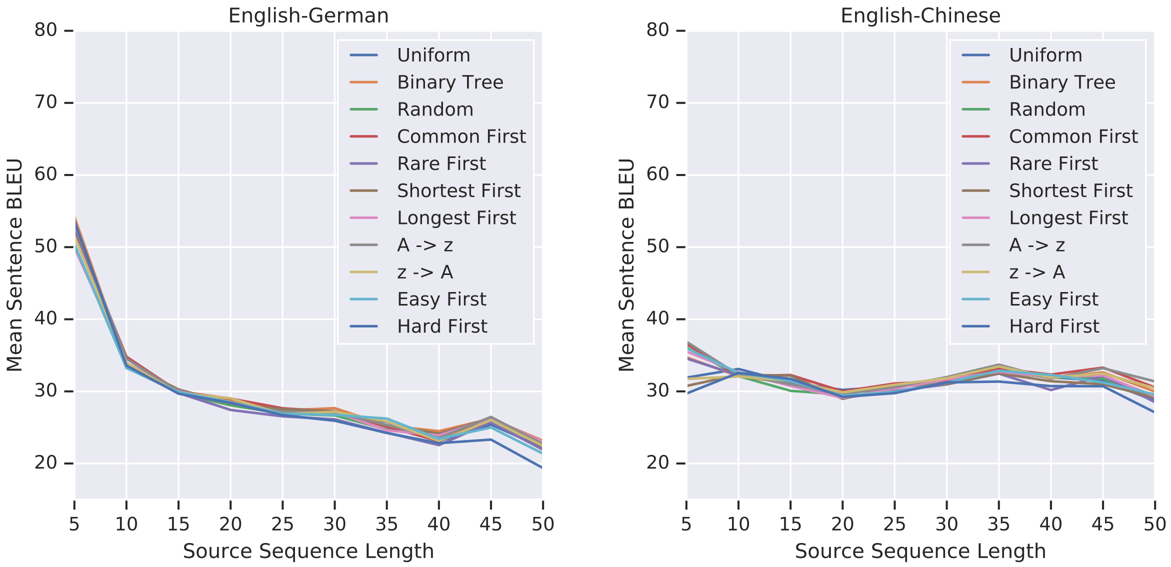
4.3 Performance vs. Sentence Length

For additional analysis, we consider how well our models perform relative to one another conditional on the length of the source sentence. Sentence length can be seen as a rough proxy measurement of the difficulty of translating a sentence. This is to determine if whether some order variations are able to achieve improved BLEU scores over other models depending on the source sentence's length. For each sentence in the En-De and En-Zh development sets, we compute their lengths and bin them into groups of size 5, up to a maximum length of 50. Within each bin, we compute sentence-level BLEU and take the mean score across all sentences. This is done for each of our model variants. Figure 6 illustrates the results of this experiment. We observe a surprisingly small model variance across all bin lengths. This suggests that sentences that are difficult to translate are difficult across all orderings, and no particular ordering appears strictly better or worse than others. One small exception to this is a performance fall-off of hard-first orderings for very long sentences across both datasets. We also observe a different distribution of BLEU scores across bin lengths for En-De and En-Zh. In particular, En-De models are approximately monotonic-decreasing in performance as source length increases, while on En-Zh performance is roughly flat across sentence length. This also highlights the importance of taking additional diverse language pairs into consideration, as certain translation properties across one language pair may not be observed in others.

Ultimately, given the similarity of the development scores across sentence lengths and the test scores for the various models, we come to the surprising conclusion that for single-sentence English-German and English-Chinese translation, generation order is relatively unimportant insofar as end-task performance is concerned.

5 Related Work

In recent work, several insertion-based frameworks have been proposed for the generation of sequences in a non-left-to-right fashion for machine translation (Stern et al., 2019; Welleck et al., 2019; Gu et al., 2019). Stern et al. (2019) introduced the Insertion Transformer and explored uniform



(a) English → German

(b) English → Chinese

Figure 6: Sentence-level BLEU scores as a function of sentence length for several of our model variants. Source sentences in each development set are binned into groups of size 5, up to length 50.

and balanced binary tree orders. We built upon and generalized this approach in order to explore a much broader set of orders. Welleck et al. (2019) explored insertions using a binary-tree formulation. They also explored uniform and model-based orders, but found them to lag significantly behind their left-to-right baselines. Additionally, despite using a binary-tree formulation for generation, they did not explore tree-based orders. Gu et al. (2019) introduced a model which did not explicitly represent the output canvas arising from insertions, but rather used an implicit representation through conditioning on the insertion sequence. They also performed an exploration of different generation orders, including random, odd-even, common-first, rare-first, and a search-adaptive order. Their search-adaptive order can be seen as a global version of our local model adaptive order, where we use the local greedy posterior as the reward function, and they use the sequence level log-probability as the reward function. Curiously, in their framework, the random order fell significantly behind the left-to-right baseline, while they showed small gains in their search adaptive order. One key difference between our work and Welleck et al. (2019) and Gu et al. (2019) is that we use a soft order-reward framework as opposed to teacher forcing. This might explain some of the performance differences, as our framework allows for a more flexible training objective. Additionally, since we use a uniform roll-in policy, our models may have less of a label bias problem, as they are trained to be able to continue from any partial output rather than just those arising from the target policy.

6 Conclusion

In this work, we investigated a broad array of generation orders for machine translation using an insertion-based sequence generation model, the Insertion Transformer. We found that regardless of the type of strategy selected, be it location-based, frequency-based, length-based, alphabetical, model-based, or even random, the Insertion Transformer is able to learn it with high fidelity and produce high-quality output in the selected order. This opens a wide range of possibilities for generation tasks where monotonic orderings are not the most natural choice, and we would be excited to explore some of these areas in future work.

Inference Strategies for Machine Translation with Conditional Masking

Julia Kreutzer and **George Foster** and **Colin Cherry**
Google Research
`{jkreutzer,fosterg,colincherry}@google.com`

Abstract

Conditional masked language model (CMLM) training has proven successful for non-autoregressive and semi-autoregressive sequence generation tasks, such as machine translation. Given a trained CMLM, however, it is not clear what the best inference strategy is. We formulate masked inference as a factorization of conditional probabilities of partial sequences, show that this does not harm performance, and investigate a number of simple heuristics motivated by this perspective. We identify a thresholding strategy that has advantages over the standard "mask-predict" algorithm, and provide analyses of its behavior on machine translation tasks.

1 Introduction

The widely successful masked language modeling paradigm popularized by BERT (Devlin et al., 2019) has recently been adapted to conditional masked language model (CMLM) training for semi-autoregressive sequence generation (Ghazvininejad et al., 2019), where model predictions are conditioned on the complete input sequence and the observed (non-masked) portion of the output sequence. The CMLM's simplicity and its clear links to the very active field of linguistic representation learning are advantages over its semi-autoregressive competitors, such as iterative refinement of token sequences (Lee et al., 2018), refinement of non-linguistic intermediate representations (Kaiser et al., 2018; Shu et al., 2020) and learning to predict parallel edit operations (Stern et al., 2019; Gu et al., 2019).

It is not obvious how to best perform inference with the CMLM. Starting from a partially-observed output sequence, the optimal choice to complete it within a single step would be to generate the most likely token at each unobserved (masked) position independently. However, it is less clear how to progress from an initial, completely masked sequence to a final hypothesis semi-autoregressively over a number of steps, with each successive step unmasking new context for the next. This requires not only ordering the tokens for generation, but also making decisions about how many tokens to simultaneously predict in each step.

Ghazvininejad et al. (2019) propose the *mask-predict* algorithm, which iteratively generates fresh model predictions for all masked positions, and then unmasks a predefined number of the most likely predictions. Given a fixed number of iterations, a decaying schedule determines how many predictions to unmask in each iteration. Each successive iteration provides mode-breaking (Gu et al., 2018) context for the next. By fixing the number of iterations, this approach allows for constant-time semi-autoregressive decoding.

The fixed-iteration strategy is very practical and has yielded empirical success in a range of machine translation experiments, but there is no guarantee that it is optimal. The tokens to be unmasked on a given iteration are all predicted independently, and therefore might contain repeated words, or words with low model confidence. These issues can be mitigated by later re-masking a token to repair it (Ghazvininejad et al., 2019) or by adapting the model to incorrect contexts (Ghazvininejad et al., 2020).

We instead adopt a fully probabilistic view of the masked prediction sequence, which we enable by simply disallowing the re-masking of previously unmasked tokens. This view guides us to a heuristic inference schedule that selects sets of unmasked tokens according to a threshold on the product of their conditionally independent model probabilities. This heuristic naturally slows down in the situations mentioned above, and speeds up in the presence of high confidence, which allows us to achieve favorable quality-to-speed trade-offs.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5774–5782,
November 16–20, 2020.

We focus on strengthening the CMLM inference (Section 3) while leaving its training algorithm unchanged (Section 2), and maintaining much of the structure of the original inference strategy. For our experiments on machine translation (Section 4), we compare inference heuristics in terms of their quality-speed trade-offs. We analyze the development of quality over iterations, and the influence of sentence length. With examples of unmasking schedules we furthermore illustrate the role of mode breaking through choosing the right contexts.

2 CMLM Model and Training

The CMLM is a model for $p(Y_{mask}|Y_{obs}, X)$, the probability of masked tokens Y_{mask} given a partially observed output sequence Y_{obs} and an input sequence X. Y_{mask} and Y_{obs} are sets of tokens at specified positions that together form a complete output sequence Y: $Y_{mask} = Y \setminus Y_{obs}$. The model is implicitly conditioned on output sequence length $N = |Y|$, and the tokens in Y_{mask} are conditionally independent: $p(Y_{mask}|Y_{obs}, X) = \prod_{y_i \in Y_{mask}} p(y_i|Y_{obs}, X, N)$. During training, masks are placed randomly: First, the mask size $S \in \{1, \dots, N\}$ is sampled from a uniform distribution, then S positions are randomly chosen to define the subsets Y_{obs} and Y_{mask}. Cross-entropy loss is incurred via $p(y_i|Y_{obs}, X)$ for each $y_i \in Y_{mask}$. An additional classifier on top of encoder representations is trained to predict the output length N.

3 CMLM Inference

Inference starts with a context of only MASK tokens. Until a stop condition is met, decoder predictions iteratively replace a subset of these in selected positions (“unmasking”). With a single iteration, inference is non-autoregressive; when the number of iterations T is less than the sentence length N it is semi-autoregressive; and when $N = T$ it is fully autoregressive. Due to the use of a uniform distribution over reference contexts, training is agnostic to these different regimes.

In general, we seek to minimize T without trading off too much quality. The challenge in doing so is to identify the subset of predictions that are most likely to provide suitable conditioning context for future iterations (Mansimov et al., 2019). Structural or linguistic dependencies in the output may also play an important role for resolving linguistic ambiguities (Martins and Kreutzer, 2017). For example, in German it might be harder to first generate the determiner before knowing the grammatical gender of the head word (see examples in Figure 6).

t	$M^{(t)}$	$Y^{(t)}$	$p(Y^{(t)} \mid Y^{(<t)}, M^{(\leq t)}, X)$
0	{1,2,3}	{}	–

2	{3}	{b}	$p(b \mid a,X)$
3	{}	{c}	$p(c \mid a,b,X)$
0	{1,2,3}	{}	–
1	{2}	{a,c}	$p(a \mid X)\ p(c \mid X)$
2	{}	{b}	$p(b \mid a,c,X)$

Figure 1: Computations for $p(Y, M|X)$, where $Y = \{a, b, c\}$, for various masking sequences M. The first sequence is fully non-autoregressive, and the second is the standard left-to-right autoregressive factorization.

The length predictor first predicts b different lengths, then one hypothesis is decoded for each length independently using the iterative process just outlined. The hypothesis with the highest length-normalized model score is selected as the output. We refer to b as the *length beam* in the following.

3.1 Update Strategies

The CMLM can make predictions at all positions, whether they correspond to masked input or not. This lends itself to various strategies for choosing how to update current predictions and masks:[1]

- *update-all*: update tokens and scores at all positions, no constraint on new mask[2]
- *update-masked*: update tokens at masked positions only, no constraint on new mask[3]
- *update-masked-sub*: update tokens at masked positions only, new mask must be a subset of the current one

In this paper we focus on the *update-masked-sub strategy*. It is empirically competitive (Section 4.1), and interesting because it corresponds to a valid probabilistic factorization of the target sequence, governed by a latent variable $M = M^{(0)} \dots M^{(T)}$

---

[1] In all cases we assume predictions to be the most likely words at each position, and scores to be the corresponding probabilities.

[2] This corresponds to a masked version of iterative refinement (Lee et al., 2018).

[3] This is the strategy used by Ghazvininejad et al. (2019).

which represents the sequence of masking decisions:

$$p(Y, M|X) = \prod_{t=1}^{T} p(Y^{(t)}|Y^{(<t)}, M^{(\leq t)}, X) \times \\ p(M^{(t)}|Y^{(<t)}, M^{(<t)}, X), \quad (1)$$

where $M^{(0)} = \{1, \dots, N\}$, $M^{(T)} = \{\}$, $M^{(t)} \subset M^{(t-1)}$, and $Y^{(t)}$ is the set of tokens *unmasked* on the tth iteration. Figure 1 illustrates this computation for various choices of M.[4]

The class of inference strategies we explore can thus be seen as *greedy search* for the mostly likely factorization, subject to a constraint on the number of iterations: at each iteration, we choose a subset of tokens to add to the current hypothesis, balancing high model probabilities with the risk of making an error and degrading future predictions. Because tokens are predicted independently, the risk of an error grows with the size of the subset.

3.2 Unmasking Heuristics

Under the *update-masked-sub* constraint, the role of greedy inference heuristics is to choose which positions to unmask, given a full set of predictions for all currently-masked positions. The *mask-predict* strategy of Ghazvininejad et al. (2019) chooses the $\lceil N/T \rceil$ highest-probability tokens, in order to finish in a constant T iterations, regardless of N. This generates more tokens per iteration for long sentences, which may not be ideal for sentences with complex structure. To measure its effect, we propose a variant that unmasks a constant K tokens per iteration, in order to achieve approximately K-fold speedup over autoregressive performance, independent of hypothesis length.

Unmasking highest-ranked tokens according to probability is reasonable, but it ignores the magnitude of the probabilities, creating the potential for selecting tokens in which the model has low confidence, and vice versa. To address this, we design several simple thresholding strategies that vary the number of tokens per iteration, ideally generating more when the conditioning context licences many confident predictions, and fewer otherwise.

1. The most straightforward strategy, *thresh*, unmasks all tokens with probabilities greater than a given threshold τ.
2. The *comb-thresh* strategy unmasks the largest set of highest-ranked tokens Y whose joint probability $p(Y) > \tau$.
3. Finally, in order to account for lower-ranked predictions, the *fcomb-thresh* strategy unmasks the largest set Y for which $p(Y) * (1 - p(\bar{Y})) > \tau$, where Y consists of the highest-ranked tokens, and $\bar{Y}$ is its complement.

All threshold strategies unmask the single highest-ranked token in contexts where the threshold criterion is not met.

4 Experiments

Our CMLM is implemented with a base Transformer (Vaswani et al., 2017) built on a TensorFlow implementation of (Ghazvininejad et al., 2019). The input to the decoder is Y_{obs}, with MASK tokens at masked positions, and the output is Y_{mask}, predictions for all masked positions without future attention masking. We use data from WMT14 en↔de (Bojar et al., 2014) and WMT17 zh↔en (Bojar et al., 2017) with a sentence piece vocabulary of 32k, focusing mainly on en→de, and providing results for all pairs in appendix A. The CMLM is trained on distilled training data from an autoregressive Transformer and initialized with its parameters.

4.1 Update Strategies

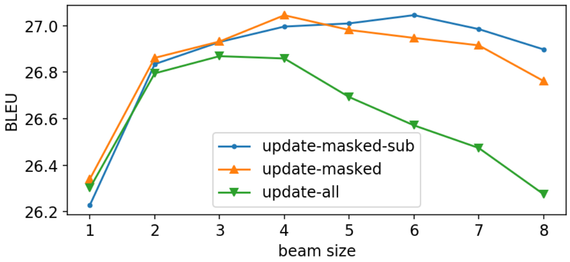

Figure 2: Performance of update strategies

Figure 2 shows the performance of the update strategies described in section 3.1 versus length beam b. All strategies use the mask-predict heuristic with a fixed 10-iteration limit. As beam size increases past 2, the update-masked strategies increasingly dominate, indicating that their scores are more reliable for choosing among length hypotheses. There is no significant difference between the two variants of update-masked. This suggests that our probabilistic factorization constraint (*update-masked-sub*) does not hurt in practice.

---

[4] Note that a probabilistic interpretation enables an unconstrained search for the most probable output, or for the unmasking sequence that assigns highest probability to a reference output, options we do not pursue in this paper.

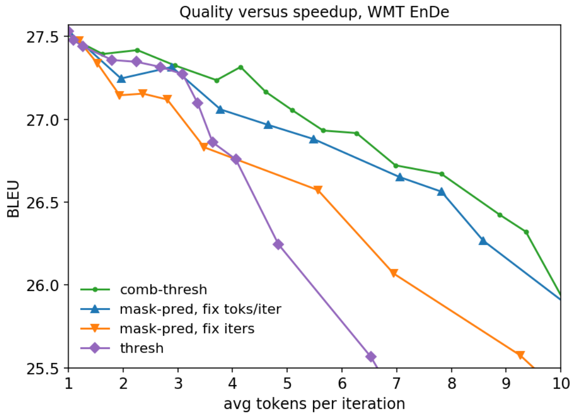

Figure 3: Heuristics with length-beam=5. The top border of the graph represents the performance of an autoregressive Transformer with beam=5. Different points in the graph correpond to different hyperparameter settings, varying the hyperparameter which controls the speed for each heuristic (T for fixed-iteration *mask-predict*, K for variable-iteration *mask-predict*, and τ for thresholding heuristics).

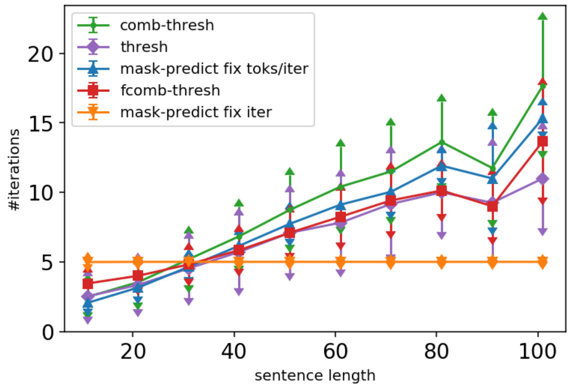

Figure 4: Number of iterations on the test set in relation to (oracle) sentence length (tokens) when generating on average ca. 5 tokens per iteration. Error bars indicate the standard deviation.

4.2 Heuristics

To compare the speed-quality trade-off of different heuristics on an equal footing, we vary the values of the hyper-parameter that controls speedup: T for fixed-iteration mask-predict, K for variable-iteration mask-predict, and τ for thresholding strategies. In each case, we measure the resulting speedup as the total number of tokens in the test set divided by the total number of iterations required for all sentences,[5] and corpus BLEU on the output of the last iteration.

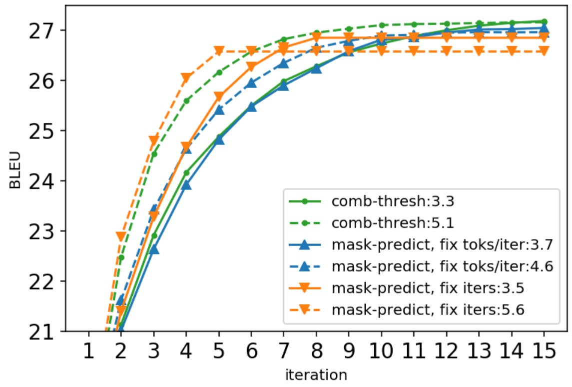

Figure 5: Development of BLEU over iterations comparing heuristics for two different generation speeds. The generation speed is expressed in average number of tokens per iteration, e.g. `comb-thresh:3.5` stands for the *comb-thresh* heuristic with a threshold value set so that 3.5 tokens are generated per iteration on average.

Figure 3 compares heuristics using 5 length candidates. First of all, fixed-K *mask-predict* beats fixed-T by a substantial margin (especially at higher speeds), indicating that it is worth allocating more iterations for longer sentences. Second, the *comb-thresh* strategy has a small but consistent advantage over fixed-K *mask-predict* across all speeds. This strategy exhibits a roughly 4x gain while sacrificing less than 0.3 BLEU relative to the equivalent autoregressive Transformer (27.6 BLEU).

Both *thresh* and *fcomb-thresh* underperform. Despite their superficial similarity to *comb-thresh*, they perform much worse; this holds for other language pairs as well (Figure 7 in Appendix A). For *thresh*, the poor performance as speedup increases reflects many relatively low-probability tokens exceeding lower thresholds, a condition that is penalized by all other heuristics, which take rank into account. For *fcomb-thresh* the effect is more subtle; we believe that it is due to the probabilities of lower-ranked tokens having worse calibration, leading to less reliable unmasking decisions.

A practical impediment to a thresholding strategy is that it does not provide direct control over desired speedup: this must be identified by tuning τ appropriately on a development set. However, we found that dev and test speedups were well correlated across speedups ranging from 1 to 11, with the largest absolute error being 0.8 (11.1 speedup on dev versus 10.3 on test), and the average error being 0.3.

---

[5] This is theoretical speedup, and we make no claims that it can be attained in practice, an objective that would likely require significant engineering effort.

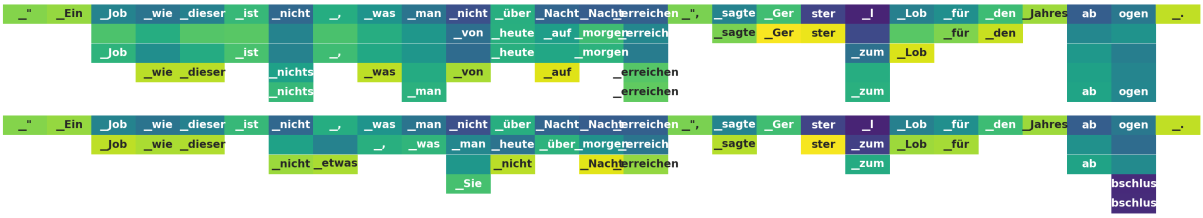

Figure 6: Unmasking over iterations for source sentence *"A job like this is not something you achieve overnight," said Gerster in praise of the annual financial statement.* with reference *"So ein Werk schüttelt man nicht einfach aus dem Ärmel", lobte Gerster mit Blick auf die Jahresrechnung.* for *mask-predict* with $T = 5$ above and *comb-thresh* with $\tau = 0.1$ below. Predicted tokens are shown when they differ from the previous iteration. Their background color indicates the model score, with yellow indicating high scores, and dark blue low scores.

4.3 Analysis

Having freed the heuristics from a globally imposed iteration limit for constant-time decoding as in the original mask-predict inference heuristic, we observed better quality-speed trade-offs in the above discussed results. Intuitively, we would expect the heuristics to allocate more iterations for longer sentences and save iterations on shorter sentences. Figure 4 shows how many iterations the models spend on sentences in relation to their length. For a fair comparison, the generation is constrained to oracle output lengths, and we set the hyperparameters such that they result in the same generation speed (5 tokens per iteration on average). We see that flexible-iteration strategies spend fewer iterations on sentences up to a length of around 30 when compared to a fixed-iteration strategy. *comb-thresh* spends on average the largest number of iterations on longer sentences (which pays off in terms of quality, see Figure 3), while *thresh* spends even fewer iterations on longer sentences than the mask-predict model.

The development of BLEU over iterations for comparable generation speeds across heuristics is shown in Figure 5.[6] We can see that speedier generation gives a faster initial increase in translation quality over iterations in exchange for slightly lower final quality (dashed vs solid lines). *Mask-predict* levels off early after reaching its fixed number of iterations, but climbs quickly before that point due to an averaging effect over short sentences. Fixed-K *mask-predict* and *comb-thresh* both extract useful work out of each iteration, with *comb-thresh* maintaining a slight edge over all iterations, especially at higher generations speeds.

Figure 6 shows an example for generation strategies under *mask-predict* and *comb-thresh* (see appendix B). They illustrate the workings of iterative decoding and main differences between strategies: Iterative decoding is crucially needed to resolve subject-verb agreement (e.g. “man [. . .] erreichen” (generic “you”) vs. “Sie [. . .] erreichen” (formal “you”) in ex. 2) and rough sentence structure (e.g. placement of the comma), and offers room for less literal translations (“von heute auf morgen” (literally “from today to tomorrow”) rather than “über Nacht” (literally “over night”) in ex. 1). The two tokens “Ger” and “ster” (a name) show how the correct conditioning changes model scores in both cases: After the former token is predicted, the probability for the latter increases drastically, since its only valid position in the sentence is there. While both strategies use the same number of iterations to generate this translation, one can see that it pays off for *comb-thresh* to unmask certain tokens earlier (“ab”, “Lob”), which allows a valid resolution of neighboring tokens (“bschluss”, “zum”).[7]

5 Conclusion

We investigated inference strategies for machine translation based on CMLM with a focus on the trade-off between generation speed and quality. We introduce a perspective which views generation sequences as probabilistic factorizations of the final output sequence, and use it to analyze and extend previous heuristics. Our new heuristics achieve better speed/quality balance by flexibly adjusting the number of total iterations, and by taking the probabilities of sets of tokens into account. For future work we would like to explore if their success transfers to other generation tasks with MLMs where inference efficiency is a concern.

---

[6] Each line on this graph is produced by doing inference with a particular hyperparameter setting, and recording BLEU for the greedily predicted tokens after each iteration.

[7] A typo (“abbschluss” vs “abschluss”) is introduced by choosing the “ab” sub-word rather than “a”, likely contributing to the model uncertainty in this area.

A Experiments on different languages

Pre-processing for all data sets follows the procedure described in (Vaswani et al., 2017).

Figure 7 shows the results for heuristics on all language pairs. As in our main experiments, quality is measured with tokenized BLEU, except for en→zh, where we use SacreBLEU (Post, 2018). In three of the language pairs, we observe a similar pattern to en→de: *comb-thresh* has a slight but consistent advantage over mask-predict, with the fixed tokens/iteration version of *mask-predict* doing consistently better than the fixed iteration version. On en→zh, all three methods perform similarly.

B Examples

Figure 8 provides more examples for *mask-predict* (Figure 8a) and *comb-thresh* (Figure 8b) heuristics under different hyperparameter settings, complementing the ones displayed in Figure 6. The source sentence is *"A job like this is not something you achieve overnight," said Gerster in praise of the annual financial statement.*, and the reference *"So ein Werk schüttelt man nicht einfach aus dem Ärmel", lobte Gerster mit Blick auf die Jahresrechnung.*. Predicted tokens are printed out when they differ from the previous iteration. Their background color indicates the model score, with yellow indicating high scores, and dark blue low scores.

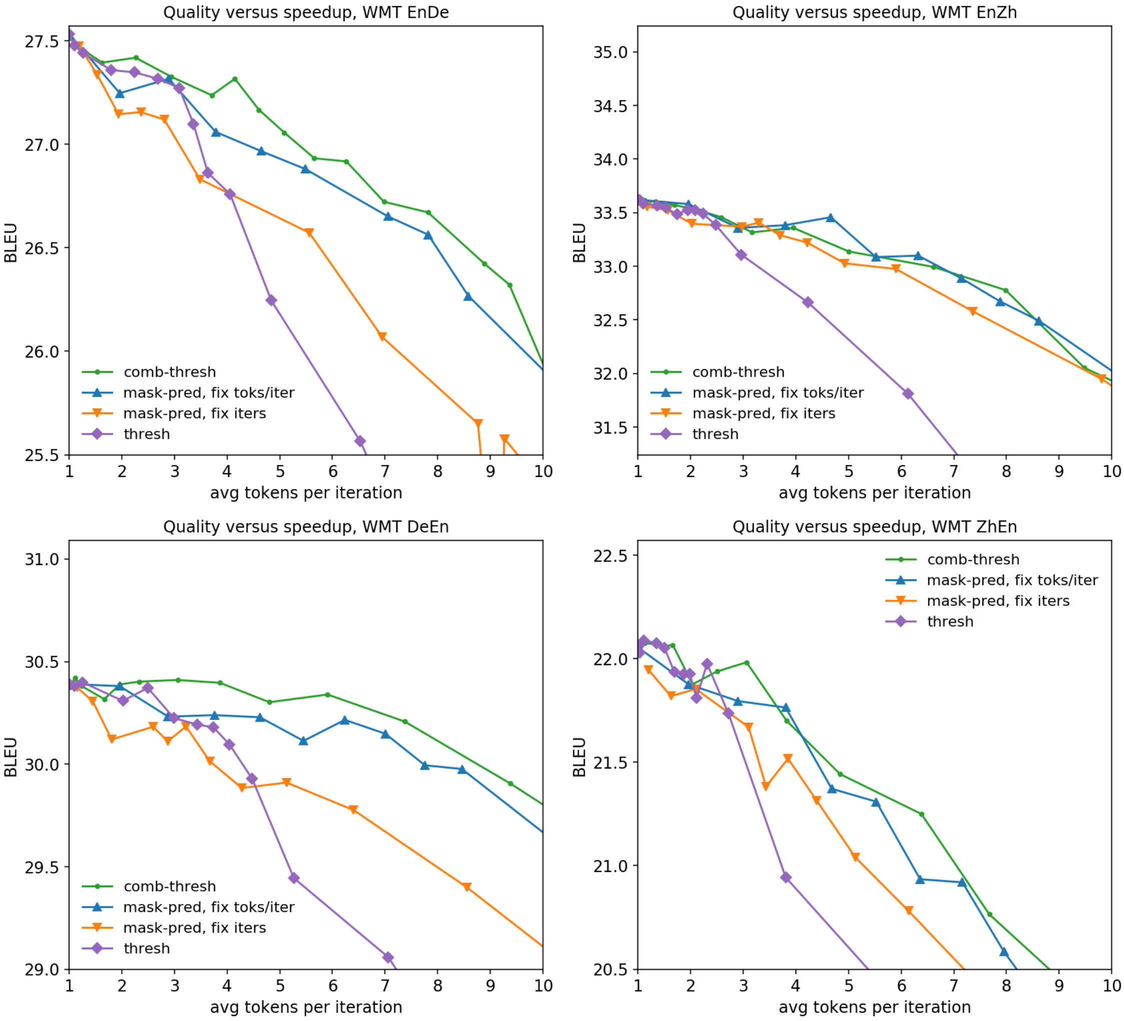

Figure 7: Results on all language pairs, with length-beam 5. The top border of each graph represents performance of the equivalent autoregressive Transformer.

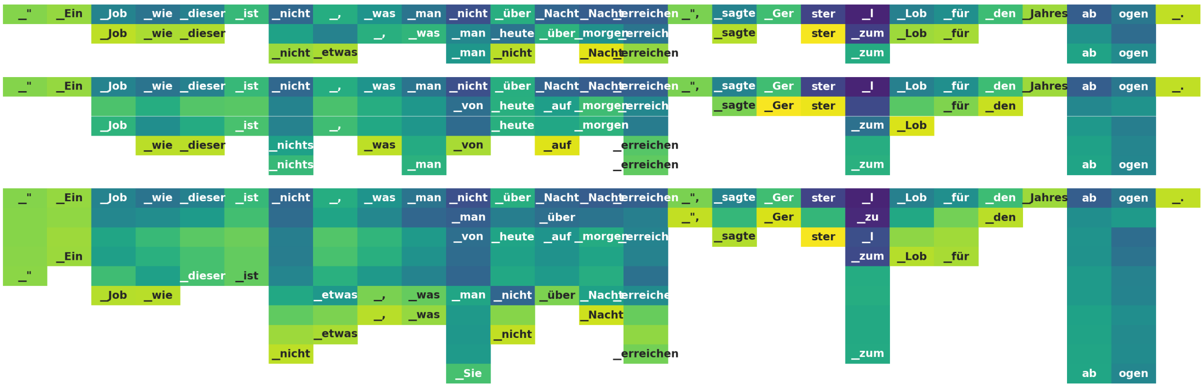
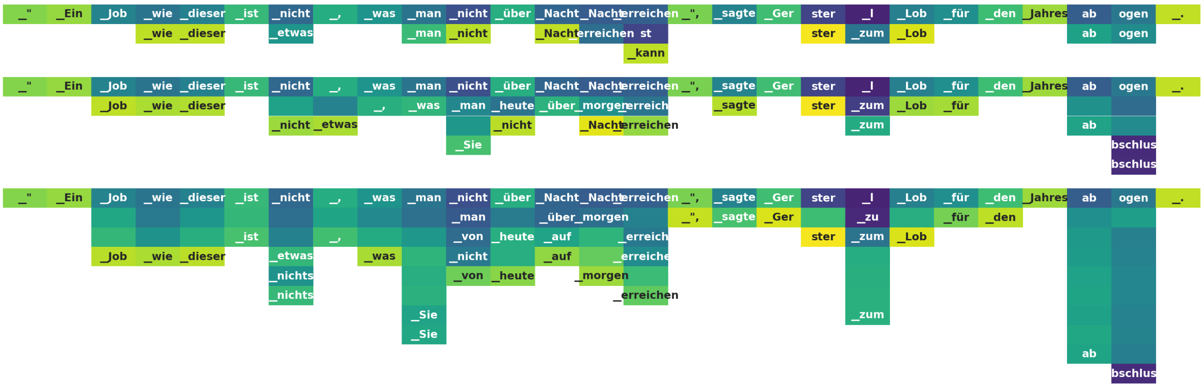


(a) Configurations of *mask predict* with fixed number of iterations: (1) $T = 3$, (2) $T = 5$, (3) $T = 10$.



(b) Configurations of *comb-thresh*: (1) $\tau = 0.002$, (2) $\tau = 0.1$, (3) $\tau = 0.4$.

Figure 8: Example unmasking schedules. Predicted tokens are shown when they differ from the previous iteration. Their background color indicates the model score, with yellow indicating high scores, and dark blue low scores.

AmbigQA: Answering Ambiguous Open-domain Questions

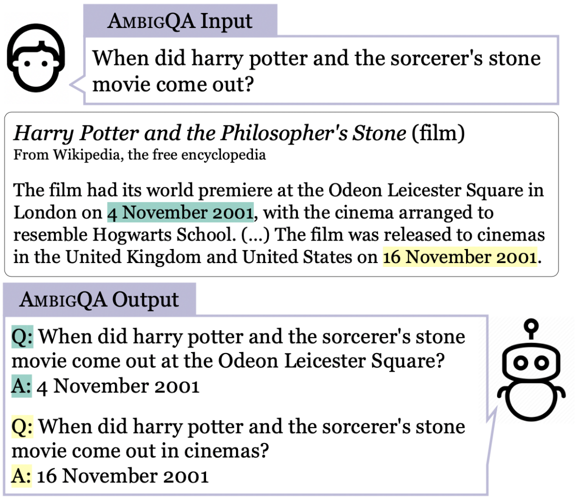
Abstract

Ambiguity is inherent to open-domain question answering; especially when exploring new topics, it can be difficult to ask questions that have a single, unambiguous answer. In this paper, we introduce AmbigQA, a new open-domain question answering task which involves finding every plausible answer, and then rewriting the question for each one to resolve the ambiguity. To study this task, we construct AmbigNQ, a dataset covering 14,042 questions from NQ-open, an existing open-domain QA benchmark. We find that over half of the questions in NQ-open are ambiguous, with diverse sources of ambiguity such as event and entity references. We also present strong baseline models for AmbigQA which we show benefit from weakly supervised learning that incorporates NQ-open, strongly suggesting our new task and data will support significant future research effort. Our data and baselines are available at `https://nlp.cs.washington.edu/ambigqa`.

