Dataset We use the CUB-200-2011 dataset (Wah et al., 2011), which contains 11,788 images for 200 species of North American birds. We randomly sample 25 bird species due to limited access to expert query budget. Following Vedantam et al. (2017), We make sure that each sampled species has one or more confusing species from the same *subfamilia* so that they are challenging to classify.

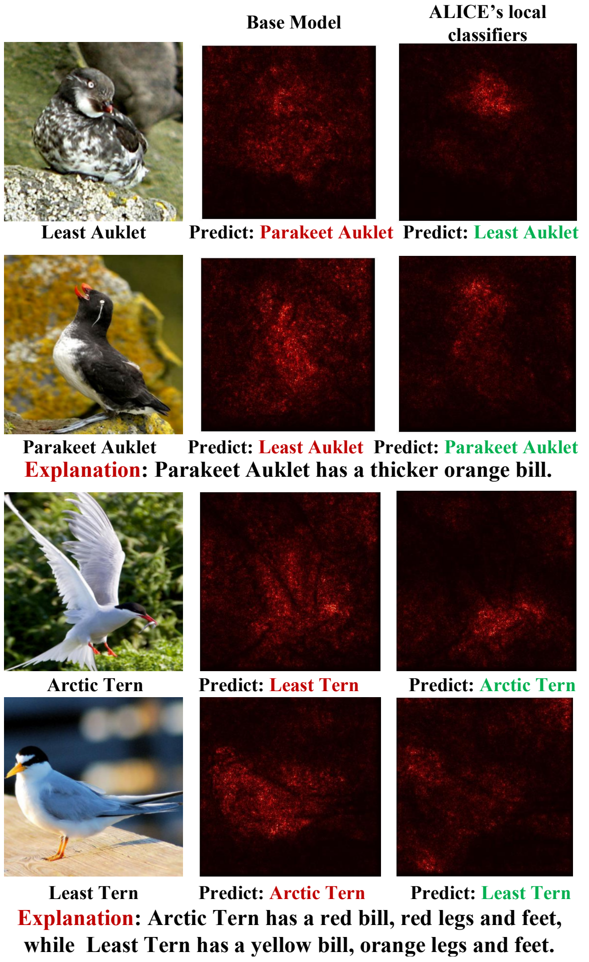

Figure 4: Saliency maps visualization. Guided by expert explanations, ALICE learn to focus on the discriminating semantic segments and make the correct prediction.

In addition, each image in the CUB data-set is also annotated with the locations of 15 semantic segments (e.g., "bill", "eye"). We use these location annotations to crop training image patches based on the explanations. We do not use any location annotation during testing. More details are provided in the Appendix, including the list of 25 sampled species. We experiment with a low-resource setting with only 15 images per bird species.

We employ an amateur bird watcher as the domain expert since we do not expect general MTurk workers to have enough domain expertise. To further ensure the annotation quality, our domain expert checks the professional birding field guide [2] before writing each explanation. We ask the expert, "How would you differentiate bird species P and bird species Q?". In total, we collect 67 contrastive natural language explanations (avg. length 18.45 words). We collect the explanations in an on-demand manner because our class-based active

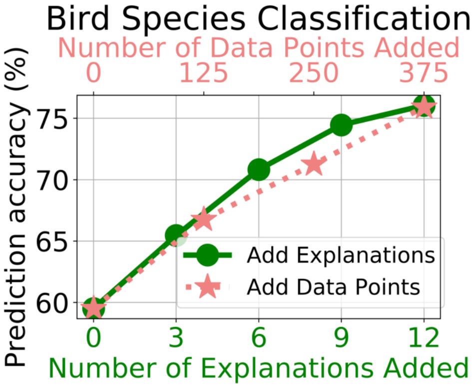

Figure 5: Comparing the performance gain of adding contrastive natural language explanations and adding training data points on bird species' prediction accuracy. Empirically, adding 1 explanation leads to similar performance gain as adding 30 labeled training data points.

learning is empirically insensitive to the change of random seeds and hyper-parameters. Our semantic parser identifies 2.36 semantic segments per explanation on average. In each experiment, we conduct $k = 4$ rounds of expert queries, with a query budget $b = 3$ for each round.

Discussion on CUB Description Dataset The CUB description dataset collects descriptions of visual appearance for each image rather than explanations of why the bird in the image belongs to a certain class (Reed et al., 2016; Hendricks et al., 2016). For example, an image with a Ring-billed gull has the description: *"This is a white bird with a grey wing and orange eyes and beak."* However, this description also fits perfectly with a California gull (Figure 1). So the crowd-sourced descriptions in the CUB description dataset is not ideal to support classification. We collected expert explanations: *"Ring-billed gull has a bill with a black ring near the tip while California gull has a red spot near the tip of lower mandible."* to improve classification data efficiency. In addition, we also conducted experiments to incorporate CUB descriptions (5 sentences per image), but we did not find improved performance in our setting.

Model Ablations and Metrics We compare ALICE to its several ablations (Table 2) and evaluate the performance on the test set. We report classification accuracy on species as well as subfamilia. For subfamilia accuracy, a prediction is counted as correct as long as the predicted species' subfamilia is the same as the labeled species' subfamilia. (1) *Base(Inception v3)* fine-tunes the pre-trained Inception v3 to perform a flat-25 way classification. (2) *ALICE w/o Grounding* copies the final neural architecture from ALICE but does not have access to the discriminating semantic segments (§ 4.3). (3) *ALICE w/o Hierarchy* has the same neural architecture as (1) but has access to the discriminating semantic segments. (4) *ALICE w/ Random Grounding* has the semantic segments that are randomly sampled. (5) *ALICE w/ Random Pairs* replaces class-based active learning with randomly selected class pairs. The randomly selected class pairs are used to query experts and change the learning model's neural architecture. (9-12) *ALICE i^{th} round* shows ALICE's performance after the i^{th} round of expert queries. (6-8) *RandomSampling + x% extra data* augments (1) with x% extra training data points.

No.	Model	Accuracy (%)	
		species	*subfamilia*
(1)	Base(Inception v3)	59.51	86.50
(2)	ALICE w/o Grounding	66.47	87.95
(3)	ALICE w/o Hierarchy	59.22	86.94
(4)	ALICE w/ Random Ground	64.44	87.52
(5)	ALICE w/ Random Pairs	42.67	75.33
(6)	RandomSampling + 33% extra data	66.76	88.39
(7)	RandomSampling + 66% extra data	71.26	91.00
(8)	RandomSampling + 100% extra data	75.91	91.58
(9)	ALICE (1^{st} round)	65.46	86.07
(10)	ALICE (2^{nd} round)	70.83	89.84

(12)	**ALICE (4^{th} round)**	**76.05**	**91.87**

Table 2: Test accuracy comparison among variants of ALICE on the bird species classification task.

Results Our first takeaway is that incorporating contrastive natural language explanations is more data-efficient than adding extra training data points. Figure 5 visualizes the performance gain of adding explanations and adding data points. ((6-12) in Table 2). As shown in Figure 5, adding 1 explanation leads to the same amount of performance gain of adding 30 labeled data points. For example, adding 12 explanations (ALICE (4^{th} round), 76.05%) achieves comparable performance gain of adding 375 training images (RandomSampling + 100% extra data, 75.91%). We note that writing one explanation for an expert is typically faster than labeling 15-30 examples. As an estimate, Zhou et al. (2020); Hancock et al. (2018); Zaidan and Eisner (2008) perform user study and find that collecting natural language explanations is only twice as costly as collecting labels for their tasks. Our experiment shows that adding 1 explanation leads to similar performance gain as adding 30 labeled training data points, yielding a 6× speedup.

Our second takeaway is that both the ground-

No.	Method	Species Acc (%)	
		+33% data	*+66% data*
(1)	RandomSampling	66.76	71.26
(2)	CoreSet	68.06	73.09
(3)	LeastConfidence	67.34	71.94
(4)	MarginSampling	66.04	70.36
(5)	EntropySampling	66.91	72.52
(6)	BALDdropout	66.33	71.65

Table 3: Instance-based active learning baselines on the bird species classification task. We note that ALICE (4^{th} round, Acc 76.05%) in Table 2 (12) outperforms all instance-based active learning baselines with 66% extra training data (Acc 70.36%-73.09%).

ing of explanations' semantics and the hierarchical neural architecture improves classification performance a lot. Removing the grounded training image patches degrades ALICE's performance (ALICE w/o Grounding, 66.47%). Substituting the discriminating semantic segments' image patches with other semantic segments' patches leads to worse performance (ALICE w/ Random Grounding, 64.44%). The hierarchical neural architecture is also important. As shown in Table 2, a baseline model augmented with hierarchical classification (ALICE w/o Grounding, 66.74%) outperforms the flat C way classification (Base(Inception v3), 59.51%). Similarly, removing the hierarchical neural architecture from ALICE drops the performance a lot (ALICE w/o Hierarchy, 59.22% v.s. ALICE (4^{th} round), 76.05%). ALICE morphs the neural architecture based on class-based active learning (§ 4.2). If we replace class-based active learning with a random selection of class pairs, ALICE learns a bad model structure that leads to reduced performance (ALICE w/ Random Pairs, 42.67%).

Additional Experiments Table 3 shows our experiments with several common instance-based active learning baselines. We show the test accuracy of adding 33% extra training data (i.e., 125 extra data points) and adding 66% extra training data (i.e., 250 extra data points) using the instance-based active learning baselines. In this case, we observe that ALICE with 12 explanations (Accuracy 76.05%, Table 2 (12)) outperforms all instance-based active learning baselines with 250 extra data points(Accuracy 70.36%-73.09%, Table 3). We delay the combination of instance-based active learning and our class-based active learning as future work. To testify whether ALICE could work robustly with smaller amount of training data, we present an experiment on CUB starting with as few as 5 images per species. ALICE with 12 explanations ($k = 4$, $b = 3$) improves the accuracy of the base model from 49.76% to 62.80%, outperforming the base model with 15 images per class (Accuracy 59.51%, Table 2).

No.	Model	Accuracy (%)	
		relation	*domain*

(7)	**ALICE (2^{nd} round)**	**36.41**	**47.38**

Table 4: Test accuracy comparison among variants of ALICE on the social relationship classification task.

Visualization We show how the explanations help the learning model as shown in Figure 4. We visualize the saliency maps (Simonyan et al., 2014) corresponding to the correct class on four example images. As shown in Figure 4, the base model does not know which semantic segments to focus and makes wrong predictions. In contrast, ALICE's local classifiers obtain knowledge from the expert explanations and successfully learns to focus on the discriminating semantic segments to make the correct predictions.

6 Social Relationship Classification Task

Dataset We also evaluate ALICE on the People in Photo Album Relation dataset (Zhang et al., 2015; Sun et al., 2017). An example is shown in Figure 6. The dataset was originally collected from Flickr photo albums and involves 5 social domains and 16 social relations. We focus on the images that have only two people since handling more than two people requires task-specific neural architecture. The details of dataset pre-processing are included in Appendix. After pre-processing, we obtain 1,679 training images and 802 testing images. We experiment with a low-resource setting with 15% of the remaining training images (i.e., 264 images). We obtain explanations by converting the knowledge graph collected by Wang et al. (2018) into a parsed format. The semantic segments here are contextual objects like soccer. The knowledge graph contains heuristics to distinguish social relations by the occurrence of contextual objects (e.g., "soccer" for sports v.s. colleagues). We use a faster-RCNN-based object detector (Ren

Figure 6: Examples of social relationship classification. Explanations are reconstructed from Wang et al. (2018)

et al., 2017) trained on the COCO dataset (Lin et al., 2014) to localize the semantic segments (contextual objects) during training. The object detector is not used during testing. We set rounds of expert queries $k = 2$ and the query budget $b = 4$.

Results We compare ALICE to its several ablations (Table 4) and evaluate the performance on the testing set. We report classification accuracy on social relationships as well as social domains. We observe similar benefits of incorporating explanations to ALICE as in the bird species classification task. As shown in Table 4, the base model with 40% extra training data (i.e., 105 images) still slightly underperforms ALICE with 8 explanations (RandomSampling + 40% extra data, 36.28% v.s. ALICE (2^{nd} round), 36.41%). As shown in Figure 7, adding 1 explanation leads to similar performance gain as adding 13 labeled training data points. Our ablation experiment also confirms the importance of class-based active learning. If we replace class-based active learning with a random selection of class pairs, ALICE learns a bad model structure that leads to reduced performance (ALICE w/ Random Pairs, 22.94%). The performance drop in domain accuracy is also significant. We suspect it is because the bad model structure confuses the global classifier a lot. If the global classifier calls a wrong local classifier, the local classifier is forced to make a prediction on such a out-of-distribution data. In addition, our ablation experiment also verify the importance of having knowledge beyond having the localization model. Substituting the discriminating semantic segments' image patches with other semantic segments' patches leads to worse performance (ALICE w/ Random Grounding, 27.20%). One reason is that there are many objects in each image. Under our low resource setting, learning on the image patches of random semantic segments may make the model to latch on to sample-specific artifacts in the training images, which leads to poor generalization.

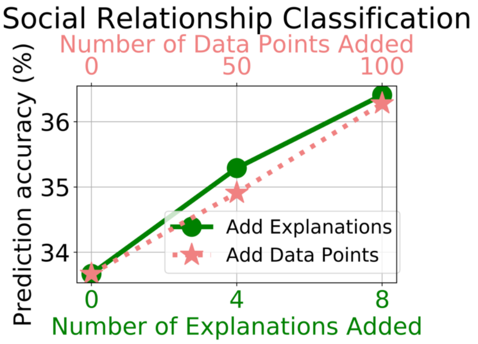

Figure 7: Comparing the performance gain of adding contrastive natural language explanations and adding training data points on social relationship classification.

7 Conclusion

We propose an expert-in-the-loop training framework ALICE to utilize contrastive natural language explanations to improve a learning algorithm's data efficiency. We extend the concept of active learning to class-based active learning for choosing the most informative query pair. We incorporate the extracted knowledge from expert natural language explanation by changing our algorithm's neural network structure. Our experiments on two visual recognition tasks show that incorporating natural language explanations is far more data-efficient than adding extra training data. In the future, we plan to examine the hierarchical classification architecture's potential for reducing computational runtime.

Acknowledgments

We would like to sincerely thank EMNLP 2020 Chairs and Reviewers for their review efforts and helpful feedback. We thank Yanbang Wang and Jingjing Tian for their help in early experiments. We would also like to extend our gratitude to Zhihua Jin, Xuandong Zhao and Can Liu for their valuable feedback and suggestions.

Appendix

Additional Implementation Details

We use Inception v3 (Szegedy et al., 2016) as our image encoder ϕ. The global pooling layer g_{pool} is a global average pooling layer. The input image size is $(448, 448)$. We implement our model in `PyTorch`. We implement the shared attention infrastructure of fine-grained classifiers by noting that calculating QK^T is equivalent to an efficient $1 \times 1 \times d$ convolution on the activation map $\phi(x) \in \mathbb{R}^{H \times W \times d}$, with M latent attention queries as M convolutional kernels. We use the same hyper-parameters for both datasets. We adopt Inception v3 (Szegedy et al., 2016) as the backbone and choose `Mix6e` layer as the activation map. We tune the hyper-parameters on the unused training images. We train the models using Stochastic Gradient Descent (SGD) with the momentum of 0.9, weight decay of $1e-5$. We decay the learning rate of each parameter group by 0.9 every 2 epochs using `torch.optim.lr_scheduler.StepLR`. The global pooling g is a global average pooling layer. We set M the number of learnable latent attention queries to 6. The total number of parameters of our model is $15, 114, 476$. The training time for our approach is less than 20 minutes since our resource constraint setting has a limited amount of training data. Unlike previous active learning on data-points, our class-based active learning is empirically insensitive to the change of random seeds and hyper-parameter (e.g., batch size). Therefore, we could collect the explanations in an on-demand manner.

Bird Species Classification Dataset

We adopt the random sampling method in (Vedantam et al., 2017), to make sure that the sampled species are challenging to classify. The sampling method is based on birds' biological hierarchy (Barz and Denzler, 2020) from Wikispecies. The 25 randomly sampled bird species are: Crested Auklet, Least Auklet, Parakeet Auklet, Tropical Kingbird, Gray Kingbird, Belted Kingfisher, Green Kingfisher, Pied Kingfisher, Ringed Kingfisher, Scarlet Tanager, Summer Tanager, Brown Thrasher, Sage Thrasher, California Gull, Heermann Gull, Ivory Gull, Ring billed Gull, Black capped Vireo, Blue headed Vireo, White eyed Vireo, Yellow throated Vireo, Artic Tern, Black Tern, Caspian Tern, Least Tern.

Saliency Map Visualization

We use the techniques in Simonyan et al. (2014) to visualze the saliency map. A saliency map tells us the degree to which each pixel in the image affects the classification score for that image. To compute it, we compute the gradient of the unnormalized score corresponding to the correct class (which is a scalar) with respect to the pixels of the image. If the image has shape $(3, H, W)$ then this gradient will also have shape $(3, H, W)$; for each pixel in the image, this gradient tells us the amount by which the classification score will change if the pixel changes by a small amount. To compute the saliency map, we take the absolute value of this gradient, then take the maximum value over the 3 input channels; the final saliency map thus has shape (H, W) and all entries are nonnegative.

Social Relationship Classification Dataset

PIPA-Relation dataset (Sun et al., 2017) is built on PIPA dataset (Zhang et al., 2015). We exclude the images with more than two people since it requires task-specific neural architecture. Since we have annotations of people pairs for each image, we could easily identify and remove images with more than two people. However, the dataset becomes heavily unbalanced after this step since images of certain relationships tend to have less people. To tackle this issue, we truncate the classes that have more than 200 training images left to 200 training images. Similarly, we truncate the classes that have more than 100 testing images left to 100 testing images. We finally get 1679 training images and 802 testing images.