1 Introduction

In the open-domain setting, it can be difficult to formulate clear and unambiguous questions. For example, Figure 1 shows a Google search query (Kwiatkowski et al., 2019) that, perhaps surprisingly, has two possible interpretations given the evidence in Wikipedia. Although open-domain question answering (QA) systems aim to answer any factoid question (Voorhees et al., 1999), existing methods assume questions have a single well-defined answer. Nonetheless, ambiguity arises frequently in open-domain QA, where questions are written during information gathering (e.g., search queries) without knowledge of the answer. As we will see in Section 4, over 50% of the questions we sampled from a set of Google search queries are ambiguous. Furthermore, identifying ambiguities is difficult both for humans and machines. As shown in Figure 1, ambiguity is a function of both the question and the evidence provided by a large text corpus.



When did harry potter and the sorcerer's stone movie come out?

Harry Potter and the Philosopher's Stone (film)
From Wikipedia, the free encyclopedia

The film had its world premiere at the Odeon Leicester Square in London on 4 November 2001, with the cinema arranged to resemble Hogwarts School. (...) The film was released to cinemas in the United Kingdom and United States on 16 November 2001.

A: 4 November 2001

Q: When did harry potter and the sorcerer's stone movie come out in cinemas?
A: 16 November 2001

Figure 1: An AmbigNQ example where the prompt question (top) appears to have a single clear answer, but is actually ambiguous upon reading Wikipedia. AmbigQA requires producing the full set of acceptable answers while differentiating them from each other using disambiguated rewrites of the question.

To study this challenge, we introduce AmbigQA (Answering Ambiguous Open-domain Questions), a new task which involves disambiguating and answering potentially ambiguous questions. Specifically, the model must (1) find a set of distinct, equally plausible answers to the question, and (2) provide minimal yet unambiguous rewrites of the question that clarify the interpretation which leads to each answer. Figure 1 shows two such disambiguated questions and their answers.

To support the study of this task, we construct a dataset called AmbigNQ using 14,042 questions from an open-domain version of Natural Questions (Kwiatkowski et al., 2019), denoted NQ-open. For each question, annotators search for,

Table 1: Breakdown of the types of ambiguity in 100 randomly sampled items from the AMBIGNQ development data. Each example may fall into multiple categories.

navigate, and read multiple Wikipedia pages to find as many answers as possible. The high prevalence of ambiguity makes the task difficult even for human experts; it is inherently difficult to know if you have found every possible interpretation of a question. Nonetheless, we are able to collect high quality data covering high levels of ambiguity (2.1 distinct answers per question on average) with high estimated agreement (89.0 F1) on valid answers. The types of ambiguity are diverse and sometimes subtle (Table 1), including ambiguous entity or event references, or ambiguity over the answer type; many are only apparent after examining one or more Wikipedia pages.

To establish initial performance levels on this data, we present a set of strong baseline methods. We extend a state-of-the-art QA model (Karpukhin et al., 2020) with three new components: (1) set-based question answering with a sequence-to-sequence model, (2) a question disambiguation model, and (3) a modification to democratic co-training (Zhou and Goldman, 2004) which leverages the partial supervision available in the full NQ-OPEN dataset. We also do an ablation study and qualitative analysis, which suggest there is significant room for future work on this task.

To summarize, our contributions are threefold.

1. We introduce AMBIGQA, a new task which requires identifying all plausible answers to an open-domain question, along with disambiguated questions to differentiate them.
2. We construct AMBIGNQ, a dataset with 14,042 annotations on NQ-OPEN questions containing diverse types of ambiguity.
3. We introduce the first baseline models that produce multiple answers to open-domain questions, with experiments showing their effectiveness in learning from our data while highlighting avenues for future work.

2 Related Work

Open-domain Question Answering requires a system to answer any factoid question based on evidence provided by a large corpus such as Wikipedia (Voorhees et al., 1999; Chen et al., 2017). Existing benchmarks use questions of various types, from open-ended information-seeking (Berant et al., 2013; Kwiatkowski et al., 2019; Clark et al., 2019) to more specialized trivia/quiz (Joshi et al., 2017; Dunn et al., 2017). To the best of our knowledge, all existing formulations assume each question has a single clear answer.

Our work is built upon an open-domain version of NATURAL QUESTIONS (Kwiatkowski et al., 2019), denoted NQ-OPEN, composed of questions posed by real users of Google search, each with an answer drawn from Wikipedia. NQ-OPEN has promoted several recent advances in open-domain question answering (Lee et al., 2019; Asai et al., 2020; Min et al., 2019a,b; Guu et al., 2020; Karpukhin et al., 2020). Nonetheless, Kwiatkowski et al. (2019) report that the answers to such questions are often debatable, and the average agreement rate on NQ-OPEN test data is 49.2%,[1] in large part due to ambiguous questions. In this work, we embrace this ambiguity as inherent to information seeking open-domain QA, and present the first methods for returning sets of answers paired with different interpretations of the question.

Clarification Questions have been used to study question ambiguity in other settings. Research on community Q&A (Braslavski et al., 2017; Rao and Daumé III, 2018, 2019) studies finding underspecification in the question, but it does not find the answer to the original question. In recent work, Xu et al. (2019) study clarification of questions that are intentionally annotated with pre-specified entity reference ambiguities. Aliannejadi et al. (2019) and Zamani et al. (2020) use clarification questions to refine intents of simple query logs without immediately apparent information needs (e.g., single keywords like *dinosaur*[2]).

In contrast, we study open-domain factoid questions asked by real users: these present clear information needs, but carry diverse naturally occurring ambiguities (see Table 1). Furthermore, instead of prolonging the user's information-seeking session with clarification questions, our task formulation provides a complete and immediate solution with unambiguous rewrites of the original question.

Question Rewriting is a novel, well-defined task which we propose for differentiating distinct answers. To the best of our knowledge, it has not been studied for resolving ambiguity; we are only aware of Elgohary et al. (2019) which use question rewriting to convert conversational questions into self-contained questions.

3 Task: AMBIGQA

3.1 AMBIGQA Setup

Figure 1 depicts the AMBIGQA task. The input is a prompt question q, and the output is a list of n question-answer pairs $(x_1, y_1), \ldots, (x_n, y_n)$, where each y_i is an equally plausible answer to q, and each x_i is a minimally edited modification of q whose answer is unambiguously y_i. We consider two subtasks.

Multiple Answer Prediction. Given a question q, output a set of semantically distinct and equally plausible answers $y_1, \ldots, y_n$, where n is unknown.

Question Disambiguation. Given q and a set of answers $y_1, \ldots, y_n$, generate *disambiguated questions* $x_1, \ldots, x_n$, where each x_i is a *minimal edit* of q which makes it unambiguous so that y_i is a correct answer and all y_j for all $j \neq i$ are incorrect. When $n = 1$, this task is trivial, as $x_1 = q$.

We choose to represent ambiguity with a set of disambiguated questions because it is well-defined, immediately human-interpretable, and allows for straightforward annotation of a wide range of ambiguities without complex guidelines.

3.2 Evaluation Metrics

To evaluate model performance, we present several ways to compare a model prediction with m question-answer pairs $(x_1, y_1), \ldots, (x_m, y_m)$ with a gold reference set with n pairs $(\bar{x}_1, \bar{\mathcal{Y}}_1), \ldots, (\bar{x}_n, \bar{\mathcal{Y}}_n)$. Since there may be more than one way to refer to a single answer (e.g., *Michael Jordan* and *Michael Jeffrey Jordan*) each gold answer $\bar{\mathcal{Y}}_i$ is a set of acceptable answer strings, where all $\bar{\mathcal{Y}}_i$ are disjoint.

We assign each predicted question-answer pair (x_i, y_i) a *correctness score* based on a string similarity function f valued in $[0, 1]$.

$$c_i = \max_{1 \leq j \leq n} \mathbb{I}[y_i \in \bar{\mathcal{Y}}_j] f(x_i, \bar{x}_j).$$

Intuitively, c_i considers (1) the correctness of the answer and (2) the similarity $f(x_i, \bar{x}_j)$ between the predicted and reference question. We calculate F1 treating the c_i as measures of correctness:

$$\text{prec}_f = \frac{\sum_i c_i}{m}, \qquad \text{rec}_f = \frac{\sum_i c_i}{n},$$
$$\text{F1}_f = \frac{2 \times \text{prec}_f \times \text{rec}_f}{\text{prec}_f + \text{rec}_f}.$$

We consider three choices of F_f. $\text{F1}_{\textbf{ans}}$ is the F1 score on answers only, where f always yields 1. This may be used without the question disambiguation step. $\text{F1}_{\textbf{BLEU}}$ accounts for string similarity between questions, calculating f with BLEU (Papineni et al., 2002). $\text{F1}_{\textbf{EDIT-F1}}$ uses EDIT-F1 as f, where EDIT-F1 is a new measure that represents each disambiguated question by its added and

---

[1] The NQ-OPEN test data has 5-way annotations; we compute their pairwise agreement based on string match.

[2] The average query length in Zamani et al. (2020) is 2.6.

deleted unigrams compared to the prompt question, and computes the F1 score between them. For example, consider the prompt question "Who made the play the crucible?", the reference "Who wrote the play the crucible?" and the prediction "Who made the play the crucible in 2012?". The gold edits[3] here are ⟅ `-made` , `+wrote` ⟆ while the predicted edits are ⟅ `+in` , `+2012` ⟆. Their EDIT-F1 is thus zero, even though the questions are similar. Unlike BLEU which we use to directly measure similarity to the gold question, this metric only gives credit for getting the key semantic differences correct between the original question and the clarification.

4 Data: AMBIGNQ

4.1 Data Collection

We construct AMBIGNQ using prompt questions from NQ-OPEN and English Wikipedia as the evidence corpus. We use Amazon Mechanical Turk for crowdsourcing.

The crucial annotation challenge is maximizing recall: finding all possible distinct answers to a question. This is difficult, as ambiguities are often only apparent after carefully searching the evidence for multiple possible answers. However, we can collect high quality data with high levels of ambiguity using careful worker selection and a two stage pipeline: *generation* and *validation*.

Generation. Workers in the first stage are given a prompt question and a search box that uses the Google Search API restricted to English Wikipedia. Allowing annotators to find Wikipedia pages on their own closely approximates the real process people use to answer open-ended questions—an approach with no existing large-scale dataset.[4]

Workers find all plausible answers to the question; when there are multiple, each answer is paired with a minimal edit of the prompt question which differentiates it from the other answers, in line with our task requirements. A distinct answer may be annotated as multiple possible spans (e.g., *Michael Jordan* and *Michael Jeffrey Jordan*).

As a special case, some questions contain *temporal deixis* which depends on the time of writing, e.g., "When does the new family guy season come out?". To avoid unmanageably many answers, we instruct workers to remove the time-dependence by rewriting the prompt question for up to three most recent events before Jan 1, 2018, e.g., "When does family guy season 16 come out?" (see Table 1).

Split	# data	# QAs %			
		1	2	3	4+
Train	10,036	53	24	14	10
Dev	2,002	49	23	14	13
Test	2,004	44	24	16	16

Table 2: Data statistics. For the number of QA pairs (# QAs), the minimum is taken when there are more than 1 accepted annotations.

Validation. Workers in the validation stage review the annotations provided by multiple generators. Validators mark each generator's annotations as correct or incorrect, or provide a new set of question-answer pairs by combining the valid ones from each generator. They search Wikipedia as generators do, and are additionally given Wikipedia pages that generators viewed to speed up the process. Validation is skipped when annotated answers from all generators exactly match (37% of cases).

Quality control. We recruit highly qualified workers through a qualification test (details in Appendix A). Although the task was difficult for most workers, we found that our highly qualified full-time workers, given quick and detailed feedback on their work, produced high accuracy and recall. For development and test data, we use two generators and one validator per prompt question. For training data, we skip validation and only use one generator per question.

Inter-annotator agreement. Evaluating generators against each other on the development set yields 60.8 $\mathrm{F1}_{\mathrm{ans}}$. All annotations passed validation for 76% of questions, while validators made changes (edits or exclusions) in the remaining 24%. The average $\mathrm{F1}_{\mathrm{ans}}$ between co-authors and workers on a sample of 50 validations was 89.0%. This indicates that, despite the intrinsic difficulty and subjectivity of the task, humans agree on the boundary between valid and invalid answers in most cases.

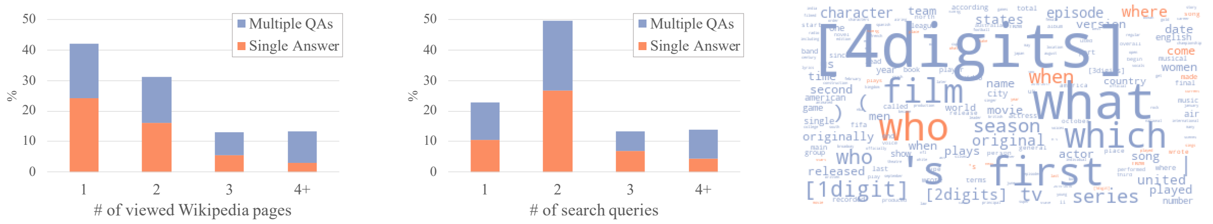
4.2 Data Analysis

The final dataset contains 14,042 annotated examples, split consistently with NQ-OPEN. As shown in Table 2, over 50% of development and test examples contain multiple question-answer pairs. This

---

[3] Represented as multisets, written using ⟅`bag`⟆ notation.

[4] For instance, answers in NQ-OPEN are annotated over pre-specified Wikipedia pages from the Google search engine.



(a) Number of unique Wikipedia pages visited by crowdworkers.[†]

(b) Number of search queries written by crowdworkers.

(c) Word cloud of the edits made in questions; 🟦 and 🟧 indicate added and deleted unigrams, respectively.

Figure 2: Data Analysis on the development data. [†]This is actually an underestimate; we could not track when annotators viewed pages by following hyperlinks for technical reasons.

indicates a high rate of ambiguity in NQ-OPEN, even though previous work has studied it with the assumption that each question has a single answer. We also find a discrepancy between development and test; this is likely due to the way in which NQ-OPEN is constructed, which over-samples difficult questions in the test set (see Appendix B for details). The training set contains relatively fewer ambiguous examples (47%), presumably because using only one worker per training example yielded slightly lower recall.

Types of ambiguity. Table 1 shows a breakdown of the types of ambiguity in AMBIGNQ. They are diverse, including ambiguity in entity references, event references, properties, and answer types, with a relatively uniform distribution between them. In comparison to Xu et al. (2019), who intentionally elicit questions with ambiguous entity references, our analysis shows that *unintended* ambiguity comes from diverse sources. In many cases, ambiguity is not apparent from the prompt question alone, but only after researching the question on Wikipedia, as evidenced by differences in model performance (Section 6.2).

Annotator behavior. Figures 2a and 2b show the number of unique Wikipedia pages and the number of search queries used by workers during annotation. More often than not, workers used multiple queries and navigated multiple Wikipedia pages, showing how our setup captures ambiguity in the *retrieval* step of open-domain question answering, which is missed in approaches that assume a prespecified evidence document.

Distribution of edits. Figure 2c shows unigram edits made to questions in the development data, where we remove stopwords except wh-words and group numeric values by the number of digits. Adding numerals such as years is common, as they can easily disambiguate entity or event references or remove time dependence. Wh-word changes are also common, especially for specifying the answer type (e.g., from *who* to *which group*; see Table 1). The distribution of edits is fairly long-tailed, with the 100 most frequent edits covering 36% of the total, and the top 1,000 covering 69%.

5 Model

To set initial performance levels on AMBIGNQ, we present a baseline AMBIGQA model combining ideas from recent advances in open-domain QA (Karpukhin et al., 2020) and generation (Lewis et al., 2020). Given a prompt question q, our model predicts answers $y_1..y_n$, and generates corresponding questions $x_1..x_n$ conditioning on q, the answers $y_1..y_n$, and the evidence passages. A novel co-training step also allows the model to leverage the partial supervision available in NQ-OPEN.

Multiple Answer Prediction. Here we describe SPANSEQGEN, our model for multiple answer prediction. Following Karpukhin et al. (2020), a state-of-the-art model on NQ-OPEN, SPANSEQGEN first retrieves 100 passages with a BERT-based (Devlin et al., 2019) dual encoder, and reranks them using a BERT-based cross encoder. Then, instead of predicting an answer span from the top 1 passage as Karpukhin et al. (2020) does, SPANSEQGEN uses another sequence-to-sequence model based on BART (Lewis et al., 2020). Specifically, it conditions on the concatenation of q and the top passages in order up to 1024 tokens, and sequentially generates distinct answers token-by-token, separated by `[SEP]`. We pretrain SPANSEQGEN on NQ-OPEN and finetune it on AMBIGNQ.

We develop SPANSEQGEN primarily because Karpukhin et al. (2020) is designed for generating a single answer, but SPANSEQGEN also boosts the

Algorithm 1 Democratic co-training with weak supervision (Section 5).

```
// Each question in $D_{full}$ has an answer list annotated
// Each question in $D_{partial}$ has one answer annotated
$\hat{D}_{\text{full}} \leftarrow D_{\text{full}}$
for $iter \in \{1..N\}$ do
    // Train $C$ sequence-to-sequence QA models
    for $i \in \{1..C\}$ do
        $\phi_i \leftarrow train(\hat{D}_{\text{full}})$
    $\hat{D}_L \leftarrow D_{\text{full}}$
    for $(q^j, y^j) \in D_{\text{partial}}$ do
        // Get predictions by using $y_j$ as prefix
        $\hat{Y^j} \leftarrow \{\hat{y} \mid \hat{y} \neq y^j$, and
            $|\{i \mid \hat{y} \in \phi_i(q^j|y^j), 1 \leq i \leq C\}| > \frac{C}{2}$
        $\}$
        if $|\hat{Y}^j| > 0$ then
            // Add it as a multiple answer case
            $\hat{D}_{\text{full}} \leftarrow \hat{D}_L \cup \{(q^j, \{y^j\} \cup \hat{Y^j})\}$
        else if $\forall i = 1..C, |\phi_i(x^j) - \{y^j\}| = 0$ then
            // Add it as a single answer case
            $\hat{D}_{\text{full}} \leftarrow \hat{D}_L \cup \{(q^j, \{y^j\})\}$
```

performance on NQ-OPEN (41.5→42.2 on the test data). We include ablations on different approaches and models in Section 6.2.

Question Disambiguation. We design a question disambiguation (QD) model based on BART. The model generates each question x_i $(i = 1..n)$ conditioning on the concatenation of q, the target answer y_i, other answers $y_1..y_{i-1}, y_{i+1}..y_n$, and the top passages as used by SPANSEQGEN. We pretrain on NQ-OPEN to generate questions given an answer and passage, and then finetune it on the full task data in AMBIGNQ. We include ablations on different variants of the model in Section 6.2.

Co-training with weak supervision. Given the prevalence of unlabelled ambiguity in NQ-OPEN, we introduce a method that treats the NQ-OPEN annotations as weak supervision and learns to discover potential ambiguity in the data. We modify a democratic co-training algorithm (Zhou and Goldman, 2004) as described in Algorithm 1. We iteratively grow the training set $\hat{D}_{\text{full}}$ from AMBIGNQ (D_{full}) with silver data from NQ-OPEN (D_{partial}) predicted by a majority of a set C of SPANSEQGEN models trained on $\hat{D}_{\text{full}}$. The key step is injecting the known answer y^j from NQ-OPEN as a prefix to SPANSEQGEN's output during prediction. In each step, if a majority of C predict an additional answer, we assume we have found a false negative and add the result to the training set $\hat{D}_{\text{full}}$. If all models predict no additional answer, we add the example to $\hat{D}_{\text{full}}$ with y^j as a single answer.

6 Experiments

We describe the baseline models used in our experiments, followed by results and ablations. Implementation details and hyperparameters of all models are provided in Appendix D.

6.1 Baselines

DISAMBIG-FIRST. This baseline disambiguates the prompt question without any context from plausible answers or reference passages. Specifically, it implements the following pipeline: (1) Feed the prompt question q into a BERT-based binary classifier to determine whether it is ambiguous. (2) If q is ambiguous, pass it into a BART-based model which generates a sequence of disambiguated questions $x_1..x_n$ $(n > 1)$, separated by `[SEP]`; otherwise, consider only $x_1 = q$. (3) Feed each x_i into a state-of-the-art model on NQ-OPEN (Karpukhin et al., 2020) to produce its answer y_i.

Thresholding + QD. We also include a model based on Karpukhin et al. (2020), with thresholding for multiple answer prediction and our question disambiguation (QD) model. Karpukhin et al. (2020) outputs a likelihood score for each span; we obtain $y_1..y_n$ by taking valid spans with likelihood larger than a hyperparameter γ. The model is trained to maximize the marginal likelihood of any span in the gold answer set $\bar{\mathcal{Y}}_1..\bar{\mathcal{Y}}_n$. As with SPANSEQGEN, we pretrain on NQ-OPEN and finetune on AMBIGNQ. We then produce disambiguated questions using our BART-based QD model (Section 5).

6.2 Results

Table 3 reports the performance of our baselines; example model outputs are provided in Table 5.

Main results. We first find that DISAMBIG-FIRST is significantly worse than other models. In particular, classification accuracy on whether the prompt question is ambiguous is 67%, close to the majority baseline (60%). When the model does identify an ambiguous question, its rewrites often look reasonable on the surface, but do not match the facts. For instance, in example 1 of Table 5, it asks about filming in 2017 and during season 1 for *Snow White and the Huntsman*, which was actually a film released in 2012. This shows that reading evidence documents is crucial for identifying and characterizing ambiguities.

While SPANSEQGEN outperforms Karpukhin et al. (2020) with thresholding, the difference is

Model	F1_{ans} (*all*)		F1_{ans} (*multi*)		F1_{BLEU}		$\text{F1}_{\text{EDIT-F1}}$	
	dev	test	dev	test	dev	test	dev	test
Disambig-first	28.1	24.8	21.9	18.8	4.2	4.0	2.7	2.2

not as great as we expected. This suggests two things. First, thresholding may be a surprisingly effective baseline for outputting multiple answers, even though the answers must compete with each other for probability mass in order to surpass the threshold γ. Second, maximizing likelihood in a sequence-to-sequence model like SpanSeqGen may not produce well-calibrated results. For instance, the model seems to suffer due to variation in the length of the output sequence, outputting shorter sequences on average (3.0 tokens) than gold (6.7).[5] This leads to low recall when there are multiple answers; our best model achieves a precision of 49.6 and recall of 25.3 for its F1_{ans} of 31.7 on such questions.

Overall, SpanSeqGen achieves reasonable F1_{ans} scores. F1_{ans} on examples with multiple question-answer pairs (*multi*) are lower, indicating that predicting all plausible answers is more challenging than predicting a single answer, as expected. SpanSeqGen also obtains the best performance in F1_{BLEU} and $\text{F1}_{\text{EDIT-F1}}$, although their absolute values are low in general; we discuss this in our question disambiguation ablations below.

There is a substantial difference in performance between development and test overall, likely due to distributional differences in the original questions in NQ-open; detailed discussion is in Appendix B.

Effect of co-training. The last two rows of Table 3 reports the effect of our co-training method. As co-training requires multiple trained models, we compare with a naive ensemble. While we see gains from ensembling alone, an ensemble trained with the co-training method achieves the best performance on all metrics. This result demonstrates the potential of jointly using AmbigNQ and partial supervision from NQ-open.

Ablations on question disambiguation. Table 4 reports results of an ablation experiment on question disambiguation (QD). Among our ablations, we include models without the prompt question or untargeted answers as input, and a naive baseline that always outputs the prompt question. We report the metrics both in the scenarios of the full task and the gold answers given, to see the performance dependent on and independent from multiple answer prediction, respectively.[6]

Simply copying the prompt question gives high F1_{BLEU}, which is natural since the questions were disambiguated using minimal edits. This justifies using $\text{F1}_{\text{EDIT-F1}}$ to evaluate semantic differences from the prompt question. In addition, we find that

---

[5] This problem has also been reported in other conditional generation tasks (Sountsov and Sarawagi, 2016; Stahlberg and Byrne, 2019); we leave it for future work.

[6] Note that a high F1_{ans} and low $\text{F1}_{\text{EDIT-F1}}$ may not indicate bad question disambiguation. For instance, if a model correctly predicts one out of two answers and does not perform any edits to the question, it obtains high F1_{ans} and zero $\text{F1}_{\text{EDIT-F1}}$, despite the error being in answer prediction.

Prompt question #1: Where was snow white and the huntsman filmed?
Reference:
Q: Where were beach scenes for snow white and huntsman predominantly filmed? / A: Marloes Sands Beach
Q: Where was principal photography for snow white and huntsman filmed? / A: United Kingdom
Q: Where was castle in snow white and huntsman filmed? / A: Gateholm island
Prediction of DISAMBIG-FIRST: ($F1_{ans}$=0.40, $F1_{EDIT\text{-}F1}$=0.00)
Q: Where was snow white and the huntsman filmed in 2017? / A: Marloes Sands Beach
Q: Where was snow white and the huntsman filmed during the filming of Season 1 of the TV series? / A: Marloes Sands Beach
Prediction of SPANSEQGEN: ($F1_{ans}$=0.80, $F1_{EDIT\text{-}F1}$=0.69)
Q: Where was snow white and huntsman principal photography filmed / A: United Kingdom
Q: Where were beach scenes for snow white and huntsman mostly filmed / A: Marloes Sands Beach

Prompt question #2: When was the city of new york founded?
Reference:
Q: When was city of new york founded by dutch and initially called new amsterdam? / A: 1624
Q: When was city of new york under english control and renamed to new york? / A: 1664
Prediction of SPANSEQGEN: ($F1_{ans}$=1.00, $F1_{EDIT\text{-}F1}$=0.67)
Q: When was city of new york city founded with dutch protection? / A: 1624
Q: When was city of new york city founded and renamed with english name? / A: 1664

Table 5: Model predictions on samples from the development data. **(#1)** DISAMBIG-FIRST generates questions that look reasonable on the surface but don't match the facts. SPANSEQGEN produces the reasonable answers and questions, although not perfect. **(#2)** SPANSEQGEN produces correct answers and questions.

Reference has multiple answers	
Multiple answer prediction is correct	2%
Multiple answer prediction is partially correct[†]	40%
Multiple answer prediction is incorrect	14%
Reference has one answer	
Over-generated predictions	2%
Correct single answer prediction	26%
Incorrect single answer prediction	12%
Reference is incorrect	4%

Table 6: Analysis of predictions made by SPANSEQGEN with co-training, on 50 samples from the development data. Examples shown in Appendix (Table 10).
[†] In 15 out of 20 cases, the model generates only one answer.

our QD model conditioned on all available context is better than other variants in overall metrics.

Performance is low overall, even given the gold answers, highlighting the challenge of the task. We think there are two major reasons. First, maximizing the likelihood of the output sequence can miss the importance of *edits* to the prompt question, leading the QD model to miss the information that is most important to differentiate one answer from the others. Second, there is a lack of annotated data, especially for question disambiguation which does not benefit from weakly supervised learning with NQ-OPEN; future work can explore how to maximize the use of supervision from other available data. It is also worth noting that the metric may miss edits that are semantically correct, but phrased differently (see Table 5, example 2).

Model	NQ-OPEN EM	$F1_{ans}$ (*all*)	$F1_{ans}$ (*multi*)
Dev			
Min et al. (2019b)	34.7	30.8	20.4

Table 7: Zero-shot performance on multiple answer prediction of the models trained on NQ-OPEN. We report Exact Match (EM) on NQ-OPEN and $F1_{ans}$ on AMBIGNQ.

6.3 Zero-shot results

Since AMBIGNQ provides an evaluation set with explicit sets of multiple answers, we can also test if models trained on partial supervision only (NQ-OPEN) are capable of producing full answer sets. In fact, the problem of ambiguity already exists in previous QA tasks, and a single labeled answer can be viewed as a sample from a multi-modal distribution of answers. This setting is important for modeling in domains where single-answer datasets are available but full annotations like in AMBIGNQ are not. To this end, we present a zero-shot setting where a system predicts multiple distinct answers without using AMBIGNQ training data. We include four NQ-OPEN models including ours, consisting of diverse approaches and model architectures, as baselines. These models, when trained on NQ-OPEN, may be made to predict multiple answers via thresholding as described in Section 6.1.[7] Table 7 reports zero-shot performance. Although SPANSEQGEN outperforms Karpukhin et al. (2020) in the standard setting, it is worse in zero-shot $\mathrm{F1}_{\mathrm{ans}}$ (*multi*), potentially because thresholding exacerbates the problems that SPANSEQGEN has with long sequences (Section 6.2).

6.4 Error Analysis

Table 6 reports an analysis of predictions by SPANSEQGEN with co-training, based on 50 random samples from the development data; examples can be found in the Appendix (Table 10). When there are multiple reference answers, the model rarely gets all correct answers, although often generates a subset of them. In 15 out of 20 partially correct cases, the model produces only one answer, consistent with the under-generation we found in Section 6.2. In four out of those 15 cases, the model prediction is arguably the most likely answer,[8] but in the other 11 cases, it hard to argue for one answer over the other(s). It is also worth noting that accuracy on examples with a single answer is quite high, being correct in 13 out of 20 cases. This estimated accuracy on unambiguous questions is higher than state-of-the-art levels on NQ-OPEN (42 EM), suggesting that NQ-OPEN may substantially underestimate performance due to the prevalence of unmarked ambiguity. Together with our experimental results, this seems to indicate that recall of multiple answers is one of the primary challenges in AmbigQA.

7 Conclusion & Future Work

We introduced AMBIGQA, a new task that involves providing multiple possible answers to a potentially ambiguous open-domain question, and providing a disambiguated question corresponding to each answer. We constructed AMBIGNQ, a dataset with 14,042 annotations on NQ-OPEN questions. Our analysis shows the dataset contains diverse types of ambiguity, often not visible from the prompt question alone. We also introduced a first baseline model for producing multiple answers to open-domain questions, with experiments showing its effectiveness in learning from our data while highlighting possible areas for improvement.

Future research developing on AmbigQA models may include explicitly modeling ambiguity over events and entities or in the retrieval step, as well as improving performance on the difficult problems of answer recall and question disambiguation. Furthermore, future work may build on the AmbigQA task with more open-ended approaches such as (1) applying the approach to QA over structured data (such as ambiguous questions that require returning tables), (2) handling questions with no answer or ill-formed questions that require inferring and satisfying more complex ambiguous information needs, and (3) more carefully evaluating usefulness to end users.

Acknowledgments

This research was supported by ONR N00014-18-1-2826, DARPA N66001-19-2-403, the NSF (IIS-1252835, IIS-1562364), an Allen Distinguished Investigator Award, and the Sloan Fellowship. We thank Mandar Joshi, H2Lab members and the anonymous reviewers for their helpful comments and suggestions.

A Data Collection Details

We use Amazon Mechanical Turk[9] and Spacro (Michael et al., 2018)[10] for crowdsourcing. All data was collected in February and March of 2020. We use the Google Search API[11] restricted to English Wikipedia for the search tool.

Crowdsourcing details. Figure 3 shows the interface used for generation and validation. We use an iframe to render Wikipedia pages in a mobile view, in order to provide the document format that they are familiar with, rather than the plain text with no formatting. When workers write the questions and the answers in the generation stage, we show appropriate error messages (e.g. when the written question is the same as the prompt question) or warning messages (e.g., when the answer is composed of more than 20 words) in order to give tight feedback. Workers produce free text answers which we instruct them to copy and paste from Wikipedia.

We pay 0.75 and 0.15 USD per prompt question for generation and validation, respectively. Generators may skip the prompt question if the answer is not found in Wikipedia, or the question is ill-formed, too subjective or too ambiguous, e.g., "When did the new tax cuts go into effect?"

Quality control. We only recruit full-time workers that are dedicated to our task. We were able to recruit full-time workers by requiring the minimum number of HITs that can be achieved by working 40 hours a week. We also host a public website for them to monitor the validated statuses, ask questions on examples that they do not understand the validated result, or claim on the validation which is incorrect in their opinion. We found it very useful to communicate with workers, give feedback, and fix the incorrect annotations.

Inter-annotator agreement. When two independent generators are evaluated on the answer list from each other, they obtain 60.8 $\mathrm{F1}_{\mathrm{ans}}$. Specifically, for 76% of questions, all annotations passed validation, either automatically because they exactly matched (37%) or because they were both accepted by validators (39%). In the remaining 24% of cases, one annotator missed a possible question-answer pair that the other one found, or included an invalid question-answer pair.

To assess validation quality, two co-authors annotated a random sample of 50 validations. The average $\mathrm{F1}_{\mathrm{ans}}$ between the co-authors and workers was 89.0%.

B Discrepancy between development and test in NQ-OPEN

In our experiments on AMBIGNQ, we found a significant discrepancy between the development and test sets. Upon further investigation, we identified that this is at least in part due to a distributional difference between the development and test sets of NQ-OPEN, upon which we built the data. As this may be important for other researchers working on NQ-OPEN, we detail our findings here.

Following Lee et al. (2019), NQ-OPEN is constructed by filtering NATURAL QUESTIONS to questions where at least one annotator provided a non-null short answer to the question.[12] While the training and development sets of NQ-OPEN were all drawn from the training set of NATURAL QUESTIONS, in which one annotator answered each question, the test set of NQ-OPEN is taken from its development set, which had five annotators per question.

This difference in number of annotators introduces a sampling bias: questions for which an annotator is less likely to find an answer are overrepresented in the NQ-OPEN test set, in comparison to training and development. Suppose, for example, that a randomly sampled annotator has a 50% chance of producing a short answer for some question q. Then q has a 50% chance of making it into NQ-OPEN's development set, but a $(1-.5^5=)$ 97% chance of making it into test. Concretely, when each annotator is considered independently, 34.6% of the short answer annotations in the test set of NQ-OPEN are null answers, and the majority of annotations are null for 33.9% of questions.

As a consequence, there is a significant gap in model performance between development and test when they are evaluated under the same conditions. The official evaluation protocol for NQ-OPEN counts a prediction as correct if it matches any of the gold reference answers. Under these conditions, the gap between development and test appears marginal (Table 8, first two columns). However, as the NQ-OPEN test set was more compre-

[11] developers.google.com/custom-search/

[12] NATURAL QUESTIONS annotators answered each question with a set of short answers, which could be empty if there was no reasonable short answer. We refer to the empty cases as *null answers*. See Kwiatkowski et al. (2019) for details.