Room-Across-Room: Multilingual Vision-and-Language Navigation with Dense Spatiotemporal Grounding

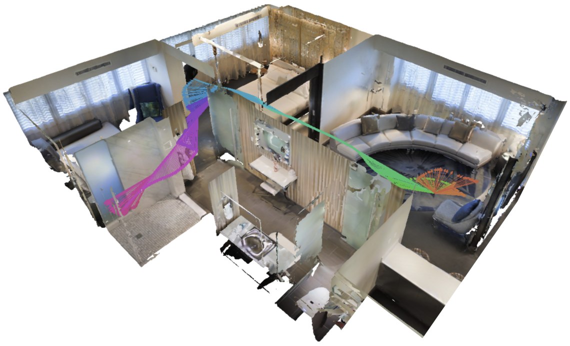
Abstract

We introduce Room-Across-Room (RxR), a new Vision-and-Language Navigation (VLN) dataset. RxR is multilingual (English, Hindi, and Telugu) and larger (more paths and instructions) than other VLN datasets. It emphasizes the role of language in VLN by addressing known biases in paths and eliciting more references to visible entities. Furthermore, each word in an instruction is time-aligned to the virtual poses of instruction creators and validators. We establish baseline scores for monolingual and multilingual settings and multitask learning when including Room-to-Room annotations (Anderson et al., 2018b). We also provide results for a model that learns from synchronized pose traces by focusing only on portions of the panorama attended to in human demonstrations. The size, scope and detail of RxR dramatically expands the frontier for research on embodied language agents in simulated, photo-realistic environments.



Our starting point is in a living room, we're facing towards a long beige sofa, and in front of the sofa there are three glass coffee tables, turn around and exit through the doorway that's in front of you, walk pass the bed that's on your right and then turn left, we're now facing towards another living room, and on the left there's an open door, walk towards that open door enter the bathroom that's in front of you, turn towards the right into the shower area, and that's your destination.

Figure 1: RxR's instructions are densely grounded to the visual scene by aligning the annotator's virtual pose to their spoken instructions for navigating a path.

1 Introduction

Vision-and-Language Navigation (VLN) tasks require computational agents to mediate the relationship between language, visual scenes and movement. Datasets have been collected for both indoor (Anderson et al., 2018b; Thomason et al., 2019b; Qi et al., 2020) and outdoor (Chen et al., 2019; Mehta et al., 2020) environments; success in these is based on clearly-defined, objective task completion rather than language or vision specific annotations. These VLN tasks fall in the Goldilocks zone: they can be tackled – but not solved – with current methods, and progress on them makes headway on real world grounded language understanding.

We introduce Room-across-Room (RxR), a VLN dataset that addresses gaps in existing ones by (1) including more paths that (2) counter known biases in existing datasets, and (3) collecting an order of magnitude more instructions for (4) three languages (English, Hindi and Telugu) while (5) capturing annotators' 3D pose sequences. As such, RxR includes dense spatiotemporal grounding for every instruction, as illustrated in Figure 1.

We provide monolingual and multilingual baseline experiments using a variant of the Reinforced Cross-Modal Matching agent (Wang et al., 2019). Performance generally improves by using monolingual learning, and by using RxR's follower paths as well as its guide paths. We also concatenate R2R and RxR annotations as a simple multitask strategy (Wang et al., 2020): the agent trained on both datasets obtains across the board improvements.

RxR contains 126K instructions covering 16.5K sampled guide paths and 126K human follower

demonstration paths. The dataset is available.[1] We plan to release a test evaluation server, our annotation tool, and code for all experiments.

2 Motivation

A number of VLN datasets situated in photo-realistic 3D reconstructions of real locations contain human instructions or dialogue: R2R (Anderson et al., 2018b), Touchdown (Chen et al., 2019; Mehta et al., 2020), CVDN (Thomason et al., 2019b) and REVERIE (Qi et al., 2020). RxR addresses shortcomings of these datasets—in particular, multilinguality, scale, fine-grained word grounding, and human follower demonstrations (Table 1). It also addresses path biases in R2R. More broadly, our work is also related to instruction-guided household task benchmarks such as ALFRED (Shridhar et al., 2020) and CHAI (Misra et al., 2018). These synthetic environments provide interactivity but are generally less diverse, less visually realistic and less faithful to real world structures than the 3D reconstructions used in VLN.

Multilinguality. The dominance of high resource languages is a pervasive problem as it is unclear that research findings generalize to other languages (Bender, 2009). The issue is particularly severe for VLN. Chen and Mooney (2011) translated(∼1K) English navigation instructions into Chinese for a game-like simulated 3D environment. Otherwise, all publicly available VLN datasets we are aware of have English instructions.

To enable multilingual progress on VLN, RxR includes instructions for three typologically diverse languages: English (en), Hindi (hi), and Telugu (te). The English portion includes instructions by speakers in the USA (en-US) and India (en-IN). Unlike Chen and Mooney (2011) and like the TyDi-QA multilingual question answering dataset (Clark et al., 2020), RxR's instructions are not translations: all instructions are created from scratch by native speakers. This especially matters for VLN, as different languages encode spatial and temporal information in idiosyncratic ways–e.g., how contact/support relationships are expressed (Munnich et al., 2001), frame of reference (Haun et al., 2011), and how temporal accounts are expressed (Bender and Beller, 2014).

Scale. Embodied language tasks suffer from a relative paucity of training data; for VLN, this has led to a focus on data augmentation (Fried et al., 2018; Tan et al., 2019), pre-training (Wang et al., 2019; Huang et al., 2019; Li et al., 2019), multi-task learning (Wang et al., 2020) and better generalization through piece-wise curriculum design (Zhu et al., 2020). To address this shortage, for each language RxR contains 14K paths with 3 instructions per path, for a total of 126K instructions and 10M words (based on whitespace tokenization). As illustrated in Table 1, this is *an order of magnitude* larger than previous datasets.

	Number of:				Includes:

RxR	3	126K	9.8M	16.5K	✓	✓	✓

†The number of dialogues. ‡Grounding limited to one object per instruction.

Table 1: VLN dataset comparison. RxR is larger, multilingual, and includes dense spatiotemporal groundings (Ground) and follower demonstrations (Demos).

Fine-Grained Grounding. Like R2R, RxR's instructions are collected by immersing *Guide* annotators in a simulated first-person environment backed by the Matterport3D dataset (Chang et al., 2017) and asking them to describe predefined paths. RxR also enhances each instruction with dense spatiotemporal groundings. Guides speak as they move and later transcribe their audio; our annotation tool records their 3D poses and time-aligns the entire *pose trace* with words in the transcription. Instructions and pose traces can thus be aligned with any Matterport data including surface reconstructions (Figure 1), RGB-D panoramas (Figure 4), and 2D and 3D semantic segmentations.

Follower Demonstrations. Annotators also act as *Followers* who listen to a Guide's instructions and attempt to follow the path. In addition to verifying instruction quality, this allows us to collect a play-by-play account of how a human interpreted the instructions, represented as a pose trace. Guide and Follower pose traces provide dense spatiotemporal alignments between instructions, visual percepts and actions – and both perspectives are useful for agent training.

Path Desiderata. R2R paths span 4–6 edges and are the shortest paths from start to goal. Thomason et al. (2019a) showed that agents can exploit effective priors over R2R paths, and Jain et al. (2019) showed that R2R paths encourage goal seeking

(a) Panorama navigation graph with room annotations. (b) Shortest path from p_8 to p_6 on the subgraph.

Figure 2: Given the panorama navigation graph P with room graph R in Figure 2a, we sample a simple room path (r_0, r_2, r_3) inducing the subgraph in Figure 2b. The generated panorama path is the shortest path in the subgraph linking sampled panoramas r_8 and r_6.

over path adherence. These matter both for generalization to new environments and fidelity to the descriptions given in the instruction—otherwise, strong performance might be achieved by agents that mostly ignore the language. RxR addresses these biases by satisfying four *path desiderata*:

1. High variance in path length, such that agents cannot simply exploit a strong length prior.
2. Paths may approach their goal indirectly, so agents cannot simply go straight to the goal.
3. Naturalness: paths should not enter cycles or make continual direction changes that would be difficult for people to describe and follow.
4. Uniform coverage of environment viewpoints, to maximize the diversity of references to visual landmarks and objects over all paths.

This increases RxR's utility for testing agents' ability to ground language. It also makes RxR a more challenging VLN dataset—but one for which human followers still achieve a 93.9% success rate.

3 Two-Level Path Sampling

We satisfy desiderata 1-3 using a two-level procedure. At a high-level, each path visits a sequence of rooms; these are *simple paths* with no repeated (room) vertices. Such paths are *not necessarily* shortest paths. The low-level sequence is then the shortest panorama path, constrained by the room sequence. Given the set of all such paths across all houses, the fourth desiderata is satisfied by iteratively selecting the path that most improves coverage while maintaining a bias against shortest paths.

Preliminaries Movement in the simulator is based on a navigation graph. Vertices correspond to 360-degree panoramic images, captured at approximately 2.2m intervals throughout 90 indoor environments. Edges are navigable links between panoramas. Chang et al. (2017) also partition panoramas via human-defined *room* annotations.

Let P be an undirected graph of interconnected panoramas, with vertices $p_i \in \mathcal{V}(P)$ and edges $(p_i, p_j) \in \mathcal{E}(P)$. Let A_R be a set of disjoint room annotations; each room $r_i \in A_R$ is a non-overlapping subset of panoramas $r_i \subseteq \mathcal{V}(P)$, as shown in Figure 2a. We abbreviate $(p_1, \cdots, p_m)$ as $p_{1:m}$.

We create R, an undirected room graph with vertices $\mathcal{V}(R) = \{\bigcup \mathcal{C}(P[r_i]) \mid r_i \in A_R\}$. $P[r_i]$ is the subgraph of P induced by room annotation r_i and $\mathcal{C}$ returns a graph's connected components. Simply put, each vertex in R encompasses a subgraph of P. An edge $(r_i, r_j) \in \mathcal{E}(R)$ exists if the subgraph of P induced by $\mathcal{V}(r_i) \cup \mathcal{V}(r_j)$ is connected.

Path Generation We generate the set of all simple paths in R that traverse at most 5 rooms and two building levels. Let $r_{p_i} \in \mathcal{V}(R)$ be the room containing panorama p_i. As shown in Figure 2b, for each room path $r_{1:n}$, we construct a directed graph $P[r_{1:n}]$ in which an edge (p_i, p_j) exists if $r_{p_i} = r_{p_j}$ (p_i and p_j are in the same room) or (r_{p_i}, r_{p_j}) is an edge in the room path. Given $P[r_{1:n}]$, we sample the start p_1 and goal p_m uniformly from r_1 and r_n, respectively. The full panorama path $p_{1:m}$ is then the shortest path between p_1 and p_m in $P[r_{1:n}]$.

Room size varies greatly, so this approach produces high path length variance. It also satisfies naturalness because people tend to ground instructions at the room level (e.g., *Exit through the carved wooden door on the other side of the room*). We find such paths easy to describe even with as many as 20 edges. Finally, these paths can approach their goal indirectly, as exemplified in Figure 2b.

Greedy Selection for Coverage The final path dataset D is constructed by repeatedly selecting a panorama path $p_{1:m}$ from all sampled paths (without replacement) until a desired size is reached. After selecting k paths, let $\mathcal{O}(p_i, D_k)$ be the number of occurrences of panorama p_i in the paths in D_k. At step $k+1$, we select the path with the minimum value for $\frac{d(p_1,p_m)}{L(p_{1:m})} + \frac{1}{m}\sum_{p_i \in p_{1:m}} \mathcal{O}(p_i, D_k)$, where L is path length in P and $d(p_1, p_m)$ is the shortest path distance between p_1 and p_m in P. The first term prefers non-shortest paths while the second encourages selection of paths that cover panoramas with low coverage in D_k. This selection step is also

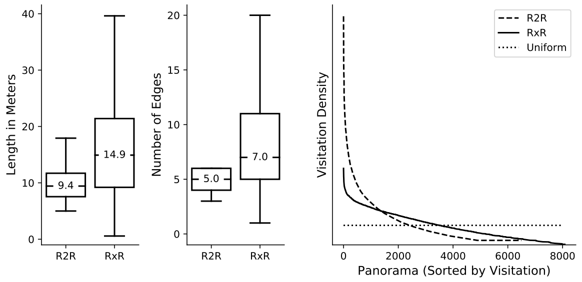

Figure 3: RxR's paths are longer on average than R2R's, exhibiting far greater variation in length (measured in both meters and edges) while achieving more uniform panorama coverage. Comparisons shown are for train and val since the R2R test set is sequestered.

subject to a maximum path length of 40m, and a maximum of 500 paths per building environment.

Path Statistics In total, we sample 16522 paths, which are split: 11089 train, 1232 val-seen (train environments), 1517 val-unseen (val environments), and 2684 test, following the same environment splits as Matterport3D and R2R. Compared to R2R, RxR paths are longer, spanning 8 edges and 14.9m on average, vs. 5 edges and 9.4m in R2R. More importantly, as shown in Figure 3, RxR paths exhibit much greater variation in length while also achieving more uniform coverage of the panoramas (and edges). Furthermore unlike R2R, 44.5% of RxR paths are *not* the shortest path from the start to the goal location. RxR paths are on average 27.4% longer than the shortest path.

4 Data Collection and Metrics

We immerse annotators in our own web-based version of the Matterport3D simulator using the panoramic images and the navigation graph. Compared to Anderson et al. (2018b), our annotation tool has additional capabilities including speech collection, virtual pose tracking, and time-alignment between transcript and pose. Figure 4 gives an example instruction with accompanying Guide and Follower pose traces. Here, we describe our collection process, analysis of the data, path evaluation metrics and simple baselines.

Guide Task Like R2R, our simulator has camera controls allowing continuous heading and elevation changes and movement between panoramas. Guides look around and move to explore a provided path and attempt to create an instruction others can follow. R2R's Guides create written instructions.

Table 2: RxR summary statistics. Times in seconds (s).

In contrast, RxR's Guides *speak* and the tool logs their entire virtual camera pose sequence. We use a 640 × 480 pixel viewing canvas and a camera vertical field of view of 75 degrees. This process is inspired by Localized Narratives (Pont-Tuset et al., 2020), an image captioning dataset for which annotators move mouse pointers around images while talking about them.

As with Localized Narratives, RxR Guides transcribe their own recordings; this produces high quality text versions of the instructions. To align text and pose traces, we generate a time-stamped transcription using automatic speech recognition.[2] The transcription and ASR output are aligned using dynamic time warping. The output of the Guide task is an audio file, a tokenized, timestamped, manually-transcribed instruction, and a *pose trace* (a series of timestamped 6-DOF camera poses). On average, Guide task annotations (including both steps, performed back-to-back) take 458 seconds.

For each language (English, Hindi and Telugu) we annotate 14K paths with three instructions each. In the English dataset, each path gets one US English instruction and two Indian English instructions. Of the 14K paths per language, 12.8K paths are common across all three languages, and 1.2K paths in each language are unique (equaling 16.5K paths in total). The fact that most paths are annotated 9 times (3 per language) creates interesting opportunities to study aligned instructions across languages. Unique paths add variety and coverage.

Follower Task As Followers, annotators begin at the start of an unknown path and try to follow the Guide's instruction. They observe the environment and navigate in the simulator as the Guide's audio plays. They can pause, rewind and skip forward in the instruction. If they believe they have reached the the end of the path, or give up, they indicate they are done and rate the instruction's clarity and their confidence in their own navigation. On average, Follower tasks take 132 seconds.

The Follower tasks objectively validate the quality of Guide instructions based on whether the Follower can succeed (i.e., reaching within 3m of the last panorama in the path). If the Follower doesn't succeed, the Guide instruction is paired with a second Follower. If the second Follower succeeds, the first Follower annotation is discarded and replaced. If the second Follower also fails, then the path is re-enqueued to generate another Guide and Follower annotation. The most successful of the three resulting Guide-Follower pairs is selected for inclusion in RxR and the others are discarded.

In addition to validating data quality, the Follower task also trains annotators to be better Guides—following bad instructions often helps one see how to produce better instructions. Most importantly, we collect the pose trace of the Follower as they execute the instruction. This provides an alternative path with dense grounding that we can compare to the Guide's pose trace and use as an additional training signal.

Dataset Analysis Table 2 provides summary statistics for RxR. The average words per instruction (using whitespace tokenization) is 78 vs R2R's 29. US English instructions are the longest on average. We attribute this to conventions developed by each annotator pool rather than language specific properties. On average Guide tasks take much longer than Follower tasks (458 vs. 132 seconds). Most of the Guide's time is spent transcribing audio (Guide audio recordings average 60 seconds).

Following a similar analysis as Chen et al. (2019), Table 3 gives examples and statistics for linguistic phenomena, based on manual analysis of instructions for 25 paths. All RxR subsets produce a higher rate of *entity references* compared to R2R. This is consistent with the extra challenge of RxR's paths and our annotation guidance that instructions should help followers stay on the path as well as reach the goal. Doing so requires more extensive use of objects in the environment. RxR's higher rate of both *coreference* and *sequencing* indicates that its instructions have greater discourse coherence and connection than R2R's. RxR also includes a far higher proportion of *allocentric relations* and *state verification* compared to R2R, and matches Touchdown (navigation instructions). Hindi contains less coreference, sequencing, and temporal

Table 4: Simple baselines on val-unseen paths. RxR proves more difficult than R2R overall, and less amenable to agents that tend to go straight (baselines 2 and 3). Note: Baseline 3 partly exploits the gold path.

conditions than the other languages. That said, it is not clear how much the differences *within* RxR exhibited in Table 3 can be attributed to language, dialect, annotator pools, or other factors.

Figure 5 (top) illustrates the close alignment between instruction progress (measured in words) and path progress (measured in steps). Figure 5 (bottom) indicates that both Guide and Tourist annotators orient themselves by looking around at the first panoramic viewpoint, after which they maintain a narrower focus. On average, Guides / Tourists observe 43% / 44% of the available spherical visual signal at the first viewpoint, and 27% / 28% at subsequent viewpoints. These findings stand in contrast to standard VLN agents that routinely consume the entire panoramic image and attend over the entire instruction sequence at each step. Inputs that the Guide / Tourist have not observed cannot influence their utterances / actions, so pose traces offer rich opportunities for agent supervision.

Evaluation We use the following standard evaluation metrics (with arrows indicating improvement): *Path Length* (**PL**), *Navigation Error* (**NE** ↓) *Success Rate* (**SR** ↑), *Success weighted by inverse Path Length* (**SPL** ↑), *Normalized Dynamic Time Warping* (**NDTW** ↑), and *Success weighted by normalized Dynamic Time Warping* (**SDTW** ↑). See Anderson et al. (2018a) and Ilharco et al. (2019) for discussion of VLN metrics. Since RxR was designed to include paths that approach their goal indirectly, we focus primarily on **NDTW** and **SDTW** which explicitly capture path adherence. See Table 4 for a comparison of the performance of several simple baselines on R2R and RxR. Each simple baseline requires a stopping criteria; we choose to stop after N steps where N is the average number of steps in the train set paths (5 in R2R and 8 in RxR). Consistent with our motivation to reduce biases in paths, these simple baselines show that going straight is far less effective in RxR than R2R.