Model	Any		First	
	dev	test	dev	test
Min et al. (2019b)	34.7	34.5	32.4	25.7
Asai et al. (2020)	31.7	32.6	28.9	23.8
Karpukhin et al. (2020)	39.8	41.5	37.0	29.8
SPANSEQGEN	42.0	42.2	38.8	31.1

Table 8: Exact Match (EM) on NQ-OPEN of different models, counting a prediction as correct if it matches *Any* gold reference, or only the *First* non-null one.

hensively annotated than development, it has a more generous evaluation; the number of unique reference answers is 1.2 and 1.8 on development and test, respectively. In order to make the evaluation more consistent, we try evaluating models against the first reference answer only, and find a significant gap between development and test (5–8%) across all models (Table 8, last two columns).[13]

Despite this discrepancy, AMBIGNQ follows the setup and data split from NQ-OPEN providing consistency with prior work. Since the AMBIGNQ development and test sets were annotated under the same conditions, this discrepancy now shows up in the metrics. We leave the distribution shift of questions on the test data as one of challenges on AMBIGNQ.

C Data Analysis Details

Mismatches with NQ-OPEN. 29.4% of AMBIGNQ development examples do not include the NQ-OPEN answer. We analyze a random sample of 50 such questions, and present a breakdown in Table 9. We find that our answers are correct in 92% of cases, among which 44% of disagreements are due to mismatched spans, 22% are due to the NQ-OPEN answer being incorrect, and 14% are due to time-dependence in the question. Of the 8% of cases where our answer is incorrect, the NQ-OPEN answers are also incorrect over half the time, indicating that these may be difficult questions.

D Baseline Implementation Details

Evidence corpus. We use English Wikipedia dump from 2018-12-20 and 2020-01-20 for NQ-OPEN and AMBIGNQ, respectively. Following Karpukhin et al. (2020), we take the plain text and split passages to be up to 100 words each.

Model implementation. All models are implemented in PyTorch (Paszke et al., 2017), PyTorch-Transformers (Wolf et al., 2019) (for BERT) and fairseq (Ott et al., 2019) (for BART). We use $\text{BERT}_{\text{BASE}}$ and $\text{BART}_{\text{LARGE}}$ for all models. We use the exact same setup and hyperparameters for any process that we follow Karpukhin et al. (2020). For the passage retrieval through a dual encoder, we use the provided multi-setting trained model. For all BART-based models, we follow the default hyparameters from BART summarization code in fairseq, using one 32GB gpu. For finetuning, we change the learning rate to be $5e-6$ on both tasks. We use beam search for decoding the sequence. We train the model for 4 epochs (when trained on NQ-OPEN or pseudo-labelled data) or 15 epochs (when trained on AMBIGNQ), and take the best checkpoint based on the development data. Note that the perplexity of the output sequence does not correlate with the metric of interest (Exact Match, F1_{ans} or $\text{F1}_{\text{EDIT-F1}}$) as briefly discussed in Section 6.2, so using the metric of interest instead of perplexity is important for hyperparamter tuning or the choice of the best checkpoint.

Details in ensemble and co-training. We use an ensemble based on voting; the answers that are predicted by the highest number of models are chosen as the final answers. The number of models used in ensemble (C) is $C=5$ before cotraining and $C=4$ after cotraining. For co-training, we use $N=2$ and $C=6$, where N is the number of iteration and C is the number of models, in line with Algorithm 1. The choice of C is determined by taking the best combination of the models as follows. We train sixteen different models, using different hyperparamers including checkpoints from NQ-OPEN, learning rates, the order of the answers in the output sequence and the random seed. We then measure the development F1_{ans} on different combinations of the models with varying C ($4 \leq C \leq 6$) and take the best one.

E Error Analysis of SPANSEQGEN

Table 10 reports an analysis of predictions by SPANSEQGEN, on 50 random samples from the development set. We refer to Section 6.4 for the discussions.

---

[13] It is unlikely that this discrepancy is due to overfitting on development, because the effect is consistent across models and not present on the other datasets that they are evaluated on.

Abstract

In this paper, we propose a novel data augmentation method, referred to as Controllable Rewriting based Question Data Augmentation (CRQDA), for machine reading comprehension (MRC), question generation, and question-answering natural language inference tasks. We treat the question data augmentation task as a constrained question rewriting problem to generate context-relevant, high-quality, and diverse question data samples. CRQDA utilizes a Transformer autoencoder to map the original discrete question into a continuous embedding space. It then uses a pre-trained MRC model to revise the question representation iteratively with gradient-based optimization. Finally, the revised question representations are mapped back into the discrete space, which serve as additional question data. Comprehensive experiments on SQuAD 2.0, SQuAD 1.1 question generation, and QNLI tasks demonstrate the effectiveness of CRQDA[1].

1 Introduction

Data augmentation (DA) is commonly used to improve the generalization ability and robustness of models by generating more training examples. Compared with the DA used in the fields of computer vision (Krizhevsky et al., 2012; Szegedy et al., 2015; Cubuk et al., 2019) and speech processing (Ko et al., 2015), how to design effective DA tailored to natural language processing (NLP) tasks remains a challenging problem. Unlike the general image DA techniques such as rotation and cropping, it is more difficult to synthesize new high-quality and diverse text.

Recently, some textual DA techniques have been proposed for NLP, which mainly focus on text classification and machine translation tasks. One way is directly modifying the text data locally with word deleting, word order changing, and word replacement (Fadaee et al., 2017; Kobayashi, 2018; Wei and Zou, 2019; Wu et al., 2019). Another popular way is to utilize the generative model to generate new text data, such as back-translation (Sennrich et al., 2016; Yu et al., 2018), data noising technique (Xie et al., 2017), and utilizing pre-trained language generation model (Kumar et al., 2020; Anaby-Tavor et al., 2020).

Machine reading comprehension (MRC) (Rajpurkar et al., 2018), question generation (QG) (Du et al., 2017; Zhao et al., 2018) and, question-answering natural language inference (QNLI) (Demszky et al., 2018; Wang et al., 2018) are receiving attention in NLP community. MRC requires the model to find the answer given a paragraph[2] and a question, while QG aims to generate the question for a given paragraph with or without a given answer. Given a question and a sentence in the relevant paragraph, QNLI requires the model to infer whether the sentence contains the answer to the question. Because the above tasks require the model to reason about the question-paragraph pair, existing textual DA methods that directly augment question or paragraph data alone may result in irrelevant question-paragraph pairs, which cannot improve the downstream model performance.

Question data augmentation (QDA) aims to automatically generate context-relevant questions to further improve the model performance for the above tasks (Yang et al., 2019; Dong et al., 2019). Existing QDA methods mainly employ the round-trip

---

* Work is done during internship at Microsoft Research Asia.

[1] The source code and dataset will be available at `https://github.com/dayihengliu/CRQDA`.

[2] It can also be a document span or a passage. For notational simplicity, we use the "paragraph" to refer to it in the rest of this paper.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5798–5810,
November 16–20, 2020.

consistency (Alberti et al., 2019; Dong et al., 2019) to synthesize answerable questions. However, the round-trip consistency method is not able to generate context-relevant unanswerable questions, where MRC with unanswerable questions is a challenging task (Rajpurkar et al., 2018; Kwiatkowski et al., 2019). Zhu et al. (2019) firstly study unanswerable question DA, which relies on annotated plausible answer to constructs a small pseudo parallel corpus of answerable-to-unanswerable questions for unanswerable question generation. Unfortunately, most question answering (QA) and MRC datasets do not provide such annotated plausible answers.

Inspired by the recent progress in controllable text revision and text attribute transfer (Wang et al., 2019; Liu et al., 2020), we propose a new QDA method called **C**ontrollable **R**ewriting based **Q**uestion **D**ata **A**ugmentation (**CRQDA**), which can generate both new context-relevant answerable questions and unanswerable questions. The main idea of CRQDA is to treat the QDA task as a constrained question rewriting problem. Instead of revising *discrete* question directly, CRQDA aims to revise the original questions in a *continuous embedding space* under the guidance of a pre-trained MRC model. There are two components of CRQDA: (i) A Transformer-based autoencoder whose encoder maps the question into a latent representation. Then its decoder reconstructs the question from the latent representation. (ii) A MRC model, which is pre-trained on the original dataset. This MRC model is used to *tell* us how to revise the question representation so that the reconstructed new question is a context-relevant unanswerable or answerable question. The original question is first mapped into a continuous embedding space. Next, the pre-trained MRC model provides the guidance to revise the question representation iteratively with gradient-based optimization. Finally, the revised question representations are mapped back into the discrete space, which act as the additional question data for training.

In summary, our contributions are as follows: (1) We propose a novel controllable rewriting based QDA method, which can generate additional high-quality, context-relevant, and diverse answerable and unanswerable questions. (2) We compare the proposed CRQDA with state-of-the-art textual DA methods on SQuAD 2.0 dataset, and CRQDA outperforms all those strong baselines consistently. (3) In addition to MRC tasks, we further apply CRQDA to question generation and QNLI tasks, and comprehensive experiments demonstrate its effectiveness.

2 Related Works

Recently, textual data augmentation has attracted a lot of attention. One popular class of textual DA methods is confined to locally modifying text in the discrete space to synthesize new data. Wei and Zou (2019) propose a universal DA technique for NLP called easy data augmentation (EDA), which performs synonym replacement, random insertion, random swap, or random deletion operation to modify the original text. Jungiewicz and Smywinski-Pohl (2019) propose a word synonym replacement method with WordNet. Kobayashi (2018) relies on word paradigmatic relations. More recently, CBERT (Wu et al., 2019) retrofits BERT (Devlin et al., 2018) to conditional BERT to predict the masked tokens for word replacement. These DA methods are mainly designed for the text classification tasks.

Unlike modifying a few local words, another commonly used textual DA way is to use a generative model to generate the entire new textual samples, including using variational autoencodes (VAEs) (Kingma and Welling, 2013; Rezende et al., 2014), generative adversarial networks (GANs) (Tanaka and Aranha, 2019), and pre-trained language generation models (Radford et al., 2019; Kumar et al., 2020; Anaby-Tavor et al., 2020). Back-translation (Sennrich et al., 2016; Yu et al., 2018) is also a major way for textual DA, which uses machine translation model to translate English sentences into another language (e.g., French), and back into English. Besides, data noising techniques (Xie et al., 2017; Marivate and Sefara, 2019) and paraphrasing (Kumar et al., 2019) are proposed to generate new textual samples. All the methods mentioned above usually generate individual sentences separately. For QDA of MRC, QG, and QNLI tasks, these DA approaches cannot guarantee the generating question are relevant to the given paragraph. In order to generate context-relevant answerable and unanswerable questions, our CRQDA method utilizes a pre-trained MRC as guidance to revise the question in continuous embedding space, which can be seen as a special *constrained* paraphrasing method for QDA.

Question generation (Heilman and Smith, 2010; Du et al., 2017; Zhao et al., 2018; Zhang and

Bansal, 2019) is attracting attention in the field of natural language generation (NLG). However, most previous works are not designed for QDA. That is, they do not aim to generate context-relevant questions for improving downstream model performance. Compared to QG, QDA is relatively unexplored. Recently, some works (Alberti et al., 2019; Dong et al., 2019) utilize round-trip consistency technique to synthesize answerable questions. They first use a generative model to generate the question with the paragraph and answer as model input, and then use a pre-trained MRC model to filter the synthetic question data. However, they are unable to generate context-relevant unanswerable questions. It should be noted that our method and round-trip consistency are orthogonal. CRQDA can also rewrite the synthetic question data by other methods to obtain new answerable and unanswerable question data. Unanswerable QDA is firstly explored in Zhu et al. (2019), which constructs a small pseudo parallel corpus of paired answerable and unanswerable questions and then generates relevant unanswerable questions in a supervised manner. This method relies on annotated plausible answers for the unanswerable questions, which does not exist in most QA and MRC datasets. Instead, our method rewrites the original answerable question to a relevant unanswerable question in an unsupervised paradigm, which can also rewrite the original answerable question to another new relevant answerable question.

Our method is inspired by the recent progress on controllable text revision and text attribute transfer (Wang et al., 2019; Liu et al., 2020). However, our approach differs in several ways. First, those methods are used to transfer the attribute of the single sentence alone, but our method considers the given paragraph to rewrite the context-relevant question. Second, existing methods jointly train an attribute classifier to revise the sentence representation, while our method unitizes a pre-trained MRC model that shares the embedding space with autoencoder as the guidance to revise the question representation. Finally, the generated questions by our method serve as augmented data can benefit the downstream tasks.

3 Methodology

3.1 Problem Formulation

We consider an extractive MRC dataset $\mathcal{D}$, such as SQuAD 2.0 (Rajpurkar et al., 2018), which has $|\mathcal{D}|$ 5-tuple data: (q, d, s, e, t), where $|\mathcal{D}|$ is the data size, $q = \{q_1, ..., q_n\}$ is a tokenized question with length n, $d = \{d_1, ..., d_m\}$ is a tokenized paragraph with length m, $s, e \in \{0, 1, ..., m-1\}$ are inclusive indices pointing to the start and end of the answer span, and $t \in \{0, 1\}$ represents whether the question q is answerable or unanswerable with d. Given a data tuple (q, d, s, e, t), we aim to rewrite q to a new answerable or unanswerable question q' and obtain a new data tuple (q', d, s, e, t') that fulfills certain requirements: (*i*) The generated answerable question can be answered with the answer span (s, e) with d, while the generated unanswerable question cannot be answered with d. (*ii*) The generated question should be relevant to the original question q and paragraph d. (*iii*) The augmented dataset $\mathcal{D}'$ should be able to further improve the performance of the MRC models.

3.2 Method Overview

Figure 1 shows the overall architecture of CRQDA. The proposed model consists of two components: a pre-trained language model based MRC model as described in § 3.3, and a Transformer-based autoencoder as introduced in § 3.4. Given a question q from the original dataset $\mathcal{D}$, we first map the question q into a continuous embedding space. Then we revise the question embeddings by gradient-based optimization with the guidance of the MRC model (§ 3.5). Finally, the revised question embeddings are inputted to the Transformer-based autoencoder to generate a new question data.

3.3 Pre-trained Language Model based MRC Model

In this paper, we adopt the pre-trained language model (e.g., BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019b)) based MRC models as our MRC baseline model. Without loss of generality, we take the BERT-based MRC model as an example to introduce our method, which is shown in the left part of Figure 1.

Following Devlin et al. (2018), given a data tuple (q, d, s, e, t), we concatenate a “[CLS]” token, the tokenized question q with length n, a “[SEP]” token, the tokenized paragraph d with length m, and a final “[SEP]” token. We feed the resulting sequence into the BERT model. The question q and paragraph d are first mapped into two sequence of embeddings:

$$\mathbf{E}^q, \mathbf{E}^d = \mathrm{BertEmbedding}(q, d), \qquad (1)$$

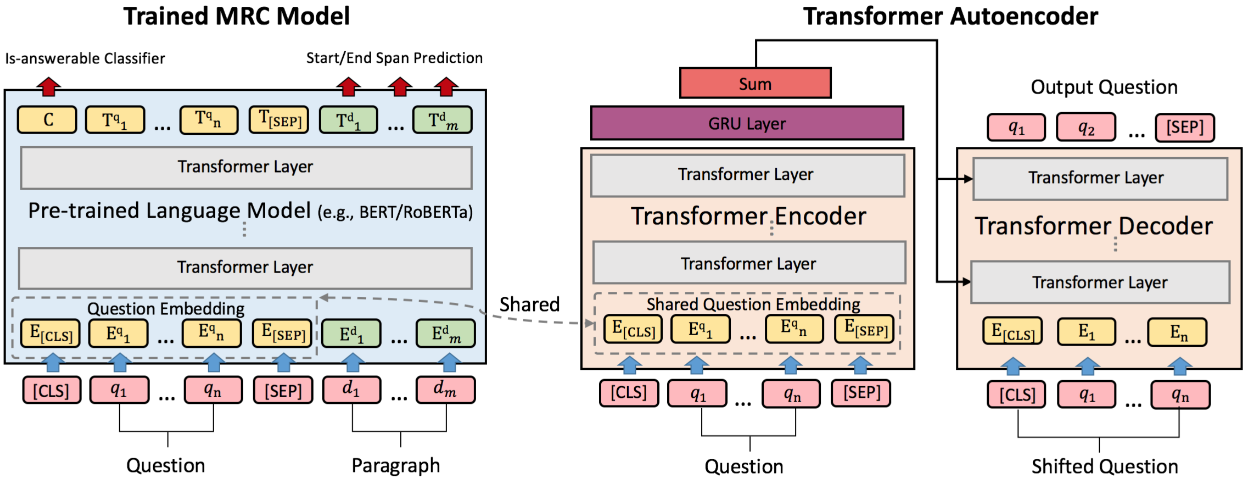

Figure 1: The architecture of CRQDA.

where $\mathrm{BertEmbedding}(\cdot)$ denotes the BERT embedding layer which sums the corresponding token, segment, and position embeddings, $\mathbf{E}^q \in \mathbb{R}^{(n+2)\times h}$ and $\mathbf{E}^d \in \mathbb{R}^{m\times h}$ represent the question embedding and the paragraph embedding.

$\mathbf{E}^q$ and $\mathbf{E}^d$ are further fed into BERT layers which consist of multiple Transformer layers (Vaswani et al., 2017) to obtain the final hidden representations $\{\mathbf{C}, \mathbf{T}^q_1, ..., \mathbf{T}^q_n, \mathbf{T}_{[SEP]}, \mathbf{T}^d_1, ..., \mathbf{T}^d_m\}$ as shown in Figure 1. The representation vector $\mathbf{C} \in \mathbb{R}^h$ corresponding to the first input token ([CLS]) are fed into a binary classification layer to output the probability of whether the question is answerable:

$$P_a(\text{is-answerable}) = \mathrm{Sigmoid}(\mathbf{C}\mathbf{W}_c^T + \mathbf{b}_c), \quad (2)$$

where $\mathbf{W}_c \in \mathbb{R}^{2\times h}$ and $\mathbf{b}_c \in \mathbb{R}^2$ are trainable parameters. The final hidden representations of paragraph $\{\mathbf{T}^d_1, ..., \mathbf{T}^d_m\} \in \mathbb{R}^{m\times h}$ are inputted into two classifier layer to output the probability of the start position and the end position of the answer span:

$$P_s(i =< \text{start} >) = \mathrm{Sigmoid}(\mathbf{T}^d_i \mathbf{W}_s^T + b_s), \quad (3)$$

$$P_e(i =< \text{end} >) = \mathrm{Sigmoid}(\mathbf{T}^d_i \mathbf{W}_e^T + b_e), \quad (4)$$

where $\mathbf{W}_s \in \mathbb{R}^{1\times h}$, $\mathbf{W}_e \in \mathbb{R}^{1\times h}$, $b_s \in \mathbb{R}^1$, and $b_e \in \mathbb{R}^1$ are trainable parameters.

For the data tuple (q, d, s, e, t), the total loss of MRC model can be written as

$$\begin{aligned} \mathcal{L}_{\text{mrc}} &= \lambda \mathcal{L}_a(t) + \mathcal{L}_s(s) + \mathcal{L}_e(e), \quad (5)\\ &= -\lambda \log P_a(t) - \log P_s(s) - \log P_e(e), \end{aligned}$$

where λ is a hyper-parameter.

3.4 Transformer-based Autoencoder

As shown in the right part of Figure 1, the original question q is firstly mapped into question embedding $\mathbf{E}^q$ with the BERT embedding layer. It should be noted that the Transformer encoder and the pre-trained MRC model share[3] the parameters of the embedding layer, which makes the question embedding of the two models in the same continuous embedding space.

We obtain the encoder hidden states $\mathbf{H}_{enc} \in \mathbb{R}^{(n+2)\times h}$ from the Transformer encoder. The objective of the Transformer autoencoder is to reconstruct the input question itself, which is optimized with cross-entropy (Dai and Le, 2015). A trivial solution of the autoencoder would be to simply copy tokens in the decoder side. To avoid this, we do not directly feed the whole $\mathbf{H}_{enc}$ to the decoder, but use an RNN-GRU (Cho et al., 2014) layer with sum pooling to obtain a latent vector $\mathbf{z} \in \mathbb{R}^h$. Then we feed $\mathbf{z}$ to the decoder to reconstruct the question, which follows Wang et al. (2019).

$$\begin{aligned} \mathbf{H}_{enc} &= \mathrm{TransformerEncoder}(q), & (6)\\ \mathbf{z} &= \mathrm{Sum}(\mathrm{GRU}(\mathbf{H}_{enc})), & (7)\\ \hat{q} &= \mathrm{TransformerDecoder}(\mathbf{z}). & (8) \end{aligned}$$

We can train the autoencoder on the question data of $\mathcal{D}$ or pre-train it on other large-scale corpora, such as BookCorpus (Zhu et al., 2015) and English Wikipedia.

---

[3] The parameters of the Transformer encoder's embedding layer are copied from the pre-trained MRC, and are fixed during training.

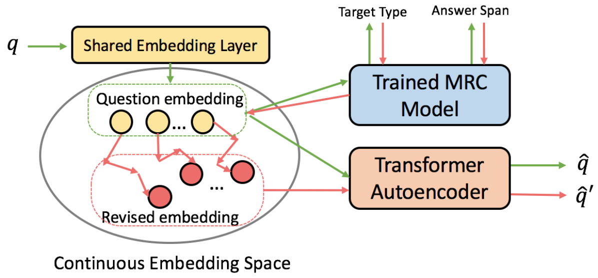

Figure 2: The question rewriting process of CRQDA.

Algorithm 1 Question Rewriting with Gradient-based Optimization.

```
Input: Data tuple $(q, d, s, e, t)$; Original question embedding
    $\mathbf{E}^q$; pre-trained MRC model and Transformer autoencoder;
    A set of step size $S_\eta = \{\eta_i\}$; Step size decay
    coefficient $\beta_s$; the target answerable or unanswerable label
    $t'$; Threshold $\beta_t, \beta_a, \beta_b$;
Output: a set of new answerable and unanswerable question
    data tuples $\mathcal{D}' = \{(\hat{q}', d, s, e, t'), .., (\hat{q}', d, s, e, t)\}$;
 1: $\mathcal{D}' = \{\}$;
 2: for each $\eta \in S_\eta$ do
 3:     for max-steps do
 4:         revise $\mathbf{E}^{q'}$ by Eq. (10) or Eq. (9)
 5:         $\hat{q}' =$ TransformerAutoencoder $\left(\mathbf{E}^{q'}\right)$
 6:         if $P_a(t') > \beta_t$ and $\mathcal{J}(q, \hat{q}') \in [\beta_a, \beta_b]$ then
 7:             add $(\hat{q}', d, s, e, t')$ to $\mathcal{D}'$;
 8:         end if
 9:         $\eta = \beta_s \eta$;
10:     end for
11: end for
12: return $\mathcal{D}'$;
```

3.5 Rewriting Question with Gradient-based Optimization

As mentioned above, the question embedding of the Transformer encoder and pre-trained MRC are in the same continuous embedding space, where we can revise the question embedding with the gradient guidance by MRC model. The revised question embedding $\mathbf{E}^{q'}$ is fed into Transformer autoencoder to generate a new question data $\hat{q}'$.

Figure 2 illustrates the process of question rewriting. Specifically, we take the process of rewriting an answerable question to a relevant unanswerable question as an example to present the process. Given an answerable question q, the goals of the rewriting are: (I) the revised question embedding should make the pre-trained MRC model predict the question from answerable to unanswerable with the paragraph d; (II) The modification size of $\mathbf{E}^q$ should be adaptive to prevent the revision of $\mathbf{E}^q$ from falling into local optimum; (III) The revised question $\hat{q}'$ should be similar to the original q, which helps to improve the robustness of the model.

For goal-(I), we take the label $t' = 0$, which denotes the label of question is unanswerable, to calculate the loss $\mathcal{L}_a(t')$ and the gradient of $\mathbf{E}^q$ by the pre-trained MRC model (see the red line in Figure 2). We iteratively revise $\mathbf{E}^q$ with gradients from the pre-trained MRC model until the MRC model predicts the question is unanswerable with the revised $\mathbf{E}^{q'}$ as its input, which means the $P_a(t'|\mathbf{E}^{q'})$ is large than a threshold β_t. Note that here we use the gradient to only modify $\mathbf{E}^q$, and all the model parameters during rewriting process are fixed. The process of each iteration can be written as:

$$\mathbf{E}^{q'} = \mathbf{E}^q - \eta(\nabla_{\mathbf{E}^q} \mathcal{L}_a(t')), \tag{9}$$

where η is the step size. Similarly, we can revise the $\mathbf{E}^q$ of a data tuple (q, d, s, e, t) to generate a new answerable question whose answer is still the original answer span (s, e) as follows:

$$\mathbf{E}^{q'} = \mathbf{E}^q - \eta \left(\nabla_{\mathbf{E}^q} (\lambda \mathcal{L}_a(t) + \mathcal{L}_s(s) + \mathcal{L}_e(e)) \right). \tag{10}$$

Rewriting the answerable question into another answerable question can be seen as a special constrained paraphrasing, which requires that the question after the paraphrasing is context-relevant answerable and its answer remains unchanged.

For goal-(II), we follow (Wang et al., 2019) to employ the dynamic-weight-initialization method to allocate a set of step-sizes $S_\eta = \{\eta_i\}$ as initial step-sizes. For each initial step-size, we perform a pre-defined max-step revision with the step size value decay (corresponds to Algorithm 1 line 2-11) to find the target question embedding. For goal-(III), we select the $\hat{q}'$ whose unigram word overlap rate with the original question q is within a threshold range $[\beta_a, \beta_b]$. The unigram word overlap is computed by:

$$\mathcal{J}(q, \hat{q}') = \frac{\text{count}(w_q \cap w_{\hat{q}})}{\text{count}(w_q \cup w_{\hat{q}})}, \tag{11}$$

here w_q is the word in q and $w_{\hat{q}}$ is the word in $\hat{q}'$. The whole question rewriting procedure is summarized in Algorithm 1.

4 Experiments

In this section, we describe the experimental details and results. We first conduct the experiment on the SQuAD 2.0 dataset (Rajpurkar et al., 2018) to compare CRQDA with other strong baselines, which is reported in § 4.1. The ablation study and further analysis are provided in § 4.2. Then we evaluate our method on additional two tasks including question generation on SQuAD 1.1 dataset (Rajpurkar et al., 2016) in § 4.3, and question-answering language inference on QNLI dataset (Wang et al., 2018) in § 4.4.

Methods	EM	F1
$\text{BERT}_{\text{large}}$ (Devlin et al., 2018) (original)	78.7	81.9
+ EDA (Wei and Zou, 2019)	78.3	81.6
+ Back-Translation (Yu et al., 2018)	77.9	81.2
+ Text-VAE (Liu et al., 2019a)	75.3	78.6
+ AE with Noise	76.7	79.8
+ 3M synth (Alberti et al., 2019)	80.1	82.8
+ UNANSQ (Zhu et al., 2019)	80.0	83.0
+ CRQDA (ours)	**80.6**	**83.3**

Table 1: Comparison results on SQuAD 2.0.

4.1 SQuAD

The extractive MRC benchmark SQuAD 2.0 dataset contains about 100,000 answerable questions and over 50,000 unanswerable questions. Each question is paired with a Wikipedia paragraph.

Implementation Based on *RobertaForQuestionAnswering*[4] model of Huggingface (Wolf et al., 2019), we train a $\text{RoBERTa}_{\text{large}}$ model on SQuAD 2.0 as the pre-trained MRC model for CRQDA. The hyper-parameters are the same as the original paper (Liu et al., 2019b). For training the autoencoder, we copy the word embedding parameters of the pre-trained MRC model to autoencoder and fix them during training. Both of its encoder and decoder consist of 6-layer Transformers, where the inner dimension of feed-forward networks (FFN), hidden state size, and the number of attention head are set to 4096, 1024, and 16.

The autoencoder trains on BookCorpus (Zhu et al., 2015) and English Wikipedia (Devlin et al., 2018). The sequence length, batch size, learning rate, and training steps are set to 64, 256, 5e-5 and 100,000. For each original answerable data, we use CRQDA to generate new unanswerable question data, resulting in about 220K data samples (including the original data samples). The hyper-parameter of β_s, β_t, β_a, β_b, and max-step are set to 0.9, 0.5, 0.5, 0.99, and 5, respectively.

Baselines We compare our CRQDA against the following baselines: (1) **EDA** (Wei and Zou, 2019): it augments question data by performing synonym replacement, random insertion, random swap, or random deletion operation. We implement EDA with their source code[5] to synthesize a new question data for each question of SQuAD 2.0; (2) **Back-Translation** (Yu et al., 2018; Prabhumoye et al., 2018): it uses machine translation model to translate questions into French and back into English. We implement Back-Translation based on the source code[6] to generate a new question data for each original question; (3) **Text-VAE** (Bowman et al., 2016; Liu et al., 2019a): it uses RNN-based VAE to generate a new question data for each question of SQuAD 2.0. The implementation is based on the source code[7]; (4) **AE with Noise**: it uses the same autoencoder of CRQDA for question data rewriting. The only difference is that the autoencoder cannot utilize the MRC gradient but only uses a noise (sampled from Gaussian distribution) to revise the question embedding. This experiment is designed to show necessity of the pre-trained MRC. (5) **3M synth** (Alberti et al., 2019): it employs round-trip consistency technique to synthesize 3M questions on SQuAD 2.0; (6) **UNANSQ** (Zhu et al., 2019): it employs a pair-to-sequence model to generate 69,090 unanswerable questions. Following previous methods (Zhu et al., 2019; Alberti et al., 2019), we use each augmented dataset to fine-tune $\text{BERT}_{\text{large}}$ model, where the implementation is also based on Huggingface.

Results For SQuAD 2.0, Exact Match (EM) and F1 score are used as evaluation metrics. The results on SQuAD 2.0 development set are shown in Table 1. The popular textual DA methods (including EDA, Back-Translation, Text-VAE, and AE with Noised), do not improve the performance of the MRC model. One possible reason might be that they introduce detrimental noise to the training process as they augment question data without considering the paragraphs and the associated answers. In sharp contrast, the QDA methods (including 3M synth, UNANSQ, and CRQDA) improve the model performance. Besides, our CRQDA outperforms all the strong baselines, which brings about 1.9 absolute EM score and 1.5 F1 score improvement

based on BERT$_{\text{large}}$. We provide some augmented data samples of each baseline in **Appendix A**.

4.2 Ablation and Analysis

Our ablation study and further analysis are designed for answering the following questions: **Q1**: How useful is the augmented data synthesized by our method if trained by other MRC models? **Q2**: How does the choice of the corpora for autoencoder training influence the performance? **Q3**: How do different CRQDA augmentation strategies influence the model performance?

Methods	EM	F1
BERT$_{\text{base}}$	73.7	76.3
+ CRQDA	**75.8** (+2.1)	**78.7** (+2.4)
BERT$_{\text{large}}$	78.7	81.9
+ CRQDA	**80.6** (+1.9)	**83.3** (+1.4)
RoBERTa$_{\text{base}}$	78.6	81.6
+ CRQDA	**80.2** (+1.6)	**83.1** (+1.5)
RoBERTa$_{\text{large}}$	86.0	88.9
+ CRQDA	**86.4** (+0.4)	**89.5** (+0.6)

Table 2: Results of different MRC models with CRQDA on SQuAD 2.0.

To answer the first question (**Q1**), we use the augmented SQuAD 2.0 dataset in § 4.1 to train different MRC models (BERT$_{\text{base}}$, BERT$_{\text{large}}$, RoBERTa$_{\text{base}}$, and RoBERTa$_{\text{large}}$). The hyper-parameters and implementation are based on Huggingface (Wolf et al., 2019). The results are presented in Table 2. We can see that CRQDA can improve the performance of each MRC model, yielding 2.4 absolute F1 improvement with BERT$_{\text{base}}$ model and 1.5 absolute F1 improvement with RoBERTa$_{\text{base}}$. Besides, although we use a RoBERTa$_{\text{large}}$ model to guide the rewriting of question data, the augmented dataset can further improve its performance.

Methods	EM	F1	R-L	B4
BERT$_{\text{base}}$	73.7	76.3	-	-
+ CRQDA (SQuAD 2)	74.8	77.7	82.9	59.6
+ CRQDA (2M ques)	75.3	78.2	97.8	94.7
+ CRQDA (Wiki)	**75.8**	**78.7**	99.3	98.4
+ CRQDA (Wiki+Mask)	75.4	78.4	**99.7**	**99.4**

Table 3: Results of training autoencoder on different corpora. R-L is short for ROUGE-L, and B4 is short for BLEU-4.

For the second question (**Q2**), we conduct experiments to use the following different corpora to train the autoencoder of CRQDA: (1) **SQuAD 2.0**: we use all the questions from the training set of SQuAD 2.0; (2) **2M questions**: we collect 2,072,133 questions from the training sets of several MRC and QA datasets, including SQuAD2.0, Natural Questions, NewsQA (Trischler et al., 2016), QuAC (Choi et al., 2018), TriviaQA (Joshi et al., 2017), CoQA (Reddy et al., 2019), HotpotQA (Yang et al., 2018), DuoRC (Saha et al., 2018), and MS MARCO (Bajaj et al., 2016); (3) **Wiki**: We use the large-scale corpora English Wikipedia and BookCorpus (Zhu et al., 2015) to train autoencoder; (4) **Wiki+Mask**: We also train autoencoder on English Wikipedia and BookCorpus as **Wiki**. In addition, we randomly mask 15% tokens of the encoder inputs with a special token, which is similar to the mask strategy used in (Devlin et al., 2018; Song et al., 2019).

We firstly measure the reconstruction performance of the autoencoders on the question data of SQuAD 2.0 development set. We use BLEU-4 (Papineni et al., 2002) and ROUGE-L (Lin, 2004) metrics for evaluation. Then we use these autoencoders for the CRQDA question rewriting with the same settings in § 4.1. These augmented SQuAD 2.0 datasets are used to fine-tune BERT$_{\text{base}}$ model. We report the performance of fine-tuned BERT$_{\text{base}}$ model in Table 3. It can be observed that with more training data, the reconstruction performance of autoencoder is better. Also, the performance of fine-tuned BERT$_{\text{base}}$ model is better. When trained with Wiki and Wiki+Mask, the autoencoders can reconstruct almost all questions well. The reconstruction performance of model trained with Wiki+Mask performs the best. However, the fine-tuned BERT$_{\text{base}}$ model with autoencoder trained on Wiki performs better than that trained on Wiki+Mask. The reason might be that the autoencoder trained with denoising task will be insensitive to the word embedding revision of CRQDA. In other words, some revisions guided by the MRC gradients might be filtered out as noises by the autoencoder, which is trained with a denoising task.

Methods	EM	F1
RoBERTa$_{\text{large}}$ (Liu et al., 2019b)	86.00	88.94
+ CRQDA (*unans*, $\beta_a = 0.7$)	86.39	89.31
+ CRQDA (*unans*, $\beta_a = 0.5$)	**86.43**	**89.50**
+ CRQDA (*unans*, $\beta_a = 0.3$)	86.26	89.35
+ CRQDA (*ans*)	86.22	89.30
+ CRQDA (*ans+unans*)	86.36	89.38

Table 4: Results of using differnt CRQDA augmented datasets for MRC training.

For the last question **Q3**, we use CRQDA for question data augmentation with different settings. For each answerable original question data sample from the training set of SQuAD 2.0, we use CRQDA to generate both answerable and unanswerable question examples. Then the augmented *unanswerable* question data (*unans*), the augmented *answerable* question data (*ans*), and all of them (*ans* + *unans*) are used to fine-tune RoBERTa$_{\text{large}}$ model. To further analyze the effect of β_a (a larger β_a value means that the generated questions are closer to the original question in the discrete space), we use different $\beta_a = 0.3, 0.5, 0.7$ for question rewriting. The results are reported in Table 4. It can be observed that the MRC achieves the best performance when $\beta_a = 0.5$. Moreover, all of *unans*, *ans*, and *ans* + *unans* augmented datasets can further improve the performance. However, we find that the RoBERTa$_{\text{large}}$ model fine-tuned on *ans* + *unans* performs worse than fine-tuned on *unans* only. The result is mixed in that using more augmented data is not always beneficial.

Method	B4	MTR	R-L
UniLM (Dong et al., 2019)	22.12	25.06	51.07
ProphetNet (Yan et al., 2020)	25.01	26.83	52.57

UniLM (Dong et al., 2019)	23.75	25.61	52.04
ProphetNet (Yan et al., 2020)	26.72	27.64	53.79
ProphetNet + CRQDA	**27.21**	**27.81**	**54.21**

Table 5: Results on SQuAD 1.1 question generation. B4 is short for BLEU-4, MTR is short for METEOR, and R-L is short for ROUGE-L. The first block follows the data split in Du et al. (2017), while the second block is the same as in Zhao et al. (2018).

4.3 Question Generation

Answer-aware question generation task (Zhou et al., 2017) aims to generate a question for the given answer span with a paragraph. We apply our CRQDA method to SQuAD 1.1 (Rajpurkar et al., 2016) question generation task to further evaluate CRQDA. The settings of CRQDA are the same as in § 4.1 and § 4.2. The augmented answerable question dataset is used to fine-tune the ProphetNet (Yan et al., 2020) model which achieves the best performance on SQuAD 1.1 question generation task. The implementation is based on their source code[8]. We also compare with the previous state-of-the-art model UniLM (Dong et al., 2019). Following Yan et al. (2020), we use BLEU-4, METEOR (Banerjee and Lavie, 2005), and ROUGE-L metrics for evaluation, and we split the SQuAD 1.1 dataset into training, development and test set. We also report the results on the another data split setting as in Yan et al. (2020), which reverses the development set and test set. The results are shown in Table 5. We can see that CRQDA improves ProphetNet on all three metrics and achieves a new state-of-the-art on this task.

Methods	Accuracy
BERT$_{\text{large}}$ (Devlin et al., 2018)	92.3
BERT$_{\text{large}}$ + CRQDA	**93.0**

Table 6: Results on QNLI.

4.4 QNLI

Given a question and a context sentence, question-answering NLI asks the model to infer whether the context sentence contains the answer to the question. QNLI dataset (Wang et al., 2018) contains 105K data samples. We apply CRQDA to QNLI dataset to generate new entailment and non-entailment data samples. Note that this task does not include the MRC model, but uses a text entailment classification model. Similarly, we train a BERT$_{\text{large}}$ model based on the code of *BertForSequenceClassification* in Huggingface to replace the "pre-trained MRC model" of CRQDA to guide the question data rewriting. Following the settings in § 4.1, we use CRQDA to synthesize about 42K new data samples as augmented data. Note that we only rewrite the question but keep the paired context sentence unchanged. Then the augmented data and original dataset are used to fine-tine BERT$_{\text{large}}$ model. Table 6 shows the results. CRQDA increases the accuracy of the BERT$_{\text{large}}$ model by 0.7%, which also demonstrates the effectiveness of CRQDA.

5 Conclusion

In this work, we present a novel question data augmentation method, called CRQDA, for context-relevant answerable and unanswerable question generation. CRQDA treats the question data augmentation task as a constrained question rewriting problem. Under the guidance of a pre-trained MRC model, the original question is revised in a continuous embedding space with gradient-based optimization and then decoded back to the discrete space as a new question data sample. The experimental results demonstrate that CRQDA outperforms

---

[8] `https://github.com/microsoft/ProphetNet`.

other strong baselines on SQuAD 2.0. The CRQDA augmented datasets can improve multiple reading comprehension models. Furthermore, CRQDA can be used to improve the model performance on question generation and question-answering language inference tasks, which achieves a new state-of-the-art on the SQuAD 1.1 question generation task.

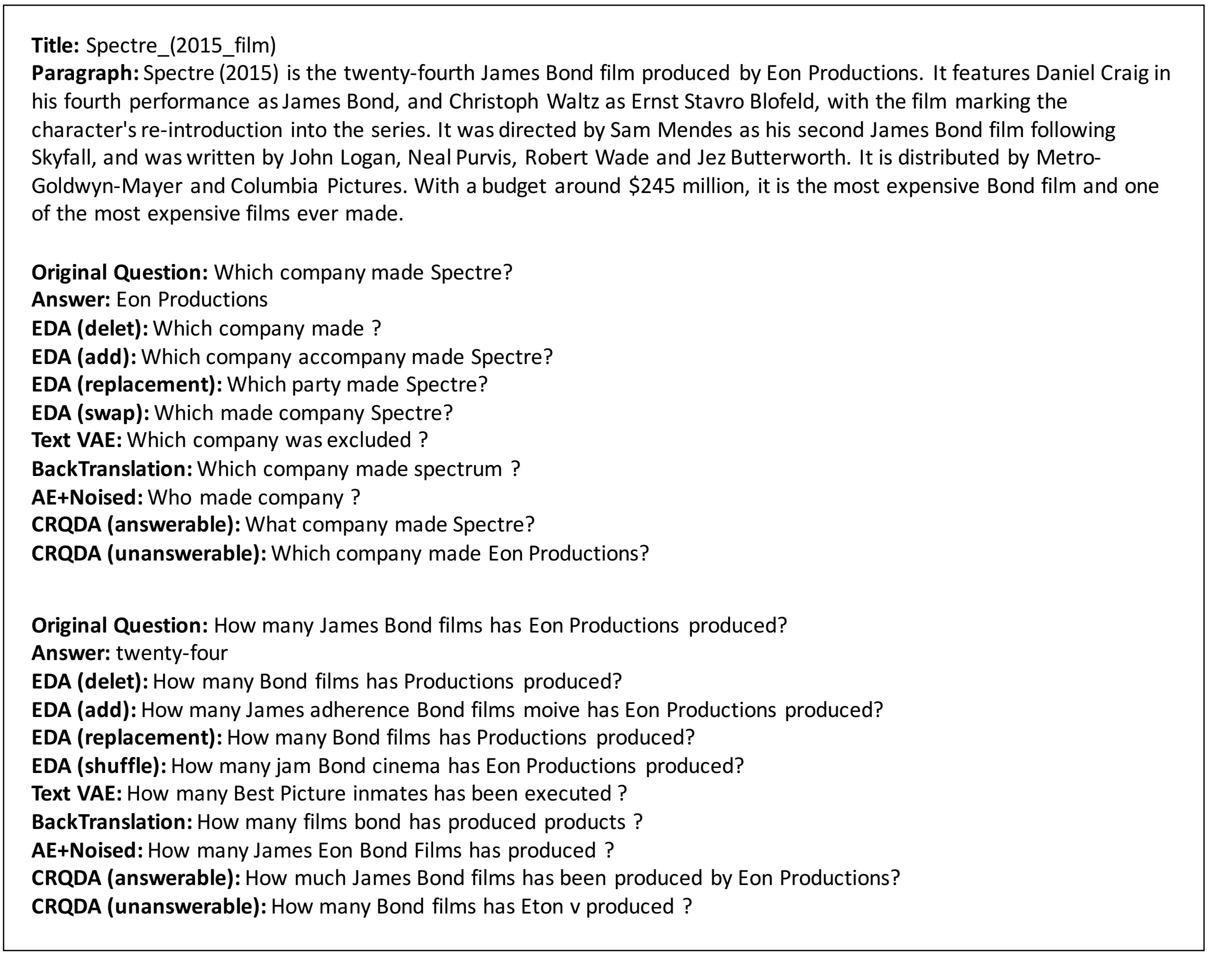
A Augmented Dataset

Figure 3 and Figure 4 provide some augmented data samples of each baseline on SQuAD 2.0. We can see that the baseline **EDA** tends to introduce noise which destroys the original sentence structure. The baselines of **Text VAE**, **BackTranslation** and **AE+Noised** often change some important words of the original question. This can cause the augmented question to miss the original key information and not to able to infer the original answer. In contrast, it can be observed that the generated answerable questions of **CRQDA** still maintain the key information for the original answer inference. Its generated unanswerable questions tend to introduce some context-relevant words to convert an original answerable question into an unanswerable one.



Title: Spectre_(2015_film)
Paragraph: Spectre (2015) is the twenty-fourth James Bond film produced by Eon Productions. It features Daniel Craig in his fourth performance as James Bond, and Christoph Waltz as Ernst Stavro Blofeld, with the film marking the character's re-introduction into the series. It was directed by Sam Mendes as his second James Bond film following Skyfall, and was written by John Logan, Neal Purvis, Robert Wade and Jez Butterworth. It is distributed by Metro-Goldwyn-Mayer and Columbia Pictures. With a budget around $245 million, it is the most expensive Bond film and one of the most expensive films ever made.

Original Question: Which company made Spectre?
Answer: Eon Productions
EDA (delet): Which company made ?
EDA (add): Which company accompany made Spectre?
EDA (replacement): Which party made Spectre?
EDA (swap): Which made company Spectre?
Text VAE: Which company was excluded ?
BackTranslation: Which company made spectrum ?
AE+Noised: Who made company ?
CRQDA (answerable): What company made Spectre?
CRQDA (unanswerable): Which company made Eon Productions?

Original Question: How many James Bond films has Eon Productions produced?
Answer: twenty-four

Title: Space_Race
Paragraph: The Space Race was a 20th-century competition between two Cold War rivals, the Soviet Union (USSR) and the United States (US), for supremacy in spaceflight capability. It had its origins in the missile-based nuclear arms race between the two nations that occurred following World War II, enabled by captured German rocket technology and personnel. The technological superiority required for such supremacy was seen as necessary for national security, and symbolic of ideological superiority. The Space Race spawned pioneering efforts to launch artificial satellites, unmanned space probes of the Moon, Venus, and Mars, and human spaceflight in low Earth orbit and to the Moon. The competition began on August 2, 1955, when the Soviet Union responded to the US announcement four days earlier of intent to launch artificial satellites for the International Geophysical Year, by declaring they would also launch a satellite "in the near future". The Soviet Union beat the US to this, with the October 4, 1957 orbiting of Sputnik 1, and later beat the US to the first human in space, Yuri Gagarin, on April 12, 1961. The Space Race peaked with the July 20, 1969 US landing of the first humans on the Moon with Apollo 11. The USSR tried but failed manned lunar missions, and eventually cancelled them and concentrated on Earth orbital space stations. A period of détente followed with the April 1972 agreement on a co-operative Apollo–Soyuz Test Project, resulting in the July 1975 rendezvous in Earth orbit of a US astronaut crew with a Soviet cosmonaut crew.

Original Question: On what date did the Space Race begin?
Answer: August 2, 1955
EDA (delet): On what date did the Space Race?
EDA (add): On what date time did the Space Race begin?
EDA (replacement): On what date time did the room Race begin?
EDA (swap): On what date time did the Race Space begin?
Text VAE: On what date did the Red Death begin ?
BackTranslation: On what date the Space Race begin ?
AE+Noised: On what date the Space did begin ?
CRQDA (answerable): When did the Space Race start?
CRQDA (unanswerable): On what date did the Space Russians begin ?

Original Question: Who was the first person in space?
Answer: Yuri Gagarin
EDA (delet): Who was the person in space?
EDA (add): Who was the second first person in space?
EDA (replacement): Who was the start person in space?
EDA (shuffle): Who first was the in person space?
Text VAE: Who was the first person in room ?
BackTranslation: Who was the first person in space ?
AE+Noised: Who was the man in space ?
CRQDA (answerable): Who was the first in space?
CRQDA (unanswerable): Who was the first Russians in space ?

[§]Rice University, Houston, Texas, USA.

Abstract

Question and answer generation is a data augmentation method that aims to improve question answering (QA) models given the limited amount of human labeled data. However, a considerable gap remains between synthetic and human-generated question-answer pairs. This work aims to narrow this gap by taking advantage of large language models and explores several factors such as model size, quality of pretrained models, scale of data synthesized, and algorithmic choices. On the SQUAD1.1 question answering task, we achieve higher accuracy using solely synthetic questions and answers than when using the SQUAD1.1 training set questions alone. Removing access to real Wikipedia data, we synthesize questions and answers from a synthetic text corpus generated by an 8.3 billion parameter GPT-2 model and achieve 88.4 Exact Match (EM) and 93.9 F1 score on the SQUAD1.1 dev set. We further apply our methodology to SQUAD2.0 and show a 2.8 absolute gain on EM score compared to prior work using synthetic data.

1 Introduction

One of the limitations of developing models for question answering, or any Deep Learning application for that matter, is the availability and cost of labeled training data. A common approach to alleviate this need is semi-supervised learning, wherein one trains a model on existing data and uses it to label more data for training (Zhu, 2005; Chapelle et al., 2009; Zhu and Goldberg, 2009; Kingma et al., 2014). This technique has demonstrated benefits in recent literature for image classification (Xie et al., 2019) and question answering (QA) tasks (Alberti et al., 2019a; Dong et al., 2019). However, the complexities of generating questions and answers in natural language proves challenging for existing methods, with a large gap in quality remaining between synthetic and human-generated data.

Text	Albert Einstein is known for his theories of special relativity and general relativity. He also made important contributions to statistical mechanics, especially his mathematical treatment of Brownian motion, his resolution of the paradox of specific heats, and his connection of fluctuations and dissipation. Despite his reservations about its interpretation, Einstein also made contributions to quantum mechanics and, indirectly, **quantum field theory**, primarily through his theoretical studies of the photon.
117M	Which two concepts made Einstein's post on quantum mechanics relevant?
768M	Albert Einstein also made significant contributions to which field of theory?
8.3B	Because of his work with the photon, what theory did he indirectly contribute to?
Human	What theory did Einstein have reservations about?

Table 1: Questions generated by models of increasing capacity with the ground truth answer highlighted in bold. As model size grows, question quality becomes increasingly coherent, complex, and factually relevant.

In this work, we close this gap using only synthetic questions generated from large models. We also show that naive scaling of Alberti et al. (2019a) alone is insufficient. We demonstrate that answer candidate generation is foundational to synthetic question quality, and there are issues aligning the answer distribution which do not improve with scale. Throughout this paper we focus primarily on question generation as a data augmentation method for existing question answering tasks. Focus on this type of semi-supervised setting is a necessary first step to enable future work applying question generation to low-resource tasks.

Similar to prior work (Alberti et al., 2019a; Dong et al., 2019), we use a 3-step modeling pipeline consisting of unconditional answer extraction from text, question generation, and question filtration. Our approach for training question generators on labeled data uses pretrained GPT-2 decoder models

and a next-token-prediction language modeling objective, trained using a concatenation of context, answer, and question tokens. We demonstrate that pretraining large generative transformer models up to 8.3B parameters improves the quality of generated questions. Additionally, we propose an overgenerate and filter approach to further improve question filtration. The quality of questions produced by this pipeline can be assessed quantitatively by finetuning QA models and evaluating results on the SQUAD dataset.

We demonstrate generated questions to be comparable to supervised training with human-labeled data. We measure this by using the ratio of accuracies between a QA model trained on synthetically generated data and a model trained on human labelled data. For answerable SQUAD1.1 questions we recover 100.8% of fully supervised EM and 100.1% of fully supervised F1 scores, when training on purely synthetic questions and answers generated from unlabeled data. Specifically, we achieve scores of 88.4 and 94.1 compared to supervised training which achieves 87.7 EM and 94.0 F1. Finetuning the resulting model on real SQUAD1.1 data reaches 89.4 EM and 95.1 F1 score, which is higher than any prior BERT-based approach. In Table 1, we show that the generated questions are qualitatively similar to ground truth questions, with the quality improving with the model size.

Going further, we show that QA models can be successfully trained from fully synthetic data, by running question and answer generation on a corpus generated from an unconditional GPT-2 model, and achieve an EM of 88.4 and F1 of 93.9. This approach performs comparably to generating questions from real data recovering 100.3% of fully supervised EM and F1 scores.

In summary, our contributions are as follows:

- We demonstrate that finetuning a model on synthetic questions and answers generated from a synthetic corpus creates a QA model better in SQUAD1.1 EM and F1 scores than one trained from human-labeled data.
- We show that by scaling the model size, using better pretrained models, and leveraging large synthetically generated data, we achieve state of the art results and show 1.7 absolute gain on SQUAD2.0 EM score compared to prior work using synthetic data.
- Through detailed ablation studies we identify that the quality of answer generation is fundamental to high fidelity question generation and properly aligning the answer distribution boosts scores by 19.8 EM points.

2 Method

In this work we seek to generate high quality training data for SQUAD style extractive question answering over a given set of documents D. This requires us to sample (c, q, a) triples for given paragraph contexts $c \in D$ according to probability $p(q, a|c)$, where q is a question resulting in answer a, which exists as a contiguous span of text in c. Leveraging the roundtrip consistency method (Alberti et al., 2019a), we achieve this by using a three step approach consisting of Answer Generation $\hat{a} \sim p(a|c)$, Question Generation $\hat{q} \sim p(q|\hat{a}, c)$, and Roundtrip Filtration $\hat{a} \overset{?}{=} a^* \sim p(a|c, \hat{q})$. As illustrated by Algorithm 1 in the Appendix A.1, the synthesized dataset of triples is then used to finetune and train a BERT-based QA model similar to (Devlin et al., 2018).

2.1 Answer Generation: $\hat{a} \sim p(a|c)$

For a model to perform well on a specific dataset, we need to match its answer distribution. Our goal is to learn an answer candidate generator $p(a|c)$, that acts as a prior for the dataset's answer distribution. Earlier work (Dhingra et al., 2018; Lewis et al., 2019) using named entity and noun phrase answer candidates performed best only on those portions of the data distribution.

To achieve this we finetune a BERT-style transformer model with hidden size H for extractive span selection. However, unlike BERT finetuning for question answering we omit the question tokens. This yields an unconditional answer extractor model $p(a|c)$ that predicts the start and end of a token span $(s, e) = a$. Similar to (Alberti et al., 2019a) we used an answer extraction head that models start and end tokens jointly.

$$p(a|c; \theta_A) = \frac{e^{f(a,c;\theta_A)}}{\sum_{a''} e^{f(a'',c;\theta_A)}}$$

$$f(a, c; \theta_A) = \textsc{mlp}(\textsc{concat}(\textsc{bert}(c)[s], \textsc{bert}(c)[e]))$$

Our MLP layer consists of one hidden layer with hidden size $2H$, followed by a ReLU nonlinearity, and a projection from activations to logits.

2.2 Question Generation: $\hat{q} \sim p(q|\hat{a}, c)$

We develop a conditional question generation model, $p(q|a, c)$ using a pretrained GPT-2 model. As input to our model, we concatenate context tokens, answer tokens, and question tokens into a single sequence, separated by end of sequence tokens. We trained the question generation model with a left to right next token prediction loss modeled over the entire concatenated sequence. This method of multi-input controlled text generation draws on inspiration from prior work (Puri and Catanzaro, 2019; Raffel et al., 2019; Dong et al., 2019). More details and visualizations of the input representation and training loss can be found in Figure 3 in the Appendix A.2. To sample from our learned model we concatenate the context tokens with the answer tokens and autoregressively sample output question tokens.

To aid our model with generation we employ start and stop word filtration. We prepend '*question:*' and append '*:question*' tokens to the questions in our training dataset. During inference time, if the model does not sample a sequence containing both the start and stop words we discard the example entirely.

2.3 Roundtrip Filtration: $\hat{a} \overset{?}{=} a^* \sim p(a|c, \hat{q})$

In roundtrip filtration (Alberti et al., 2019a) an extractive question answering model $p(a|c, q)$ is trained on the available labeled data. When a new question, answer, and context triple $(c, \hat{q}, \hat{a})$ is generated we apply the QA filtration model $p(a|c, \hat{q})$ to the context and question. The resulting answer a^* from the model is compared to the answer $\hat{a}$ from the triple. If the two are equivalent then the question is considered admissible.

In the original work, however, the authors draw attention to the precision of the method. While it does discard invalid questions, several valid questions are discarded as well. To avoid losing valuable pieces of information to train our question answering models we propose generating two questions, instead of one question, for each candidate answer. Roundtrip filtration is then applied to each question individually. If a triple is decided as acceptable then it is kept regardless of whether the other triple is acceptable, leading to a scenario where both can be kept. This method is similar to prior work in overgeneration and reranking of generated questions (Heilman and Smith, 2010a).

3 Experiment Setup

For all the implementations and training of transformer models we use the Megatron-LM codebase (Shoeybi et al., 2019). For off-the-shelf weights and implementations of BERT-Large we rely on the HuggingFace's transformers codebase (Wolf et al., 2019). For model configurations, hidden size, number of layers, and attention heads, we used the configurations detailed in Megatron-LM. To finetune our GPT-2 models we reused the pretraining hyperparameters detailed in Appendix A.3, except for a batch size of 32, and a learning rate of 2e-5 decaying to zero over six epochs of finetuning data. Finetuning our BERT models for filtration, answer generation, and question answering was all done with a learning rate of 1e-5 and a cosine decay scheduled over 2 epochs of training data. BERT pretraining details are described in Appendix A.4. We refer to our models as BERT-345M (345 million parameters) and BERT-1.2B (1.2 billion parameters) and the original BERT model as BERT-Large.

To train and evaluate the question generation pipeline for our ablation studies in sections 5 and 6 we used a data partitioning scheme as shown in Figure 4 in Appendix A.5. A similar data pipeline has been employed in concurrent work of Klein and Nabi (2019). We split the SQUAD training data into equal portions, partitioning the data randomly into two sets of documents. One half of the documents is used to train the answer generator, question generator, and filtration models while the second half of the documents is used to generate synthetic data to finetune a QA model. The finetuned QA model is then evaluated on SQUAD dev set, where the evaluation results are used as a surrogate measure of synthetic data quality. The partitioning of the dataset is done to avoid leakage and overfitting between the data seen at training time and generation time thereby testing the generalization capabilities of our models. Since shuffling is done randomly we repeat this process 5 times with different seeds for every ablation study and report the mean of our results. Due to the large hyperparmeter space we do not perform any learning rate search and use the static learning schedules as described above. We note that the data partitioning is done only for the ablation studies and hyperparameter selection. For the final models in Figure 1 and Tables 2 & 3, we use the entire SQUAD dataset.

Text Source	Source Data Size	finetune data	# Questions	EM	F1
Wikipedia	638 MB	Synthetic	19,925,130	88.4	94.1
		+SQuAD	20,012,729	**89.4**	**95.2**
8.3B GPT-2	480 MB	Synthetic	17,400,016	88.4	93.9
		+SQuAD	17,487,615	**89.1**	**94.9**
SQuAD1.1	14MB	SQuAD	87,599	87.7	94.0

Table 2: Finetuning BERT-345M on synthetic and human-generated data. Using 1.2B parameter models we synthesize question answer pairs from real Wikipedia corpus and synthetic corpus generated from an 8.3B GPT-2 model. Completely synthetic data does better than training with real data. Finetuning with real SQuAD1.1 data afterwards further boosts performance.

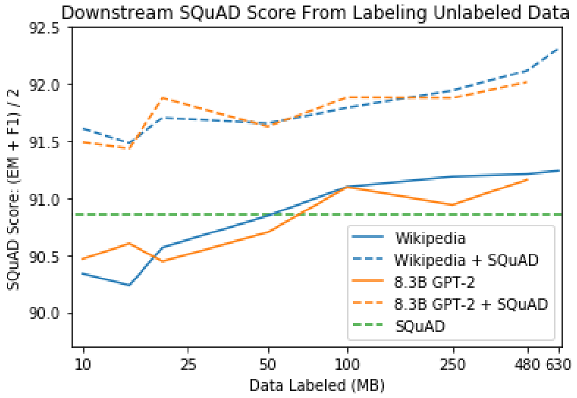

Figure 1: Effect of labeling data size on downstream SQuAD1.1 score. After finetuning BERT-345M models on synthetic data we finetune further on human generated SQuAD1.1 data.

4 Results

In this section we present our results using the best combination of models, algorithms, and parameters. In the following sections, we will perform detailed ablation study and show contributions from each of these choices.

We train a 1.2 billion parameter answer generator, question generator, and question filtering model. In these experiments we use the entire SQuAD1.1 dataset instead of only training on half of the labeled data since we are not doing any model or hyperparameter search. We then use these models to label synthetic data from two sources outside of SQuAD1.1 . We first label data from real Wikipedia documents with the overlapping documents from the SQuAD1.1 training and dev set removed. In parallel we label data from synthetic Wikipedia documents generated by an 8.3B GPT-2 model. This model was first trained with the Megatron-LM codebase for 400k iterations before being finetuned on only Wikipedia documents for 2k iterations. This allows us to generate high quality text from a distribution similar to Wikipedia by using top-p ($p = 0.96$) nucleus sampling.

Implementation	EM	F1
BERT-Large (Alberti et al., 2019a)	78.7	81.9
+ 3M Questions	80.1	82.8
UniLM (Dong et al., 2019)	80.5	83.4
+ 9M Questions	84.7	87.6
BERT-Large	77.4	80.6
+ 3M Questions	81.6	84.5
BERT-345M	84.9	88.2
+ 3M Questions	85.8	88.6
+ 8M Questions	**86.4**	**89.2**

Table 3: Comparison with prior work. Improvements in question generation allow for improved SQuAD2.0 score even without generating unanswerable questions.

Table 2 shows results when the synthetic data is finetuned on a BERT-345M QA model. We showcase that we are able to recover and surpass the performance of human-labeled data by only using synthetic data generated from synthetic corpus. Using questions synthesized on real Wikipedia data we do even better. Finetuning this model afterwards on the actual SQuAD1.1 dataset allows us to achieve a 1.7 and 1.2 point boost to our EM and F1 scores.

In Figure 1 we examine the relationship between SQuAD1.1 score and the amount of text labeled. We find that the performance of training with purely synthetic data observes a log-linear relationship that begins to saturate at approximately 100 MB of text labeled. However, finetuning these models on labeled SQuAD1.1 data demonstrates continued improvement even beyond saturation. The performance of these post finetuned models continues to improve even past 500 MB of data labeled.

In question generation we aim to effectively expand the knowledge and capabilities of our QA models by generating synthetic QA pairs not in the original dataset. The unsupervised LM takes this further to generate these QA pairs from synthetic text. Generating synthetic questions from synthetic text is important because it draws upon knowledge not explicitly stated in the original corpus. While preliminary, it's noteworthy that the fully synthetic experiment works so well, and our results point towards a promising direction for future work. We provide QA examples generated from real and synthetic Wikipedia in Appendix A.7 & A.8.

Comparison with prior work. To quantify the improvements in question generation quality derived from improvements to language models and our generation techniques we compare our results to the original roundtrip consistency work from (Alberti et al., 2019a). We generate 3 million questions from real Wikipedia text and finetune the public BERT-Large model on this data. We then finetune the model on the human-generated SQuAD2.0 dataset and evaluate on the dev set. Unlike prior work we do not generate any unanswerable questions, yet we find in Table 3 that our synthetic data approach outperforms the prior work. This is despite our BERT-Large baseline underperforming the numbers reported in (Alberti et al., 2019a) by a full point. We also compare our methods with the state of the art in synthetically trained SQuAD2.0 (Dong et al., 2019) and find that with a similar number of questions we outperform existing methods, and with even more labeled data this trend persists.

Data Labeling Cost: To label 8 million datapoints we used approximately 5200 GPU hours and 7200 CPU hours. With Azure costs of ∼3$ per GPU hour this comes out to about 16 thousand dollars for the whole dataset or .2¢ per datum. With software optimization we expect further reductions.

5 Model Scale

We show in this section that as we improve pretraining tasks, pretraining scale, and model scale, synthetic data also improves. To show improvements in question generation we track the resulting SQuAD1.1 evaluation score when a BERT-style model is finetuned on the synthetic data. Table 4 summarizes the benefits of using larger models for answer generation, question generation, and question filtration. The following subsections ablate this result to show the contributions from scaling individual components of the synthetic data pipeline.

Model Size				# Questions	EM	F1
Answer	Question	Filter	QA			
345M	345M	345M	345M	116721	85.3	92.0
1.2B	**1.2B**	**1.2B**	**345M**	**184992**	**87.1**	**93.2**
Human Generated Data			345M	42472	86.3	93.2

Table 4: SQuAD1.1 performance using synthetic data. Downstream QA models used in all experiments are 345M parameters.

Question Generator	# Questions	EM	F1
117M	42345	76.6	85.0
345M (Klein and Nabi, 2019)	-	75.4	84.4
345M (w/ BERT QA model)	42414	76.6	84.8
345M	42414	80.7	88.6
768M	42465	81.0	89.0
1.2B	42472	83.4	90.9
8.3B	**42478**	**84.9**	**92.0**
Human Generated Data	42472	86.3	93.2

Table 5: Effect of question generator scale on SQuAD1.1 performance. Ground truth answers are used to generate questions without filtration for finetuning.

Answer Generator	#Questions	EM	F1
BERT-Large	227063	77.7	87.6
BERT-345M	229297	79.1	87.9
BERT-1.2B	**229067**	**79.2**	**88.3**
Human Generated Answers	42472	83.7	91.1

Table 6: Comparison of answer generator pretraining and scale on SQuAD1.1 accuracies. Our 1.2 billion parameter question generator is used for generating questions.

5.1 Scaling Question Generation

Question generation plays a critical role in our synthetic data pipeline: it must synthesize linguistically and logically coherent text even if the text does not exist within the provided context. In this section we investigate the relationship between question generator scale and downstream SQuAD1.1 performance. We isolate the quality of question generation by using ground truth answers from the SQuAD1.1 dataset to generate questions and finetune a BERT model before evaluating it on the SQuAD1.1 dev set. We perform no question filtration in between generation and finetuning. From our experiments in Table 5 we find that SQuAD1.1 performance increases monotonically. Additionally, the number of valid samples that pass stopword filtration increase with larger models, indicating bigger models maintain coherency during sampling. For comparisons with prior work we train a question answering model with our BERT model (BERT-345M) and the original BERT-Large model. (Klein and Nabi, 2019) use a feedback loop to improve the question generator and BERT-Large question answering model. Compared to our work we find that a similarly parameterized set of models achieve equal if not better performance despite using only a single supervised pass through the data and no feedback loop.

5.2 Scaling Answer Generation

Answer generation is equally important in our data generation pipeline. Answer generation is the first component of the pipeline and must be precise to avoid compounding errors. For answer generation we use an unconditional extractive BERT model that predicts start and end spans jointly over a given sentence. From each probability distribution we sample the entire nucleus ($p = 0.9$) or the top-5 spans, choosing whichever is smaller. We arrive at this implementation based on our ablation studies in section 6.3. In qualitative studies we found that our model consistently generates diverse and valid answers (see samples in Appendix A.7), however, they rarely overlap with the answers from the SQuAD dataset making automatic metrics that rely on n-gram overlap such as BLEU not a suitable metric for analysis. To test the quality of the selected answers, we generate questions from our 1.2 billion parameter question generator and finetune a question answering model on the synthesized questions without any filtration. In Table 6 we compare answer generation quality using our two trained models and the original BERT-Large model from (Devlin et al., 2018). We find that improvements [1] in pretraining dramatically improve answer generation quality by 1.4 EM and 0.3 F1 between BERT-Large and our 345 million parameter answer generation model. We find that increasing model scale further to 1.2 billion parameters improves answer generation quality F1 by 0.4 while EM only improves by 0.1. Although these represent improvements in question quality only achieved by newer models, answer generation seems to be a large bottleneck as we discuss in section 6.1.

5.3 Scaling Question Filtration

We use the 1.2 billion parameter question generator from section 5.1 to generate questions for filtration. As described in more detail in section 6.3 we overgenerate two questions for every answer. We then filter these questions with roundtrip filtration before finetuning a question answering model. In Table 7 we find that our 345 million parameter BERT model modestly outperforms the public BERT-Large model when using synthetic answers to generate questions while our 1.2 billion parameter BERT model further improves on this score by more than a whole point. In the previous section improvements to pretraining scale and tasks made a larger difference on answer generation than increasing model scale. However, here we see the opposite: improvements to pretraining tasks results only in a modest improvement to question filtration, while increasing model size results in much more substantive improvements. We hypothesize that this is due to the larger model's ability to correctly answer more questions, and therefore allow more valid and high quality samples through to the finetuning phase as indicated by the number of questions generated by the technique.

Filter Model	# Questions	EM	F1
Synthetic Questions + Real Answers			
BERT-Large	45888	84.5	91.4
BERT-345M	34341	84.2	91.4
BERT-1.2B	**47772**	**85.6**	**92.4**
Synthetic Questions + Synthetic Answers			
BERT-Large	177712	85.5	91.9
BERT-345M	144322	85.9	92.5
BERT-1.2B	**184992**	**87.1**	**93.2**
Human Generated Data	42472	86.3	93.2

Table 7: Effect of pretraining and scale on question filtration. Synthetic questions and answers were both generated with 1.2 billion parameter models. Before finetuning, overgeneration and filtration were performed with the models ablated here.

Question Generator	# Questions	EM	F1
345M	**42414**	**80.7**	**88.6**
345M (no pretraining)	42408	42.7	51.4
345M (no stopwords)	42486	75.5	84.5
Human Generated Questions	42472	86.3	93.2

Table 8: Effect of question generator modeling choices. Questions are generated from ground truth answers without any filtration.

6 Modeling Choices

While developing our synthetic data generation pipeline we explored several modeling and algorithmic choices before scaling up the model size and data quantity used. We pursued three axis of investigation, ablating choices for each model component of our pipeline at a time.

6.1 Question Generation

To study question generation in isolation we used our 345 million parameter model to generate questions from ground truth SQuAD1.1 answers. The results of our analysis can be found in Table 8. We first investigated the use of pretrained models and found that pretraining our GPT-2 model was cru-

---

[1] Improvements include using sentence order prediction instead of next sentence prediction heads (Lan et al., 2019), whole word masking, masked ngram prediction instead of random masked prediction (Joshi et al., 2019), rearrangement of residual connection and layer norm layers (Shoeybi et al., 2019), and inclusion of data from RealNews (Zellers et al., 2019), WebText (Gokaslan and Cohen, 2019), and Common Crawl Stories (Trinh and Le, 2018)

Answer Generator	# Questions	EM	F1
NER	132729	59.3	70.5
Independent Spans	83534	77.2	87.1
Joint Spans	**229297**	**79.1**	**87.9**
Paragraph-level Joint Spans	226672	77.3	86.9
Human Generated Answers	42472	83.7	91.1

Table 9: Effect of answer generator modeling choices. Model based answer generation is performed with BERT-345M and questions are generated using a 1.2B parameter model. No filtration is applied to the generated questions.

cial for achieving reasonable question generation. We then examined the effect of stopword filtration in our question generator. Stop word filtration is performed by sampling autoregressively from the model and discarding the sample if the sample does not end with a ": question" token before the end of text. This is similar to forcing a question to end in a question mark. Stop word filtration therefore doesn't filter long or short results, it helps prevent samples that are malformed questions and don't end properly (i.e. randomly trail off with a preposition). We found that this provided a substantial boost to EM and F1 scores of 5.2 and 4.1 respectively. The goal of employing this technique was to catch generations that ramble onwards without stopping, or produce end of text prematurely in the middle of a question. On manual inspection we found qualitatively that this technique helped when generating questions on text that featured heavy use of symbols and foreign language. In these cases the model struggled with out of distribution vocabulary, autoregressive sampling degenerated, and no stopword was produced.