5 Experiments

Agent We use a model architecture similar to that of the Reinforced Cross-Modal Matching (RCM) agent (Wang et al., 2019), consisting of an instruction encoder and a sequential LSTM (Hochreiter and Schmidhuber, 1997) decoder that computes a distribution over actions at each step. However, since RxR instructions are much longer than R2R, we replace the bidirectional LSTM instruction encoder with a more parallelizable CNN encoder. In preliminary experiments on R2R we find that encoding word embeddings via successive 1D convolutions with rectified linear (ReLU) activations and residual connections (He et al., 2016) is equally effective and more time and space efficient. We denote the output of the instruction encoder by $x \in \mathbb{R}^{l \times d}$ where l is the instruction length and d is the feature dimension. In both monolingual and multilingual experiments we use features extracted from a pre-trained multilingual BERT model (Devlin et al., 2019) for the word embeddings.

At each time step t, the agent receives a panoptic encoding of its viewpoint $v_t \in \mathbb{R}^{k \times d}$ (where $k = 36$ is the number of 30° intervals that span the panorama) along with a visual encoding of navigable directions $a_t \in \mathbb{R}^{n \times d}$ (where n is the number of navigable directions). Each feature of dimension d is a pre-trained CNN feature concatenated with an angle encoding (Fried et al., 2018). The LSTM decoder computes an updated hidden state h_t by conditioning on the previous selected action in a_{t-1} and attending over the panoptic encoding v_t and the instruction x using dot-product attention (Luong et al., 2014). The distribution over next actions is computed via a similarity ranking $h_t \cdot a_{t,i}$ between hidden state h_t and each direction encoding in a_t.

For the image features we use an EfficientNet-B4 CNN (Tan and Le, 2019). Following Parekh et al. (2020), we pretrain the CNN in an image-text dual encoder setting using the Conceptual Captions dataset (Sharma et al., 2018). In preliminary experiments, we found that pretraining the CNN in this way gave noticeable improvements over the same CNN pretrained for image classification on ImageNet (Russakovsky et al., 2015).

Grounding Supervision To incorporate spatiotemporal groundings into agent training, for each Guide path (G-path) and Follower path (F-path) we convert the corresponding pose trace into: (1) a sequence of text masks $b_t \in \{0,1\}^l$ indicating which words in instruction x the Guide spoke / Follower heard *at or prior to* step t, and (2) a sequence of visual masks $M_t \in \{0,1\}^{h \times w}$ indicating which pixels were observed in the panoramic image at t (like Figure 5 bottom). We then project and max-pool M_t to a vector mask $m_t \in \{0,1\}^k$ aligning to the agent's visual input features v_t. Zeros in b_t and m_t indicate irrelevant textual and visual inputs that were not observed by the annotators, and are therefore not related to their utterances and actions.

To help prevent the agent from overfitting to superficial correlations in the training data, we use b_t and m_t to supervise the normalized textual and visual attention weights in the model. Specifically, during training whenever the agent is on the gold path we apply a cross-entropy loss to the visual attention weights given by $\mathcal{L}(z, m_t) = \log \sum_{i=1}^{k} \exp(z_i) - \log \sum_{i=1}^{k} m_{t,i} \exp(z_i)$, where z is the vector of unnormalized logits determining attention weights via a softmax. This loss forces the attention weights on irrelevant input features towards zero. The textual version is analogous.

Implementation Details Agents are implemented in VALAN (Lansing et al., 2019), a distributed reinforcement learning framework designed for VLN. We use a mix of supervised learning and policy gradients. Each minibatch is constructed from 50% behavioural cloning roll-outs (following the gold paths while minimizing cross-entropy loss), and 50% policy gradient rollouts with reward (following paths sampled from the agent's policy). As in Ilharco et al. (2019), the reward at each step is the incremental difference in NDTW, plus a linear function of navigation error after stopping. All agents are trained with Adam (Kingma and Ba, 2014) to convergence (100K iterations with batch size of 32 and initial learning rate of 1e-4).

Monolingual Results Table 5 provides results on the val-unseen split for several training settings, as well as human performance from Follower annotations. We report en-US and en-IN results together as en. Experiments 1–3 compare agents trained (1) only on G-paths, (2) only on F-paths, and (3) on both. In contrast to algorithmically generated G-paths, each F-path reflects a grounded human interpretation of an instruction, which may deviate from the G-path because multiple correct interpretations are possible (e.g., Figure 4). For training, we do not differentiate F-paths from G-paths, and each

Settings – G: instruction paired with Guide paths, F: instructions paired with Follower paths, X: cross-translated instructions.

Table 5: RxR val-unseen: Monolingual vs. multilingual results. Training with both Guide and Follower paths benefits all languages (exp. 3 vs. 1 and 2), monolingual outperforms multilingual (exp. 3 vs. 4), training with cross-translations hurts performance (exp. 5 vs. 4), and training with visual attention supervision gives mixed results (Multi* in exp. 6 vs 4).

	Train Data		**SR ↑**				**SPL ↑**				**SDTW ↑**				**NDTW ↑**			
Exp.	R2R	RxR	R2R	en	hi	te	R2R	en	hi	te	R2R	en	hi	te	R2R	en	hi	te
(7)	✓		36.5	14.5	9.6	9.7	31.7	11.2	7.5	7.4	29.5	9.8	6.3	6.1	48.1	29.0	25.4	25.2
(4)		✓	19.2	22.2	23.0	**23.1**	17.7	19.8	20.7	**20.7**	16.0	17.8	18.3	**18.4**	43.2	38.6	39.2	**38.8**
(8)	✓	✓	**37.8**	**22.5**	**23.6**	**23.1**	**34.3**	**20.1**	**21.0**	20.5	**32.0**	**18.3**	**19.2**	**18.4**	**52.3**	**38.8**	**39.4**	38.4

Table 6: Multitask and transfer learning results on RxR and R2R val-unseen. A multitask model (exp. 8) performs best on both datasets, but domain differences thwart simple transfer learning (i.e., train on X, evaluate on Y).

instruction-path pair is treated as an independent example. Experiment (3) shows that including both G- and F-paths in training benefits every metric. Given the overall positive impact of F-paths, we use both path types in our further experiments.

Multilinguality For experiment (4) in Table 5, we train a single multilingual agent on all three languages simultaneously. While the multilingual agent sees substantially more instructions than each monolingual agent, performance is worse across all metrics. This is consistent with results in multilingual machine translation (MT) and automatic speech recognition (ASR) where adding more languages can also lead to degradation for high-resource languages (Aharoni et al., 2019; Pratap et al., 2020). Experiment (5) takes this one step further by obtaining translations from every instruction into the two other languages (e.g., en → hi, te) using a MT service.[3] Including these translations hurts performance for all languages. The fact that most G-paths are shared across languages may limit the value of automatic cross-translations. Notwithstanding the higher performance of the monolingual approaches, in the remaining experiments we focus on multilingual agents for greater scalability.

Spatiotemporal Grounding Supervision Table 5 experiment (6) incorporates a loss for spatiotemporal grounding over visual attention which gives mixed results on val-unseen (better on NDTW, NE and worse on success-based metrics) compared to (4). Applying the same approach to textual attention did not improve performance. However, we stress that this is only a preliminary investigation. Using human demonstrations to supervise visual groundings is an active area of research (Wu and Mooney, 2019; Selvaraju et al., 2019). As one of the first large-scale spatially-temporally aligned language datasets, RxR offers new opportunities to extend this work from images to environments.

Multitask and Transfer Learning Table 6 reports the performance of the multilingual agent under multitask and transfer learning settings. For simplicity, the R2R model (exp. 7) is trained without data augmentation from model-generated instructions (Fried et al., 2018; Tan et al., 2019) and with hyperparameters tuned for RxR. Under these settings, the multitask model (exp. 8) performs best on both datasets. However, transfer learning performance (RxR → R2R and vice-versa) is much weaker than the in-domain results. Although RxR and R2R share the same underlying environments, we note that RxR → R2R cannot exploit R2R's

Table 8: RxR test set results, based on the monolingual agents (3) and the multilingual agent (4).

path bias, and for R2R → RxR, the much longer paths and richer language are out-of-domain.

Unimodal Ablations Table 7 reports the performance of the multilingual agent under settings in which we ablate either the vision or the language inputs during both training and evaluation, as advocated by Thomason et al. (2019a). The multimodal agent (4) outperforms both the language-only agent (9) and the vision-only agent (10), indicating that both modalities contribute to performance. The language-only agent performs better than the vision-only agent. This is likely because even without vision, parts of the instructions such as 'turn left' and 'go upstairs' still have meaning in the context of the navigation graph. In contrast, the vision-only model has no access to the instructions, without which the paths are highly random.

Test Set RxR includes a heldout test set, which we divide into two splits: test-standard and test-challenge. These splits will remain sequestered to support a public leaderboard and a challenge so the community can track progress and evaluate agents fairly. Table 8 provides test-standard performance of the mono and multilingual agents using Guide and Follower paths, along with random and human Follower scores. While the learned agent is clearly much better than a random agent, there is a great deal of headroom to reach human performance.

6 Conclusion

RxR represents a significant evolution in the scale, scope and possibilities for research on embodied language agents in simulated, photo-realistic 3D environments. RxR's paths better ensure that language itself will play a fundamental role in better agents. Evaluating on three typologically diverse languages will help the community avoid overfitting to a particular language and dataset.

We have only begun to explore the possibilities opened up by pose traces. Whereas others have retro-actively refined R2R's annotations to get alignments between sub-instructions and panorama sequences (Hong et al., 2020), RxR provides *word-level* alignments to *specific pixels* in panoramas. This is obtained as a by-product of significant work on the annotation tooling itself and designing the process to be more natural for Guides. Finally, every instruction is accompanied by a Follower demonstration, including a perspective camera pose trace that shows a play-by-play account of how a human interpreted the instructions given their position and progress through the path. We have shown that these can help with agent training, but they also open up new possibilities for studying grounded language pragmatics in the VLN setting, and for training VLN agents with perspective cameras – either in the graph-based simulator or by lifting RxR into a continuous simulator (Krantz et al., 2020).

Acknowledgments

We thank Sneha Kudugunta for analyzing the Telugu annotations, and the Google Data Compute team, especially Igor Karpov, Ashwin Kakarla and Christina Liu, for their tooling and annotation support for this project, Austin Waters and Su Wang for help with image features, and Daphne Luong for executive support for the data collection.

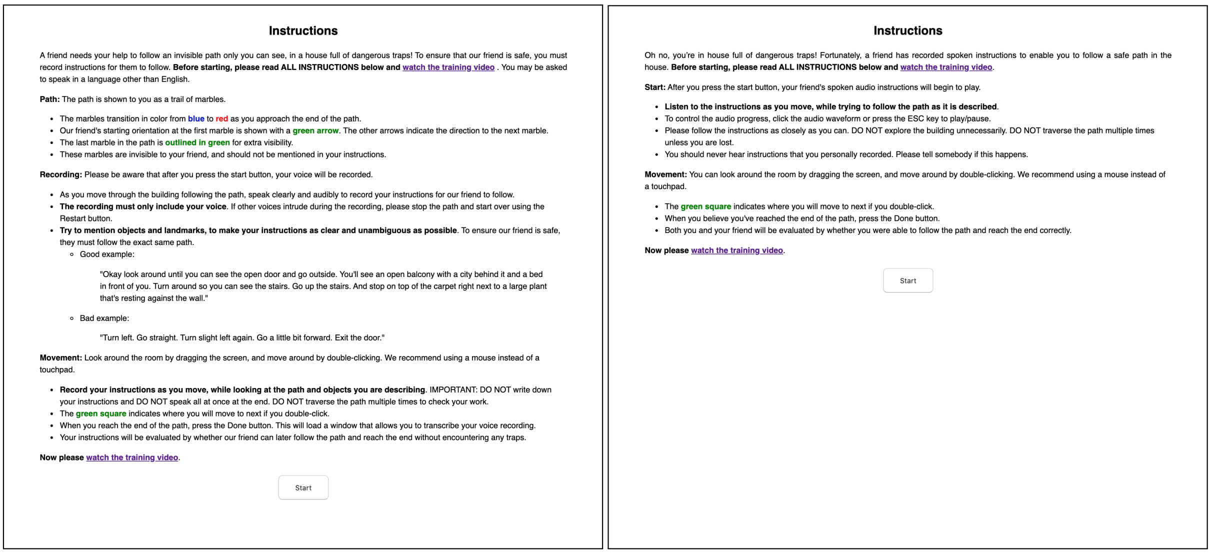
A Supplementary Material

Annotators In total, 247 annotators contributed to RxR, with 97 based in the USA and the remainder based in India and contributing to the Indian English, Hindi and Telugu annotations. The annotators were paid hourly wages that are competitive for their locale. They have standard rights as contractors. They were fluent in the language they were tasked with.

We ensure that a Guide does not annotate the same path twice. As Followers, annotators do not follow their own Guide instructions. Furthermore, we have provided annotators multiple forms of feedback as they complete tasks. After a round of pilot instructions were collected, we provided detailed analysis of common patterns that produced poor instructions and clear guidelines for producing better instructions. Annotators provided UI suggestions and interesting corner cases to us that allowed us to refine the simulator and annotation process before kicking off the full annotation process. Throughout the process, annotators have had access to a dashboard that shows them their success rate as both Guide and Follower. We indicated that their success as Guide and a Follower should be above 80%. Any annotator whose success is lower is either given further training or is taken off the task.

Unfortunately, we cannot release the audio instructions yet due to the impact of COVID-19: our annotators had to complete the tasks from home, so we need to review all recordings for safety and privacy. We hope to include the audio in a future release.



Instructions

A friend needs your help to follow an invisible path only you can see, in a house full of dangerous traps! To ensure that our friend is safe, you must record instructions for them to follow. **Before starting, please read ALL INSTRUCTIONS below and watch the training video** . You may be asked to speak in a language other than English.

Path: The path is shown to you as a trail of marbles.

- The marbles transition in color from **blue** to **red** as you approach the end of the path.
- Our friend's starting orientation at the first marble is shown with a **green arrow**. The other arrows indicate the direction to the next marble.
- The last marble in the path is **outlined in green** for extra visibility.
- These marbles are invisible to your friend, and should not be mentioned in your instructions.

Recording: Please be aware that after you press the start button, your voice will be recorded.

- As you move through the building following the path, speak clearly and audibly to record your instructions for our friend to follow.
- **The recording must only include your voice**. If other voices intrude during the recording, please stop the path and start over using the Restart button.
- **Try to mention objects and landmarks, to make your instructions as clear and unambiguous as possible**. To ensure our friend is safe, they must follow the exact same path.
  - Good example:

    > "Okay look around until you can see the open door and go outside. You'll see an open balcony with a city behind it and a bed in front of you. Turn around so you can see the stairs. Go up the stairs. And stop on top of the carpet right next to a large plant that's resting against the wall."

  - Bad example:

    > "Turn left. Go straight. Turn slight left again. Go a little bit forward. Exit the door."

Movement: Look around the room by dragging the screen, and move around by double-clicking. We recommend using a mouse instead of a touchpad.

- **Record your instructions as you move, while looking at the path and objects you are describing**. IMPORTANT: DO NOT write down your instructions and DO NOT speak all at once at the end. DO NOT traverse the path multiple times to check your work.
- The **green square** indicates where you will move to next if you double-click.
- When you reach the end of the path, press the Done button. This will load a window that allows you to transcribe your voice recording.
- Your instructions will be evaluated by whether our friend can later follow the path and reach the end without encountering any traps.

Now please watch the training video.

Instructions

Oh no, you're in house full of dangerous traps! Fortunately, a friend has recorded spoken instructions to enable you to follow a safe path in the house. **Before starting, please read ALL INSTRUCTIONS below and watch the training video**.

Start: After you press the start button, your friend's spoken audio instructions will begin to play.

- **Listen to the instructions as you move, while trying to follow the path as it is described**.
- To control the audio progress, click the audio waveform or press the ESC key to play/pause.
- Please follow the instructions as closely as you can. DO NOT explore the building unnecessarily. DO NOT traverse the path multiple times unless you are lost.
- You should never hear instructions that you personally recorded. Please tell somebody if this happens.

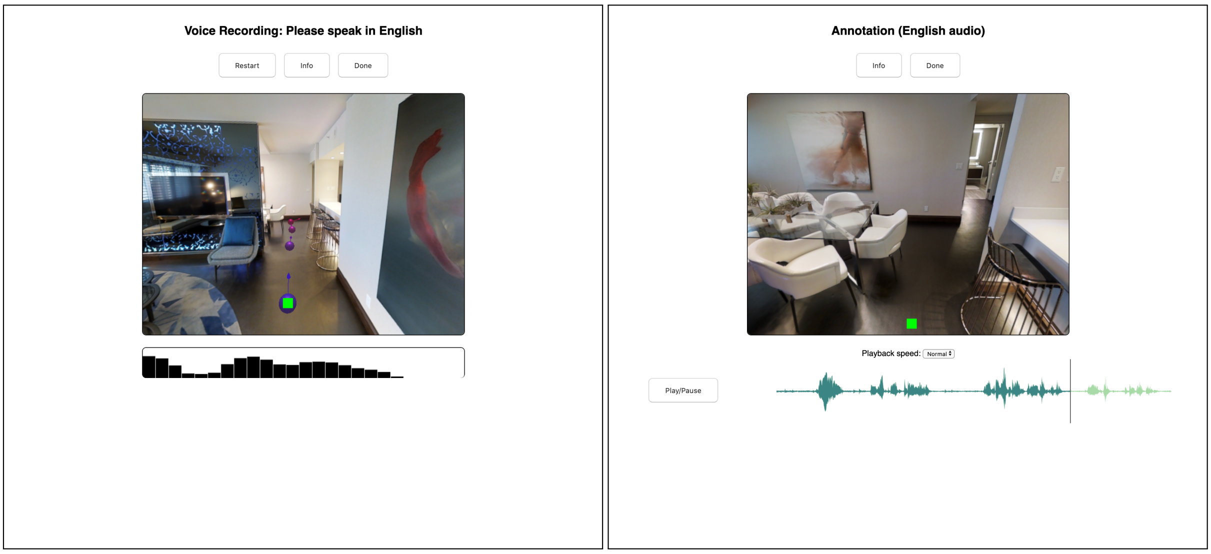
Movement: You can look around the room by dragging the screen, and move around by double-clicking. We recommend using a mouse instead of a touchpad.