6.2 Answer Generation

In our experiments we found answer generation to be a significant bottleneck in performance. In section 5.2 we found that scaling up model size allows us to close the gap between human and synthetic training performance. However, these scaling analysis were performed with our best model. In Table 9 we show that the choice of model is critical to closing the gap. Starting with a Named Entity Recognition (NER) model we find that it gets a dismal EM and F1 score. This is due to entities comprising only of $\sim$ 50% of the answer distribution for SQuAD1.1 . It's necessary to use a learned model to model the diverse set of answers present SQuAD1.1 . We then tried to use the most common SQuAD1.1 model, which models the start and end of a span independently, to extract answers from individual sentences. This performed noticeably better, boosting our score to 77.2 EM, despite producing fewer answers than NER extraction. However, upon inspection we found that modeling the span independently resulted in sampling repetitive answers. We then tried using the answer generator from (Alberti et al., 2019a) which models the start and end of a span jointly as a conditional random field. This is the model we ended up choosing as it performed the best with an exact match score of 79.1. Lastly, we also considered jointly modeling answer spans over an entire paragraph instead of a single sentence. However, we found that it performed worse than independent span modeling over sentences.

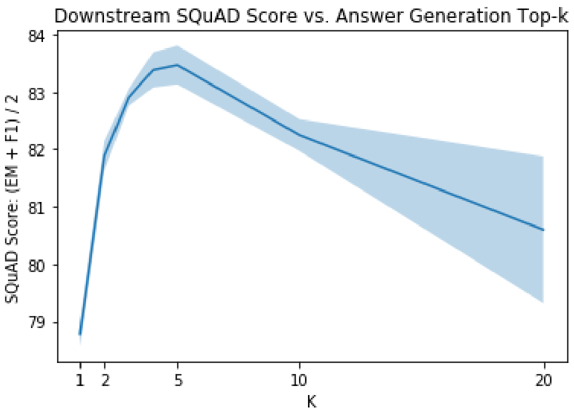

Figure 2: Effect of top-k answer generation on downstream SQuAD1.1 performance. For a particular value of k we sample all top-k candidate answers (within a nucleus of $p = 0.9$) from a sequence according to a 345M parameter answer generator.

When sampling our answer candidates we used all top-k answers comprising of the top-p ($p = 0.9$) nucleus of the distribution. We performed an ablation study to select k as we found that this had a noticeable impact on downstream accuracy. In Figure 2 we found that there was an optimal spot of $k = 5$ answers per sentence. When generating answers sampled from an entire paragraph we used $k = 24$ as we found that there were 4.86 sentences per paragraph on average. In general, answer generation proves to be a bottleneck in our question generation pipeline. The difficulty in answer generation is that not only must the answers be useful and well-formed, one must solve a one-to-many modeling problem to sample multiple answers from one passage. We believe that this might also be a contributing factor behind the poorer performance of the paragraph-level answer generation.

Filter Model	# Questions	345M QA		Large QA	
		EM	F1	EM	F1
Synthetic Questions + Real Answers					
None	42472	83.4	90.9	79.0	87.0
Roundtrip (RT)	24310	84.0	91.3	76.5	84.4
Overgenerate & RT	**47772**	**85.6**	**92.4**	**81.7**	**88.7**
Synthetic Questions + Synthetic Answers					
None	229297	79.1	87.9	78.2	86.8
Roundtrip (RT)	93866	86.3	92.7	84.1	90.5
Overgenerate & RT	**184992**	**87.1**	**93.2**	**85.2**	**91.5**
Human Generated Data	42472	86.3	93.2	82.4	89.7

Table 10: Effect of filtration modeling choices on questions generated from ground truth and synthetic answers. 1.2 billion parameter models are used for every stage of the generation pipeline. Questions from no filtration are used in the other experiments with a second set of questions generated in overgeneration experiments.

6.3 Question Filtration

Both question generation and answer generation sometimes produces poor answers. As we show in Table 10 generating synthetic data from synthetic answers without filtering deteriorates significantly, while roundtrip consistency combats this effect to perform 7.2 EM points better. However, we find that even on questions generated from ground truth answers roundtrip filtering throws away questions associated with perfectly good answers. Throwing away data significantly hurts BERT-Large whose pretrained features are not as robust as our BERT-345M model and require more finetuning data. To combat this we take an approach similar to overgeneration and reranking (Heilman and Smith, 2010a) where we generate two questions per answer and feed each into roundtrip filtration independently. We term this overgeneration and filtration. This helps avoid losing important answers in our synthesized training set. To perform overgeneration we sample one question with top-k ($k = 40$) sampling and one with top-p ($p = 0.9$) nucleus sampling. This leads approximately to a whole point of improvement for our model in both the case with and without ground truth answers.

7 Related Work

Early work using rule based question generation (Heilman and Smith, 2010b) proposed the idea of over-generating and re-ranking questions with regression models learned over handcrafted linguistic features. Du et al. (2017) used learned LSTM models on extractive question answering datasets such as SQuAD . These early works focused primarily on generating questions without explicit extracted answers in the text. Subramanian et al. (2017) proposed a two-stage neural model which added a model to estimate candidate answers and using the answers to generate questions. The current state of the art leverages transformer based language modeling including (Alberti et al., 2019a; Dong et al., 2019; Zhu et al., 2019; Klein and Nabi, 2019).

(Alberti et al., 2019a) uses seq2seq models to generate questions, and then enforce answer consistency on synthetic questions to filter out poorly generated questions in a technique called roundtrip consistency. (Dong et al., 2019) uses a unified transformer rather than a seq2seq model to generate QA data in conjunction with roundtrip consistency. (Zhu et al., 2019) learn a model that generates unanswerable questions from an answerable example.

The process of generating answers for answer-aware question generation in recent literature has primarily leveraged cloze fill-in-the-blank passages to highlight an answer in a given context. Some work uses NER or linguistic parsers to select passages for cloze translation as in (Lewis et al., 2019; Dhingra et al., 2018). These methods are only able to generate answers for a subset of questions as SQuAD1.1 is only made up of 52% Named Entity Answers. More recent work such as (Alberti et al., 2019a; Dong et al., 2019) use model based approaches to match the answer distribution of QA datasets and extract more complex answers.

To improve the quality of synthetic data generation and downstream QA models, improving language model quality is crucial. In addition to pretraining task innovation, BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2019) have showed that increasing the size of available pretraining data directly improves downstream discriminative task performance. T5 (Raffel et al., 2019), GPT-2 (Radford et al., 2019), CTRL (Keskar et al., 2019), Megatron-LM (Shoeybi et al., 2019), and (Puri and Catanzaro, 2019) have shown that increasing language model scale improves the quality, coherency, and correctness of text generation. The models used in (Raffel et al., 2019; Keskar et al., 2019; Radford et al., 2019; Puri and Catanzaro, 2019; Boyd et al., 2020) also demonstrate that larger models allow for better control in conditional language generation.

SQuAD style extractive question answering is not the only form of question answering. There are many other datasets covering a wide range of QA such as multihop (Yang et al., 2018; Welbl et al., 2018; Talmor and Berant, 2018), Yes-No question (Clark et al., 2019), trivia questions (Joshi et al., 2017; Dunn et al., 2017), analytical questions (Dua et al., 2019), conversational and generative QAs (Reddy et al., 2019), unanswerable questions (Rajpurkar et al., 2018; Alberti et al., 2019b), and large multitask question answering datasets (Talmor and Berant, 2019). While these are outside the scope of the current work, the insights developed improving quality for extractive SQUAD questions will aid question generation in other domains.

8 Conclusions and Future Work

We build upon existing work in large scale language modeling and question generation to push the quality of synthetic question generation. With our best models, we generate large question answering datasets from unlabeled Wikipedia documents and finetune a 345 million parameter BERT-style model achieving 88.4 EM score. Finetuning the resulting model on real SQUAD1.1 data further boosts the EM score to 89.4. This amounts to a 1.7 point improvement over our fully supervised baseline. Finally, we generate synthetic text from a Wikipedia-finetuned GPT-2 model, generate answer candidates and synthetic questions based on those answers, and then train a BERT-Large model and achieve similar question answering accuracy. Doing so required us to scale model size for our answer generators, question generators, and filtration models. We hope that better synthetic questions will enable new breakthroughs in question answering systems and related natural language tasks.

Of particular interest for future work is handling low-resource question answering domains. For such a regime, one needs to analyze the effect of domain transfer and bootstrapping from a very small human labelled dataset. Extension of this work to unanswerable and boolean questions is also a future work direction. More generally application of this work to multi dataset question generation with datasets such as MultiQA (Talmor and Berant, 2019) is a promising avenue for future work.

A Appendices

A.1 Question Generation Pipeline

Algorithm 1 Pipeline for generating and evaluating synthetic data.

```
1. Sample answer candidates from paragraphs using a BERT model.
2. Generate questions from answer candidates and paragraphs using a GPT-2 model.
3. Apply a BERT roundtrip consistency model to filter generated question answer pairs.
4. Train a BERT QA model using filtered synthetic questions and evaluate on development set.
```

A.2 Question Generation Input Representation

We develop a conditional question generation model, $p(q|a, c)$ using a pretrained GPT-2 model. As input to our model, we concatenate context tokens, answer tokens, and question tokens into a single sequence, separated by end of sequence tokens. We use three segment type embeddings to help the GPT-2 decoder model distinguish between different parts of the input. We also use answer segment type embeddings to highlight the presence of the answer span in the provided context tokens.

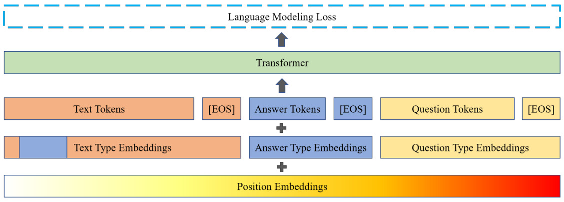

Figure 3: Question Generation input representation and language modeling loss. Answer type embeddings highlight the answer's presence in the text.

A.3 GPT-2 Pretraining Details

The GPT-2 models (Radford et al., 2019) used for question generation were each pretrained on the 174GB corpora used in Megatron-LM: Wikipedia (Devlin et al., 2018), OpenWebText (Gokaslan and Cohen, 2019), RealNews (Zellers et al., 2019), and CC-Stories (Trinh and Le, 2018). Unless otherwise noted, our GPT-2 models were trained at a batch size of 512 for 300k iterations with 3k iterations of warmup, Adamw (Loshchilov and Hutter, 2018) for optimization, a learning rate of 1.5e-4 decaying linearly to 1e-5, weight decay of 0.01, global gradient norm clipping of 1.0, and a normal initialization of $\theta \sim \mathcal{N}(0, 0.02)$.

A.4 BERT Pretraining Details

To train our BERT models we relied on a pretraining regime similar to ALBERT. We used a n-gram masked language modeling task in conjunction with a sentence order prediction task. Unlike ALBERT we did not utilize weight sharing and we used a GPT-2 style ordering of residual connections and layer normalization. We found this greatly improved stability and allowed us to train significantly larger BERT models than prior work (Lan et al., 2019) without encountering training instabilities and overfitting. We trained our BERT models with the same hyperparameters as GPT-2 except using learning rate of 1e-4 and a batch size of 1024 over 2 million iterations with 10k iterations of warmup.

A.5 Training and Evaluation Data Flow

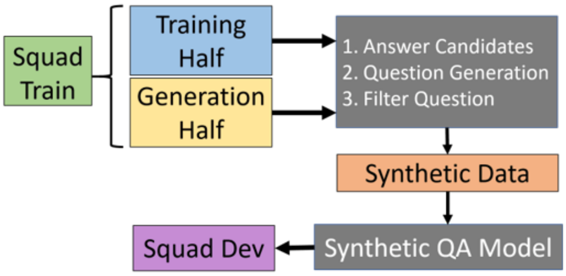

Figure 4: Data flow for training and evaluating question generation pipeline.

A.6 Training Infrastructure

All our models were trained with mixed precision training (Micikevicius et al., 2017) on NVIDIA V100 GPUs. Pretraining took place on anywhere from 4 to 32 DGX-2H servers for our largest models. Finetuning only required one DGX-1V, except in the case of finetuning the 8.3B parameter question generator which required eight DGX-1Vs.

A.7 Samples Generated from Wikipedia Documents

Below are synthetic question and answering pairs synthesized from real Wikipedia documents. Question and answer generation and filtration were performed by 1.2 billion parameter models finetuned over the entire SQuAD1.1 dataset. Generated answer spans are bolded in the text.

Question: What indicates there must be data deletion early on in the visual pathway?

Context: Evidence suggests that our visual processing system engages in bottom-up selection. For example, **inattentional blindness** suggests that there must be data deletion early on in the visual pathway. This bottom-up approach allows us to respond to unexpected and salient events more quickly and is often directed by attentional selection. This also gives our visual system the property of being goal-directed. Many have suggested that the visual system is able to work efficiently by breaking images down into distinct components. Additionally, it has been argued that the visual system takes advantage of redundancies in inputs in order to transmit as much information as possible while using the fewest resources.

Question: What type of antibiotic is cefalotin?

Context: Cefalotin (INN) or cephalothin (USAN) is a **first-generation cephalosporin** antibiotic. It was the first cephalosporin marketed (1964) and continues to be widely used. It is an intravenously administered agent with a similar antimicrobial spectrum to cefazolin and the oral agent cefalexin. Cefalotin sodium is marketed as Keflin (Lilly) and under other trade names.

Question: What did “Wanted Dead or Alive” rank on the Billboard Hot 100?

Context: “Wanted Dead or Alive” is a song by American rock band Bon Jovi. It is from their 1986 album ”Slippery When Wet”. The song was written by Jon Bon Jovi and Richie Sambora and was released in 1987 as the album’s third single. During a February 20, 2008 encore performance in Detroit, Jon Bon Jovi told the crowd about running into Bob Seger at a Pistons game. As he introduced his song “Wanted Dead or Alive”, he said it was inspired by Seger’s “Turn the Page” hit and called the song the band’s anthem. The song peaked at **#7** on the “Billboard” Hot 100 chart and #13 on the Mainstream Rock Tracks chart, making it the third single from the album to reach the Top 10 of the Hot 100. As a result, “Slippery When Wet” was the first hard rock/glam metal album to have 3 top 10 hits on the “Billboard” Hot 100.

Question: Who played the role of Othello in the scene?

Context: The book begins when Kostya and his fellow students are waiting for their first lesson with the Director. They are excited and nervous at the prospect of meeting, and are surprised when he tells them that their first exercise is to put on a few scenes from a play. Kostya and two of his friends perform scenes from “Othello”, with **Kostya** taking the leading role. Afterwards the Director tells them their mistakes.

Question: Who broke the Phantom’s mind?

Context: In the final episode of the game, it is revealed that Fulbright is in fact deceased, and that the Fulbright seen throughout the game is an international spy known as the Phantom posing as him, as well as the one behind most of the game’s major events. Seven years prior to the game’s events, the Phantom was the catalyst of the UR-1 Incident, having murdered Metis Cykes, Athena’s mother, sabotaged the HAT-1 shuttle, and leaving Simon Blackquill to take the fall for the crime after seemingly incriminating evidence was found to point to Simon as the only suspect. Simon willingly allowed himself to be imprisoned in order to protect Athena and to draw the Phantom out, but Athena suffered severe trauma from the ordeal, having believed for 7 years that she had actually murdered her mother, when in fact she stabbed the Phantom in the hand in self-defense. In the present day, the Phantom attempted to finish their case, murdering Clay Terran and bombing both the HAT-2 shuttle and a courtroom in a desperate attempt to destroy incriminating evidence from the UR-1 incident. The Phantom possesses a unique psychological makeup, showing very little, if any, emotion of any sort, nor any fear. The Phantom also has no sense of self, claiming they do not know what their original gender, face, nationality, or identity even was in the beginning; having taken on so many disguises and identities, the Phantom is an endless void. However, **Phoenix, Apollo, and Athena** eventually managed to break the emotionless Phantom severely in court, causing them to suffer a severe identity crisis, moments before an unseen sniper rifle takes the Phantom’s life.

Question: Who was Miss United Kingdom in 1997?

Context: **Vicki-Lee Walberg** (born 11 October 1975) is a model who was Miss United Kingdom in 1997, and made the top 10 at the Miss World 1997 pageant. She was the last title holder to advance to the semifinal of the contest. Walberg later went on to work in television and was a 'Dolly Dealer' in Bruce Forsyth's Play Your Cards Right on ITV during its 2002 revival.

Question: What was the final score for the Tottenham home match against Newcastle United?

Context: He scored his first Premier League hat-trick in a 4-0 away win on Boxing Day against Aston Villa. On 5 January 2013, Bale scored in the FA Cup third round fixture against Coventry City as well as assisting Clint Dempsey on both of his goals in a 3-0 win. On 30 January, Bale scored a magnificent solo effort in the 1-1 draw with Norwich City. Bale then scored against West Bromwich Albion in a 1-0 away win on 3 February. Bale then took his goal tally of the season to 15 goals with a brace against Newcastle United in a match which Spurs won **2-1**. This took Spurs into third place, and strengthened their Champions League ambitions.

Question: Who was arrested along with Ernst Sekunna?

Context: The arrests started in March 1917, with **Chandra Kanta Chakraverty** "a thin-faced, falsetto-voiced Hindu, a native of Bengal, and a speaker of many languages", and the German, Ernst Sekunna, being arrested on charges of conspiracy. Most of the others were arrested on April 8, including Franz Bopp, the German Consul General for San Francisco, E. H. von Schack, Deus Dekker and Wilhelm von Brincken. The Indian Nationalists were accused of taking "advantage of American neutrality to plot on American soil against the allies" at "the expense of the laws and hospitality of the United States". The two men had also taken out trade names to do business as "The Oriental Society", "The Oriental Kitchen",and the "Oriental Review", and purchased of land in an isolated part of New York State.

Question: What protected the hulls of the Chiyoda?

Context: "Chiyoda" was a belted cruiser based on a much scaled-down version of the Royal Navy's. The hull was made of 84 watertight compartments, protected with **Harvey armor**. Originally designed to carry 12.6 inch Canet guns, the plan was abandoned due to excessive top weight. Instead, the design was changed so that her main battery consisted of ten QF 4.7 inch /40 naval guns in single mounts, mounted one each in the bow and stern, and four on each side in sponsons. The use of the Elwick quick-firing technology resulted in an increase in the rate of fire by sixfold over previous cruiser designs. Her secondary battery consisted of 14 QF 3 pounder Hotchkiss and three 11-mm, 10-barrel Nordenfelt guns. She was also equipped with three Whitehead torpedo tubes mounted on the main deck. As was standard practice at the time, the prow was reinforced for ramming.

A.8 Samples Generated from GPT-2 Documents

Below are synthetic question and answering pairs synthesized from fake Wikipedia documents sampled unconditionally from an 8.3B GPT-2 model. Question and answer generation and filtration were performed by 1.2 billion parameter models finetuned over the entire SQuAD1.1 dataset. Generated answer spans are bolded in the text.

Question: What is a clique in a DAG?

Context: The main purpose of the conjecture is to quantify the perfect matchings of the vertices of a graph, in a way that can be related to the number of cliques. A perfect match of two vertices means that if the graph is "cut along the line segment connecting these two vertices", then the pair of vertices forms an optimal matching. A clique is **a small subgraph** that contains all but one pair of vertices in the graph and so these perfect matchings form an "array" of cliques with the same size as the original graph, and thus can be described by the same number of cliques.

Question: What property is the difference between Bis(diphenylphosphino)methane and benz(diphenylphosphino)methane?

Context: Bis(diphenylphosphino)methane has been found to be a **sterically hindered** isomer of benz(diphenylphosphino)methane (CHPH) and therefore it has an oxidation number of 1.

Question: When did Henry II invade Normandy?

Context: During the reign of Louis VII of France, Eleanor was awarded by her husband the County of Anjou. In **1157**, Henry II of England invaded Normandy to take possession of that duchy, defeating Louis's troops in the Battle of Brémule. Louis's grandson and heir, William Adelin, left Anjou for his home in the south of France, where he was crowned at Toulouse on 24 April 1158.

Question: What does Dick Grayson use as his name?

Context: Meanwhile, on his return to the fifth dimension, the leader of the Faceless Ones is killed in the ensuing battle and his daughter is captured. She asks the Faceless Ones for an escape plan and is told that she must first find her father's "labyrinth". The Faceless Ones then freeze her in time and her journey begins. Batman, now imprisoned in Arkham Asylum is visited by Dick Grayson in his new identity of **Nightwing**. Nightwing informs him that he has broken his parole and is now hunting him. Batman is shocked to discover that Nightwing has come to Arkham because of a deal he made with the Riddler to help him track down some of Batman's other enemies. Batman is sent by the Joker to assist Nightwing, Deadman, Deathstroke, and Lex Luthor, in tracking down Deadman's apparent killer. Batman eventually learns that the person who really killed Deadman was his fellow Justice League member, Zauriel. Zauriel is revealed to be a deeply troubled angel-like figure who blames the world for the suffering and death that he has witnessed as he has been with Batman since the death of Damian Wayne. The story arc culminated in a battle in the House of Mystery between the Spectre and Zauriel in an attempt to bring the demon back to Hell. In the end, Batman accepts Zauriel's invitation to follow him back to the fifth dimension to spare him any further pain and humiliation.

Question: Who do Jim, Pam, Dwight, Oscar, and Jim's father, Henry attend the wedding reception for?

Context: At the photo shoot, Andy Bernard (Ed Helms) and Erin Hannon (Ellie Kemper) go on a fake zombie honeymoon in the office, having an intimate moment that is interrupted when they encounter a horde of the undead. Michael and Dwight then stop the zombies from approaching Andy and Erin and create a barricade. The horde is scared off, but the building must be sealed off because the zombies have damaged the power generator, resulting in a total loss of power. After the power returns, Jim, Pam, Dwight, Oscar, and Jim's father, Henry (Brock Peters), begin gathering their families and friends to go to **Erin and Andy**'s wedding reception in the Scranton branch's conference room.

Question: What was the title of 50 Cent's first album?

Context: "I Got Mine" is a song by American rapper 50 Cent from his debut studio album "**Get Rich or Die Tryin'**" (2003). The song features a guest appearance from fellow New York City rapper Nas, who was also featured on the previous single from "Get Rich or Die Tryin'", "Hate Me Now".

Question: What happens to a star when it bursts into a thermonuclear reaction?

Context: When the star explodes, the material is compressed to several hundred times its original size, igniting a thermonuclear reaction. This reaction causes the star to **explode outward**. The first stage of the supernova explosion is not yet far enough away to reach this red giant stage, so the star is engulfed in a supernova explosion. As the star is heated up by the supernova explosion, the outer layers of the star collapse. The compression that occurred when the shock wave reached the star's surface begins to occur at the point where the star's surface meets its core. This core-surface compression heats up and accelerates the remaining core material, producing a shock wave that expands out from the core.

Question: What style was used in This Wonderful Life's production?

Context: In 2009, Maine College of Art (main campus) presented "This Wonderful Life" as the kick-off production to their 2009/2010 theater season. Director Todd Ziegler created a minimalist approach to the production, relying mostly on the basic premise and atmosphere of the film to create a world. The Main Stage theater was transformed into an **Art Deco**-esque set with minimal set pieces, provided by Redlich + Feuer Design. This setting was contrasted by the minimalistic approach to lighting, provided by Brian Claypool, that lent the production a somber tone. In keeping with the Art Deco styling, costume design and construction was done entirely by students of the Department of Theater and Dance. The music was provided by the joint choirs of the college and the Maine All State Honor Choir.

Question: Which road through the Texas scrublands is a controlled access road?

Context: The western terminus of US 83 is located on the southeast corner of the Texas-New Mexico border at the Van Horn, Texas-Van Horn, Texas city limit line. From the border the highway follows Texas State Highway 116, which crosses US 87 in Van Horn and overlaps US 70. US 83 then crosses US 87 again near Marfa, intersecting US 87 Business and Texas State Highway 292. US 83 continues west from Marfa along Highway 290, a route now called the Trans-Pecos Highway. While **US 290** is a controlled-access road, it still has a large number of at-grade intersections, due to the rugged terrain. Between Marfa and Valentine, US 83 travels through the Texas scrubland of the Big Bend.

Question: Who was in charge of the SOE during World War II?

Context: By 1939, the Republican cause was being supported by both the Soviet Union and the Third Reich. The SOE, led by **Colonel Hugh Sinclair**, had been active in the country since 1934, delivering weapons and propaganda material to the Republicans via agents such as future French Resistance leader Francois de La Rocque. This work came to an abrupt end in April 1939, when the Germans invaded the country. Sinclair organised a flight to France, but only about a dozen agents and journalists escaped from the country.

Few-Shot Complex Knowledge Base Question Answering via Meta Reinforcement Learning

Abstract

Complex question-answering (CQA) involves answering complex natural-language questions on a knowledge base (KB). However, the conventional neural program induction (NPI) approach exhibits uneven performance when the questions have different types, harboring inherently different characteristics, e.g., difficulty level. This paper proposes a meta-reinforcement learning approach to program induction in CQA to tackle the potential distributional bias in questions. Our method quickly and effectively adapts the meta-learned programmer to new questions based on the most similar questions retrieved from the training data. The meta-learned policy is then used to learn a good programming policy, utilizing the *trial* trajectories and their rewards for similar questions in the support set. Our method achieves state-of-the-art performance on the CQA dataset (Saha et al., 2018) while using only five trial trajectories for the top-5 retrieved questions in each support set, and meta-training on tasks constructed from only 1% of the training set. We have released our code at https://github.com/DevinJake/MRL-CQA.

1 Introduction

Knowledge-base question-answering (KBQA) interrogates a knowledge-base (KB) (Yin et al., 2016; Yu et al., 2017; Jin et al., 2019) by interpreting natural-language questions as logical forms (*annotations*), which can be directly executed on the KB to yield answers (*denotations*) (Pasupat and Liang, 2016). KBQA includes *simple questions* that retrieve answers from single-hop triples ("what is Donald Trump's nationality") (Berant et al., 2013; Yih et al., 2014), *multi-hop questions* that infer answers over triple chains of at least 2 hops under specific constraints ("who is the president of the European Union 2012") (Yih et al., 2016; Liang et al., 2017), and *complex questions* that involve set operations ("how many rivers flow through India and China") (Saha et al., 2019). In particular, complex question answering (CQA) (Saha et al., 2018) is a sophisticated KBQA task in which a sequence of discrete *actions*—e.g., set intersection and union, counting, comparison—needs to be executed, and is the subject of this paper.

Consider the complex question "How many rivers flow through India and China?". We first form a set of entities whose type is river and flow in China from the KB. We then form another set for rivers that flow through India. The answer is then generated by *counting* the entities in the *intersection* of the two sets. More concretely, the question is transformed into the action sequence "Select (China, flow, river), Intersection (India, flow, river), Count", which is executed on the KB to yield the answer. As such, the CQA task results in a massive search space beyond just entities in the KB and includes (lists of) Boolean values and integers. Multi-hop questions only require the join operator. In contrast, CQA requires various types of additional symbolic reasoning, e.g., logical, comparative, and quantitative reasoning (Shen et al., 2019; Ansari et al., 2019), where a more diverse array of complex queries is involved (Saha et al., 2019). The massive search space and complex queries make CQA considerably challenging and more complicated than multi-hop question answering.

Due to the difficulty of collecting annotations, the existing CQA dataset (Saha et al., 2018) only contains the denotations for each question. The literature takes two approaches to deal with the missing annotations. The first approach aims to transform learning a CQA model into learning by demonstration, aka imitation learning, where a *pseudo-gold* action sequence is produced for the questions in the training set (Guo et al., 2018). This is done by employing a blind search algorithm, i.e.,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5827–5837,
November 16–20, 2020.

breadth-first search (BFS), to find a sequence of actions whose execution would yield the correct answer. This pseudo-gold annotation is then used to train the programmer using teacher forcing, aka behaviour cloning. However, BFS inevitably produces a single annotation and is ignorant to many other plausible annotations yielding the correct answer. To alleviate this issue, a second approach was proposed based on reinforcement learning (RL) to use the search policy prescribed by the programmer (Hua et al., 2020; Neelakantan et al., 2016; Liang et al., 2017). Compared to BFS which is a blind search algorithm, the RL-trained programmer can be regarded as an informed search algorithm for target programs. Therefore, the RL policy not only addresses the limitation of the 1-to-1 mapping between the questions and annotations, but also produces reasonable programs faster than BFS.

The conventional approach to CQA is to train *one* model to fit the entire training set, and then use it for answering all complex questions at the test time. However, such a one-size-fits-all strategy is sub-optimal as the test questions may have diversity due to their inherently different characteristics (Huang et al., 2018). For instance, in the CQA dataset, the samples could be categorized into seven different types, e.g., those capturing logical/comparative/quantitative reasoning. The length and complexity of questions in one group are likely to differ from those in other groups. Therefore, action sequences relevant to different groups may have significant deviations, and it is hard to learn a one-size-fits-all model that could adapt to varied types of questions. An exception is (Guo et al., 2019), which proposes a few-shot learning approach, i.e., S2A, to solve the CQA problem with a retriever and a meta-learner. The retriever selects similar instances from the training dataset to form *tasks*, and the meta-learner is trained on these tasks to learn how to quickly adapt to a new task created by the target question of interest at the test time. However, Guo et al. (2019) make use of teacher forcing within the learning by demonstration approach, which suffers from the aforementioned drawbacks. Also, though S2A is the most similar to ours, the tasks are very different. S2A aims to answer *context-dependent* questions, where each question is part of a *multiple-turn* conversation. On the contrary, we consider the different task where the questions are *single-turn* and have no context. Thus, a novel challenge arises in retrieving accurate support sets without conversation-based context information.

In this paper, we propose a Meta-RL approach for CQA (MRL-CQA), where the model adapts to the target question by *trials* and the corresponding reward signals on the retrieved instances. In the meta-learning stage, our approach learns a RL policy across the tasks for both (i) collecting trial trajectories for effective learning, and (ii) learning to adapt programmer by effectively combining the collected trajectories.

The accumulated general knowledge acquired during meta-learning enables the model to generalize over varied tasks instead of fitting the distribution of data points from a single task. Thus, the tasks generated from tiny (less than 1%) portion of the training data are sufficient for meta learner to acquire the general knowledge. Our method achieves state-of-the-art performance on the CQA dataset with overall macro and micro F1 scores of 66.25% and 77.71%, respectively.

2 Meta-RL for Complex Question Answering

The problem we study in this paper is transforming a complex natural-language question into a sequence of actions, i.e., a sequence-to-sequence learning task. By executing the actions, relevant triples are fetched from the KB, from which the answer to the question is induced. We tackle this problem with few-shot meta reinforcement learning to decrease the reliance on data annotation and increase the accuracy for different questions.

Let $\boldsymbol{q}$ denote the input sequence, including the complex question and the KB artifacts, i.e., entities, relations, and types in KB that are relevant to the problem. Let $\boldsymbol{\tau}$ denotes the output sequence, i.e., an action sequence that the agent generates to answer the question. Let $R(\boldsymbol{\tau}|\boldsymbol{q}) \in [0, 1]$ denotes the partial reward feedback that tells whether or not the action sequence yields the correct answer. To simplify the notation, we denote the reward function by $R(\boldsymbol{\tau})$. The training objective is to maximize the expected reward by optimizing the parameter $\boldsymbol{\theta}$ of the policy $\pi(\boldsymbol{\tau}|\boldsymbol{q}; \boldsymbol{\theta})$, i.e., improving the accuracy of the policy in answering unseen questions. For the test, the agent needs to generate an action sequence $\boldsymbol{\tau}^*$ for the input sequence using a search algorithm, e.g., greedy decoding, which is then executed on KB to get the answer.

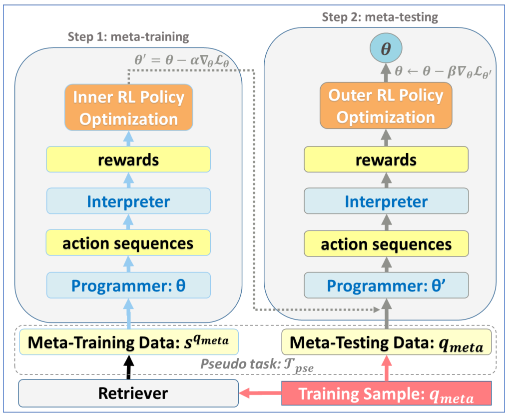

Figure 1: The high-level architecture of our approach.

2.1 Overview of the Framework

Our framework for few-shot learning of CQA is illustrated in Figure 1. In our framework, we view each new training question as the test sample of a pseudo task, and we aim to learn a specific model devoted to solving the task. When faced with a question $\boldsymbol{q_{meta}}$, we first employ the retriever to find top-N samples $\boldsymbol{s^{q_{meta}}}$ in the training dataset, which are the most similar to $\boldsymbol{q_{meta}}$. We consider $\boldsymbol{s^{q_{meta}}}$ as meta-training data used to learn a particular model, and view the question $\boldsymbol{q_{meta}}$ as the meta-testing data to evaluate the model. Therefore, meta-training data $\boldsymbol{s^{q_{meta}}}$ and meta-testing data $\boldsymbol{q_{meta}}$ form a pseudo task $\boldsymbol{\mathcal{T}_{pse}}$.

In the meta-training step (Step 1 in Figure 1), the action sequences that correspond to $\boldsymbol{s^{q_{meta}}}$ will be generated based on the current parameter $\boldsymbol{\theta}$ of the *programmer*. The *interpreter* executes the action sequences and evaluates the generated answers to produce rewards. The rewards lead to gradient updates that finetune the current model to get a task-specific *programmer* with the parameter of $\boldsymbol{\theta'}$. After that, in the meta-testing step (Step 2 in Figure 1), the actions of $\boldsymbol{q_{meta}}$ are produced based on $\boldsymbol{\theta'}$ and are evaluated to update $\boldsymbol{\theta}$. The training approach is depicted in Algorithm 1. In both the meta-training and meta-testing steps, REINFORCE (Williams, 1992) is used to optimize the *programmer*.

Similarly, in the inference phase, we consider each test question as a new individual task. We retrieve top-N data points from the training dataset to form the meta-training data. Instead of applying the general *programmer* with $\boldsymbol{\theta}$ directly, the meta-training data is used to finetune a specific parameter $\boldsymbol{\theta'}$ that fits the test question and infer the output.

2.2 Programmer and Interpreter

Programmer Our *programmer* is a sequence-to-sequence (Seq2Seq) model. Given the input sequence $\boldsymbol{q}$ with tokens $(w_1, \ldots, w_M)$, the *programmer* produces actions $(a_1, \ldots, a_T)$. The input sequence is the original complex question concatenated with the KB artifacts appear in the query, and the output is the words or tokens. The output at each time step is a single token.

In the *programmer*, the encoder is a Long Short Term Memory (LSTM) network that takes a question of variable length as input and generates an encoder output vector $\boldsymbol{e}_i$ at each time step i as: $(\boldsymbol{e}_i, \boldsymbol{h}_i) = LSTM[\phi_E(w_i), \boldsymbol{h}_{i-1}]$. Here $\phi_E(w_i)$ is word embedding of token w_i, and $(\boldsymbol{e}_i, \boldsymbol{h}_i)$ is the output and hidden vector of the i-th time step. The dimension of $\boldsymbol{e}_i$ and $\boldsymbol{h}_i$ are set as the same.