- The **green square** indicates where you will move to next if you double-click.
- When you believe you've reached the end of the path, press the Done button.
- Both you and your friend will be evaluated by whether you were able to follow the path and reach the end correctly.

Now please watch the training video.

(a) Guide Worker Instructions (49.1 seconds)

(b) Follower Worker Instructions (38.5 seconds)

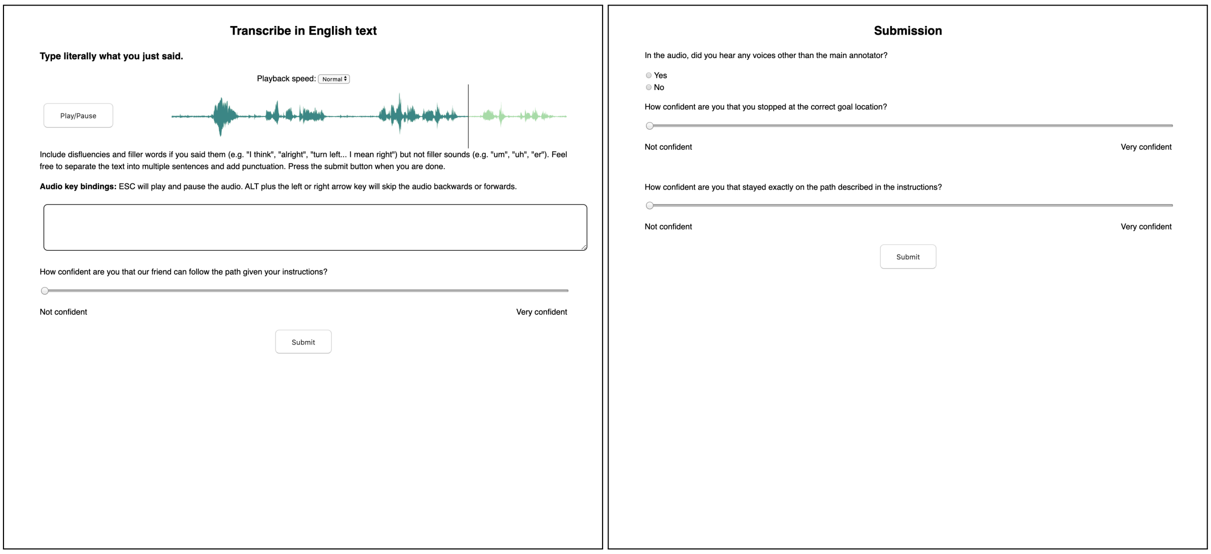


Voice Recording: Please speak in English

Annotation (English audio)

(c) Guide Annotation (64.4 seconds)

(d) Follower Verification (89.8 seconds)



Transcribe in English text

Type literally what you just said.

Include disfluencies and filler words if you said them (e.g. "I think", "alright", "turn left... I mean right") but not filler sounds (e.g. "um", "uh", "er"). Feel free to separate the text into multiple sentences and add punctuation. Press the submit button when you are done.

Audio key bindings: ESC will play and pause the audio. ALT plus the left or right arrow key will skip the audio backwards or forwards.

How confident are you that our friend can follow the path given your instructions?

Not confident — Very confident

Submission

In the audio, did you hear any voices other than the main annotator?

○ Yes
○ No

How confident are you that you stopped at the correct goal location?

Not confident — Very confident

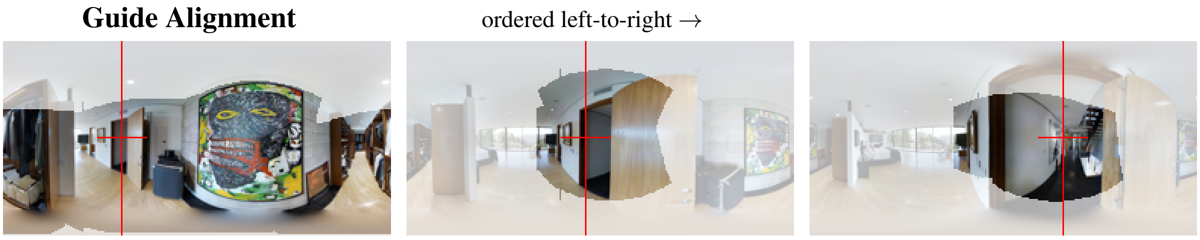
How confident are you that stayed exactly on the path described in the instructions?

Not confident — Very confident

(e) Guide Transcription (358.3 seconds)

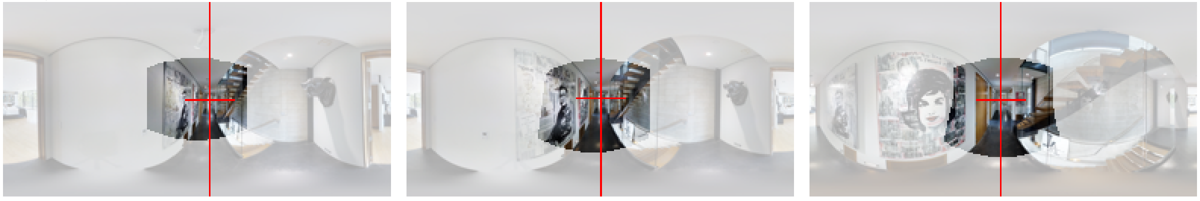
(f) Follower Survey (15.2 seconds)

Figure 6: Screenshots of the Guide (a, c, e) and Follower (b, d, f) views in our annotation tool, and the average duration for each phase during collection of the first 33K instructions.



You're starting in a closet, facing an abstract painting on your right. Just slightly to your left will be an open, wooden door next to an amp. Walk through that wooden door.

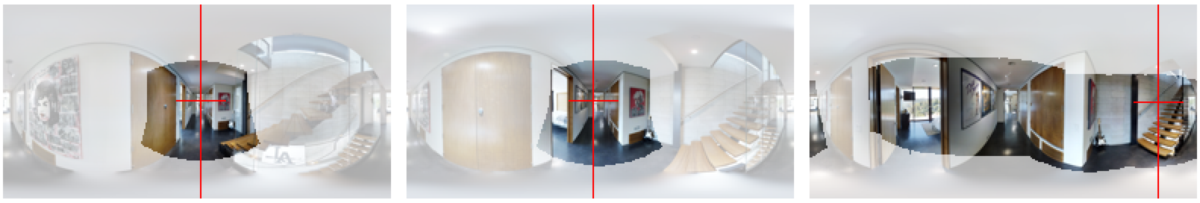
This will take you to a hallway with stairs going up on the right hand side. Just go straight down the hallway...



...about five steps...

...steps. You're going to pass the...

...the stairs.



Go one...

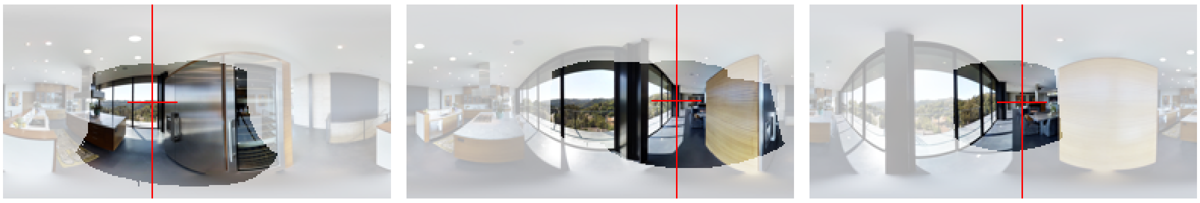
...one step past the stairs. You'll just pass the Albert Einstein painting on your right, and an open doorway on your left.

There will be a guitar on the floor. At this point, turn around and go up the stairs.

Once you get to the Jimi Hendrix painting, turn...

...turn to your right and walk between the stair railing and the white kitchen cabinet toward...

...toward the refrigerator. Take a step in front of the refrigerator.



Take another step toward the windows overlooking the trees.

Then take a right at the end of the refrigerator. You'll take three steps...

...toward the fireplace.

Once you get...

...get to the fireplace, it will be on your right hand side. This is where you stop.

Figure 7: Spatiotemporal alignment of textual instructions, visual percepts and actions for a long (19-step) en-US **Guide** path. The next action is indicated in red and unseen pixels in the panoramic images are faded.

Figure 8: Spatiotemporal alignment of textual instructions, visual percepts and actions for a long en-US **Follower** path. The next action is indicated in red and unseen pixels in the panoramic images are faded.

You begin in a large wooden room with a dining table, an immense fireplace, and a lovely carpet. turn to your right, and move along the edge of that carpet you're nearest to, towards the wooden doorway into another interior room. You should see a large circular table with an urn in the center of it when you enter that room. Skirt the edge of that table to the left, moving towards the staircase. Don't go to the staircase, but instead proceed to the left of it, down the large rectangular rug. Continue through the open glass door,, and the second glass door across the small hallway from it. Step inside this small... Dining area? If you are just inside the room with the circular table in the middle of it, a couch on the left hand wall, two armchairs across from the entrance, and one armchair, striped, just next to you, you're in the right place, and you are done.

Starting facing a large ornate vase with gold leaf on it as well as a curtained window, we are going to turn towards the dinning room table we are face. We are going to hop around it and come to just beside the painting in the background. Once we're behind the head of the table chair, we are going to face forward and notice that there is a marble staircase before us. Head towards that, but don't head up the stairs and don't exit the room, instead we're going to turn to the left and you should see a kitchen before you. Let's go ahead and enter the kitchen through the archway, and here walk to the right of the China cabinet, and towards the island with the dark cabinets and the granite countertop. Once we've turned the corner, and we're beside the large gas range and the stainless steel hood, we're going to walk between the stove and the kitchen island, towards the refrigerator, and you should see an open doorway before you, to the right of the fridge. Go ahead and walk towards this open door and through it. Walk all the way down and turn to the right, passed the closed door, until you're faced with another flight of stairs. Let's go ahead and move up them. When you've ascended the stairs, turn and face your right, and walk towards the music room that we can see in the distance with its grande piano. We are going to come to a stop right at the base of another small flight of stairs, and looking into the sitting room with a grande piano and marble mantle over a fireplace.

You are beside the bed in your bed room, turn towards your left and keep moving forward. Go near the stair case support and turn towards your right, keep moving forwards and you can find a long corridor on your left. Go through the corridor and the opposite end you can find a gaming room. Go through that gaming room and opposite end of a room, towards your slight right, you can find a air hockey table. Go and stand near that table and you reached your destination.

You are facing towards the white door. Turn left and walk towards the swimming pool. Turn left and walk towards the gym equipment. Turn right. Walk a few steps ahead and stand beside the swimming pool. There is a window towards your left side. You have reached your point.

now you are on a stair case facing the stairs, climb up the stair case, now you will enter a big hall, now walk to the other end of the hall and now you will see two doors which are wide opened, exit through the doors and take a right turn and walk on the corridor, to the send window from the right is your destination.

Right now you're facing towards a curtain. Now turn behind and move towards the wall which is in front of you. Now turn left and exit the room, there are portraits to your left. Now turn right and move forward in the walkway. You can see an open door to your left, move towards the door and turn left. Now enter in to the room, there are two washing machines to your right and you can see shelves in front of you, move towards the shelves and stand in front of it and it is your end point.

You are in a living area, facing towards the corner of a door. Turn towards your slight right and keep moving forward. In front, towards your slight right, you find an other section. Go near that section and turn towards your left. You find a brown door, go pass through the door and move forward. You enter into your bedroom. In front, you find a bed, walk towards the bed and stand near it. You reached your destination.

Right now you're facing towards a bed. Now slightly turn right, there is an open door in front of you, move towards the door and exit the room. There is a walkway in front of you and some portraits on the wall to your right and a staircase to your left, move forward in the walkway, continue moving forward in the walkway, until you reach an open door in front of you, there is an open door to your right, move towards the door and turn right. Now enter in to the room, there is a portrait in between two windows in front of you. Now slightly turn left, there is a sliding door in front of you, which guides to the balcony, move towards the door and enter in to the balcony. Now turn left, you can see a sliding door in front of you, move towards the sliding door and enter in to the room and this is your end point.

Figure 9: Randomly selected English navigation instructions from RxR train. The first two examples are US English and the others are Indian English.

हलका सा बाए मुड़े और सीधे आगे बड़े सामने आपको मेज़ और कुर्सी नज़र आ रही होगी हलका सा दाहिने ले और और आखरी वाली कुर्सी के पीछे तक जाए फिर हलका सा बाए ले और सीधे आगे बड़े दीवार के कोने तक फिर हलका सा दाहिने ले सामने आपको काले रंग का सोफा नज़र आ रहा होगा सीधे सोफे के पास जाए और रुक जाए।

आप अभी सीढ़ी के बाज़ू में हैं,आप को सीधे आगे बढ़ना है,सामने मेज़ के बाज़ू से बाएं मुड़ना है,और सामने कमान में प्रवेश करना है,बिलकुल सामने भूरे रंग का बंद द्वार है,आप को वहीँ पे जाकर रुक जाना है.

आप अभी फ्रिज के पास खड़े हुवे हैं आप को हल्का सा बाएं मुड़ना है,और सामने आगे बढ़ना है,आगे बढ़ने के बाद छोटी सी अलमारी है जिसपर किताबें रखी हुई हैं, उसके बाज़ू में दीवार पर एक चित्र लटका हुवा है,और उसके नीचे एक बैठक भी है,बैठक तक जाने के बाद आप को पीछे मुड़ना है,पीछे आप को किताबों की एल्मा ऋ दिखाई देगी उस के बाज़ू में एक द्वार है आप को उस द्वार तक जाना है,फिर उस द्वार से वापस आप को दाहिने की तरफ बाहर निकलना है,जहाँ पर गोल मेज़ है उस पर एक गुलदस्ता है,वहां पर दो कुर्सियां भी हैं, आप को वहां पर आ करके रुक जाना है.

आप भूरे रंग के दिवार के ओर मुड़कर खड़े हुए है। वहा से हल्का सा दाए ओर मुड़कर एक कदम आगे बढे। और वहा से बाए ओर मुड़े और सामने आपको भूरे रंग का खुला दरवाजा नज़र आएगा। उस से कमरे के बाहर जाकर दाए ओर मुड़े और सीधा आगे बढे। सामने आपको कांच का बंद दरवाजा नज़र आएगा।आप वहा से दाए ओर मुड़कर भूरे रंग के खुले दरवाजे में प्रवेश करके सामने आपको एक कुर्सी नज़र आएगी। उस कुर्सी के बाजू रुक जाए। आपके बाए ओर भूरे रंग का कांच का खुला दरवाजा होगा। और आपके सामने सफ़ेद रंग का पलंग होगा।

पीछे मुड़े और द्वार के अंदर प्रवेश करे हल्का बाए मुड़े और गलियारे मे आगे बढे आपके दोनों तरफ भूरे रंग की अलमारी है आगे बढे और रुक जाना है आपकी बाए तरफ अलमारी में कपडे है.

आप बाहर खड़े हो। पीछे मुड़कर खुले दरवाज़े से अंदर जाए। अन्दर जाते ही आपके बाए तरफ भूरे रंग का खुला दरवाज़ा हैं। आपको उस दरवाज़े से अंदर जाना हैं। अंदर जाते ही आपके सामने बिस्तर के बाजु भूरे रंग के मेज़ पे दीपक हैं। आपको उस दीपक के पास जाना हैं। वह जाते ही आपके बाए तरफ भूरे रंग का खुला दरवाज़ा हैं। आपको उस दरवाज़े से अंदर जाना हैं। वह जाते ही आपको दाहिने मुड़ना हैं। दाहिने मुड़ते ही आपके सामने गलियारा हैं। आपको गलियारे मे सीधा चलना हैं। सीधा चलते हुवे आपके अंत मे भूरे रंग का खुला दरवाज़ा दिखाए देगा। आपको उस दरवाज़े से अंदर जाना हैं। अंदर जाते ही आपके बाए तरफ बटी हैं। आपको बटी के सामने जाना हैं। वह जते ही पको दाहिने मुड़ना हैं। दाहिने मुड़ते ही आपके सामने गोल आकर के मेज़ के साथ दो सफ़ेद रंग के सोफे हैं। आपको बाए वाले सोफे के पास जाना हैं। वह जाते ही आपको दाहिने मुड़कर सफ़ेद रंग के फूलदान के पास जाकर रुक जाना हैं।

आप सामने वाले छोटे भूरे रंग के अलमारी के ओर मुड़कर खड़े हुए है। वहा से दाए ओर मुड़े और सीधा आगे बढे। आपके सामने सफ़ेद रंग का कुर्सी होगा। उस तक जाकर वहा से बाए ओर मुड़े और सामने वाले दिवार जिसपर एक चित्र है,उस तक जाए। वहा से बाए ओर मुड़े और सामने वाले खुले सफ़ेद रंग के दरवाजे में प्रवेश करके फिरसे उल्टा मुड़कर बाए ओर वाले खुले सफ़ेद रंग के दरवाजे में प्रवेश करके फिरसे बाए ओर मुड़े और कमोड के सामने रुक जाए। आपके सामने स्नान घर होगा।

पीछे मुड़े, सीढ़ियों से नीचे उतरे, नीचे जाए, दाए लेकर मेज़ के दाए तरफ़ जाए, यहाँ से सामने की ओर जाए, दाए लेकर आगे जाए, सामने की ओर जाए, बाए ले और आगे जाए, आपको यहाँ पर मेज़ के पास बाए लेना है, आप इस वक़्त एक भूरे रंग की कुर्सी के सामने खड़े है, आपके पीछे किताबें है, आपको यही पर कोने में इस भूरे रंग की कुर्सी के सामने जिसके पीछे किताबें है वही रुक जाना है, आप देख सकते है आपको दाए तरफ़ भी एक कुर्सी दिख रही है आपको यहाँ पर बाए तरफ़ कुर्सी के सामने रुकना है.

आपके सामने स्नान कक्ष है। पीछे मुड़कर सफ़ेद खुले दरवाज़े की चौखट पर जाए। सामने आपको सीढ़िया नज़र आएँगी। सीढ़ियों के दाए और से आगे बड़े। सामने आपको तीन सीढ़िया नज़र आएँगी। नीचे उतरे। गलियारे में सीधा आगे बड़े। दाए तरफ के दो काले रंग के कुर्सियों को पार करते हुए आगे बड़े। हलके दाए मुड़कर दाए तरफ के सफ़ेद खुले दरवाज़े की चौखट पर जाए। आगे बढ़कर कमरे में प्रवेश करे। बाए तरफ के पलंग को पार करते हुए कांच की खिड़की के सामने जाकर रुक जाए। बाए तरफ आपको एक गोल मेज़ नज़र आएगा। जिस पर संगणक है। दाए तरफ हरे रंग का सोफा है। जिस पर दो तकिये है।

आप एक सफ़ेद गोल मेज़ के पास खड़े हैं। दाएं मुड़िये। सामने गलीचे के अंत तक जाइये। फिर हल्का बाएं मुड़िये और सामने दिख रहे सीढ़ी से ३ कदम निचे उतर कर रुक जाइये।

आपके आगे दिवार होगी वह से बाए मुड़े। आपके आगे सोफा होगा।थोड़ा सा आगे प्रवेश करे।आपके आगे दूरदर्शन यंत्र होगा। वह से बाए मुड़े आगे प्रवेश करे। आपके बाए में सीढ़ियां होगी।आप उस सीढ़ियां से पूरा ऊपर आकर खड़े होजाइये।आपके आगे चित्र होगा।

पीछे पलट कर भूरे रंग के दरवाज़े से बाहर निकले फिर दाए मुड़े एक कदम आगे जाए फिर दाए मुड़े भूरे रंग के दरवाज़े से अंदर जाए और रुक जाए।

Figure 10: Randomly selected Hindi navigation instructions from RxR train.

మీరు ఉన్న దిక్కు నుండి కొంచెం ఎడమవైపు తిరిగి, నేరుగా ద్వారం బయటకి వెళ్ళి, వెంటనే ఎడమవైపు తిరిగి నేరుగా నడుస్తూ వెళ్ళి, వెంటనే ఎడమవైపు తిరిగి నేరుగా ముందుకు నడిచి ఆగండి. మీకు ఎదురుగా కొంచెం దూరంలో మూసి ఉన్న ద్వారం ఉంటుంది.

ఇప్పుడు మనం ఉన్న దగ్గర నుండి కొంచం ముందుకు వెళ్ళండి, అక్కడ కుడిపక్కకు తిరిగి కొంచం ముందుకు వెళ్తే ఒక గది నుండి బయటికి వెళ్తాము, అక్కడ ఎడమపక్కకు తిరిగి కొంచం మునుకు వెళ్ళండి, అక్కడ నుండి ఇంకా కొంచం ముందుకు వెళ్ళండి, అక్కడ నుండి ఇంకా కొంచం ముందుకు వెళ్ళండి, అక్కడ నుండి ఇంకా కొంచం ముందుకు వెళ్ళండి, అక్కడ నుండి ఇంకా కొంచం ముందుకు వెళ్తే ఒక గది నుండి బయటికి వెళ్తాము, అక్కడ నుండి కుడిపాకకు తిరిగి కొంచం ముందుకు వెళ్లి ఒక మూడు మెట్లు ఎక్కండి, అక్కడ నుండి కుడిపక్కకు తిరిగి ఒక ఐదు మెట్లు ఎక్కండి, అక్కడ నుండి ఒక రెండు మెట్లు ఎక్కి కుడిపక్కకు తిరిగి ఒక నాలుగు మెట్లు ఎక్కండి, అక్కడ నుండి ఇంకొక రెండు మెట్లు ఎక్కి కొంచం ముందుకు వెళ్ళండి, అక్కడ ఎడమపక్కకు తిరిగి కొంచం ముందుకు వెళ్ళండి, అక్కడ కొంచం కుడిపక్కకుగా తిరిగి కొంచం ముందుకు వెళ్ళండి, ఇంకా కొంచం ముందుకు వెళ్లి ఒక గది ముందు ఆగండి.

కుడివైపుకు తిరిగి, ఎదురుగా ఉన్న తివాచి మీద నడుచుకుంటూ నేరుగా ముందుకు వెళ్ళండి. ఇక్కడ ఎదురుగా ఉన్న ద్వారము గుండా నేరుగా ముందుకు వెళ్ళండి. ఎదురుగా ఉన్న మరొక ద్వారము గుండా బయటకు వెళ్ళండి. ఇక్కడ ఎదురుగా మెట్లు ఉన్నాయి. వాటిని ఎక్కుతూ పైకి వెళ్ళండి. ఎదురుగా ఉన్న ద్వారము గుండా గది లోపలికి వెళ్ళిన వెంటనే, ఎడమవైపుకు తిరిగి, నేరుగా ముందుకు వెళ్ళండి. ఎదురుగా ఉన్న చొక్కాలు అల్మారా ముందు కుడివైపుకు తిరిగి, కొంచెము ముందుకు వెళ్ళి, కుడివైపు ఉన్న చొక్కాలు అల్మారా ముందు ఆగండి.

ఇప్పుడు మీరు ద్వరంకి ఎదురుగా ఉన్నారు. కాస్త కుడివైపుకి జరిగి, ముందుకు వెళ్లి ద్వారం నుండి లోపలికి వెళ్ళండి. కాస్త లోపలికి వెళ్లి భోజన బల్ల మరియు మీ ఎడమవైపు ద్వారం మధ్యలో ఆగండి.

మీరు నిల్చున్న చోటు నుండి కుడివైపు తిరిగి, మంచం ముందుకి వెళ్లి, కుడివైపు తెరిచి ఉన్న ద్వారం దగ్గర ఆగండి.

మీరు గాజు ద్వారంవైపు ఉన్నారు. వెనుకకి తిరిగి, తెరిచి ఉన్న ద్వారంలోంచి బయటికి వెళ్ళండి. మీ ఎదురుగా చిత్రపటం ఉంటుంది. కుడివైపు ఉన్న ద్వారంలోంచి బయటికి వెళ్ళి, ఎదురుగా ఉన్న తివాచీపైకి వెళ్ళండి. కాస్త ఎడమవైపుగా ఉన్న మెట్లను పూర్తిగా ఎక్కండి. కాస్త కుడివైపుకి తిరిగి, ముందుకు వెళ్ళండి. ఎడమవైపు ఉన్న ద్వారంలోంచి లోపలికి వెళ్తే, మీ ముందు మంచం ఉంటుంది. కాస్త కుడివైపుకి తిరిగి, మంచం ముందుకు వెళ్ళి ఆగండి. మీ ఎడమవైపు మంచం, కుడివైపు సోఫా ఉంటాయి.

మీరు ఉన్న దిక్కు నుండి నేరుగా ఉన్న గదిలోనికి వెళ్ళి, తివాచీని దాటుకొని వెళ్ళి, ఎదురుగా తెరిచి ఉన్న ద్వారం ముందు ఆగండి.

మీరు దూరదర్శిని వైపు ముఖం చేసి ఉన్నారు. అక్కడ నుండి కుడివైపుకు తిరిగి నేరుగా ద్వారం నుండి బయటకి వెళ్ళండి. ఇప్పుడు మీకు ఎడమవైపున చిత్రపట్టం కుడివైపున ఒక్క ద్వారం ఉంటుంది. ఆ ద్వారం లోపటికి వెళ్ళి ఆగండి. అదే మీ గమ్యం.

ఉన్న చోట నుంచి కుడివైపుకు తిరిగి, మరల ఎడమవైపు తిరిగి మెట్ల దిగండి. అలా మెట్లు దిగాక, మీకు ఎడమ పక్కకు కనిపిస్తున్నా దారిగుండా వెళ్ళండి . ఇప్పుడు మీ ఎడమ పక్క ఒక చెట్టు ఉంటుంది. ఆ చెట్టు దగ్గరికి వెళ్లి కుడివైపుకు తిరగండి. నేరుగా ముందుకు నడవండి. ఎడమ వైపు కనిపిస్తున్నా ఉన్న ద్వారం లోపలి కి వెళ్లి మరల నేరుగా నడవండి. ఇప్పుడు మీకు చెట్టు కనిపిస్తుంది. ఆ చెట్టు దగ్గరికి వెళ్లి కుర్చీ వెనక ఆగండి. ఇదే మీ గమ్య స్థానం

మనకి ఎడమవైపున ఒక బల్ల ఉంది. కొంచం కుడివైపుకు మల్లి , కొంచం ముందుకు నడిచి , అక్కడ మనకు ఒక కుర్చీ మరియు చెత్త వేసే బుట్ట మరియు ఒక బల్ల కనపడుతుంది. అక్కడ నుంచి కొంచం ముందుకు నడిచి , మనకి ఎడమవైపున ఒక ఆట ఆడే బల్ల కనపడుతుంది . దాని వెనుక వైపు నుంచి కొంచం దూరం నడిచి , ఎడమవైపు మళ్ళాలి. అక్కడ మనకు రెండు రకాల బల్లలు కనపడతాయి . కొంచం ముందుకు నడిచి , ఎడమకు మల్లి, అక్కడ మనకు కుర్చీలతో కూడిన ఒక బల్ల కనపడుతుంది. ఆ బల్ల వైపున వెనుక నుంచి ముందుకు నడిచి , ఇంకా కొంచం ముందుకు నడిచి అక్కడ మనకు కుడివైపున ఒక తెల్లటి కుర్చీ మరియు ఒక బల్ల కనపడుతుంది . కుడివైపు మెట్లు కూడా ఉంటాయి. మనము ఆ బల్లదగ్గర ఆగండి .

ఇప్పుడు మీరు ఉన్న దేగ్గెర నుండి కొద్దిగా కుడి పక్కకి తిరిగి ఎదురుగా తెరిచి ఉన్న గాజు ద్వారము నుండి బైటికి రావాలి. ఇప్పుడు మీరు ఉన్న దేగ్గెర నుండి చూస్తే మీ కుడి వైపు మళ్ళి తెరిచి ఉన్న గాజు ద్వారము కనిపిస్తుంది ఇదే మీ గమ్యం.

మీకు ఎదురుగా ఉన్న ద్వారంలో నుంచి నేరుగా వెళ్లి. అక్కడ వెనకు తిరిగి, కుడివైపుగా నేరుగా వెళ్లి. అక్కడి నుంచి నేరుగా వెళ్లి, ఎడమవైపుగా తిరిగి నేరుగా వెళ్తే. మీరు ఒక్క ద్వారాన్ని చేరుకుంటారు. అక్కడి నుంచి నేరుగా వెళ్లి, అక్కడ స్నానాల తొట్టిలో ఆగండి.

నిల్చున్న చోటు నుండి ఎడమవైపు తిరిగి, కుడివైపు తెరిచి ఉన్న ద్వారం దగ్గరికి వెళ్లి, కుడివైపు తిరిగి, ఎడమవైపు ఉన్న సోఫా పక్కకు వెళ్లి, ఎదురుగా ఉన్న మరో ద్వారం దగ్గరికి వెళ్లి, ఎదురుగా మూసి ఉన్న గాజు ద్వారం ముందర ఆగండి.

Figure 11: Randomly selected Telugu navigation instructions from RxR train.

B DATASHEET: ROOM-ACROSS-ROOM (RxR)

This document is based on *Datasheets for Datasets* (Gebru et al., 2020). Please see the most updated version here.

MOTIVATION

For what purpose was the dataset created?
RxR was created to advance progress on vision-and-language navigation (VLN) in multiple languages (English, Hindi, Telugu). It addresses gaps in existing datasets by including more paths that counter known biases and an order of magnitude more navigation instructions for three languages plus annotators' 3D virtual pose sequences.

Who created this dataset (e.g., which team, research group) and on behalf of which entity (e.g., company, institution, organization)?
This dataset was created by Alexander Ku, Peter Anderson, Roma Patel, Eugene Ie, Jason Baldridge and the Google Data Compute team on behalf of Google Research.

What support was needed to make this dataset?
Funding was provided by Google Research.

COMPOSITION

What do the instances that comprise the dataset represent (e.g., documents, photos, people, countries)?
The instances in RxR are natural language navigation instructions paired with trajectories in reconstructed 3D buildings. Each navigation instruction has been recorded as speech and transcribed by the speaker. The dataset includes the text transcriptions, but not the audio files, although they may be released in future. The trajectories are provided as paths, consisting of sequences of viewpoint ids corresponding to navigation graphs from Anderson et al. (2018b), and pose traces, consisting of sequences of virtual camera poses situated in the underlying building reconstructions which are from the Matterport3D dataset (Chang et al., 2017). Pose traces and text transcriptions are timestamped and aligned. Pose traces are provided for both the instruction annotator (the Guide), and a second annotator charged with following the Guide's instructions (the Follower).

How many instances are there in total (of each type, if appropriate)?
RxR contains 126K Guide instructions covering 16.5K sampled paths and 126K human Follower demonstration paths. Annotations are split equally across the three languages in the dataset. Refer to Table 1 for a comparison of the number of instances to previous datasets and Table 2 for summary statistics.

Does the dataset contain all possible instances or is it a sample (not necessarily random) of instances from a larger set?
Refer to Section 3 for a detailed description of the sampling procedure used to select the paths for annotation.

What data does each instance consist of?
Each instance consists of a trajectory through a building from the Matterport3D dataset (Chang et al., 2017) paired with a natural language navigation instruction. A trajectory can be visualized as a sequence of 360-degree panoramic images, or as path traversing a 3D reconstruction of the building represented as a textured mesh. Refer to Table 3 for an analysis of linguistic phenomena in the instructions and Figures 9, 10 and 11 for instruction examples in English, Hindi and Telugu respectively.

Is there a label or target associated with each instance?
When training wayfinding agents to navigate from natural language instructions, the trajectory is the target. Instructions and paths are annotated with unique identifiers.

Is any information missing from individual instances?
We do not provide the Guide audio recordings, for reasons outlined in Appendix A.

Are relationships between individual instances made explicit (e.g., users' movie ratings, social network links)?
Trajectories may belong to the same building or different buildings; each instance is annotated with

a scan (building) identifier.

Are there recommended data splits (e.g., training, development/validation, testing)?
Yes. We follow the same building splits as Matterport3D and R2R. Refer to Section 3 for details regarding the RxR train/validation/test instance splits.

Are there any errors, sources of noise, or redundancies in the dataset?
The process we followed to validate instruction quality using Follower annotations is described in Section 4.

Is the dataset self-contained, or does it link to or otherwise rely on external resources (e.g., websites, tweets, other datasets)?
This dataset is based on building reconstructions from the Matterport3D dataset (Chang et al., 2017) and viewpoint navigation graphs from the R2R dataset (Anderson et al., 2018b). Apart from these dependencies, RxR is self-contained, i.e., it does not rely on web resources.

Does the dataset contain data that might be considered confidential (e.g., data that is protected by legal privilege or by doctor-patient confidentiality, data that includes the content of individuals' non-public communications)?
No.

Does the dataset contain data that, if viewed directly, might be offensive, insulting, threatening, or might otherwise cause anxiety?
No.

Does the dataset identify any subpopulations (e.g., by age, gender)?
No.

Is it possible to identify individuals (i.e., one or more natural persons), either directly or indirectly (i.e., in combination with other data) from the dataset?
No.

Does the dataset contain data that might be considered sensitive in any way (e.g., data that reveals racial or ethnic origins, sexual orientations, religious beliefs, political opinions or union memberships, or locations; financial or health data; biometric or genetic data; forms of government identification, such as social security numbers; criminal history)?
Each natural language instruction in the sample is either in English, Hindi or Telugu, thus potentially revealing linguistic origin. However, no other annotator data is included in the dataset.

COLLECTION

How was the data associated with each instance acquired?
Refer to Section 4 for details of the annotation procedure, as well as measures undertaken to validate the data.

Over what timeframe was the data collected?
The dataset was collected between March 2020 and September 2020.

What mechanisms or procedures were used to collect the data (e.g., hardware apparatus or sensor, manual human curation, software program, software API)?
We developed a web-based annotation tool to collect the data. It is described further in Section 4 and screenshots are included in Figure 6.

If the dataset is a sample from a larger set, what was the sampling strategy (e.g., deterministic, probabilistic with specific sampling probabilities)?
Please see Section 3 and Figure 2 for details of the strategy for selecting paths for annotation.

Who was involved in the data collection process (e.g., students, crowdworkers, contractors) and how were they compensated (e.g., how much were crowdworkers paid)?
Refer to Appendix A.

Does the dataset relate to people?
Yes.

Did you collect the data from the individuals in question directly, or obtain it via third parties or other sources (e.g., websites)?
Directly from the individuals.

Were the individuals in question notified about the data collection?
Yes.

Did the individuals in question consent to the collection and use of their data?
Yes.

PREPROCESSING / CLEANING / LABELING

Was any preprocessing/cleaning/labeling of the data done(e.g.,discretization or bucketing, tokenization, part-of-speech tagging, SIFT feature extraction, removal of instances, processing of missing values)?
Please see Section 4 describing the process used to remove and re-annotate instances in which the Follower was not able to correctly follow the path described in the Guide's instruction.

Was the "raw" data saved in addition to the preprocessed/cleaned/labeled data (e.g., to support unanticipated future uses)?
Yes.

Is the software used to preprocess/clean/label the instances available?

We plan to publicly release our web-based annotation tool.

USES

Has the dataset been used for any tasks already?
We have used RxR to train vision-and-language navigation (VLN) agents as described in the paper.

Is there a repository that links to any or all papers or systems that use the dataset?
No, although we plan to release a test server and leaderboard to support the research community using the dataset.

What (other) tasks could the dataset be used for?
Training models to generate natural language navigation instructions, visual referring expression grounding and comprehension, grounded dialog tasks, pre-training for various other vision-and-language tasks, multilingual learning and so on.

Is there anything about the composition of the dataset or the way it was collected and preprocessed/cleaned/labeled that might impact future uses?
No.

DISTRIBUTION

Will the dataset be distributed to third parties outside of the entity (e.g., company, institution, organization) on behalf of which the dataset was created?
Yes, this dataset is open to use by the research community.

How will the dataset will be distributed (e.g., tarball on website, API, GitHub)?
Via GitHub and Google Cloud Storage.

When will the dataset be distributed?
This dataset has been distributed on publication.