Our decoder of the *programmer* is another attention-based LSTM model that selects output token a_t from the output vocabulary $\mathcal{V}_{output}$. The decoder generates a hidden vector $\boldsymbol{g}_t$ from the previous output token a_{t-1}. The previous step's hidden vector $\boldsymbol{g}_{t-1}$ is fed to an attention layer to obtain a context vector $\boldsymbol{c}_t$ as a weighted sum of the encoded states using the standard attention mechanism. The current step's $\boldsymbol{g}_t$ is generated via $\boldsymbol{g}_t = LSTM\{\boldsymbol{g}_{t-1}, [\phi_D(a_{t-1}), \boldsymbol{c}_t]\}$, where ϕ_D is the word embedding of input token a_{t-1}. The decoder state $\boldsymbol{g}_t$ is used to compute the score of the target word $v \in \mathcal{V}_{output}$ as,

$$\pi(a_t = v|\boldsymbol{a}_{<t}, \boldsymbol{q}) = \mathrm{softmax}(\mathbf{W} \cdot \boldsymbol{g}_t + \boldsymbol{b})_v \quad (1)$$

where $\mathbf{W}$ and $\boldsymbol{b}$ are trainable parameters, and $\boldsymbol{a}_{<t}$ denotes all tokens generated before the time step t. We view all the weights in the *programmer* as the parameter $\boldsymbol{\theta}$, thus we have the probability that the *programmer* produces an action sequence $\boldsymbol{\tau}$ with tokens $\{a_1, ..., a_T\}$ as,

$$\pi(\boldsymbol{\tau}|\boldsymbol{q}; \theta) = \prod_{t=1}^{T} \pi(a_t = v|\boldsymbol{a}_{<t}, \boldsymbol{q}). \quad (2)$$

When adapting the policy to a target question, our *programmer* outputs action sequences following the distribution computed by equation 2. By treating decoding as a stochastic process, the *programmer* performs random sampling from the probability distribution of action sequences to increase the output sequences' diversity.

Interpreter After the *programmer* generates the entire sequence of actions, the *interpreter* executes the sequence to produce an answer. It compares the predicted answer with the ground-truth answer and outputs a partial reward. If the type of the output answer is different from that of the ground-truth answer, the action sequence that generates this answer will be given a reward of 0. Otherwise, to alleviate the sparse reward problem, the *interpreter* takes the Jaccard score of the output answer set and the ground-truth answer set as the partial reward, and sends it back to update parameters of the *programmer* as the supervision signal.

2.3 Meta Training and Testing

We formulate training of the programmer in a RL setting, where an agent interacts with an environment in discrete time steps. At each time step t, the agent produces an action (in our case a word/token) a_t sampled from the policy $\pi(a_t|\boldsymbol{a}_{<t}, \boldsymbol{q}; \boldsymbol{\theta})$, where $\boldsymbol{a}_{<t}$ denotes the sequence generated by the agent from step 1 to $t-1$, and $\boldsymbol{q}$ is the input sequence. The policy of the agent is the *programmer*, i.e., LSTM-attention model M with parameter $\boldsymbol{\theta}$. The natural-language question concatenated with the KB artifacts will be fed into the encoder as an input, and a sequence of actions is output from the decoder. In our work, we regard each action sequence produced by the model as one trajectory. The action sequence is therefore executed to yield a generated answer, and the similarity between the output answer with the ground-truth answer is then computed. The environment considers the similarity as the reward R corresponding to the trajectory $\boldsymbol{\tau}$ and gives it back to the agent. In standard RL, the parameter of the policy $\boldsymbol{\theta}$ is updated to maximize the expected reward, $\mathbb{E}_{\boldsymbol{\tau}\sim\pi(\boldsymbol{\tau}|\boldsymbol{q};\boldsymbol{\theta})}[R(\boldsymbol{\tau})]$.

In our work, answering each question in the training dataset is considered as an individual task, and a model adaptive to a new task is learned from the support set questions. To make the meta-learned model generalize to all unseen tasks, we sample the tasks following the distribution of tasks in the training dataset. We first sample a small subset of the questions Q_{meta} from the training dataset and expand the questions into tasks $\mathcal{T}_{meta}$ through retrieving the top-N samples, then extract a batch of tasks $\mathcal{T}'$ from $\mathcal{T}_{meta}$ under the distribution of tasks in $\mathcal{T}_{meta}$ to update parameters.

To fully use the training dataset and decrease training time, we study how to train a competitive model by using as few training samples as possible. As we view CQA as a RL problem under few-shot learning conditions, we make use of Meta-RL techniques (Finn et al., 2017) to adapt the programmer to a new task with a few training samples. Meta-RL aims to meta-learn an agent that can rapidly learn the optimal policy for a new task $\mathcal{T}$. It amounts to learn optimized $\boldsymbol{\theta}^*$ using K trial trajectories and the rewards for the support set of a new task.

We use the gradient-based meta-learning method to solve the Meta-RL problem such that we can obtain the optimal policy for a given task after performing a few steps of vanilla policy gradient (VPG) (Williams, 1992; Sutton et al., 2000). We divide the meta-learning process into two steps to solve a task, namely the meta-training step and the meta-testing step. Suppose we are trying to solve the pseudo-task $\mathcal{T}_{pse}$, which consists of N meta-training questions $\boldsymbol{s}^{\boldsymbol{q}_{meta}}$ that are the most similar to the meta-testing sample q_{meta}. The model first generates K trajectories for each question in $\boldsymbol{s}^{\boldsymbol{q}_{meta}}$ based on $\boldsymbol{\theta}$. The reward of each trajectory is given by the environment and then subsequently used to compute $\boldsymbol{\theta}'$ adapted to task $\mathcal{T}_{pse}$, as

$$\boldsymbol{\theta}' \leftarrow \boldsymbol{\theta} + \eta_1 \nabla_{\boldsymbol{\theta}} \sum_{\boldsymbol{q}\in \boldsymbol{s}^{\boldsymbol{q}_{meta}}} \mathbb{E}_{\boldsymbol{\tau}\sim\pi(\boldsymbol{\tau}|\boldsymbol{q};\theta)}[R(\boldsymbol{\tau})] \quad (3)$$

During meta-testing, another K' trajectories corresponding to question $\boldsymbol{q}_{meta}$ are further produced by $\boldsymbol{\theta}'$. The reward of K' trajectories are considered as the evaluation of the adapted policy $\boldsymbol{\theta}'$ for the given task $\mathcal{T}_{pse}$; thus we have the objective,

$$J(\boldsymbol{\theta}') \overset{\text{def}}{=} \mathbb{E}_{\boldsymbol{\tau}'\sim\pi(\boldsymbol{\tau}'|\boldsymbol{q}_{meta};\boldsymbol{\theta}')}[R(\boldsymbol{\tau}')] \quad (4)$$

The parameter of the generic policy $\boldsymbol{\theta}$ are then trained by maximising the objective $J(\boldsymbol{\theta}')$,

$$\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \eta_2 \nabla_{\boldsymbol{\theta}} J(\boldsymbol{\theta}') \quad (5)$$

In each VPG step, since we have N samples in $\boldsymbol{s}^{\boldsymbol{q}_{meta}}$, we use N policy gradient adaptation steps to update $\boldsymbol{\theta}'$. Meanwhile, we use one policy gradient step to optimize θ based on the evaluation of $\boldsymbol{\theta}'$. Monte Carlo integration is used as the approximation strategy in VPG (Guu et al., 2017). We summarise the meta-learning approach in Alg.1.

When making inferences, for each question $\boldsymbol{q}_{test}$, the retriever creates a pseudo-task, similar to the meta-learning process. The top-N similar questions to $\boldsymbol{q}_{test}$ form the support set $\boldsymbol{s}^{\boldsymbol{q}_{test}}$, and are used to obtain the adapted model $\boldsymbol{\theta}^{*'}$, starting from the meta learned policy $\boldsymbol{\theta}^*$. The adapted model is then used to generate the program and compute the target question's final answer.

Algorithm 1: Meta-RL (training time)

```
Input: Dataset $Q_{train}$, step size $\eta_1$, $\eta_2$
Output: Meta-learned policy $\boldsymbol{\theta}^*$
Randomly initialize $\boldsymbol{\theta}$
Randomly sample $Q_{meta} \sim Q_{train}$
Expand $Q_{meta} \rightarrow \mathcal{T}_{meta}$
while not done do
    Sample a batch of tasks $\mathcal{T}' \sim \mathcal{T}_{meta}$
    for $\mathcal{T}_{pse} \in \mathcal{T}'$ do
        $\mathcal{L} \leftarrow 0$
        for each question $\boldsymbol{q} \in \boldsymbol{s}^{\boldsymbol{q}_{meta}}$ do
            Sample $K$ trajectories: $\boldsymbol{\tau}_k \sim \pi(\boldsymbol{\tau}|\boldsymbol{q};\boldsymbol{\theta})$
            $\mathcal{L} \leftarrow \mathcal{L} + \frac{1}{K}\sum_{k=1}^{K} R(\boldsymbol{\tau_k}) logp_{\boldsymbol{\theta}}(\boldsymbol{\tau_k})$
        $\boldsymbol{\theta}' \leftarrow \boldsymbol{\theta} + \eta_1 \nabla_{\boldsymbol{\theta}} \mathcal{L}$
        Sample $K'$ trajectories: $\boldsymbol{\tau}_{k'} \sim \pi(\boldsymbol{\tau}|\boldsymbol{q}_{meta};\boldsymbol{\theta}')$
        $J_{\boldsymbol{q}_{meta}}(\boldsymbol{\theta}') \leftarrow \frac{1}{K'}\sum_{k'=1}^{K'} R(\boldsymbol{\tau}_{k'}) logp_{\boldsymbol{\theta}'}(\boldsymbol{\tau}_{k'})$
    $\boldsymbol{\theta} \leftarrow \boldsymbol{\theta} + \eta_2 \nabla_{\boldsymbol{\theta}} \sum_{\mathcal{T}_{pse} \in \mathcal{T}'} J_{\boldsymbol{q}_{meta}}(\boldsymbol{\theta}')$
Return The meta-learned policy $\boldsymbol{\theta}^* \leftarrow \boldsymbol{\theta}$
```

2.4 Question Retriever

We propose an unsupervised retriever that finds, from the training dataset, relevant support samples for the tasks in both the training and test phases. We propose a relevance function that measures the similarity between two questions in two aspects: (1) the number of KB artifacts (i.e., entities, relations, and types) in the questions and (2) question semantic similarity.

If the two questions have the same number of KB artifacts, the structure of their corresponding action sequences are more likely to be resembled. We calculate the similarity in terms of the number of entities of two questions $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ by $sim_e(\boldsymbol{q}_1, \boldsymbol{q}_2) = 1 - \frac{|q_e(\boldsymbol{q}_1) - q_e(\boldsymbol{q}_2)|}{\max(q_e(\boldsymbol{q}_1), q_e(\boldsymbol{q}_2))}$. The function $q_e(\boldsymbol{q})$ counts the number of entities in the question. Similarly, we compute the similarities in terms of relations and types in the same way with $sim_r(\boldsymbol{q}_1, \boldsymbol{q}_2)$ and $sim_t(\boldsymbol{q}_1, \boldsymbol{q}_2)$ respectively. The KB artifact similarity $sim_a(\boldsymbol{q}_1, \boldsymbol{q}_2)$ is computed by the product of the above three similarities.

For two questions, the more common words they have, the more semantically similar they are. Based on this intuition, we propose a semantic similarity function based on Jaccard similarity in an unsupervised way. Suppose there is a set of i words $\{w_1^1, ..., w_1^i\}$ in $\boldsymbol{q}_1$ and j words $\{w_2^1, ..., w_2^j\}$ in $\boldsymbol{q}_2$, and word similarity $sim(w^i, w^j)$ is calculating using the Cosine similarity.

For each word in $\boldsymbol{q}_1$, we first collect the word pairs from the words in $\boldsymbol{q}_2$, whose highest similarity exceeds a pre-defined threshold value. We denote with $sem_{int}(\boldsymbol{q}_1, \boldsymbol{q}_2)$ the sum of similarity values of the word pairs:

$$sem_{int}(\boldsymbol{q}_1, \boldsymbol{q}_2) = \sum_{m=1}^{i} (\max_{n=1}^{j}(sim(w_1^m, w_2^n))) \tag{6}$$

After removing this set of highly similar words from the two questions, we denote the remaining tokens as $\{w_1^{remain}\}$ and $\{w_2^{remain}\}$, which represent the different parts of the two questions. We sum up the embeddings of the words in $\{w_1^{remain}\}$ as $\mathbf{w}_1^{remain}$, and compute $\mathbf{w}_2^{remain}$ in the same way. The function $sem_{diff}(\boldsymbol{q}_1, \boldsymbol{q}_2)$ measures how different $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ are:

$$\begin{aligned} sem_{diff}(\boldsymbol{q}_1, \boldsymbol{q}_2) = \max(|\{w_1^{remain}\}|, |\{w_2^{remain}\}|) \\ *(1 - sim(\mathbf{w}_1^{remain}, \mathbf{w}_2^{remain})), \end{aligned} \tag{7}$$

where $|\{w\}|$ returns the cardinality of the set $\{w\}$.

We define the semantic similarity between $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ as: $sim_s(\boldsymbol{q}_1, \boldsymbol{q}_2) = \frac{sem_{int}(\boldsymbol{q}_1, \boldsymbol{q}_2)}{sem_{int}(\boldsymbol{q}_1, \boldsymbol{q}_2) + sem_{diff}(\boldsymbol{q}_1, \boldsymbol{q}_2)}$, and therefore calculate the similarity between $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$ with $sim_a(\boldsymbol{q}_1, \boldsymbol{q}_2) * sim_s(\boldsymbol{q}_1, \boldsymbol{q}_2)$.

3 Experiments

In this section, we present the empirical evaluation of our MRL-CQA framework.

Dataset. We evaluated our model on the large-scale CQA (Complex Question Answering) dataset (Saha et al., 2018). Generated from the Wikidata KB (Vrandecic and Krötzsch, 2014), CQA contains 944K/100K/156K QA pairs for training, validation, and testing, respectively. In the CQA dataset, each QA pair consists of a complex, natural-language question and the corresponding ground-truth answer (i.e., denotation). We note that annotations, i.e., gold action sequences related to the questions, are not given in the CQA dataset. The CQA questions are organized into seven categories of different characteristics, as shown in the Table 1. Some categories have entities as answers (e.g., "Simple Question"), while others have (lists of) numbers (e.g., "Quantitative (Count)") or Booleans (e.g., "Verification (Boolean)") as answers. The size of different categories in CQA is uneven. The number of instances in each category in the training set is 462K, 93K, 99K, 43K, 41K, 122K, and 42K for Simple Question, Logical Reasoning, Quantitative Reasoning, Verification (Boolean), Comparative Reasoning, Quantitative (Count), and Comparative (Count), respectively.

Based on the length of the induced programs and performance of the best models, we further organized the seven categories into two groups: *easy*—the first four categories, and *hard*—the last three types, in Table 1. We used the same evaluation metrics employed in the original paper (Saha et al., 2018), the F1 measure, to evaluate models.

Training Configuration. In the CQA dataset, since the annotated action sequence are not provided, we randomly sampled 1% of the training set (approx. 10K out of 944K training samples) and followed (Guo et al., 2019) to annotate them with pseudo-gold action sequences by using a BFS algorithm. We denoted the 1% questions and relevant pseudo-gold action sequences as Q_{pre}. The Q_{pre} was used to train the LSTM-based programmer, which was further optimized through the Policy Gradient (PG) algorithm (Williams, 1992; Sutton et al., 2000) with another 1% unannotated questions from the training set. We denoted this model by **PG**, which is also a model variant proposed in (Hua et al., 2020). We trained the meta learner on another 2K training samples (Q_{meta} in Alg.1), representing only approx. 0.2% of the training set. This meta learner is our full model: **MRL-CQA**.

In our work, we chose the attention-based LSTM model instead of the Transformer (Vaswani et al., 2017) to design the *programmer*. We set the sizes of embedding and hidden units in our LSTM model as 50 and 128 respectively, thus the maximum number of the parameters in our model is about 1.2M. However, the base model of the Transformer (12 layers, 12 heads, and 768 hidden units) has 110M parameters (Wolf et al., 2019), which are much more than those of our model. Given the small size of the training samples and the weak supervision signal (reward in our work), it is harder to train the model with more parameters. Therefore we chose LSTM rather than the Transformer.

We implemented our model in PyTorch and employed the Reptile meta-learning algorithm to optimize the meta-learned policy (Nichol and Schulman, 2018). The weights of the model and the word embeddings were randomly initialized and further updated within the process of training. In meta-learning, we set $\eta_1 = 1e-4$ (Equation 3) and $\eta_2 = 0.1$ (Equation 5). We set $N = 5$ and threshold value at 0.85 when forming the support set. For each question, we generate five action sequences to output the answers. The Adam optimizer is used in RL to maximizes the expected reward.

Among the baseline models, we ran the open-source code of KVmem (Saha et al., 2018) and CIPITR (Saha et al., 2019) to train the model. As the code of NSM (Liang et al., 2017) has not been made available, we re-implemented it and incorporated our programmer to predict programs, and employed the reinforcement learning settings in NSM to optimize the programmer. When inferring the testing samples, we used the top beam, i.e., the predicted program with the highest probability in the beam to yield the answers. We presented the best result we got to compare the baseline models.

3.1 Model Comparisons

We evaluated our model, MRL-CQA, against three baseline methods on the CQA dataset: KVmem, NSM, and CIPITR. It must be pointed out that CIPITR separately trained *one single model for each of the seven question categories*. We denote the model learned in this way as **CIP-Sep**. CIPITR also trained *one single model over all categories of training instances* and used this single model to answer all questions. We denote this single model as **CIP-All**. We separately present the performance of these two variations of CIPITR in Table 1. On the contrary, we tuned MRL-CQA on all categories of questions with one set of model parameters.

Table 1 summarizes the performance in F1 of the six models on the test set of CQA, organised into seven question categories. We note that the first four categories (first four rows in Table 1) are relatively simple, and the last three (middle three rows) are more challenging. We also report the overall macro and micro F1 values (last two rows).

As can be seen, our MRL-CQA model achieves the overall best macro and micro F1 values, achieving state-of-the-art results of 66.25% and 77.71%, respectively. MRL-CQA also achieves the best or second-best performance in six out of the seven categories. Of the three hardest categories (the last three types in Table 1), MRL-CQA delivers the best performance in all three types. This validates the effectiveness of our meta-learning-based approach in

Table 1: Performance comparison (measured in F1) of the seven methods on the CQA test set. For each category, best result is **bolded** and second-best result is underlined.

Question category	**KVmem**	**NSM**	**CIP-All**	**CIP-Sep**	**PG**	**MRL-CQA**
Simple Question	41.40%	<u>88.83%</u>	41.62%	**94.89%**	85.20%	88.37%
Logical Reasoning	37.56%	80.21%	21.31%	**85.33%**	78.23%	<u>80.27%</u>
Quantitative Reasoning	0.89%	36.68%	5.65%	33.27%	<u>44.22%</u>	**45.06%**
Verification (Boolean)	27.28%	58.06%	30.86%	61.39%	<u>84.42%</u>	**85.62%**
Comparative Reasoning	1.63%	<u>59.45%</u>	1.67%	9.60%	59.43%	**62.09%**
Quantitative (Count)	17.80%	58.14%	37.23%	48.40%	<u>61.80%</u>	**62.00%**
Comparative (Count)	9.60%	32.50%	0.36%	0.99%	<u>38.53%</u>	**40.33%**
Overall macro F1	19.45%	59.12%	19.82%	47.70%	<u>64.55%</u>	**66.25%**
Overall micro F1	31.18%	74.68%	31.52%	73.31%	<u>75.40%</u>	**77.71%**

effectively learning task-specific knowledge. Note that the two categories that MRL-CQA performs the best, Comparative Reasoning and Comparative (Count), both account for less than 5% of the training set, which further demonstrates our model's excellent adaptability.

Also, our RL-based programmer PG achieves second-best result in overall macro and micro F1, with about 2% difference below MRL-CQA. Moreover, PG achieves second-best in four categories. Such strong performance indicates the effectiveness of our CQA framework.

Besides the above main result, several important observations can be made from Table 1.

1. CIP-Sep got the best result in two categories, i.e., "Simple Question" and "Logical Reasoning". However, it performed poorly for the three hard categories. Consequently, the overall macro F1 value of CIP-Sep is substantially lower than both PG and MRL-CQA. Note that CIP-Sep trained a different model separately for each of the seven question categories. The results reported for each category were obtained from the models tuned specifically for each category (Saha et al., 2019), which necessitated a classifier to be trained first to recognize the question categories. Thus, CIP-Sep needs to re-train the models to adapt to new/changed categories, which impedes it from generalizing to unseen instances. However, we tuned our models on all questions with one set of model parameters, disregarding the question category information.

2. As presented in Table 1, CIP-All, the model that trained over all types of the questions, performed much worse in all the categories than CIP-Sep. A possible reason for CIP-All's significant performance degradation is that it is hard for such a one-size-fits-all model to find the weights that fit the training data when the examples vary widely. Besides, the imbalanced classes of questions also deteriorate the performance of the model. Different from CIPITR, MRL-CQA is designed to adapt appropriately to various categories of questions with one model, thus only needs to be trained once.

3. Our programmer and carefully-defined primitive actions presented in this work were used in our re-implementation of NSM. In the hard categories, by comparing the F1 scores of PG and MRL-CQA, it could be observed that NSM performed competitively. Furthermore, NSM performed the second best in "Simple Question" and "Comparative Reasoning" categories. This helps to validate the effectiveness of our proposed techniques. However, NSM is worse than MRL-CQA in six out of the seven categories. This verifies the adaptability of our model, which can quickly adapt to new tasks by employing the learned task-specific knowledge.

Note that our model was trained only on 1% of the training set, whereas the baseline models use the entire training set. Besides, our method trains one model to solve all questions, while CIP-Sep trains seven models, one for each category of problems. Thus our model is compared with seven individually trained models in CIPITR but still achieves the best overall performance, demonstrating the effectiveness of our technique.

3.2 Model Analysis

We conduct an ablation experiment to study the effect of meta-learning. We also study the effect of smaller training samples by comparing MRL-CQA's performance trained on 500 and 1K samples, against 2K used in the full model.

Table 2: Ablation study on the test set on macro F1 score change with different sizes of training samples.

Feature	Overall macro F1
PG	75.40%
MRL-CQA	
500-training	+0.01%
1,000-training	+0.58%
2,000-training	+2.31%

Table 2 summarizes the ablation study result. Trained on 500 samples only, MRL-CQA slightly improves performance by 0.01 percentage points compared to PG. When training sample increases to 1K, MRL-CQA outperforms PG by 0.58 percentage points. The full MRL-CQA model, trained on 2K samples, achieves a performance improvement over PG of 2.31 percentage points. These results demonstrate the ability to design a specific model for answering each question precisely, which is afforded by meta-learning.

3.3 Case Study

We provide a case study of different types of questions that MRL-CQA could answer, but our RL-based model, aka PG, could not solve. The comparison is given in Table 3, which lists the action sequences and the corresponding results these two models predicted when answering the same questions. We highlight the different parts of the action sequences that the two models generated.

For example, when answering the Logical Reasoning question in Table 3, PG was confused about what relations should be used to form feasible actions. It could be seen that PG failed to distinguish the two different relations for the two actions and thus produced a wrong answer.

Similarly, when answering the Verification question in Table 3, PG also yielded an infeasible action sequence. After forming a set of political territories that Hermine Mospointner is a citizen of, the bool action should be used to judge whether Valdeobispo and Austria are within the set. It can be seen that PG missed one action: *Bool (Austria)*.

The different optimization goals lead to the different results of the two models. PG, as a typical one-size-fits-all model, aims to estimate the globally optimal parameters by fitting itself to the training samples. Such a model extracts the information from the training data to update model parameters, applies the parameters to the new samples without modification thereafter. Therefore, when facing a wide variety of questions, it is hard for the model to find a set of parameters that fits all samples. Under the circumstances, like what is presented in Table 3, such a one-size-fits-all model could not handle the questions well.

However, our MRL-CQA model aims to learn general knowledge across tasks and fix the knowledge into the initial parameters. We thus learn a model that can subsequently adapt the initial parameters to each new given question and specialize the adapted parameters to the particular domain of the new questions. Therefore, with the help of the adapted parameters, MRL-CQA can answer each new question more precisely than PG.

4 Related Work

Imitation Learning. Imitation Learning aims to learn the policy based on the expert's demonstration by supervised learning. Saha et al. (2018) propose a CQA model that combines Hierarchical Recurrent Encoder-Decoder (HRED) with a Key-Value memory (KVmem) network and predicts the answer by attending on the stored memory. Guo et al. (2018) present a Dialog-to-Action (D2A) approach to answer complex questions by learning from the annotated programs. D2A employs a deterministic BFS procedure to label questions with pseudo-gold actions and trains an encoder-decoder model to generate programs by managing dialog memory. Multi-task Semantic Parsing (MaSP) (Shen et al., 2019) jointly optimizes two modules to solve the CQA task, i.e., entity linker and semantic parser, relying on annotations to demonstrate the desired behaviors. Different from the above approaches, our model performs better while removing the need for annotations.

Neural Program Induction (NPI). NPI is a paradigm for mapping questions into executable programs by employing neural models. Neural-Symbolic Machines (NSM) (Liang et al., 2017) is proposed to answer the multi-hop questions. NSM annotates the questions and then anchors the model to the high-reward programs by assigning them with a deterministic probability. Neural-Symbolic Complex Question Answering (NS-CQA) model (Hua et al., 2020) augments the NPI approach with a memory buffer to alleviate the sparse reward and data inefficiency problems appear in the CQA task. Complex Imperative

Table 3: A comparison of the action sequences and results that PG (the second column) and MRL-CQA (the third column) yield when answering the same questions.

An Example of Logical Reasoning Question

Question Information	PG	MRL-CQA
Question: Which occupations are the professions of Sergio Piacentini **or** were a position held by Antoinette Sandbach?	**Action sequence:** *Select (Sergio Piacentini, position_held, occupation)* *Union (Antoinette Sandbach, position_held, occupation)*	**Action sequence:** *Select (Sergio Piacentini, occupation_of, occupation)* *Union (Antoinette Sandbach, position_held, occupation)*
Ground-truth answer: Member of the National Assembly for Wales, association football manager, association football player	**Execution result:** Member of the National Assembly for Wales	**Execution result:** Member of the National Assembly for Wales, association football manager, association football player

An Example of Verification (Boolean) Question

Question Information	PG	MRL-CQA
Question: Is Hermine Mospointner a civilian of Valdeobispo **and** Austria?	**Action sequence:** *Select (Hermine Mospointner, country_of_citizenship, political territory)* *Bool (Valdeobispo)*	**Action sequence:** *Select (Hermine Mospointner, country_of_citizenship, political territory)* *Bool (Valdeobispo)* *Bool (Austria)*
Ground-truth answer: False and True	**Execution result:** False	**Execution result:** False and True

Program Induction from Terminal Rewards (CIPITR) (Saha et al., 2019) relies on auxiliary awards, KB schema, and inferred answer types for training an NPI model to solve the CQA task. However, CIPITR separately trains one model for each category of questions with a different difficulty level. Compared with the NPI models, our model can flexibly adapt to the question under processing.

Meta-learning. Meta-learning, aka learning-to-learn, aims to make learning a new task more effective based on the inductive biases that are meta-learned in learning similar tasks in the past. Huang et al. (2018) use MAML to learn a Seq2Seq model to convert questions in WikiSQL into SQL queries. More closely related to our work, Guo et al. (2019) propose Sequence-to-Action (S2A) by using MAML to solve CQA problems. They label all the examples in training set with pseudo-gold annotations, then train an encoder-decoder model to retrieve relevant samples and a Seq2Seq based semantic parser to generate actions based on the annotations. Unlike S2A, we introduce a Meta-RL approach, which uses RL to train an NPI model without annotating questions in advance.

5 Conclusion

CQA refers to answering complex natural language questions on a KB. In this paper, we propose a meta-learning method to NPI in CQA, which quickly adapts the programmer to unseen questions to tackle the potential distributional bias in questions. We take a meta-reinforcement learning approach to effectively adapt the meta-learned programmer to new questions based on the most similar questions retrieved. To effectively create the support sets, we propose an unsupervised retriever to find the questions that are structurally and semantically similar to the new questions from the training dataset. When evaluated on the large-scale complex question answering dataset, CQA, our proposed approach achieves state-of-the-art performance with overall macro and micro F1 score of 66.25% and 77.71%, respectively.

In the future, we plan to improve MRL-CQA by designing a retriever that could be optimized jointly with the programmer under the meta-learning paradigm, instead of manually pre-defining a static relevance function. Other potential directions of research could be toward learning to cluster questions into fine-grained groups and assign each group a set of specific initial parameters, making the model finetune the parameters more precisely.

Abstract

Offensive content is pervasive in social media and a reason for concern to companies and government organizations. Several studies have been recently published investigating methods to detect the various forms of such content (e.g. hate speech, cyberbulling, and cyberaggression). The clear majority of these studies deal with English partially because most annotated datasets available contain English data. In this paper, we take advantage of English data available by applying cross-lingual contextual word embeddings and transfer learning to make predictions in languages with less resources. We project predictions on comparable data in Bengali, Hindi, and Spanish and we report results of 0.8415 F1 macro for Bengali, 0.8568 F1 macro for Hindi, and 0.7513 F1 macro for Spanish. Finally, we show that our approach compares favorably to the best systems submitted to recent shared tasks on these three languages, confirming the robustness of cross-lingual contextual embeddings and transfer learning for this task.

1 Introduction

Offensive posts on social media result in a number of undesired consequences to users. They have been investigated as triggers of suicide attempts and ideation, and mental health problems (Bonanno and Hymel, 2013; Bannink et al., 2014). One of the most common ways to cope with offensive content online is training systems to be capable of recognizing offensive messages or posts. Once recognized, such offensive content can be set aside for human moderation or deleted from the respective platform (e.g. Facebook, Twitter), preventing harm to users and controlling the spread of abusive behavior in social media.

There have been several recent studies published on automatically identifying various kinds of offensive content such as abuse (Mubarak et al., 2017), aggression (Kumar et al., 2018, 2020), cyber-bullying (Rosa et al., 2019), and hate speech (Malmasi and Zampieri, 2018). While there are a few studies published on languages such as Arabic (Mubarak et al., 2020) and Greek (Pitenis et al., 2020), most studies and datasets created so far include English data. Data augmentation (Ghadery and Moens, 2020) and multilingual word embeddings (Pamungkas and Patti, 2019) have been applied to take advantage of existing English resources to improve the performance in systems dealing with languages other than English. To the best of our knowledge, however, state-of-the-art cross-lingual contextual embeddings such as XLM-R (Conneau et al., 2019) have not yet been applied to offensive language identification. To address this gap, we evaluate the performance of cross-lingual contextual embeddings and transfer learning (TL) methods in projecting predictions from English to other languages. We show that our methods compare favorably to state-of-the-art approaches submitted to recent shared tasks on all datasets. The main contributions of this paper are the following:

1. We apply cross-lingual contextual word embeddings to offensive language identification. We take advantage of existing English data to project predictions in three other languages: Bengali, Hindi, and Spanish.
2. We tackle both off-domain and off-task data for Bengali. We show that not only can these methods project predictions for different languages but also for different domains (e.g. Twitter vs. Facebook) and tasks (e.g. binary vs. three-way classification).
3. We provide important resources to the community: the code, and the English model will be freely available to everyone interested in working on low-resource languages using the same methodology.

November 16–20, 2020.

2 Related Work

There is a growing interest in the development of computational models to identify offensive content online. Early approaches relied heavily on feature engineering combined with traditional machine learning classifiers such as naive bayes and support vector machines (Xu et al., 2012; Dadvar et al., 2013). More recently, neural networks such as LSTMs, bidirectional LSTMs, and GRUs combined with word embeddings have proved to outperform traditional machine learning methods in this task (Aroyehun and Gelbukh, 2018; Majumder et al., 2018). In the last couple of years, transformer models like ELMO (Peters et al., 2018) and BERT (Devlin et al., 2019) have been applied to offensive language identification achieving competitive scores and topping the leaderboards in recent shared tasks (Liu et al., 2019; Ranasinghe et al., 2019). Most of these approaches use existing pre-trained transformer models which can also be used as text classification models.

The clear majority of studies on this topic deal with English (Malmasi and Zampieri, 2017; Yao et al., 2019; Ridenhour et al., 2020) partially motivated by the availability English resources (e.g. corpora, lexicon, and pre-trained models). In recent years, a number of studies have been published on other languages such as Arabic (Mubarak et al., 2020), Danish (Sigurbergsson and Derczynski, 2020), Dutch (Tulkens et al., 2016), French (Chiril et al., 2019), Greek (Pitenis et al., 2020), Italian (Poletto et al., 2017), Portuguese (Fortuna et al., 2019), Slovene (Fišer et al., 2017), and Turkish (Çöltekin, 2020) creating new datasets and resources for these languages.

Recent competitions organized in 2020 such as TRAC (Kumar et al., 2020) and OffensEval (Zampieri et al., 2020) have included datasets in multiple languages providing participants with the opportunity to explore cross-lingual learning models opening exciting new avenues for research on languages other than English and, in particular, on low-resource languages. The aforementioned deep learning methods require large annotated datasets to perform well which is not always available for low-resource languages. In this paper, we address the problem of data scarcity in offensive language identification by using transfer learning and cross-lingual transformers from a resource rich language like English to three other languages: Bengali, Hindi, and Spanish.

3 Data

We acquired datasets in English and three other languages: Bengali, Hindi, and Spanish (listed in Table 1). The four datasets have been used in shared tasks in 2019 and 2020 allowing us to compare the performance of our methods to other approaches. As our English dataset, we chose the Offensive Language Identification Dataset (OLID) (Zampieri et al., 2019a), used in the SemEval-2019 Task 6 (OffensEval) (Zampieri et al., 2019b). OLID is arguably one of the most popular offensive language datasets. It contains manually annotated tweets with the following three-level taxonomy and labels:

A: Offensive language identification - offensive vs. non-offensive;

B: Categorization of offensive language - targeted insult or thread vs. untargeted profanity;

C: Offensive language target identification - individual vs. group vs. other.

We chose OLID due to the flexibility provided by its hierarchical annotation model that considers multiple types of offensive content in a single taxonomy (e.g. targeted insults to a group are often *hate speech* whereas targeted insults to an individual are often *cyberbulling*). This allows us to map OLID level A (offensive vs. non-offensive) to labels in the other three datasets. OLID's annotation model is intended to serve as a general-purpose model for multiple *abusive language detection subtasks* (Waseem et al., 2017). The transfer learning strategy used in this paper provides us with an interesting opportunity to evaluate how closely the OLID labels relate to the classes in datasets annotated using different guidelines and sub-task definitions (e.g. *aggression* and *hate speech*).