Will the dataset be distributed under a copyright or other intellectual property (IP) license, and/or under applicable terms of use (ToU)?
RxR is released under a CC-BY license.

Have any third parties imposed IP-based or other restrictions on the data associated with the instances?
Yes, the Matterport3D dataset is governed by the Matterport3D Terms of Use.

MAINTENANCE

How can the owner/curator/manager of the dataset be contacted (e.g., email address)?
Email contact: `rxrvln@google.com`.

Will the dataset be updated (e.g., to correct labeling errors, add new instances, delete instances)?
No.

SSCR: Iterative Language-Based Image Editing via Self-Supervised Counterfactual Reasoning

Tsu-Jui Fu[†], Xin Eric Wang[‡], Scott T. Grafton[†], Miguel P. Eckstein[†], William Yang Wang[†]

Abstract

Iterative Language-Based Image Editing (ILBIE) tasks follow iterative instructions to edit images step by step. Data scarcity is a significant issue for ILBIE as it is challenging to collect large-scale examples of images before and after instruction-based changes. However, humans still accomplish these editing tasks even when presented with an unfamiliar image-instruction pair. Such ability results from counterfactual thinking and the ability to think about alternatives to events that have happened already. In this paper, we introduce a Self-Supervised Counterfactual Reasoning (SSCR) framework that incorporates counterfactual thinking to overcome data scarcity. SSCR allows the model to consider out-of-distribution instructions paired with previous images. With the help of cross-task consistency (CTC), we train these counterfactual instructions in a self-supervised scenario. Extensive results show that SSCR improves the correctness of ILBIE in terms of both object identity and position, establishing a new state of the art (SOTA) on two IBLIE datasets (i-CLEVR and CoDraw). Even with only 50% of the training data, SSCR achieves a comparable result to using complete data.

1 Introduction

Digital design tools like Illustrator or Photoshop are widely used nowadays. Though having considerable user demand, they require prior knowledge and multiple steps to use successfully. These applications would significantly improve the accessibility if they can automatically perform corresponding editing actions based on the language instructions given by users for each step.

Iterative language-based image editing (ILBIE) task follows iterative instructions to edit images step by step, as illustrated in Fig. 1. To accomplish ILBIE, models are required not only to modify images but also to understand the visual differences between the previous and resulting image, based on the given instructions. One of the primary limitations of ILBIE is data scarcity. Since collecting large-scale previous-resulting images with instructions is difficult, it makes learning the association between vision and language challenging.

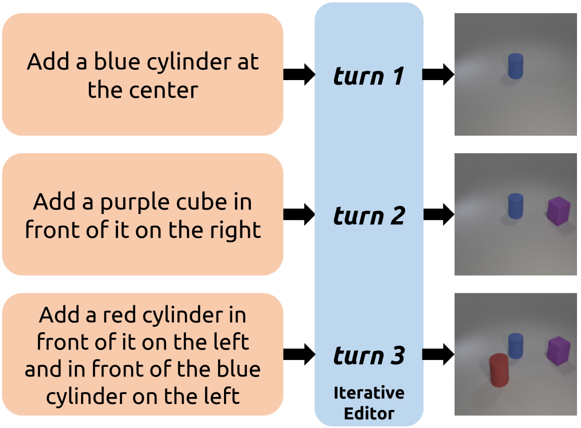

Figure 1: An example of the iterative language-based image editing (ILBIE) task. During each turn, the model edits the image from the previous turn based on the current instruction. Eventually, a desired image is accomplished after iterative editing. Note that the generation is at the pixel level.

A GAN-based (Goodfellow et al., 2015) model, GeNeVA (El-Nouby et al., 2019), is proposed to perform ILBIE, where a conditional generator serves as the image editor, and a discriminator provides the training loss by discriminating a resulting image. Though it yields promising results, GeNeVA neglects the data scarcity issue of ILBIE. As a binary classifier, the discriminator easily suffers from data scarcity given the shortage of ground-truth instruction-and-resulting-image pairs and thus limits the model's generalization ability to new instructions.

Despite lacking prior experiences with images or instructions, humans can still accomplish editing under unfamiliar image-instruction pairs. For ex-

ample, for a given instruction “add a purple cube in front of the blue cylinder”, humans can think about the resulting image if the instruction changed to “adding a blue square” or “on the right of”. This process is known as counterfactual thinking (Roese, 1997), which allows humans to operate in data-scarce scenarios by considering alternative instructions from the seen examples.

In this paper, we introduce self-supervised counterfactual reasoning (SSCR) that incorporates counterfactual thinking to deal with the data scarcity issue. SSCR allows the model to think about expected, resulting images under unseen instructions. Since there are no ground-truth resulting images, we propose cross-task consistency (CTC), which adopts an iterative explainer to reconstruct the instruction of each step. With CTC, we can supply detailed token-level training loss (e.g., wrong objects or wrong positions), which is better than only using the discriminator, and consider these counterfactual instructions in a self-supervised scenario.

The experimental results on i-CLEVR (El-Nouby et al., 2019) and CoDraw (Kim et al., 2019) show that our SSCR can improve the correctness of the ILBIE task in both aspects of object identity and position. In summary, our contributions are three-fold:

- We introduce SSCR that incorporates counterfactual thinking into the ILBIE task to deal with the data scarcity issue.
- The proposed cross-task consistency (CTC) and counterfactual reasoning methods help train the generator better, improve the generalizability, and achieve the SOTA results on i-CLEVR and CoDraw.
- Extensive ablation studies show that SSCR is effective even with only partial training data.

2 Related Work

Text-to-Image (T2I) generates an image that matches the given instruction. T2I is challenging yet important that has a vast potential in practical applications like art generation or automatic design (Nguyen et al., 2017; Reed et al., 2017; Tan et al., 2019). With the success of a generative adversarial network (Goodfellow et al., 2015) on the image generation task, several works (Reed et al., 2016; Zhang et al., 2017; Xu et al., 2018) introduce different GAN-based models to synthesize an image from a text description. Unlike T2I, we focus on image editing, where a model needs to understand the visual differences between two images rather than generating an image from scratch.

Language-based Image Editing (LBIE) tasks a model to edit an image based on the guided text description. PixelTone (Laput et al., 2013) and Image Spirit (Cheng et al., 2013) are both rule-based, which accept only pre-defined instructions and semantic labels that can significantly decrease the practicality of LBIE. Some studies (Chen et al., 2018; Shinagawa et al., 2017) adopt the conditional GAN model to attend on the instruction and perform LBIE as image colorization. However, image colorization is not truly an editing task since it only supports fixed object templates, and the objects and the scene of the image remain the same after editing. In contrast, the editing processes of Photoshop or Illustrator are not accomplished in a single pass. GeNeVA (El-Nouby et al., 2019) proposes an iterative GAN-based generator to accomplish iterative language-based image editing (ILBIE) but neglects the data scarcity issue.

Counterfactual Thinking (Roese, 1997) is a concept that refers to the human propensity to consider possible alternatives to events that have happened already. People can consider different outcomes from a wide range of conditions and engage in causal reasoning by asking questions like “What if ...?” or “If I had only....” Previous works (Kusner et al., 2017; Garg et al., 2019) have shown how counterfactual fairness improves the robustness of the model and makes it more explainable. Furthermore, counterfactual thinking has also been applied to augment training targets (Zmigrod et al., 2019; Fu et al., 2020). In this paper, we incorporate counterfactual thinking into that ILBIE task that considers counterfactual instructions to deal with the data scarcity issue and improve the generalizability.

3 Self-Supervised Counterfactual Reasoning (SSCR)

3.1 Task Definition

During each turn t, an editor edits the image from the previous turn V_{t-1} into the current turn V_t based on instruction I_t. After a final turn T, we get the predicted final image V_T and evaluate the outcome with the ground truth resulting image O_T. Note that the editing process is at a pixel level where the model has to generate each pixel of the image:

$$\begin{aligned} V_t &= \text{Editor}(V_{t-1}, I_t), \\ \text{eval} &= \text{Compare}(V_T, O_T). \end{aligned} \tag{1}$$

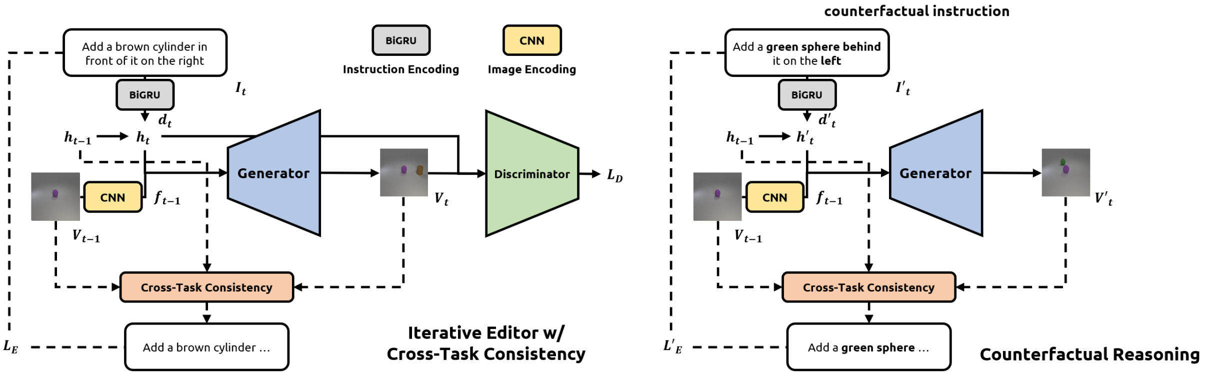

Figure 2: An overview of our self-supervised counterfactual reasoning (SSCR). The iterative editor modifies an image based on current instruction and editing history. Counterfactual reasoning allows the model to think about various counterfactual instructions that can improve the generalizability and deal with data scarcity. Since there are no ground-truth images, we propose cross-task consistency (CTC) to not only provide explicit training signal but also train these counterfactual instructions self-supervisedly.

3.2 Overview

To overcome data scarcity, we introduce self-supervised counterfactual reasoning (SSCR). The overall framework is illustrated in Fig, 2. The iterative editor is a conditional generator that modifies an image based on current instruction and editing history.

Counterfactual reasoning allows the model to think about the expected, resulting images under various counterfactual instructions. In this way, the editor can consider more diverse instructions than the original data to improve the generalizability, even if under data scarcity. Since there are no ground-truth resulting images for these counterfactual instructions, we propose cross-task consistency (CTC). CTC adopts an iterative explainer to reconstruct the given instruction of each editing step. With the help of this cross-task matching, we can not only provide a detailed token-level training signal to train the editor better but also supply training loss for counterfactual reasoning in a self-supervised scenario.

3.3 Iterative Editor

Similar to GeNeVA (El-Nouby et al., 2019), the iterative editor is a GAN-based architecture that contains a conditional generator G and a discriminator D. We first apply a bidirectional GRU (Chung et al., 2014) to encode the instruction I_t as d_t for each turn t. And another GRU is used to encode the history of instructions h_t as following:

$$h_t = \text{GRU}(d_t, h_{t-1}). \tag{2}$$

Then, to perform the editing for turn t, we adopt a convolutional neural network (CNN) (Miyato and Koyama, 2018) to extract image features f_{t-1} from the previous image V_{t-1}, concatenate with the instruction history h_t, and feed into G to predict the resulting image V_t:

$$V_t = G([f_{t-1}, h_t]). \tag{3}$$

After all iterations, there is the final image V_T after the final turn T.

For each turn, D provides a binary training signal by discriminating a resulting image that is generated from either G or the ground-truth data according to the instruction history h_t:

$$L_G = \sum_{t=1}^{T} \mathbb{E}_{V_t \sim \mathcal{P}_{G_t}}[\log(D([V_t, h_t]))], \tag{4}$$

where L_G is the binary loss from D.

For training D, similar to T2I (Reed et al., 2016), we add additional [real image, wrong instruction] pairs as false examples:

$$L_D = \sum_{t=1}^{T} L_{D_{\text{real}_t}} + \frac{1}{2}(L_{D_{\text{false}_t}} + L_{D_{\text{wrong}_t}}), \tag{5}$$

where

$$\begin{aligned} L_{D_{\text{real}_t}} &= \mathbb{E}_{O_t \sim \mathcal{P}_{\text{data}}}[\log(D([O_t, h_t]))], \\ L_{D_{\text{false}_t}} &= \mathbb{E}_{V_t \sim \mathcal{P}_{G_t}}[\log(1 - D([V_t, h_t]))], \\ L_{D_{\text{wrong}_t}} &= \mathbb{E}_{O_t \sim \mathcal{P}_{\text{data}}}[\log(1 - D([O_t, h'_t]))], \end{aligned} \tag{6}$$

with ground-truth data distribution $\mathcal{P}_{\text{data}}$ and h'_t being the wrong instruction history by randomly selecting another instruction.

Then G and D are optimized through an alternating minmax game:

$$\max_{G} \min_{D} L_G + L_D. \tag{7}$$

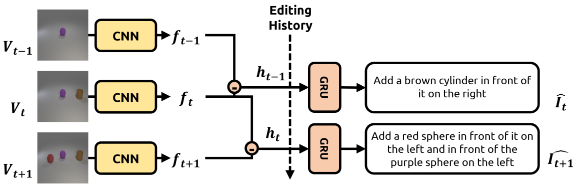

Figure 3: The architecture of our iterative explainer. We consider the previous-resulting image pair and the encoded instruction history as input to reconstruct the editing instruction by an attention-based GRU decoder.

3.4 Cross-Task Consistency (CTC)

Though we can train the iterative editor for ILBIE, D only supports a binary training loss, which is not explicit enough to express the complex association between the visual difference and the text description. To supply a more explicit training loss, we propose cross-task consistency (CTC). Despite being image generation, we consider instruction generation, which explains the visual difference between previous-resulting image pairs, to do reasoning for the editing process in a cross-task scenario. During CTC, an iterative explainer provides a token-level training signal that encourages the matching between the predicted image and the original instruction.

Iterative Explainer Our iterative exaplainer E is an instruction decoder which considers previous-resulting image pair and the instruction history as input, as shown in Fig. 3:

$$\hat{I}_t = E(V_t, V_{t-1}, h_{t-1}). \tag{8}$$

Similar to the iterative editor, we apply CNN to extract visual feature f for both previous and predicted resulting image:

$$f_{t-1} = \text{CNN}(V_{t-1}), f_t = \text{CNN}(V_t). \tag{9}$$

Then, a GRU serves as an attention-based language decoder (Xu et al., 2015) which reconstructs the instruction $\hat{I}_t$ according to the feature difference and instruction history h_{t-1} of previous turn:

$$\begin{aligned} g_0 &= [f_d, h_{t-1}], \\ \hat{w}_i, g_i &= \text{GRU}(w_{i-1}, g_{i-1}), \\ \hat{I}_t &= \{\hat{w}_1, \hat{w}_2, ..., \hat{w}_L\}, \end{aligned} \tag{10}$$

where $f_d = f_t - f_{t-1}$ represents the visual difference by subtracting previous and result feature, g_i is the decoding history, and $\hat{w}_i$ is the predicted word token of the instruction. All w_i are combined as the reconstruction where L is the length of the instruction. The iterative explainer considers not only the visual difference but also instruction history so that we can reconstruct the instruction, which explains the editing of the resulting image following by the editing history.

Dataset	Token Type	Example
i-CLEVR	color object relation	blue, purple cylinder, cube at the center, in front of
CoDraw	size object relation	small, meidum sun, boy in the middle, on the left

Table 1: Types of token on i-CLEVR and CoDraw.

Finally, we provide an explicit token-level training signal L_E by computing the teacher-forcing loss (Williams and Zipser, 1989) between the original instruction I_t and the reconstructed one $\hat{I}_t$:

$$L_E = \sum_{i=1}^{L} \text{CELoss}(\hat{w}_i, w_i), \tag{11}$$

where w_i is the ith token of I_t and CELoss means the cross-entropy loss.

By minimizing L_E, G learns to match the original instruction with this cross-task consistency. Different from L_G, which only supplies binary but vague loss, L_E provides token-level loss about the information of the wrong object or wrong position (by comparing $\hat{w}_i$ with w_i) that can train G better for each editing turn. In the experiments, E is pretrained by the ground-truth image pairs and is fixed during the following training.

3.5 Counterfactual Reasoning

We assume that $\mathcal{U}$ is the available training data. Because of the practical challenge of collecting large-scale previous-resulting images with instructions, $\mathcal{U}$ suffers from data scarcity. To deal with this issue, we propose counterfactual reasoning to allow the model to consider various instructions out of the distribution of $\mathcal{U}$. For instance, an instruction $I' \sim \mathcal{U}'$ from the intervention data $\mathcal{U}'$ replaces the original instruction, and we edit the image based on the counterfactual instruction I'.

Instruction Intervention To get the intervention data U' that provides diverse instructions, we do interventions on the original instructions I:

$$\begin{aligned} I, O &= \mathcal{U}, \\ I' &= \text{intervention}(I), \\ \mathcal{U}' &= \{I', O\}, \end{aligned} \tag{12}$$

where O is the image in the original $\mathcal{U}$.

Algorithm 1 Iterative Editor with CTC

```
$G$: the generator model
$D$: the discriminator model
$H$: the instruction history encoder
$E$: our iterative explainer in CTC
$\mathcal{U}$: the original training set

Pre-train RE with $\mathcal{U}$
Initialize G, D

while TRAIN_EDITOR do
    for $t \leftarrow 1$ to $T$ do
        $I_t, O_t \leftarrow \mathcal{U}$
        $h_t \leftarrow H(h_{t-1}, I_t)$
        $V_t \leftarrow G(h_t, O_{t-1})$    ▷ teacher-forcing training
        $\hat{I}_t \leftarrow E(V_t, O_{t-1}, h_{t-1})$

        $L_G \leftarrow$ binary loss from $D$    ▷ Eq. 4
        $L_E \leftarrow$ explicit loss from $E$    ▷ Eq. 11
        Update $G$ by maximizing $L_G - L_E$

        $L_D \leftarrow$ loss for $D$    ▷ Eq. 5
        Update $D$ by minimizing $L_D$
    end for
end while
```

Algorithm 2 Counterfactual Reasoning

```
while COUNTERFACTUAL_REASONING do
    for $t \leftarrow 1$ to $T$ do
        $\mathcal{U}' \leftarrow$ intervention($\mathcal{U}$)
        $\_, O_t \leftarrow \mathcal{U}$
        $I'_t, \_ \leftarrow \mathcal{U}'$    ▷ counterfactual instruction

        $h_t \leftarrow H(h_{t-1}, I_t)$    ▷ real history
        $h'_t \leftarrow H(h_{t-1}, I'_t)$    ▷ counterfactual history
        $V'_t \leftarrow G(h'_t, O_{t-1})$    ▷ counterfactual editing
        $\hat{I}'_t \leftarrow E(V'_t, O_{t-1}, h_{t-1})$

        $L'_E$ = counterfactual loss from $E$    ▷ Eq. 14
        Update $G$ by minimizing $L'_E$
    end for
end while
```

First, we apply NLTK (Bird and Loper, 2004) to parse out *tokens* in the original I. The types of *token* on i-CLEVR and CoDraw are shown in Table 1.

We then replace these *tokens* with randomly sampled *tokens* of the same type to get the counterfactual I'. Finally, I' combines with the original image G as the intervention data $\mathcal{U}'$. Our experiments show that this simple yet effective intervention makes the training data more diverse and deals with data scarcity during our counterfactual reasoning.

For each turn t, with I'_t from U', we predict the counterfactual resulting image V'_t:

$$V'_t = G([f_{t-1}, h'_t]), \tag{13}$$

where h'_t is the counterfactual instruction history encoded from I'.

Since there is no ground-truth image for the counterfactual instruction I'_t, we adopt the iterative explainer E to provide counterfactual training loss L'_E in a self-supervised scenario:

$$\begin{aligned} \hat{I}'_t &= E(V'_t, V_{t-1}, h_{t-1}), \\ L'_E &= \sum_{i=1}^{L} \text{CELoss}(\hat{w}'_i, w'_i), \end{aligned} \tag{14}$$

where $\hat{w}'_i$ and w'_i are the ith word token.

By minimizing L'_E, the model has an opportunity to access U', which is different from the original training data. With the help of our iterative explainer, SSCR improves the generalizability by reasoning diverse counterfactual instructions I' even if under data scarcity.

3.6 Learning of SSCR

Alg. 1 presents the learning process of training the iterative editor with CTC. Since ILBIE is also a sequential generation process, we apply the widely used teacher-forcing where we feed in the ground-truth resulting image (O_{t-1}) from the previous turn instead of our predicted one (V_{t-1}) to make the training more robust. When training the iterative editor, for each turn t, we adopt G to perform image editing. We maximize the binary loss from D (L_G) with minimizing the explicit token-level loss from E (L_E) to train G. We also update D by minimize L_D:

$$\max_G \min_D L_G + L_D - L_E. \tag{15}$$

During counterfactual reasoning, as shown in Alg. 2, we first perform an intervention on $\mathcal{U}$ to get the counterfactual instructions (I'). Then, we edit the image based on I'. Since there is no ground-truth resulting image for the counterfactual editing, we adopt CTC to compute the cycle-consistency loss (L'_E) self-supervisedly. Similar to the iterative editor, we also apply teacher-forcing training (feeding in O_{t-1} and h_{t-1}) to further update G. In this way, G can improve the generalizability by considering the counterfactual U', which is more diverse than U.

4 Experiments

4.1 Experimental Setup

Datasets We evaluate our counterfactual framework on two ILBIE datasets, i-CLEVR (El-Nouby

	i-CLEVR				CoDraw			
Method	Precision	Recall	F1	RelSim	Precision	Recall	F1	RelSim
GeNeVA	71.01	42.61	53.26	30.66	54.38	54.42	54.40	38.93
w/ CTC only	72.24	45.51	55.84	33.67	57.69	55.60	56.62	38.68
w/ SSCR	**73.75**	**46.39**	**56.96**	**34.54**	**58.17**	**56.61**	**57.38**	**39.11**

Table 2: The testing results of the baseline (GeNeVA[1]), with only cross-task consistency (CTC only), and with whole self-supervised counterfactual reasoning (SSCR) for both i-CLEVR and CoDraw.

et al., 2019) and CoDraw (Kim et al., 2019). Each example in i-CLEVR consists of a sequence of 5 (image, instruction) pairs. The instruction describes where the object should be placed relative to existing objects. In i-CLEVR, there are 6,000, 2,000, and 2,000 examples for training, validation, and testing, respectively.

CoDraw is a more difficult art-like dataset of children playing in a park. There are 58 objects and children with different poses. We use the same split as in CoDraw where 7,988, 1,002, and 1,002 are for training, validation, and testing.

Evaluation Metrics Standard metrics like Inception Score (Salimans et al., 2016) or Frechet Inception Distance (FID) (Heusel et al., 2017) cannot detect whether the editing is correct based on the instruction (El-Nouby et al., 2019). Following GeNeVA (El-Nouby et al., 2019), we adopt F1 and RelSim to evaluate the editing result.

The F1 score is based on a pre-trained object detector (Szegedy et al., 2016) (˜99% accuracy on both i-CLEVR and CoDraw), which detects the objects in the predicted images that meet the ground-truth resulting images. To evaluate not only object type but also object position, we build the scene graph according to the object detector. The edges are given by the left-right and front-back relations between the vertices (objects). Then, RelSim determines how many of the ground-truth relations are in the predicted images:

$$\text{RelSim}(E_{\text{gt}}, E_{\text{pd}}) = \text{recall} \times \frac{|E_{\text{pd}} \cap E_{\text{gt}}|}{|E_{\text{gt}}|}, \quad (16)$$

where E_{gt} and E_{pd} are relational edges for ground-truth resulting images and predicted image. Note that we only evaluate the final predicted image of each example for both F1 and RelSim.

Baseline We use the SOTA model GeNeVA[1] as our baseline: it shares the same model architecture as our iterative editor and is trained with the GAN objective but without the cross-task consistency (CTC) and our counterfactual reasoning.

Implementation Detail We apply the ResBlocks (Miyato and Koyama, 2018) into G and D where the visual feature size is 1024. For our E, we add self-attention (Zhang et al., 2019) for the concatenation of the visual difference and the encoded instruction history. We adopt Adam (Kingma and Ba, 2015) to optimize the iterative editor with learning rate 1e-4 for L_G and L_E, 4e-4 for L_D. The learning rate of L'_E during the counterfactual reasoning is 5e-5.

4.2 Quantitative Results

Table 2 presents the testing F1 and RelSim results. First, with our cross-task consistency (CTC only), which provides a more explicit training signal, we can improve the baseline on the i-CLEVR dataset in terms of all metrics. In particular, CTC improves 1.2% on precision, 2.9% on recall, and 2.6% on F1. Additionally, for whole self-supervised counterfactual reasoning (SSCR), which allows the model to consider out-of-distribution instructions, it brings more improvements and achieves new SOTA results, *e.g.*, 56.9% on F1 and 34.5% on RelSim.

Similar trends can be found on CoDraw. Since the instructions under CoDraw are more complex, the improvement of relation correctness (RelSim) is not as high as i-CLEVR. But for object correctness, CTC still improves baseline with 2.2% F1, and SSCR further achieves the new SOTA on all metrics, *e.g.*, 57.4% F1 and 39.1% RelSim.

4.3 Ablation Study

Under Data Scarcity To examine the framework's effectiveness under the data scarcity scenario, we compare models trained using 100%, 80%, and 50% data. Note that our E is also pre-trained using the same 100%, 80%, and 50% data. The results are shown in Fig. 4.

We can observe that on both i-CLEVR and CoDraw datasets, the baseline performance drops dras-

---

[1] We reproduce the result for GeNeVA by their official GitHub repo (https://github.com/Maluuba/GeNeVA). We apply the default hyperparameters as them, and issue #2 can support that the results are comparable.

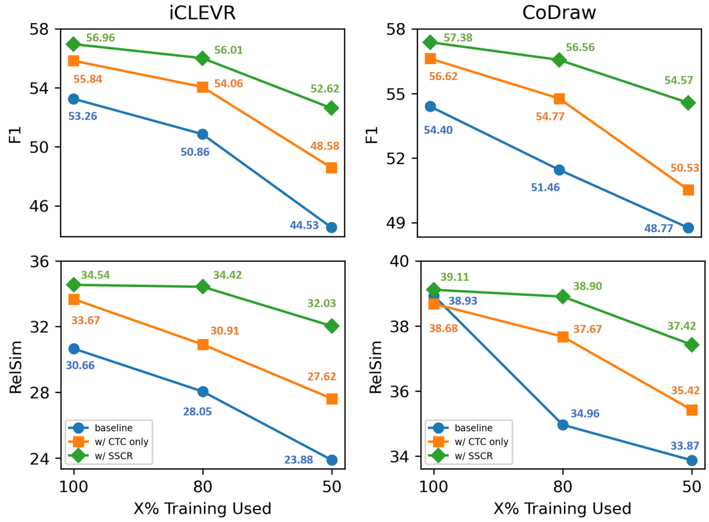

Figure 4: Result comparison among baseline, with only cross-task consistency (CTC only), and with whole self-supervised counterfactual reasoning (SSCR) under different ratios of training data. Note that the iterative explainer is also pre-trained using the same available data for each result.

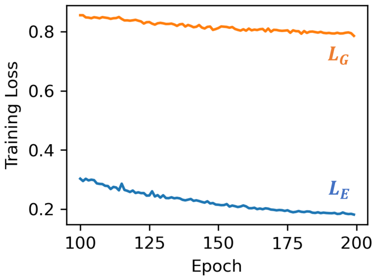

Figure 5: The learning curve of training loss provided from the discriminator (L_G) and our iterative explainer (L_E) on i-CLEVR.

X% Training Used	PPL	BLEU
100%	0.1073	50.236
80%	0.1295	48.873
50%	0.1163	48.763

Table 3: The PPL and BLEU of our iterative explainer with different ratios of training data on i-CLEVR.

	100%		50%	
Method	F1	RelSim	F1	RelSim
GeNeVA	53.26	30.66	44.53	23.88
w/ SSCR (D)	54.05	30.87	43.31	22.99
w/ SSCR (E)	**56.95**	**34.54**	**52.62**	**32.03**

Table 4: Results of discriminator (D) or iterative explainer (E) used for the counterfactual reasoning (SSCR) on i-CLEVR.

Method	F1	RelSim
GeNeVA	42.23	23.70
w/ CTC Only	<u>43.91</u>	<u>25.26</u>
w/ SSCR	**48.30**	**29.09**

Table 5: Results of zero-shot generalization.

tically as the training data decreases, and our SSCR consistently outperforms the baseline. More importantly, the baseline severely suffers from the data scarcity issue, while SSCR is relatively resilient to data decrease and only drops 4.34 F1 score and 2.51 RelSim score (*vs.* 8.73 and 6.78 reduced by the baseline) on iCLEVR when there is only 50% data. Similar results can be observed on CoDraw. Furthermore, comparing SSCR with 50% data and the baseline with 100%, we can notice that our method can achieve comparable results to the baseline with only half the data used for training. Therefore, incorporating counterfactual thinking to explore out-of-distribution instructions indeed makes the model better capable of generalization and avoiding performances drops from data scarcity.

Table 3 presents the performance of our iterative explainer E with different ratios of training examples. Perplexity (PPL) and BLEU (Papineni et al., 2002) are calculated between the reconstructed instructions and the original ones. We can see that the PPL and BLEU under 50% are similar to 100%. It shows that E still supplies meaningful training loss for SSCR even if only using 50% data.

Zero-shot Generalization To further demonstrate the effectiveness of SSCR under severe data scarcity, we conduct a zero-shot experiment for the i-CLEVR dataset. The zero-shot setting is as following. There are 3 shapes (*cube*, *sphere*, *cylinder*) and 8 colors (*gray*, *red*, *blue*, *green*, *brown*, *purple*, *cyan*, *yellow*), which lead to 24 different objects on the i-CLEVR dataset. We remove examples containing "*gray cube*, *red cube*, *green sphere*, or *purple cylinder*" in the training set but still evaluate the full testing set with all kinds of objects.

The result is shown in Table 5. Since there is no example like "*gray cube*" in the training set, CTC can only consider those seen objects and improves marginally. However, the iterative explainer (E) can disentangle color and shape information from "*gray sphere*" and "*green cube*," and generalize to the unseen object "*gray cude*". During SSCR, when we intervene the counterfactual instructions to contain "*gray cube*," the iterative explainer can still provide self-supervised loss to make the model consider unseen objects. Hence, SSCR can bring out obvious improvements on both F1 and RelSim, even if under the zero-shot setting.

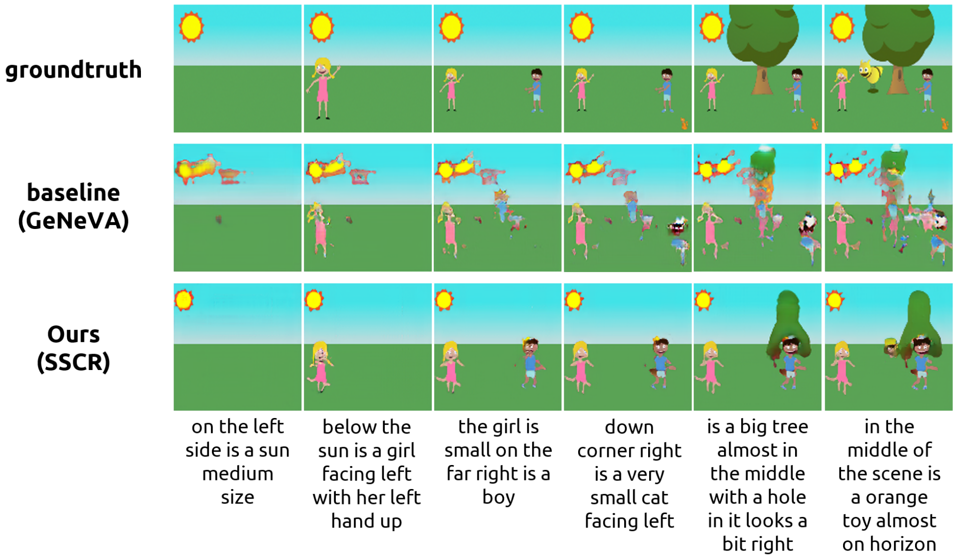

Figure 6: Visulaization example of baseline (GeNeVA) and our SSCR on CoDraw.

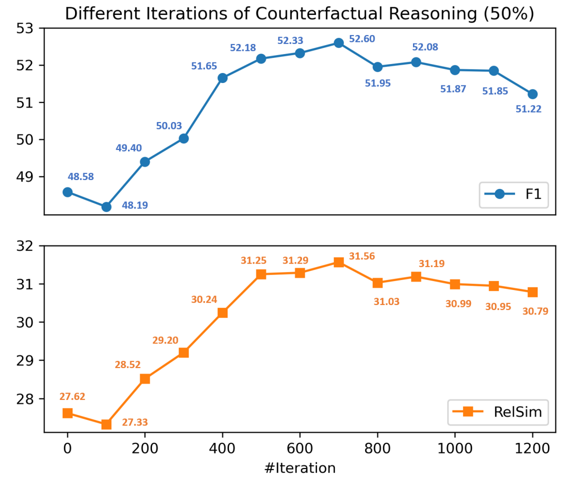

Figure 7: The validation F1 and RelSim on i-CLEVR with 50% training data under different instructions of counterfactual reasoning.

Iterative Explainer *vs.* Discriminator Fig. 5 shows the learning curve of the training losses of the discriminator D (L_G) and our iterative explainer E (L_E). We can see that the relative decrease of L_G over time is very little, which means that D can barely provide extra training signal after 100 epochs. In contrast, since E can supply explicit token-level loss instead of vague binary loss, L_E keeps decreasing much and training the model.

Table 4 shows the comparison when using D and our E to provide the training loss during the counterfactual reasoning. If using D, since there are not ground-truth resulting images of those counterfactual instructions, we cannot feed them into D as true examples. It can only provide training loss by discriminating predicted images as false. Therefore, using D during SSCR cannot improve the model much, and may even hurt the generalizability under data scarcity, *e.g.*, 23.9 drops to 23.0 on RelSim for 50%.

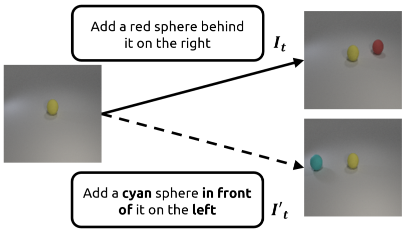

Figure 8: Example of counterfactual reasoning.

In comparison, since our E does not suffer from data scarcity, it supports SSCR by providing meaningful training loss to perform counterfactual reasoning, and thus improves the generalizability, *e.g.*, 23.9 increases to 32.0 on RelSim for 50%.

Counterfactual Reasoning: The More The Better? Despite allowing the model to explore various instructions and become more generalized, excessive counterfactual reasoning may result in overfitting to existing images and degrade the performance. Fig. 7 presents the validation performance under different iterations. It shows a trade-off between the model's generalizability and the iterations of the counterfactual reasoning. The performance keeps improving until the best 700 iteration and then drops down, possibly due to overfitting to existing images and the imperfect cost function for instruction prediction.

Qualitative Results Fig. 8 present an example of counterfactual instructions and the predicted resulting image. We replace *color token* "red" with “cyan””, *color token* “behind” with “in front of”, and “right” with ”left.” By considering counterfactual instructions, SSCR allows the model to explore diverse instruction-image pairs, that deals with the data scarcity issue.

Fig. 6 demonstrates an example of the iterative editing on CoDraw. For baseline GeNeVA, since there is only a discriminator to provide vague loss that the pixels of those generated objects are almost broken, it makes the predicted images low quality. In contrast, for our SSCR, CTC can help train the generator better, which leads to defined objects. Furthermore, counterfactual reasoning also makes the predicted images more aligned to the instructions.

5 Conclusion and Future Work

We present a self-supervised counterfactual reasoning (SSCR) framework that introduces counterfactual thinking to cope with the data scarcity limitation for iterative language-based image editing. SSCR allows the model to consider new instruction-image pairs. Despite without ground-truth resulting images, we propose cross-task consistency (CTC) to provide a more explicit training signal and train these counterfactual instructions in a self-supervised scenario. Experimental results show that our counterfactual framework not only trains the image editor better but also improves the generalizability, even under data scarcity.