The Hindi dataset (Mandl et al., 2019) was used in the HASOC 2019 shared task, while the Spanish dataset (Basile et al., 2019) was used in SemEval-2019 Task 5 (HatEval). They both contain Twitter data and two labels. The Bengali dataset (Bhattacharya et al., 2020) was used in the TRAC-2 shared task (Kumar et al., 2020) on aggression identification. It is different than the other three datasets in terms of domain (Facebook instead of Twitter) and set of labels (three classes instead of binary), allowing us to compare the performance of cross-lingual embeddings on off-domain data and off-task data.

Lang.	Inst.	S	Labels
Bengali	4,000	F	overtly aggressive, covertly aggressive, non aggressive
English	14,100	T	offensive, non-offensive
Hindi	8,000	T	hate offensive, non hate-offensive
Spanish	6,600	T	hateful, non-hateful

Table 1: Instances (Inst.), source (S) and labels in all datasets. F stands for Facebook and T for Twitter.

4 Methodology

Transformer models have been used successfully for various NLP tasks (Devlin et al., 2019). Most of the tasks were focused on English language due to the fact the most of the pre-trained transformer models were trained on English data. Even though, there were several multilingual models like BERT-m (Devlin et al., 2019) there was much speculations about its ability to represent all the languages (Pires et al., 2019) and although BERT-m model showed some cross-lingual characteristics it has not been trained on crosslingual data (Karthikeyan et al., 2020). The motivation behind this methodology was the recently released cross-lingual transformer models - XLM-R (Conneau et al., 2019) which has been trained on 104 languages. The interesting fact about XLM-R is that it is very compatible in monolingual benchmarks while achieving the best results in cross-lingual benchmarks at the same time (Conneau et al., 2019). The main idea of the methodology is that we train a classification model on a resource rich, typically English, using a cross-lingual transformer model, save the weights of the model and when we initialise the training process for a lower resource language, start with the saved weights from English. This process is also known as transfer learning and is illustrated in Figure 1.

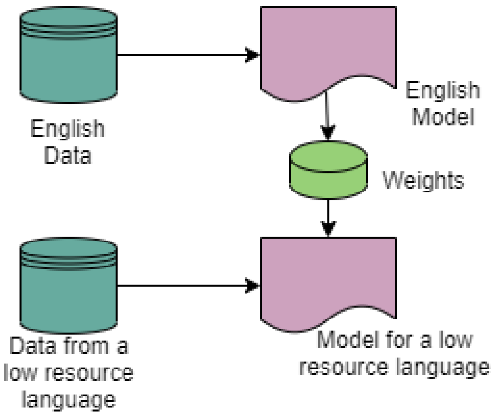

Figure 1: Transfer learning strategy.

There are two main parts of the methodology. Subsection 4.1 describes the classification architecture we used for all the languages. In Subsection 4.2 we describe the transfer learning strategies used to take advantage of English offensive language data in predicting offense in less-resourced languages.

4.1 XLM-R for Text Classification

Similar to other transformer architectures XLM-R transformer architecture can also be used for text classification tasks (Conneau et al., 2019). XLM-R-large model contains approximately 125M parameters with 12-layers, 768 hidden-states, 3072 feed-forward hidden-states and 8-heads (Conneau et al., 2019). It takes an input of a sequence of no more than 512 tokens and outputs the representation of the sequence. The first token of the sequence is always [CLS] which contains the special classification embedding (Sun et al., 2019).

For text classification tasks, XLM-R takes the final hidden state **h** of the first token [CLS] as the representation of the whole sequence. A simple softmax classifier is added to the top of XLM-R to predict the probability of label c: as shown in Equation 1 where W is the task-specific parameter matrix.

$$p(c|\mathbf{h}) = softmax(W\mathbf{h}) \quad (1)$$

We fine-tune all the parameters from XLM-R as well as W jointly by maximising the log-probability of the correct label. The architecture diagram of the classification is shown in Figure 2. We specifically used the XLM-R large model.

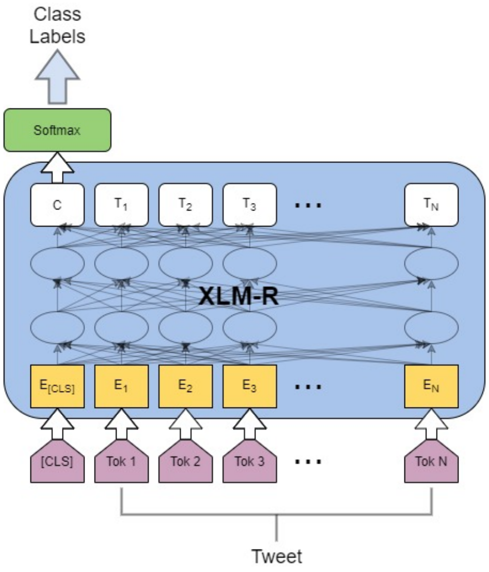

Figure 2: Text classification architecture with XLM-R.

4.2 Transfer-learning strategies

When we adopt XLM-R for multilingual offensive language identification, we perform transfer learning in two different ways.

Inter-language transfer learning We first trained the XLM-R classification model on first level of English offensive language identification dataset (OLID) (Zampieri et al., 2019a). Then we save the weights of the XLM-R model as well as the softmax layer. We use these saved weights from English to initialise the weights for a new language. To explore this transfer learning aspect we experimented on Hindi language which was released for HASOC 2019 shared task (Mandl et al., 2019) and on Spanish data released for Hateval 2019 (Basile et al., 2019).

Inter-task and inter-language transfer learning Similar to the inter-language transfer learning strategy, we first trained the XLM-R classification model on the first level of English offensive language identification dataset (OLID) (Zampieri et al., 2019a). Then we only save the weights of the XLM-R model and use the saved weights to initialise the weights for a new language. We did not use the weights of the last softmax layer since we wanted to test this strategy on data that has a different number of offensive classes to predict. We explored this transfer learning aspect with Bengali dataset released with TRAC - 2 shared task (Kumar et al., 2020). As described in the Section 3 the classifier should make a 3-way classification in between 'Overtly Aggressive', 'Covertly Aggressive' and 'Non Aggressive' text data.

We used a Nvidia Tesla K80 GPU to train the models. We divided the dataset into a training set and a validation set using 0.8:0.2 split on the dataset. We predominantly fine tuned the learning rate and number of epochs of the classification model manually to obtain the best results for the validation set. We obtained $1e^{-}5$ as the best value for learning rate and 3 as the best value for number of epochs for all the languages. Training for English language took around 1 hour while training for other languages took around 30 minutes. The code and the pretrained English model is available on GitHub.[1]

5 Results and Evaluation

We evaluate the results obtained by all models using the test sets provided by the organizers of each competition. We compared our results to the best systems in TRAC-2 for Bengali, HASOC for Hindi, HatEval for Spanish in terms of weighted and macro F1 score according to the metrics reported by the task organizers - TRAC-2 reported only macro F1, HatEval reported only weighted F1, and HASOC reported both.

Finally, we evaluate the improvement of the transfer learning strategy in the performance of both BERT and XLM-R. We present the results along with the majority class baseline for each language in Table 2. *TL* indicates that the model used the inter language transfer learning strategy described in Subsection 4.2.

Language	**Model**	**M F1**	**W F1**
Bengali	XLM-R (TL)	0.8415	0.8423
	Risch and Krestel (2020)	0.8219	
	BERT-m (TL)	0.8197	0.8231
	XLM-R	0.8142	0.8188
	BERT-m	0.8132	0.8157
	Baseline	0.2498	0.4491
Hindi	XLM-R (TL)	0.8568	0.8580
	BERT-m (TL)	0.8211	0.8220
	Bashar and Nayak (2019)	0.8149	0.8202
	XLM-R	0.8061	0.8072
	BERT-m	0.8025	0.8030
	Baseline	0.3510	0.3798
Spanish	XLM-R (TL)	0.7513	0.7591
	BERT-m (TL)	0.7319	0.7385
	Vega et al. (2019)		0.7300
	Pérez and Luque (2019)		0.7300
	XLM-R	0.7224	0.7265
	BERT-m	0.7215	0.7234
	Baseline	0.3700	0.4348

Table 2: Results ordered by macro (M) F1 for Bengali and weighted (W) F1 for Hindi and Spanish.

For Hindi, transfer learning with XLM-R cross lingual embeddings provided the best results achieving 0.8568 and 0.8580 weighted and macro F1 score respectively. In HASOC 2019 (Mandl et al., 2019), the best model by Bashar and Nayak (2019) scored 0.8149 Macro F1 and 0.8202 Weighted F1 using convolutional neural networks.

For Spanish transfer learning with XLM-R cross lingual embeddings also provided the best results achieving 0.7513 and 0.7591 macro and weighted F1 score respectively. The best two models in HatEval (Basile et al., 2019) for Spanish scored 0.7300 macro F1 score. Both models applied SVM classi-

---

[1] The public GitHub repository are available on `https://github.com/tharindudr/DeepOffense`

fiers trained on a variety of features like character and word n-grams, POS tags, offensive word lexicons, and embeddings.

The results for Bengali deserve special attention because the Bengali data is off-domain with respect to the English data (Facebook instead of Twitter), and it contains three labels (covertly aggressive, overtly aggressive, and not aggressive) instead of the two labels present in the English dataset (offensive and non-offensive). *TL* indicates that the model used the inter-task, inter-domain, and inter-language transfer learning strategy described in Subsection 4.2. Similar to the Hindi and Spanish, transfer learning with XLM-R cross lingual embeddings provided the best results for Bengali achieving 0.7513 and 0.7591 macro and weighted F1 respectively thus outperforming the other models by a significant margin. The best model in the TRAC-2 shared task (Kumar et al., 2020) scored 0.821 weighted F1 score in Bengali using a BERT-based system.

We look closer at the test set predictions by XLM-R (TL) for Bengali in Figure 3. We observe that the performance for the non-aggressive class is substantially better than the performance for the overtly aggressive and covertly aggressive classes following a trend observed by the TRAC-2 participants including Risch and Krestel (2020).

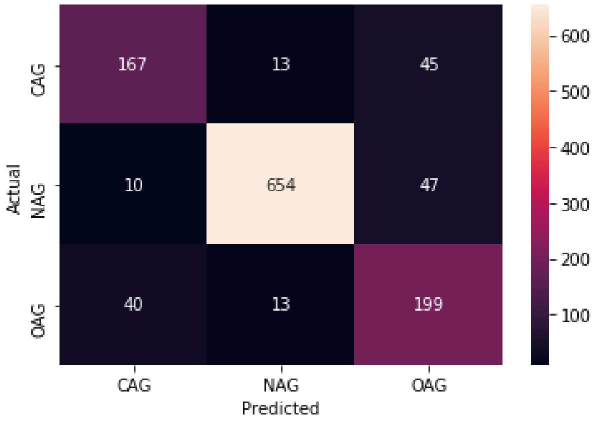

Figure 3: Heat map of the Bengali test set predictions by XLM-R (TL).

Finally, it is clear that in all the experimental settings, the cross-lingual embedding models fine-tuned with transfer learning, outperforms the best system available for the three languages. Furthermore, the results show that the cross-lingual nature of the XLM-R model provided a boost over the multilingual BERT model in all languages tested.

6 Conclusion

This paper is the first study to apply cross-lingual contextual word embeddings in offensive language identification projecting predictions from English to other languages using benchmarked datasets from shared tasks on Bengali (Kumar et al., 2020), Hindi (Mandl et al., 2019), and Spanish (Basile et al., 2019). We have showed that XLM-R with transfer learning outperforms all of the other methods we tested as well as the best results obtained by participants of the three competitions.

The results obtained by our models confirm that OLID's general hierarchical annotation model encompasses multiple types of offensive content such as *aggression*, included in the Bengali dataset, and *hate speech* included in the Hindi and Spanish datasets, allowing us to model different subtasks jointly using the methods described in this paper. Furthermore, the results we obtained for Bengali show that it is possible to achieve high performance using transfer learning on off-domain (Twitter vs. Facebook) and off-task data when the labels do not have a direct correspondence in the projected dataset (two in English and three in Bengali). This opens exciting new avenues for future research considering the multitude of phenomena (e.g. *hate speech, aggression, cyberbulling*), annotation schemes and guidelines used in offensive language datasets.

In future work, we would like to further evaluate our models using SOLID, a novel large English dataset with over 9 million tweets (Rosenthal et al., 2020), along with datasets in four other languages (Arabic, Danish, Greek, and Turkish) that were made available for the second edition of OffensEval (Zampieri et al., 2020). These datasets were collected using the same methodology and were annotated according to OLID's guidelines. Finally, we would also like to apply our models to languages with even less resources available to help coping with the problem of offensive language in social media.

Acknowledgement

We would like to thank the HASOC, HatEval, and OffensEval shared task organizers for making the datasets used in this paper available.

We further thank the anonymous EMNLP reviewers for providing us with valuable feedback to improve this paper.

Abstract

We solve difficult word-based substitution codes by constructing a decoding lattice and searching that lattice with a neural language model. We apply our method to a set of enciphered letters exchanged between US Army General James Wilkinson and agents of the Spanish Crown in the late 1700s and early 1800s, obtained from the US Library of Congress. We are able to decipher 75.1% of the cipher-word tokens correctly.

1 Introduction

Cryptography has been used since antiquity to encode important secrets. There are many unsolved ciphers of historical interest, residing in national libraries, private archives, and recent corpora collection projects (Megyesi et al., 2019; Pettersson and Megyesi, 2019). Solving classical ciphers with automatic methods is a needed step in analyzing these materials.

In this work, we are concerned with automatic algorithms for solving a historically-common type of *book code*, in which word tokens are systematically replaced with numerical codes. Encoding and decoding are done with reference to a dictionary possessed by both sender and recipient. While this type of code is common, automatic decipherment algorithms do not yet exist. The contributions of our work are:

- We develop a algorithm for solving dictionary-based substitution codes. The algorithm uses a known-plaintext attack (exploiting small samples of decoded material), a neural language model, and beam search.
- We apply our algorithm to decipher previously-unread messages exchanged between US Army General James Wilkinson and agents of the Spanish Crown in the late 1700s and early 1800s, obtaining 72.1% decipherment word accuracy.

Code (word)	Rossignols' Grand Chiffre	Mexico-Nauen code Scovell code Wilkinson code *(this work)*

Figure 1: Simplified typology of substitution-based cryptosystems, with some examples. Ciphers involve character-level substitutions (e.g, $f \rightarrow q$), while codes involve word-level substitutions (e.g., *forest* → *5731*).

2 Related Work

Figure 1 gives a simplified typology of classical, substitution-based cryptosystems.[1]

Table-based Ciphers involve character-based substitutions. The substitution may take the form of a simple offset, as in the Caesar substitution system, e.g., ($a \rightarrow d$), ($b \rightarrow e$), ($c \rightarrow f$), etc. The Caesar cipher can be easily solved by algorithm, since there are only 26 offsets to check. The algorithm need only be able to recognize which of the 26 candidate plaintexts form good English. Since 25 of the candidates will be gibberish, even the simplest language model will suffice.

A *simple substitution cipher* uses a substitution table built by randomly permuting the alphabet. Since there are $26! \approx 4 \cdot 10^{26}$ possible tables, algorithmic decipherment is more difficult. However, there are many successful algorithms, e.g., (Hart, 1994; Knight and Yamada, 1999; Hauer et al., 2014; Olson, 2007; Ravi and Knight, 2008; Corlett and Penn, 2010). Many of these systems

---

[1] Our typology is geared toward explaining our contribution in the context of related systems. For a fuller picture of classical cryptology, the reader is directly to Kahn (1996) and Singh (2000). For example, we do not discuss here systems in which a substitution key evolves during the encoding process, such as the Vigenère cipher or the German Enigma machine.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5845–5854,
November 16–20, 2020.

search for substitution tables that result in candidate plaintexts that score well according to a character n-gram language model (Shannon, 1951), and they use search techniques like hill-climbing, expectation-maximization, beam search, and exact search. The main practical challenge is to decipher short messages. In a very long ciphertext, it is easy to "spot the *q*" because it is always followed by the same cipher character, which we can immediately guess stands for plaintext *u*, and so forth.

More sophisticated ciphers use *homophonic* substitution, in which plaintext characters are replaced non-deterministically. By applying high nondeterminism to frequent characters, the cryptographer can flatten out ciphertext character frequencies. Homophonic ciphers occur frequently in historical collections. The Copiale cipher (Knight et al., 2011) is a well-known example from a German secret society in the 1700s. These ciphers can also be attacked successfully by algorithm. For example, the homophonic Zodiac 408 cipher can be solved with EM with restarts (Berg-Kirkpatrick and Klein, 2013), Bayesian sampling (Ravi and Knight, 2011), or beam search (Nuhn et al., 2014) (all with n-gram character language models). Kambhatla et al. (2018) employ a more powerful character-based neural language model to break short ciphers more accurately. In the present work, we use a word-based neural language model.

Book-based ciphers increase homophony, and also avoid physical substitution tables that can be stolen or prove incriminating. In a book-based cipher, sender and recipient verbally agree up front on an innocuous-looking shared document (the "book"), such as the US Declaration of Independence, or a specific edition of the novel *Moby Dick*. When enciphering a plaintext letter token like *f*, the sender selects a random letter *f* from the shared document—if it is the 712th character in the document, the plaintext *f* might be enciphered as *712*. The next plaintext *f* might be enciphered differently.

Nuhn et al. (2014) solve one of the most well-known book ciphers, part two of the Beale Cipher (King, 1993). Surprisingly, they treat the cipher as a regular homophonic cipher, using the same beam-search algorithm as for the table-based Zodiac 408 cipher, together with an 8-gram character language model. One might imagine exploiting the fact that the book is itself written in English, so that if ciphertext unit *712* is known to be *f*, then ciphertext unit *713* is probably not *h*, as *fh* is unlikely to appear in the book. Nuhn et al. (2014)'s simple, effective algorithm ignores such constraints. Other methods have been proposed for attacking book ciphers, such as *crib dragging* Churchhouse (2002).

Codes, in contrast to ciphers, make substitutions at the whole-word level.[2] A large proportion of the encrypted material in Megyesi et al. (2019) consists of **table-based codes**. A famous example is Antoine Rossignol's *Grand Chiffre*, used during the reign of Louis XIV. The sender and receiver each own copies of huge specially-prepared tables that map words onto numbers (e.g., *guerre* → *825*). If the enciphering tables are kept secret, this type of code is very hard to break. One might guess that the most frequent cipher token stands for the word *the*, but it quickly becomes challenging to decide which number means *practice* and which means *paragon*. Even so, Dou and Knight (2012) take on the task of automatically deciphering newswire encrypted with an arbitrary word-based substitution code, employing a slice-sampling Bayesian technique. Given a huge ciphertext of ∼50,000 words, they can decipher ∼50% of those tokens correctly. From one billion ciphertext tokens, they recover over 90% of the word tokens. However, this method is clearly inapplicable in the world of short-cipher correspondence.

In the present work, we consider **book-based codes**. Instead of using specially-prepared tables, the sender and receiver verbally agree to use an already-existing book as a key. Because it may be difficult to find a word like *paragon* in a novel like *Moby Dick*, the sender and receiver often agree on a shared pocket dictionary, which has nearly all the words. If *paragon* were the 10,439th word in the dictionary, the sender might encode it as *10439*.

Such codes have been popular throughout history, employed for example by George Scovell during the Napoleonic Wars (Urban, 2002), and by John Jay during the US Revolutionary War (Blackwood, 2009). They were used as late as World War II, when German diplomats employed the *Langenscheidt's Spanish-German Pocket Dictionary* as a key to communicate between the cities of Chapultepec, Mexico and Nauen, Germany (NSA,

---

[2] Commonly, a single historical system will mix letter substitutions and word substitutions. Such a system is called a *nomenclator*.

	Word tokens	Word types
Deciphered letters	approx. 800	326
Evaluation set	483	226
Test set	341	192

Table 1: Summary of transcribed data. Deciphered and evaluation sets have gold-standard decipherments; the evaluation set is held out. The test set has no gold-standard decipherment.

2011). In that case, the US Coast Guard intercepted messages and was able to make a bit of headway in deciphering them, but the real breakthrough came only when they obtained the applicable dictionary (key).

Unfortunately, there appear to be no automatic algorithms for solving book-based codes without the key.[3] According to Dunin and Schmeh (2020):

> "So far, there are no computer programs for solving codes and nomenclators available. This may change, but in the time being, solving a code or nomenclator message is mainly a matter of human intelligence, not computer intelligence."

In this paper, we develop an algorithm for automatically attacking book-based codes, and we apply it to a corpus of historically-important codes from the late 1700s.

3 Wilkinson Letters

Our cipher corpus consists of letters to and from US General James Wilkinson, who first served as a young officer in the US Revolutionary War. He subsequently served as Senior Officer of the US Army (appointed by George Washington) and first Governor of the Louisiana Territory (appointed by Thomas Jefferson). Wilkinson also figured in the Aaron Burr conspiracy (Isenberg, 2008).

Long after his death, letters in a Cuban archive revealed the famous Wilkinson to be an agent of the Spanish Crown during virtually his entire service, and his reputation collapsed (Linklater, 2009).

Table 1 summarizes our Wilkinson correspondence data.[4] We transcribe scans of manuscripts in the US Library of Congress. We have 73pp of undeciphered text (Figure 3a) and 28pp of deciphered text (Figure 3b), with some overlap in content. Deciphered correspondence, with plaintext above ciphertext, likely resulted from manual encryption/decryption carried out at the time.

4 Encryption Method

As is frequent in book codes, there are two types of substitutions. Some plaintext words are enciphered using a large shared table that maps words onto numbers (**table-based code**). Other words are mapped with a shared dictionary (**book-based code**). Despite serious efforts, we have not been able to obtain the dictionary used in these ciphers.

In our transcription, we mark entries from the table portion with a caret over a single number, e.g., [123]^. Before [160]^, the table seems to contain a list of people or place names; between [160]^ ("a") and [1218]^ ("your"), a list of common words in alphabetic order; and finally more common words. The last block was likely added after the initial table was constructed, suggesting that the table was used to avoid having to look up common words in the dictionary.

The ciphertext for the dictionary code has two numbers that mark a word's dictionary page and row number, respectively, plus one or two bars over the second number indicating the page column. For example, 123.[4]= refers to the fourth row of the second column of the 123rd page in the dictionary. From the distribution of cipher tokens, the dictionary is about 780 pages long with 29 rows per column, totaling about 45,000 words.

The cipher usually does not contain regular inflected forms of words, though inflections are sometimes marked with a superscript (e.g., $^{+ing}$). Numbers and some words are left in plaintext. Long horizontal lines mark the ends of sentences, but other punctuation is not marked.

5 Automatic Decryption Method

As the corpus includes a handful of deciphered pages, we employ a known-plaintext attack (Kahn, 1996).

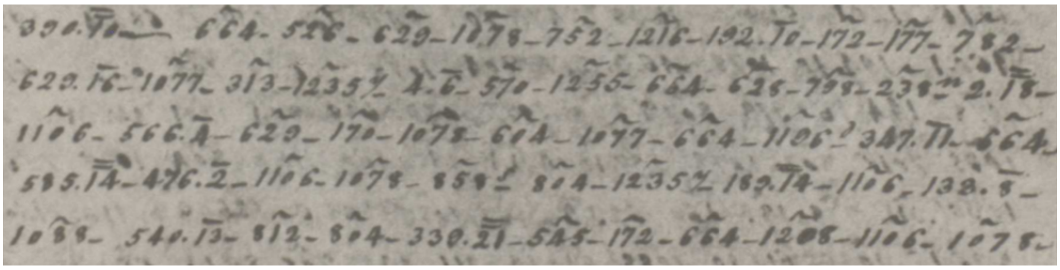
We first extract a small *wordbank* of known mappings, shown in Figure 3. Next, we apply the wordbank to our held-out evaluation ciphertext. We find that 40.8% of word tokens can be deciphered, mainly common words. After this step, we render a ciphertext as:

```
I ? he the man you ? and ? very ? that
```

---

[3] Kahn (1996) suggests that national security services have long ago digitized all published books and applied brute-force to find the book that renders a given code into natural plaintext.

[4] All data is included with our released code (https://github.com/c2huc2hu/wilkinson/).



```

This is not yet a useful result. However, the wordbank also helps us to recover the rest of the plaintext. Since both the table and dictionary are in alphabetical order, we use the wordbank to constrain the decipherment of unknown words.

For example, given cipher word [163]ˆ, we know from Figure 3 that its plaintext must lie somewhere between the two anchor-words [160]ˆ (which stands for "a") and [172]ˆ (which stands for "and"). Moreover, it is likely to be closer to "a" than "and". Repeating this for every cipher word in an undeciphered document, we construct a word lattice of all possible decipherments, shown in Figure 4. Our goal is then to search for the most fluent path through this lattice. Following are the details of our method:

Anchors. To propose candidate words between two anchors, we use a modern lemma-based dictionary with 20,770 entries.[5] In this dictionary, for example, there are 1573 words between "attachment" and "bearer".

Probabilities. We assign a probability to each candidate based on its distance from the ideal candidate. For example, in the table code, [163]ˆ is 30% of the way from [160]ˆ to [172]ˆ (Figure 5), so our ideal candidate decipherment of [172]ˆ will be 30% of the way between "a" and "and" in our modern dictionary. To apply this method to the dictionary code, we convert each cipher word's page/column/row to a single number n (the "Index" in Figure 3), which estimates that the cipher word corresponds to the nth word in the shared dictionary.

We use a beta distribution for assigning probabilities to candidate words, because the domain is bounded. We parameterize the distribution $B'(x; m, \beta)$ with mode m and sharpness parameter β=5. This is related to the standard parameterization, $B(x; \alpha, \beta)$, by:

$$B'(x; m, \beta) = B\left(x; \alpha = \frac{m\beta - 2m + 1}{1 - m}, \beta\right)$$

The sample space (0 to 1) is divided equally between the M words in the modern dictionary, so the i^{th} word gets probability:

$$\int_{\frac{i-1}{M}}^{\frac{i}{M}} B'(x; m, \beta) dx$$

In our example, because [163]ˆ is 30% of the way from [160]ˆ to [172]ˆ, we have $m = 0.3$. There are $M = 650$ words in the modern dictionary between these two anchors, so the $i = 105^{th}$ word ("access"), gets probability 0.00231.

Inflections. We expand our lattice to include inflected forms of words (e.g., "find" → "find", "found", "finding"). We generate inflections with the *Pattern* library (De Smedt and Daelemans, 2012). Some words are generated more than once, e.g., "found" is both a base verb and the past tense of "find". *Pattern* inflects some uncommon words incorrectly, but such inflections are heavily penalized in the best-path step. Inflections divide the probability of the original word equally.

Table edge cases. We replace unknown entries before the first anchor in the table with an arbitrary proper noun ("America"), and words outside the alphabetic section of the table with equal probability over a smaller vocabulary containing the 1000 most common words.[6]

Scoring lattice paths. After we have constructed the lattice, we automatically search for the best path. The best path should be fluent English (i.e., assigned high probability by a language model), and also be likely according to our wordbank (i.e., contain high-probability lattice transitions).

To score fluency, we use the neural GPT2 word-based language model (Radford et al., 2019), pretrained on ~40GB of English text. We use the

---

[6] simple.wiktionary.org/wiki/Wiktionary:BNC_spoken_freq_01HW

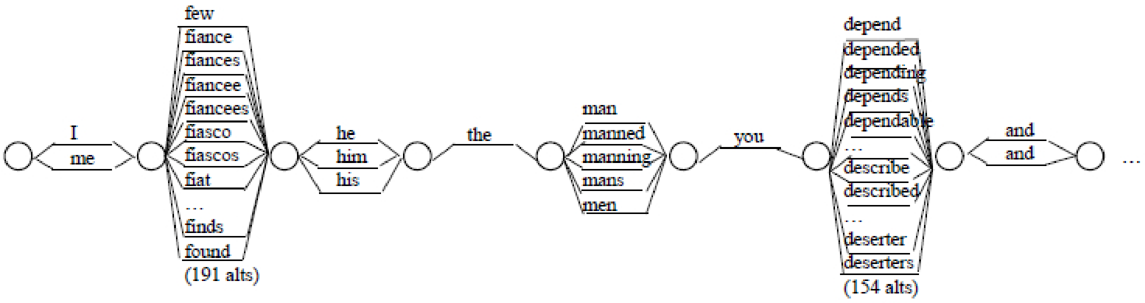

Figure 4: Turning an encrypted letter into a lattice of possible decipherments. Segments with few alternatives come from wordbank substitutions (and their automatically-produced morphological variants), while other segments come from interpolation-based guesses. Each link has an associated probability (not shown here). On average, we supply 692 alphabetically-close alternatives per segment, but supply fewer than ten for most.

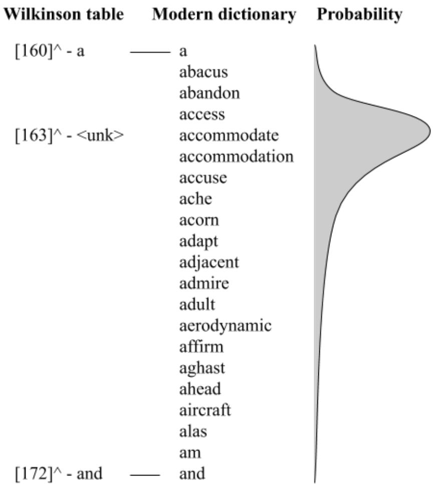

Figure 5: Interpolating a ciphertext word not present in the wordbank. When deciphering [163]^, we list candidate decipherments using a modern dictionary. We assign probabilities to candidates based on interpolation between anchor words, in this case "a" and "and".

HuggingFace implementation[7] with 12 layers, 768 hidden units, 12 heads, and 117M parameters.

Neural language models have significantly lower perplexity than letter- or word-based n-gram language models. For example, Tang and Lin (2018) benchmark WikiText-103 results for a Kneser-Ney smoothed 5-gram word model (test perplexity = 152.7) versus a quasi-recurrent neural network model (test perplexity = 32.8). This gives neural language models a much stronger ability to distinguish good English from bad.

Beam search. We search for the best lattice path using our own beam search implementation. To score a lattice transition with GPT, we must first tokenize its word into GPT's subword vocabulary. Since alphabetically-similar words often start with the same subword, we create a subword trie at each lattice position; when a trie extension falls off the beam, we can efficiently abandon many lattice transitions at once.

6 Evaluation

To evaluate, we hold out one deciphered document from wordbanking. Some plaintext in that document is unreadable or damaged, so decryptions are added when known from the wordbank or obvious from context.

Table 2 gives our results on per-word-token decipherment accuracy. Our method is able to recover 73.8% of the word tokens, substantially more than using the wordbank alone (40.8%). We also outperform a unigram baseline that selects lattice paths consisting of the most popular words to decipher non-wordbank cipher tokens (46.9%).

The maximum we could get from further improvements to path-extraction is 91.3%, as 8.7% of correct answers are outside the lattice. This is due to unreadable plaintext, limitation of our modern dictionary, use of proper names [1]^ to [159]^, transcription errors, etc.

Table 3 details the effect of beam size on decipherment accuracy, runtime, and path score (combining GPT log probability with lattice scores). Increasing beam size leads us to extract paths with better scores, which correlate experimentally with higher task accuracy.

Figure 6 shows a portion of our solution versus the gold standard.

For tokens where our system output does not match the original plaintext, we asked an outside annotator to indicate whether our model captures

Method	Token accuracy
Apply wordbank	40.8
Unigram baseline	46.9
Our method, beam size = 1	68.3
Our method, beam size = 4	73.0
+ domain-tuning	73.2
+ self-learning	**75.1**
Our method, beam size = 16	73.8
+ domain-tuning + self-learning	75.1
Oracle	91.3

Table 2: Token decipherment accuracy. The Unigram baseline selects the most frequent word at each point in the lattice. Our method uses beam search to extract the path with highest GPT and lattices scores. Oracle selects the path through the lattice that most closely matches the gold decipherment.

Beam size	Runtime	Internal Best Path Score	Task Accuracy
1	1m 38s	-3714.9	68.3
4	6m 19s	-3569.6	73.0
16	25m 31s	-3544.9	73.8

Table 3: Effect of beam size on decipherment. A larger beam lets us extract paths with better internal scores, which correlate with better task accuracy.

the same meaning. For example, when our system outputs "I am much sorry" instead of "I am very sorry," the annotator marks all four words as *same-meaning*. Under this looser criterion, accuracy rises from 73.0% to 80.1%.

We also decipher a Wilkinson ciphertext letter for which we have no plaintext. Transcription is less accurate, as we cannot confirm it using decipherment. The letter also includes phrases in plaintext French, which we translate to English before adding them to the lattice. Despite these challenges, the model still outputs relatively fluent text, including, for example: "…as may tend most powerfully and most directly to dissolve the whole America of the first states from the east and to cease the intercourse of the west." This passage is consistent with Wilkinson's plan to seek independence for parts of America.

7 Additional Methods

We experiment with three additional decipherment methods.

Weighted scoring. When scoring paths, we sum log probabilities from GPT and the lattice transitions, with the two sources equally weighted. This turns out to be optimal. Table 4 gives results when we multiply the lattice-transition score by a.

a	Accuracy	β	Accuracy
0.2	70.5	1	67.8
0.5	71.6	3	71.6
1	**73.0**	5	**73.0**
2	72.2	10	70.7

Table 4: Effects on decipherment accuracy of a (weight applied to lattice scores vs. GPT scores for each path) and β (sharpness parameter for candidate-word probabilities).

Halving the weight of the lattice scores degrades accuracy from 73.0 to 71.6 (-1.4 for beam=4), while doubling it degrades from 73.0 to 72.2 (-0.8 for beam=4). Table 4 also shows the impact of the sharpness parameter β on accuracy.

Domain-tuned language model. We collect letters written by Wilkinson[8] totalling 80,000 word tokens, and fine-tune the GPT language model for one epoch on this data. The domain-tuned GPT increases decipherment accuracy from 73.0 to 73.2 (+0.2 for beam=4). Fine tuning for more than one epoch degrades decipherment accuracy. We found experiments with COFEA[9] (American English sources written between 1765 and 1799) to be fruitless. We fine-tune a language model on a COFEA subset consisting of 3.8 million word tokens for one epoch, but this degrades accuracy from 73.0% to 65.6%.

Iterative self-learning. We apply iterative self-learning to improve our decipherment. After extracting the best path using beam search, we take the words with the smallest increases in perplexity on the lattice and language models, and we add them to the wordbank. The new wordbank provides tighter anchor points. We then construct a new lattice (using the expanded wordbank), search it, and repeat. This further improves decoding accuracy to 75.1 (+1.9 for beam=4).

8 Synthetic Data Experiments

We next experiment with synthetic data to test the data efficiency of our method. To create arbitrary amounts of parallel plaintext-ciphertext data, we encipher a book from Project Gutenberg,[10] using a different machine readable dictionary.[11] We build wordbanks from parallel documents and use them to decipher a separately-enciphered book by the

Parallel plain-cipher tokens	Wordbank size	Coverage of test tokens	Decipherment accuracy
500	227	53.8	66.0
800	351	58.3	69.6
2000	691	68.7	73.5
20000	2904	76.6	79.6

Table 5: Experiments with synthetic data. By enciphering material from Project Gutenberg, we produce arbitrary-sized wordbanks from arbitrary amounts of parallel plaintext-ciphertext. We then test how well those wordbanks support decipherment of new material.

same author.[12] The results are shown in Table 5.

9 Conclusion and Future Work

In this work, we show that it is possible to decipher a book-based cipher, using a known-plaintext attack and a neural English language model. We apply our method to letters written to and from US General James Wilkinson, and we recover 75.1% of the word tokens correctly.

We believe word-based neural language models are a powerful tool for decrypting classical codes and ciphers. Because they have much lower perplexities than widely-used n-gram models, they can distinguish between candidate plaintexts that resemble English at a distance, versus candidate plaintexts that are grammatical, sensible, and relevant to the historical context.

Abstract

Although prediction of dialects is an important language processing task, with a wide range of applications, existing work is largely limited to coarse-grained varieties. Inspired by geolocation research, we propose the novel task of *Micro-Dialect Identification (MDI)* and introduce MARBERT, a new language model with striking abilities to predict a fine-grained variety (as small as that of a city) given a *single*, *short* message. For modeling, we offer a range of novel spatially and linguistically-motivated multi-task learning models. To showcase the utility of our models, we introduce a new, large-scale dataset of Arabic micro-varieties (low-resource) suited to our tasks. MARBERT predicts micro-dialects with 9.9% F_1, $\sim 76\times$ better than a majority class baseline. Our new language model also establishes new state-of-the-art on several external tasks.[1]

1 Introduction

Sociolinguistic research has shown how language varies across geographical regions, even for areas as small as different parts of the same city (Labov, 1964; Trudgill, 1974). These pioneering studies often used field work data from a handful of individuals and focused on small sets of carefully chosen features, often phonological. Inspired by this early work, researchers have used geographically tagged social media data from hundreds of thousands of users to predict user location (Paul and Dredze, 2011; Amitay et al., 2004; Han et al., 2014; Rahimi et al., 2017; Huang and Carley, 2019b; Tian et al., 2020; Zhong et al., 2020) or to develop language identification tools (Lui and Baldwin, 2012; Zubiaga et al., 2016; Jurgens et al., 2017a; Dunn and Adams, 2020). Whether it is possible at all to predict the *micro-varieties* [2] of the same general language is a question that remains, to the best of our knowledge, unanswered. In this work, our goal is to investigate this specific question by introducing the *novel* task of *Micro-Dialect Identification* (MDI). Given a single sequence of characters (e.g., a single tweet), the goal of MDI is to predict the particular micro-variety (defined at the level of a city) of the *community of users* to which the posting user belongs. This makes MDI different from geolocation in at least two ways: in geolocation, **(1)** a model consumes a *collection of messages* (e.g., 8-85 messages in popular datasets (Huang and Carley, 2019a) and **(2)** predicts the *location* of the posting user (i.e., user-level). In MDI, a model takes as input a *single message*, and predicts the *micro-variety* of that message (i.e., message-level).

While user location and micro-dialect (MD) are conceptually related (e.g., with a tag such as *Seattle* for the first, and *Seattle English*, for the second), they arguably constitute two *different* tasks. This is because location is an attribute of a *person* who authored a Wikipedia page (Overell, 2009) or posted on Facebook (Backstrom et al., 2010) or Twitter (Han et al., 2012), whereas MD is a characteristic of *language within a community of speakers* who, e.g., use similar words to refer to the same concepts in real world or pronounce certain sounds in the same way. To illustrate, consider a scenario where the same user is at different locations during different times. While a geolocation model is required to predict these *different* locations (for that *same* person), an MDI model takes as its target predicting the *same* micro-variety for texts authored by the person (regardless of the user location). After all, while the language of a person can, and does, change when they move from one region to another, such a change takes time.

Concretely, although to collect our data we use location as an initial *proxy* for user MD, we do not just exploit data where n number of posts (usually

---

[1] Our labeled data and models will be available at: https://github.com/UBC-NLP/microdialects.

[2] We use *micro-variety* and *micro-dialect* interchangeably.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 5855–5876,
November 16–20, 2020. ©2020 Association for Computational Linguistics

n=10) came from the location of interest (as is usually the case for geolocation). Rather, to the extent it is possible, we take the additional *necessary* step of manually verifying that a user does live in a given region, and has not moved from a different city or country (at least recently, see Section 2). We hypothesize that, if we are able to predict user MD based on such data, we will have an empirical evidence suggesting MD does exist and can be detected. As it turns out, while it is almost impossible for humans to detect MD (see Section 2.3 for a human annotation study), our models predict varieties as small as those of cities surprisingly well (9.9% F_1, $\sim 76\times$ higher than a majority class baseline based on a single, short message) (Sections 6 and 7).

Context. MDI can be critical for multilingual NLP, especially for social media in global settings. In addition to potential uses to improve machine translation, web data collection and search, and pedagogical applications (Jauhiainen et al., 2019), MDI can be core for essential real-time applications in health and well-being (Paul and Dredze, 2011), recommendation systems (Quercia et al., 2010), event detection (Sakaki et al., 2010), and disaster response (Carley et al., 2016). Further, as technology continues to play an impactful role in our lives, access to nuanced NLP tools such as MDI becomes an issue of equity (Jurgens et al., 2017b). The great majority of the world's currently known 7,111 living languages,[3] however, are not NLP-supported. This limitation also applies to closely related languages and varieties, even those that are widely spoken.

We focus on one such situation for the Arabic language, a large collection of similar varieties with ∼400 million native speakers. For Arabic, currently available NLP tools are limited to the standard variety of the language, Modern Standard Arabic (MSA), and a small set of dialects such as Egyptian, Levantine, and Iraqi. Varieties comprising dialectal Arabic (DA) differ amongst themselves and from MSA at various levels, including phonological and morphological (Watson, 2007), lexical (Salameh and Bouamor, 2018; Abdul-Mageed et al., 2018; Qwaider et al., 2018), syntactic (Benmamoun, 2011), and sociological (Bassiouney, 2020). Most main Arabic dialects, however, remain understudied. The situation is even more acute for MDs, where very limited knowledge (if at all) currently exists. The prospect of research on Arabic MDs is thus large.

A major limitation to developing robust and equitable language technologies for Arabic language varieties has been absence of large, diverse data. A number of pioneering efforts, including shared tasks (Zampieri et al., 2014; Malmasi et al., 2016; Zampieri et al., 2018), have been invested to bridge this gap by collecting datasets. However, these works either depend on automatic geocoding of user profiles (Abdul-Mageed et al., 2018), which is not quite accurate, as we show in Section 2; use a small set of dialectal seed words as a basis for the collection (Zaghouani and Charfi, 2018; Qwaider et al., 2018), which limits text diversity; or are based on translation of a small dataset of sentences rather than naturally-occurring text (Salameh and Bouamor, 2018), which limits the ability of resulting tools. The recent Nuanced Arabic Dialect Identification (NADI) shared task (Abdul-Mageed et al., 2020a) aims at bridging this gap.

In this work, following Gonçalves and Sánchez (2014); Doyle (2014); Sloan and Morgan (2015), among others, we use *location as a surrogate for dialect* to build a very large scale Twitter dataset (∼6 billion tweets), and automatically label a subset of it (∼500M tweets) with coverage for all 21 Arab countries at the nuanced levels of state and city (i.e., micro-dialects). In a departure from geolocation work, we then *manually* verify user locations, excluding $\sim$ 37% of users. We then exploit our data to develop highly effective hierarchical and multi-task learning models for detecting MDs.

Other motivations for choosing Arabic as the context for our work include that **(1)** Arabic is a *diaglossic* language (Ferguson, 1959; Bassiouney, 2020) with a so-called 'High' variety (used in educational and formal settings) and 'Low' variety (used in everyday communication). This allows us to exploit dialgossia in our models. In addition, **(2)** for historical reasons, different people in the Arab world *code-switch* in different foreign languages (e.g., English in Egypt, French in Algeria, Italian in Libya). This affords investigating the impact of code-switching on our models, thereby bringing yet another novelty to our work. Further, **(3)** while recent progress in *transfer learning* using language models such as BERT (Devlin et al., 2018) has proved strikingly useful, Arabic remains dependent on multilingual models such as mBERT trained on the restricted Wikipedia domain with limited

---

[3] Source: `https://www.ethnologue.com`.

data. Although an Arabic-focused language model, AraBERT (Baly et al., 2020), was recently introduced, it is limited to MSA rather than dialects. This makes AraBERT sub-optimal for social media processing as we show empirically. We thus present a novel Transformer-based Arabic language model, MARBERT, for MDs. Our new model exploits a massive dataset of 1B posts, and proves very powerful: It establishes new SOTA on a wide range of tasks. Given the impact self-supervised language models such as BERT have made, our work has the potential to be a key milestone in *all* Arabic (and perhaps multilingual) NLP.

To summarize, we offer the following contributions: (1) We collect a massive dataset from Arabic social media and exploit it to develop a large human-labeled corpus for Arabic MDs. (2) For modeling, we introduce a novel, *spatially* motivated hierarchical attention multi-task learning (HA-MTL) network that is suited to our tasks and that proves highly successful. (3) We then introduce *linguistically* guided multi-task learning models that leverage the diaglossic and code-switching environments in our social data. (4) We offer a new, powerful Transformer-based language model trained with self-supervision for Arabic MDs. (5) Using our powerful model, we establish new SOTA results on several external tasks.

The rest of the paper is organized as follows: In Section 2, we introduce our methods of data collection and annotation. Section 3 is about our experimental datasets and methods. We present our various models in Section 4 and our new microdialectal model, MARBERT, in Section 5. We investigate model generalization in Section 6, and the impact of removing MSA from our data in Section 7. Section 8 is a discussion of our findings. We compare to other works in Section 9, review related literature in Section 10, and conclude in Section 11.

2 Data Acquisition and Labeling

We first acquire a large user-level dataset covering the whole Arab world. We then use information in user profiles (available only for a subset of users) to automatically assign city, state, and country labels to each user. Since automatic labels can be noisy (e.g., due to typos in city names, use of different languages in user profiles), we manually fix resulting errors. To further account for issues with human mobility (e.g., a user from one country moving to another), we manually inspect user profiles, tweets, and network behavior and verify assigned locations. Finally, we propagate city, state, and country labels from the user to the tweet level (each tweet gets the label assigned to its user). We now describe our data methods in detail.

2.1 A Large User-Level, Tagged Collection

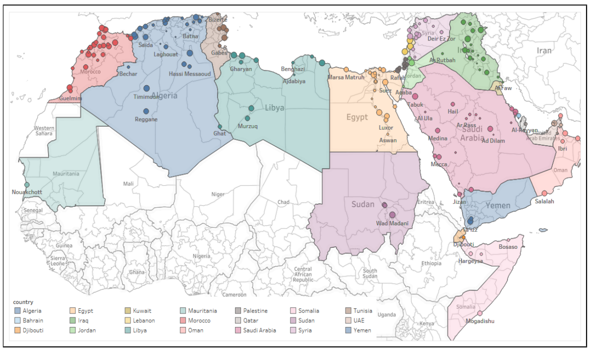

Figure 1: All 21 Arab countries in our data, with states demarcated in thin black lines within each country. All 319 cities from our user location validation study, in colored circles, are overlayed within respective states.

To develop a large scale dataset of Arabic varieties, we use the Twitter API to crawl up to 3,200 tweets from ∼2.7 million users collected from Twitter with bounding boxes around the Arab world. Overall, we acquire ∼6 billion tweets. We then use the Python geocoding library *geopy* to identify user location in terms of countries (e.g., Morocco) and cities (e.g., Beirut).[4] Out of the 2.7 million users, we acquired *both* 'city' and 'country' label for ∼233K users who contribute ∼ 507M tweets. The total number of cities initially tagged was 705, but we manually map them to only 646 after correcting several mistakes in results returned by geopy. Geopy also returned a total of 235 states/provinces that correspond to the 646 cities, which we also manually verified. We found all state names to be correct and to correspond to their respective cities and countries.[5]

2.2 Validation of User Location

Even after manually correcting location labels, it cannot be guaranteed that a user *actually* belongs to

---

[4] Geopy (`https://github.com/geopy`) is a client for several popular geocoding web services aiming at locating the coordinates of addresses, cities, countries, and landmarks across the world using third-party geocoders. In particular, we use the Nominatim geocoder for OpenStreetMap data (`https://nominatim.openstreetmap.org`). With Nominatim, geopy depends on user-provided geographic information in Twitter profiles such as names of countries or cities to assign user location.

[5] More information about manual correction of city tags is in Section A.1 in the Appendix.

(i.e., is a local of) the region (city, state, and country) they were assigned. Hence, we manually verify user location through an annotation task. To the extent it is possible, this helps us avoid assigning false MD labels to users whose profile information was captured rightly in the previous step but who indeed are *not* locals of automatically labeled places. Before location verification, we exclude *cities* that have $<$ 500 tweets and *users* with $<$ 30 tweets from the data. This initially gives us 417 cities. We then ask two native Arabic annotators to consider the automatic label for each task (city and country) [6] and assign one label from the set $\{$*local, non-local, unknown*$\}$ per task for each user in the collection. We provide annotators with links to users' Twitter profiles, and instruct them to base their decisions on each user's network and posting content and behavior. As a result, we found that 81.00% of geopy tags for country are correct, but only 62.29% for city. This validates the need for the manual verification. Ultimately, we could verify a total of 3,085 users for *both* country and city from all 21 countries but only from 319 cities.[7] Figure 1 shows a map of all 21 Arab countries, each divided into its states with cities overlayed as small colored circles.

2.3 Can Humans Detect Micro-Dialect?

We were curious to know whether humans can identify micro-dialect from a *single message*, and so we performed a small annotation study. We extracted a random set of 1,050 tweets from our labeled collection and asked two native speakers from two non-neighboring Arab countries to tag each tweet with a *country* then (choosing from a drop-down menu) a *state* label. Annotators found the state-level task very challenging (or rather "impossible", to quote one annotator) and so we did not complete it. Hence, we also did not go to the level of *city* since it became clear it will be almost impossible for humans. For country, annotators reported trying to identify larger regions (e.g. Western Arab world countries), then pick a specific country (e.g., Morocco). To facilitate the task, we asked annotators to assign an "unknown" tag when unsure. We calculated inter-annotator agreement and found it at Cohen's (Cohen, 1960) Kappa *(K)*=0.16 ("poor" agreement). When we calculate the subset of data where both annotators assigned an actual country label (i.e., rather than "unknown"; n=483 tweets), we found the Kappa *(K)* to increase to 0.47 ("moderate" agreement). Overall, the annotation study emphasizes challenges humans face when attempting to identify dialects (even at the level of country sometimes).

3 Datasets and Methods

3.1 Datasets

Preprocessing. To keep only high-quality data, we remove all retweets, reduce all consecutive sequences of the same character to only 2, replace usernames with <USER> and URLs with <URL>, and remove all tweets with less than 3 Arabic words. This gives $\sim$ 277.4K tweets. We tokenize input text only lightly by splitting off punctuation.[8] Ultimately, we extract the following datasets for our experiments:

Micro-Ara (Monolingual). Extracted from our manually verified users, this is our core dataset for modeling. We randomly split it into 80% training (TRAIN), 10% development (DEV), and 10% test (TEST). To limit GPU time needed for training, we cap the number of tweets in our TRAIN in any given country at 100K. We describe the distribution of classes in Micro-Ara in Tables B.1 and B.2 in the Appendix. We note that Micro-Ara is reasonably balanced. Table 1 shows our data splits.

CodSw (Code-Switching). As explained in Section 1, Arabic speakers code-switch to various foreign languages. We hypothesize the distribution of foreign languages will vary across different regions (which proves to be true, as we show in Figure 2), thereby providing modeling opportunities that we capture in a multi-task setting (in Section 4.5). Hence, we introduce a code-switching dataset (CodSw) by tagging the non-Arabic content in all tweets in our wider collection with the langid tool (Lui and Baldwin, 2012). Keeping only tweets with at least 3 Arabic words and at least 4 non-Arabic words, we acquire $\sim$ 934K tweets. CodSw is diverse, with a total of 87 languages. We split CodSw as is shown in Table 1.

DiaGloss (Diaglossia). We also explained in Section 1 that Arabic is a diaglossic language, with MSA as the "High" variety and dialects as the "Low" variety. MDs share various linguistic features (e.g., lexica) with MSA, but to varying degrees. We use an auxiliary task whose goal is to tease apart MSA from dialectal varieties. We

---

[6] Note that we have already manually established the link between states and their corresponding cities and countries.

[7] More information about manual user verification is in Section A.2 of the Appendix.

[8] For most DA varieties, there are no available tokenizers.

use existence of diacritics (at least 5) as a proxy for MSA,[9] and direct responses (vs. tweets or retweets) as a surrogate for dialectness. In each class, we keep 500K tweets, for a total of 1M tweets split as in Table 1.We refer to this dataset as DiaGloss.

Datasets	Train	Dev	Test
Micro-Ara	1,099,711	202,509	202,068
CodSw	747,173	93,431	93,565
DiaGloss	800K	100K	100K

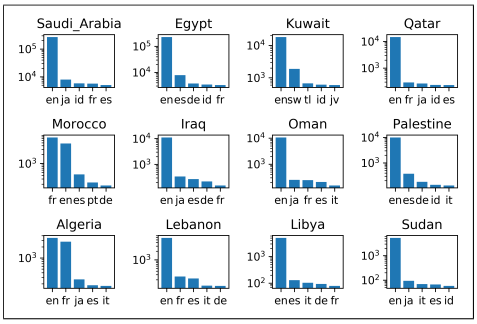

Figure 2: Code-switching over select countries (with different code-switching profiles) in CodSw.

3.2 Methods

BiGRUs and BERT. We perform dialect identification at the country, state, and city levels. We use two main neural network methods, Gated Recurrent Units (GRUs) (Cho et al., 2014), a variation of Recurrent Neural Networks (RNNs), and Google's Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018). We model each task independently, but also under multi-task conditions.

Multi-Task Learning. *Multi-Task Learning (MTL)* is based on the intuition that many real-world tasks involve predictions about closely related labels or outcomes. For related tasks, MTL helps achieve inductive transfer between the various tasks by leveraging additional sources of information from some of the tasks to improve performance on the target task (Caruana, 1993). By using training signals for related tasks, MTL allows a learner to prefer hypotheses that explain more than one task (Caruana, 1997) and also helps regularize models. In some of our models, we leverage MTL by training a *single* network for our city, state, and country tasks where network layers are shared but with an independent output for each of the 3 tasks.

4 Models

Here, we describe our baselines and present our MDI models. These are (i) our single- and multi-task BiGRU models (Sections 4.1, 4.2, and 4.3), (ii) single-task BERT (Section 4.4), and (iii) multi-task BERT (Section 4.5).

4.1 Baselines

For all our experiments, we remove diacritics from the input text. We use two baselines: the majority class in TRAIN (Baseline I) and a single-task BiGRU (Baseline II, described below). For all our experiments, we tune model hyper-parameters and identify best architectures on DEV. We run all models for 15 epochs (unless otherwise indicated), with early stopping 'patience' value of 5 epochs, choosing the model with highest performance on DEV as our best model. We then run each best model on TEST, and report *accuracy* and *macro* F_1 *score*.[10]

Single-Task BiGRUs. As a *second baseline* (Baseline II), we build 3 independent networks (each for one of the 3 tasks) using the same architecture and model capacity. Each network has 3 hidden BiGRU layers, with 1,000 units each. More information about each of these networks and how we train them is in Section C.1 in the Appendix. Table 2 presents our results on TEST.

4.2 Multi-Task BiGRUs

With MTL, we design a single network to learn the 3 tasks simultaneously. In addition to our hierarchical attention MTL (HA-MTL) network, we design two architectures that differ as to how we endow the network with the *attention mechanism*. We describe these next. We provide illustrations of our MTL networks in Figures C.1 and C.2 in the Appendix.

Shared and Task-Specific Attention. We first design networks with attention at the same level in the architecture. Note that we use the same hyper-parameters as the single-task networks. We have two configurations:

Shared Attention. This network has 3 hidden BiGRU layers, each of which has 1,000 units per layer (500 in each direction).[11] All the 3 layers are shared across the 3 tasks, including the third layer.

---

[9] Unlike dialect, MSA is usually diacritized.

[10] We include tables with results on DEV in Section C in the Appendix.

[11] Again, 4 hidden-layered network for both the *shared* and *task-specific* attention settings were sub-optimal and so we do not report their results here.

Only the third layer has attention applied. We call this setting *MTL-common-attn*.

Task-Specific Attention. This network is similar to the previous one in that the first two hidden layers are shared, but differs in that the third layer (attention layer) is task-specific (i.e., independent for each task). We call this setting *MTL-spec-attn*. This architecture will allow each task to specialize its own attention within the same network. As Table 2 shows, both *MTL-common-attn* and *MTL-spec-attn* improve over each of the two baselines (with first performing generally better).

4.3 Hierarchical Attention MTL (HA-MTL)

Instead of a 'flat' attention, we turn to hierarchical attention (spatially motivated, e.g., by how a smaller regions is a part of a larger one): We design a single network for the 3 tasks but with supervision at different layers. Overall, the network has 4 BiGRU layers (each with a total of 1,000 units), the bottom-most of which has no attention. Layers 2, 3, and 4 each has dot-product attention applied, followed directly by one task-specific fully-connected layer with softmax for class prediction. In the two scenarios, state is supervised at the middle layer. These two architectures allow information flow with different granularity: While the city-first network tries to capture what is in the physical world a more fine-grained level (city), the country-first network does the opposite. Again, we use the same hyper-parameters as the single-task and MTL networks, but we use a dropout rate of 0.70 since we find it to work better. As Table 2 shows, our proposed HA-MTL models significantly outperform single-task and other BiGRU MTL models. They also outperform our Baseline II with 12.36%, 10.01%, and 13.22% acc on city, state, and country prediction respectively, thus demonstrating their effectiveness on the task.

Setting	**City**		**State**		**Country**	
Eval Metric	**acc**	**F1**	**acc**	**F1**	**acc**	**F1**
Baseline I	1.31	0.01	3.11	0.03	9.19	0.80
Baseline II	1.65	0.25	6.13	1.92	31.14	15.84
MTL (common-attn)	2.86	0.74	5.12	1.01	26.51	12.41
MTL (spec-attn)	2.40	0.68	4.60	0.90	27.04	10.98
HA-MTL (city 1^{st})	**14.01**	**14.02**	**16.14**	**15.90**	**44.36**	32.14
HA-MTL (cntry 1^{st})	13.23	13.06	15.84	15.40	44.17	**32.37**
mBERT	19.33	19.45	**21.24**	21.67	47.74	38.12
MTL-mBERT (DiGls)	**19.88**	**20.11**	21.04	**21.69**	48.30	**38.34**
MTL-mBERT (CodSw)	19.47	19.86	20.76	21.47	**48.61**	38.20

Table 2: Performance on TEST. **Baseline I:** majority in TRAIN. **Baseline II:** single task Attn-BiGRU. **MTL-mBERT (DiGls):** Multi-Task BERT with diaglossia. **CodSw:** code-switching.

4.4 Single-Task BERT

We use the BERT-Base, Multilingual Cased model released by the authors.[12] For fine-tuning, we use a maximum sequence length of 50 words and a batch size of 32. We set the learning rate to 2e-5. We train for 15 epochs, as mentioned earlier. As Table 2 shows, BERT performs consistently better on the three tasks. It outperforms the best of our two HA-MTL networks with an acc of 5.32% (city), 5.10% (state), 3.38% (country). To show how a small network (and hence deployable on machines with limited capacity with quick inference time) can be trained on knowledge acquired by a bigger one, we distill (Hinton et al., 2015; Tang et al., 2019) BERT representation (big) with a BiGRU (small). We provide related results in Section C.2 in the Appendix.

4.5 Multi-Task BERT

We investigate two linguistically-motivated auxiliary tasks trained with BERT, as follows:

Exploiting Diaglossia. As Table 2 shows, a diaglossia-based auxiliary task improves over the single task BERT for both city (0.55% acc) and country (0.56% acc).

Exploiting Code-Switching. We run 4 experiments with our CodSw dataset, as follows: **(1)** with the two tasks supervised at the city level, **(2)** at the country level, **(3 & 4)** with the levels reversed (city-country vs. country-city). Although the code-switching dataset is automatically labeled, we find that when we supervise with its country-level labels, it helps improve our MDI on city (0.14% acc) and on country (0.87% acc). Related results are shown in Table 2. We now describe our new language model, MARBERT.

5 MARBERT: A New Language Model

We introduce MARBERT, a new language model trained with self-supervision on 1B tweets from from our unlabaled Twitter collection (described in Section 2). We train MARBERT on 100K wordPiece vocabulary, for 14 epochs with a batch size of 256 and a maximum sequence length of 128. Training took 14 days on 8 Google Cloud TPUs. We use the same network architecture as mBERT, but without the next sentence prediction objective since tweets are short. MARBERT has much larger token count than BERT (Devlin et al., 2018) (15.6B

---

[12] `https://github.com/google-research/bert/blob/master/multilingual.md`.

vs. 3.3B), and is trained on 5× bigger data than AraBERT (Baly et al., 2020) (126GB vs. 24GB of text). Unlike AraBERT, which is focused on MSA, MARBERT has diverse coverage of dialects in addition to MSA. As Table 3 shows, MARBERT significantly outperforms *all* other models across the 3 tasks, with improvements of 4.13% and 3.54% acc over mBERT and AraBERT respectively on the country task. We also run a set of **MTL experiments** with MARBERT, fine-tuning it with a diaglossia auxiliary task, a code-switching auxiliary task, and *both* diaglossia and code-switching as auxiliary tasks. As Table 3 shows, MTL does not bring acc improvements, and helps the country task only slightly (0.30% acc gain with CodSW). This reflects MARBERT's already-powerful representation, with little need for MTL. We provide an ***error analysis*** of MARBERT's MDI in Section E.1 of the Appendix.

Setting	**City**		**State**		**Country**	
Eval Metric	**acc**	**F1**	**acc**	**F1**	**acc**	**F1**
mBERT (Devlin et al. (2018))	19.33	19.45	21.24	21.67	47.74	38.12
AraBERT (Baly et al. (2020))	18.82	18.73	20.73	20.87	48.33	38.09
MARBERT (Ours)	**20.78**	**20.41**	**22.97**	**22.58**	**51.87**	**42.17**
MTL-MARBERT (DiaGloss)	20.19	**20.60**	**23.22**	22.97	51.53	41.75
MTL-MARBERT (CodSw)	**20.77**	20.56	23.21	**23.16**	51.78	**42.36**
MTL-MARBERT (CSD)	20.76	20.23	23.18	23.15	**52.17**	42.27

Table 3: MARBERT (ours) outperforms mBERT and AraBERT (TEST results). **CSD:** DiaGloss+CodSw.

6 Model Generalization

For the experiments reported thus far, we have split our Micro-Ara (monolingual) dataset randomly at the tweet level. While this helped us cover the full list of our 319 cities, including cities from which we have as few as a single user, this split does not prevent tweets from the *same* user to be divided across TRAIN, DEV, and TEST. In other words, while the tweets across the splits are unique (not shared), users who posted them are not unique. We hypothesize this may have the consequence of allowing our models to acquire knowledge about user identity (idiolect) that interact with our classification tasks. To test this hypothesis, we run a set of experiments with different data splits where users in TEST are *never* seen in TRAIN. To allow the model to see enough users during training, we split the data only into TRAIN and TEST and use no DEV set. We use the same hyper-parameters identified on previous experiments. An exception is the number of epochs, where we report the best epoch identified on TEST. To alleviate the concern about absence of a DEV set, we run each experiment 3 times. Each time we choose a different TEST set, and we average out performance on the 3 TEST sets. This is generally similar to cross-validation.

For this set of experiments, we first remove all cities from which we have only one user (79 cities) and run experiments across 3 different settings (**narrow**, **medium**, and **wide**).[13] We provide a description of these 3 settings in Section D.1 in the Appendix. For the *narrow* setting only, we also run with the same code-switching and diaglossic auxiliary tasks (individually and combined) as before. We use mBERT fine-tuned on each respective TRAIN as our baseline for the current experiments.

As Table 4 shows, MARBERT significantly ($p < 0.01$) outperforms the strong mBERT baseline across the 3 settings. With the *narrow* setting on MDs, MARBERT reaches 8.12% F_1 (61 cities). These results drop to 5.81% (for *medium*, 116 cities) and 3.59% (for *wide*, 240 cities). We also observe a positive impact[14] from the combined code-switching and diaglossic auxiliary tasks. All results are also *several folds better* than a majority class city baseline (city of Abu Dhabi, UAE; not shown in Table 4). For example, results acquired with the two (combined) auxiliary tasks are 4.7× better in acc and 229× better for F_1 than the majority class.

Importantly, although results in Table 4 are not comparable to those described in Section 5 (due to the different data splits), these results suggest that our powerful transformer models in Section 5 may have made use of user-level information (which may have caused inflated performance). To further investigate this issue in a reasonably comparable set up, we apply the models based on the narrow, medium and wide settings *and* our single task MARBERT model (shown in Table 3) *all* to a completely new test set. This additional evaluation iteration, which we describe in Section D.2 of the Appendix, verifies the undesirable effect of sharing users between the data splits.[15] For this reason, we strongly advise against sharing users across data splits for tweet-level tasks *even* if the overall dataset involves several thousand users.

7 Impact of MSA

Our efforts thus far focused on teasing apart tweets regardless of their (degree of) dialectness. Our

---

[13] We give each setting a name that reflects its respective geographical coverage. For example, *wide* has wider coverage than *medium*, which in turn has wider coverage than *narrow*.

[14] But not significant ($p < 0.07$ for city-level with *narrow*), since MARBERT is already powerful.

[15] Relevant results are in Appendix Table D.1.

Setting	City		State		Country	
Eval Metric	**acc**	**F1**	**acc**	**F1**	**acc**	**F1**
mBERT-wide	4.58	3.18	7.88	4.05	35.39	24.73
MARBERT-wide	**5.06**	**3.59**	**8.92**	**4.77**	**39.49**	**28.77**
mBERT-medium	6.39	4.92	9.33	6.11	38.48	28.16

mBERT-narw	9.60	6.63	12.08	8.55	51.32	33.87
MARBERT-narw	**11.66**	**8.12**	**14.62**	**10.09**	**57.27**	**39.93**
MTL-MARBERT-narw (DiaGloss)	11.76	8.35	14.37	10.23	56.74	39.68
MTL-MARBERT-narw (CodSw)	11.59	8.33	15.45	10.27	57.78	40.32
MTL-MARBERT-narw (CSD)	**11.78**	**8.44**	**15.25**	**10.34**	**57.75**	**40.46**

Table 4: Performance on TEST sets with unique users (i.e., users with no data in TRAIN). Setting names are suffixed to each model. **CSD:** DiaGloss+CodSw.

dataset comprises posts either solely in MSA or in MSA mixed with dialectal content. Since MSA is shared across different regions, filtering it out is likely to enhance system ability to distinguish posts across our 3 classification tasks. We test (and confirm) this hypothesis by removing MSA from both TRAIN and TEST in our *narrow* setting data (from Section 6) and fine-tuning MARBERT on the resulting ('dialectal') data only.[16] As Table 5 shows, this procedure results in higher performance across the 3 classification tasks.[17] For micro-dialects, performance is at 14.09% acc. and 9.87% F_1. Again, this performance is much better ($3.3\times$ better acc and $75.9\times$ better F_1) than the majority class baseline (city of Abu Dhabi, UAE, in 2 of our 3 runs).

Setting	City		State		Country	
Eval Metric	**acc**	**F1**	**acc**	**F1**	**acc**	**F1**
mBERT-narrow-DA	11.72	8.45	15.41	10.95	69.30	45.46

Table 5: Performance on predicted dialectal data.

8 Discussion

As we showed in Sections 6 and 7, our models are able to predict variation at the city-level significantly better than *all* competitive baselines. This is the case even when we do not remove MSA content, but better results are acquired after removing it. A question arises as to whether the models are indeed capturing micro-linguistic variation between the different cities, or simply depending on different topical and named entity distributions in the data. To answer this question, we visualize attention in ~ 250 examples from our TEST set using one of our MARBERT-narrow models reported in Table 4.[18] Our analysis reveals that the model *does* capture micro-dialectal variation. We provide two example visualizations in Section E in the Appendix demonstrating the model's micro-dialectal predictive power. Still, we also observe that the model makes use of especially names of places. For this reason, we believe future research should control for topical and named entity cues in the data.

9 Comparisons and Impact

Comparisons to Other Dialect Models. In absence of similar-spirited nuanced language models, we compare our work to existing models trained at the country level. These include the tweet-level 4-country SHAMI (Qwaider et al., 2018) which we split into TRAIN (80%), DEV (10%), and TEST (10%) for our experiments, thus using less training data than Qwaider et al. (2018) (who use cross-validation). We also compare to (Zhang and Abdul-Mageed, 2019), the winning team in the the 21-country MADAR Shared Task-2 (Bouamor et al., 2019b). Note that the shared task targets user-level dialect based on a collection of tweets, which our models are not designed to directly predict (since we rather take a single tweet input, making our task harder). [19] For the purpose, we train two models, one on MADAR data (shared tasks 1 and 2) and another on our Micro-Ara+MADAR data. We also develop models using the 17-country Arap-Tweet (Zaghouani and Charfi, 2018), noting that authors did not preform classification on their data and so we include a unidirectional 1-layered GRU, with 500 units as a baseline for Arap-Tweet. Note that we do not report on the dataset described in Abdul-Mageed et al. (2018) since it is automatically labeled, and so is *noisy*. We also do not compare to the dataset in Salameh and Bouamor (2018) since it is small, *not naturally occurring* (only 2,000 translated sentences per class), and the authors have already reported linear classifiers outperforming a deep learning model due to small data size. As Table 7 shows, our models achieve new SOTA on all three tasks with a significant margin. Our results on MADAR show that if we have up to 100 messages from a user, we can detect their MD at 80.69% acc.

Impact on External Tasks: We further demon-

---

[16] To filter out MSA, we apply an in-house MSA vs. dialect classifier ($acc = 89.1\%, F_1 = 88.6\%$) on the data, and remove tweets predicted as MSA. More information about the MSA vs. dialect model is in Section D.3 of the Appendix. We cast more extensive investigation of the interaction between dialects and MSA vis-a-vis our classification tasks, including based on manually-filtered MSA, as future research.

[17] MARBERT is significantly better than mBERT with $p < 0.03$ for city, $p < 0.01$ for state, and $p < 0.0004$ for country.

[18] Namely, we use the model fine-tuned in split B in Table D.2.

[19] We follow (Zhang and Abdul-Mageed, 2019) in assigning a user-level label based on message-level majority class.

Dataset	#cls	Model	acc	F1
Arap-TWT	17	GRU-500	38.79	39.17

strate the impact of our newly-developed model, MARBERT, by fine-tuning it on a range of text classification tasks. These involve 4 sentiment analysis datasets: ArSAS (Elmadany et al., 2018), ASTD (Nabil et al., 2015), SemEval-2017 task 4-A benchmark dataset (Rosenthal et al., 2017), and Arabic sentiment collection (ASC) in Abdul-Mageed et al. (2020b); and a benchmark for offensive language (OFF) from OSACT4 Arabic Offensive Language Detection Shared Task (Mubarak et al., 2020). More information about each dataset can be found in the respective sources. We compare to the SOTA on each dataset, using the same metrics for each respective systems: For ArSAS, ASTD, and SemEval, we use F_1^{PN}.[20] And for OFF and ASC, we use $macro\ F_1$. As Table 7 shows, our models set new SOTA on *all* 5 datasets.

	ArSAS	ASTD	SemEv	ASC	OFF