For the real world, both visual and linguistic will be more complicated. To accomplish real-world image editing, large-scale pre-trained language encoders and image generators should be applied to understand the diverse instructions and model the interaction for editing. From a theoretical perspective, our SSCR is a model-agnostic framework that can incorporate with any image generator, for GAN or non-GAN architecture, to perform real-world image editing. Currently, the interactive explainer and counterfactual intervention in SSCR both improve the editing quality in the token-level. To make it more suitable for real-world images, semantic-level intervention for the diverse natural instructions can support better counterfactual reasoning. Also, a stronger explainer that explains not only token-level error but also global editing operation between two images can provide robust self-supervised loss.

Identifying Elements Essential for BERT's Multilinguality

Philipp Dufter, Hinrich Schütze
Center for Information and Language Processing (CIS), LMU Munich, Germany
`philipp@cis.lmu.de`

Abstract

It has been shown that multilingual BERT (mBERT) yields high quality multilingual representations and enables effective zero-shot transfer. This is surprising given that mBERT does not use any crosslingual signal during training. While recent literature has studied this phenomenon, the reasons for the multilinguality are still somewhat obscure. We aim to identify architectural properties of BERT and linguistic properties of languages that are necessary for BERT to become multilingual. To allow for fast experimentation we propose an efficient setup with small BERT models trained on a mix of synthetic and natural data. Overall, we identify four architectural and two linguistic elements that influence multilinguality. Based on our insights, we experiment with a multilingual pretraining setup that modifies the masking strategy using VecMap, i.e., unsupervised embedding alignment. Experiments on XNLI with three languages indicate that our findings transfer from our small setup to larger scale settings.

1 Introduction

Multilingual models, i.e., models capable of processing more than one language with comparable performance, are central to natural language processing. They are useful as fewer models need to be maintained to serve many languages, resource requirements are reduced, and low- and mid-resource languages can benefit from crosslingual transfer. Further, multilingual models are useful in machine translation, zero-shot task transfer and typological research. There is a clear need for multilingual models for the world's 7000+ languages.

With the rise of static word embeddings, many multilingual embedding algorithms have been proposed (Mikolov et al., 2013; Hermann and Blunsom, 2014; Faruqui and Dyer, 2014); for a survey see (Ruder et al., 2019). Pretrained language models (Peters et al., 2018; Howard and Ruder, 2018; Devlin et al., 2019) have high performance across tasks, outperforming static word embeddings. A simple multilingual model is multilingual BERT[1] (*mBERT*). It is a BERT-Base model (Devlin et al., 2019) trained on the 104 largest Wikipedias with a shared subword vocabulary. There is no additional crosslingual signal. Still, mBERT yields high-quality multilingual representations (Pires et al., 2019; Wu and Dredze, 2019; Hu et al., 2020).

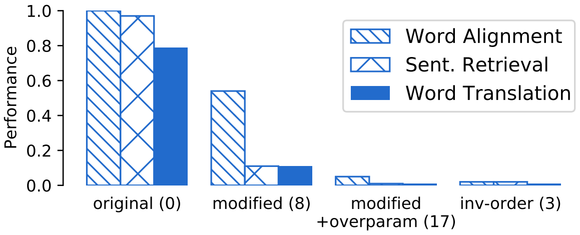

Figure 1: Multilinguality in our BERT model (0) is harmed by three architectural modifications: lang-pos, shift-special, no-random (8); see §2.3 for definitions. Together with overparameterization almost no multilinguality is left (17). Pairing a language with its inversion (i.e., inverted word order) destroys multilinguality as well (3). Having parallel training corpora is helpful for multilinguality (not shown). Results are for embeddings from layer 8.

The exact reason for mBERT's multilinguality is – to the best of our knowledge – still debated. K et al. (2020) provide an extensive study and conclude that a shared vocabulary is not necessary, but that the model needs to be deep and languages need to share a similar "structure". Artetxe et al. (2020) show that neither a shared vocabulary nor joint pretraining is required for BERT to be multilingual. Conneau et al. (2020b) find that BERT models across languages can be easily aligned and

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4423–4437,
November 16–20, 2020.

that a necessary requirement for achieving multilinguality are shared parameters in the top layers. This work continues this line of research. We find indications that six elements influence the multilinguality of BERT. Figure 1 summarizes our main findings.

1.1 Contributions

- Training BERT models consumes tremendous resources. We propose an experimental setup that allows for fast experimentation.
- We hypothesize that BERT is multilingual because of a limited number of parameters. By forcing the model to use its parameters efficiently, it exploits common structures by aligning representations across languages. We provide experimental evidence that the number of parameters and training duration is interlinked with multilinguality and an indication that generalization and multilinguality might be conflicting goals.
- We show that shared special tokens, shared position embeddings and the common masking strategy to replace masked tokens with random words contribute to multilinguality. This is in line with findings from (Conneau et al., 2020b).
- We show that having identical structure across languages, but an inverted word order in one language destroys multilinguality. Similarly having shared position embeddings contributes to multilinguality. We thus hypothesize that word order across languages is an important ingredient for multilingual models.
- Using these insights we perform initial experiments to create a model with higher degree of multilinguality.
- We conduct experiments on Wikipedia and evaluate on XNLI to show that our findings transfer to larger scale settings.

Our code is publicly available.[2]

2 Setup and Hypotheses

2.1 Setup

We aim at having a setup that allows for gaining insights quickly when investigating multilinguality.

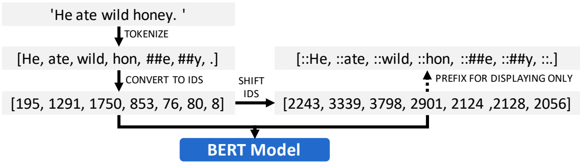

Figure 2: Creating a Fake-English sentence by adding a shift of 2048 to token indices.

Our assumption is that these insights are transferable to a larger scale real world setup. We verify this assumption in §5.

Languages. K et al. (2020) propose to consider English and Fake-English, a language that is created by shifting unicode points by a large constant. Fake-English in their case has the exact same linguistic properties as English, but is represented by different unicode points. We follow a similar approach, but instead of shifting unicode points we simply shift token indices after tokenization by a constant; shifted tokens are prefixed by "::" and added to the vocabulary. See Figure 2 for an example. While shifting indices and unicode code points have similar effects, we chose shifting indices as we find it somewhat cleaner.[3]

Data. For our setup, aimed at supporting fast experimentation, a small corpus with limited vocabulary is desirable. As training data we use the English Easy-to-Read version of the Parallel Bible Corpus (Mayer and Cysouw, 2014) that contains the New Testament. The corpus is structured into verses and is word-tokenized. We sentence-split verses using NLTK (Loper and Bird, 2002). The final corpus has 17k sentences, 228k words, a vocabulary size of 4449 and 71 distinct characters. The median sentence length is 12 words. By creating a Fake-English version of this corpus we get a shifted replica and thus a sentence-parallel corpus.

As development data we apply the same procedure to the first 10k sentences of the Old Testament of the English King James Bible. All our evaluations are performed on development data, except for word translation and when indicated explicitly.

Vocabulary. We create a vocabulary of size 2048 from the Easy-to-Read Bible with the wordpiece tokenizer (Schuster and Nakajima, 2012).[4]

---

[2] https://github.com/pdufter/minimult

[3] For example, the BERT tokenizer treats some punctuation as special symbols (e.g., "dry-cleaning" is tokenized as ["dry", "-", "##cleaning"], not as ["dry", "##-", "##cleaning"]). When using a unicode shift, tokenizations of English and Fake-English can differ.

[4] https://github.com/huggingface/tokenizers

Using the same vocabulary for English and Fake-English yields a final vocabulary size of 4096.

Model. We use the BERT-Base architecture (Devlin et al., 2019), modified to achieve a smaller model: we divide hidden size, intermediate size of the feed forward layer and number of attention heads by 12; thus, hidden size is 64 and intermediate size 256. While this leaves us with a single attention head, K et al. (2020) found that the number of attention heads is important neither for overall performance nor for multilinguality. We call this smaller model *BERT-small*.

As a consistency check for our experiments we consider random embeddings in the form of a randomly initialized but untrained BERT model, referred to as ***"untrained"***.

Training Parameters. We mostly use the original training parameters as given in (Devlin et al., 2019). Learning rate and number of epochs was chosen to achieve reasonable perplexity on the training corpus (see supplementary for details). Unless indicated differently we use a batch size of 256, train for 100 epochs with AdamW (Loshchilov and Hutter, 2019) (learning rate 2e-3, weight decay .01, epsilon 1e-6), and use 50 warmup steps. We only use the masked-language-modeling objective, without next-sequence-prediction. With this setup we can train a single model in under 40 minutes on a single GPU (GeForce GTX 1080Ti). We run each experiment with five different seeds, and report mean and standard deviation.

2.2 Evaluation

We evaluate two properties of our trained language models: the *degree of multilinguality* and – as a consistency check – the *overall model fit* (i.e., is the trained language model of reasonable quality).

2.2.1 Multilinguality

We evaluate the degree of multilinguality with three tasks. Representations from different layers of BERT can be considered. We use layer 0 (uncontextualized) and layer 8 (contextualized). Several papers have found layer 8 to work well for monolingual and multilingual tasks (Tenney et al., 2019; Hewitt and Manning, 2019; Sabet et al., 2020). Note that representations from layer 0 include position and segment embeddings besides the token embeddings as well as layer normalization.

Word Alignment. Sabet et al. (2020) find that mBERT performs well on word alignment. By construction, we have a sentence-aligned corpus with English and Fake-English. The gold word alignment between two sentences is the identity alignment. We use this automatically created gold-alignment for evaluation.

To extract word alignments from BERT we use (Sabet et al., 2020)'s Argmax method. Consider the parallel sentences $s^{(\text{eng})}, s^{(\text{fake})}$, with length n. We extract d-dimensional wordpiece embeddings from the l-th layer of BERT to obtain embeddings $\mathcal{E}(s^{(k)}) \in \mathbb{R}^{n \times d}$ for $k \in \{\text{eng}, \text{fake}\}$. The similarity matrix $S \in [0,1]^{n \times n}$ is computed by $S_{ij} := \text{cosine-sim}\left(\mathcal{E}(s^{(\text{eng})})_i, \mathcal{E}(s^{(\text{fake})})_j\right)$. Two wordpieces i and j are aligned if

$$(i = \arg\max_l S_{l,j}) \wedge (j = \arg\max_l S_{i,l}).$$

The alignments are evaluated using precision, recall and F_1 as follows:

$$\text{p} = \frac{|P \cap G|}{|P|}, \ \text{r} = \frac{|P \cap G|}{|G|}, \ F_1 = \frac{2\,\text{p}\,\text{r}}{\text{p} + \text{r}},$$

where P is the set of predicted alignments and G the set of true alignment edges. We report F_1.

Sentence Retrieval is popular for evaluating crosslingual representations (e.g., (Artetxe and Schwenk, 2019; Libovický et al., 2019)). We obtain the embeddings $\mathcal{E}(s^{(k)})$ as before and compute a sentence embedding $e_s^{(k)}$ simply by averaging vectors across all tokens in a sentence (ignoring CLS and SEP tokens). Computing cosine similarities between English and Fake-English sentences yields the similarity matrix $R \in \mathbb{R}^{m \times m}$ where $R_{ij} = \text{cosine-sim}(e_i^{(\text{eng})}, e_j^{(\text{fake})})$ for m sentences.

Given an English query sentence $s_i^{(\text{eng})}$, we obtain the retrieved sentences in Fake-English by ranking them according to similarity. Since we can do the same with Fake-English as query language, we report the mean precision of these directions, computed as

$$\rho = \frac{1}{2m} \sum_{i=1}^{m} \mathbb{1}_{\arg\max_l R_{il} = i} + \mathbb{1}_{\arg\max_l R_{li} = i}.$$

We also evaluate **word translation.** Again, by construction we have a ground-truth bilingual dictionary of size 2048. We obtain word vectors by feeding each word in the vocabulary individually to BERT, in the form "[CLS] {token} [SEP]". We then evaluate word translation like sentence retrieval and denote the measure with τ.

Multilinguality Score. For an easier overview we compute a multilinguality score by averaging retrieval and translation results across both layers. That is $\mu = 1/4(\tau_0 + \tau_8 + \rho_0 + \rho_8)$ where τ_k,ρ_k means representations from layer k have been used. We omit word alignment here as it is not a suitable measure to compare all models: with shared position embeddings, the task is almost trivial given that the gold alignment is the identity alignment.

Figure 3: lang-pos: input indices to BERT with language specific position and segment embeddings.

2.2.2 Model Fit

MLM Perplexity. To verify that BERT was successfully trained we evaluate the models on perplexity (with base e) for training and development data. Perplexity is computed on 15% of randomly selected tokens that are replaced by "[MASK]". Given those randomly selected tokens in a text $w_1, \dots, w_n$ and probabilities $p_{w_1}, \dots, p_{w_n}$ that the correct token was predicted by the model, perplexity is calculated as $\exp(-1/n \sum_{k=1}^{n} \log(p_{w_k}))$.

2.3 Architectural Properties

Here we formulate hypotheses as to which architectural components contribute to multilinguality.

Overparameterization: *overparam*. If BERT is severely overparameterized the model should have enough capacity to model each language separately without creating a multilingual space. Conversely, if the number of parameters is small, the model has a need to use parameters efficiently. The model is likely to identify common structures among languages and model them together, thus creating a multilingual space.

To test this, we train a larger BERT model that has the same configuration as BERT-base (i.e., hidden size: 768, intermediate size: 3072, attention heads: 12) and is thus much larger than our standard configuration, BERT-small. Given our small training corpus and the small number of languages, we argue that BERT-base is overparameterized. For the overparameterized model we use learning rate 1e-4 (following (Devlin et al., 2019)).

Shared Special Tokens: *shift-special*. It has been found that a shared vocabulary is not essential for multilinguality (K et al., 2020; Artetxe et al., 2020; Conneau et al., 2020b). Similar to prior studies, in our setting each language has its own vocabulary, as we aim at breaking the multilinguality of BERT. However in prior studies, special tokens ([UNK], [CLS], [SEP], [MASK], [PAD]) are usually shared across languages. Shared special tokens may contribute to multilinguality because they are very frequent and could serve as "anchor points". To investigate this, we shift the special tokens with the same shift as applied to token indices.

Shared Position Embeddings: *lang-pos*. Position and segment embeddings are usually shared across languages. We investigate their contribution to multilinguality by using language-specific position (*lang-pos*) and segment embeddings. For an example see Figure 3.

Random Word Replacement: *no-random*. The MLM task as proposed by Devlin et al. (2019) masks 15% of tokens in a sentence. These tokens are replaced with "[MASK]" in $p_{\text{[mask]}} = 80\%$, remain unchanged in $p_{\text{[id]}} = 10\%$ and are replaced with a random token of the vocabulary in $p_{\text{[rand]}} = 10\%$ of the cases. The randomly sampled token can come from any language resulting in Fake-English tokens to appear in English sentences and vice-versa. We hypothesize that this random replacement could contribute to multilinguality. We experiment with the setting $p = (0.8, 0.2, 0.0)$ where p denotes the triple $(p_{\text{[mask]}}, p_{\text{[id]}}, p_{\text{[rand]}})$.

2.4 Linguistic Properties

Inverted Word Order: *inv-order*. K et al. (2020) shuffled word order in sentences randomly and found that word order has some, but not a severe effect on multilinguality. They conclude that "structural similarity" across languages is important without further specifying this term. We investigate an extreme case: inversion. We invert each sentence in the Fake-English corpus: $[w_1, w_2, \dots, w_n] \rightarrow [w_n, w_{n-1}, \dots, w_1]$. Note that, apart from the reading order, all properties of the languages are preserved, including ngram statistics. Thus, the structural similarity of English and inverted Fake-English is arguably very high.

Comparability of Corpora: *no-parallel*. We hypothesize that the similarity of training corpora contributes to "structural similarity": if we train on a parallel corpus we expect the language structures to be more similar than when we train on two independent corpora, potentially from different domains. For mBERT, Wikipedias across languages are in the same domain, share some articles and thus are comparable, yet not parallel. To test our

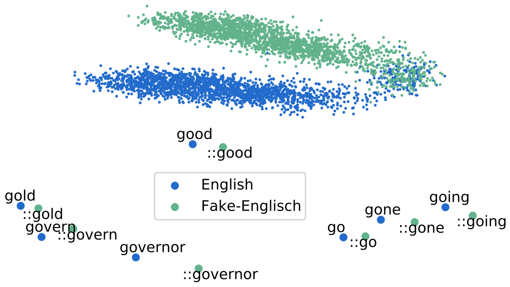

Figure 4: *Top*: PCA of the **token embeddings** from layer 0 of the original model (ID 0). The representations of the two languages clearly have a similar structure. *Bottom*: PCA of a sample of **token embeddings**. Corresponding tokens in English and Fake-English are nearest neighbors of each other or nearly so. This is quantitatively confirmed in Table 1.

hypothesis, we train on a non-parallel corpus. We create it by splitting the Bible into two halves, using one half for English and Fake-English each, thus avoiding any parallel sentences during training.

3 Results

3.1 Architectural Properties

Table 1 shows results. Each model has an associated ID that is consistent with the code. The original model (ID 0) shows a high degree of multilinguality. As mentioned, alignment is an easy task with shared position embeddings yielding $F_1 = 1.00$. Retrieval works better with contextualized representations on layer 8 (.97 vs. .16) whereas word translation works better on layer 0 (.88 vs. .79), as expected. Overall the embeddings seem to capture the similarity of English and Fake-English exceptionally well (see Figure 4 for a PCA of token embeddings). The untrained BERT models perform poorly (IDs 18, 19), except for word alignment with shared position embeddings.

When applying our **architectural modifications** (lang-pos, shift-special, no-random) individually we see medium to slight decreases in multilinguality (IDs 1, 2, 4). lang-pos has the largest negative impact. Apparently, applying just a single modification can be compensated by the model. Indeed, when using two modifications at a time (5–7) multilinguality goes down more, only with 7 there is still a high degree of multilinguality. With all three modifications (8) the degree of multilinguality is drastically lowered (μ .12 vs. .70).

We see that the language model quality (see columns MLM-Perpl.) is stable on train and dev across models (IDs 1–8) and does not deviate from original BERT (ID 0) by much.[5] Thus, we can conclude that each of the models has fitted the training data well and poor results on μ are not due to the fact that the architectural changes have hobbled BERT's language modeling performance.

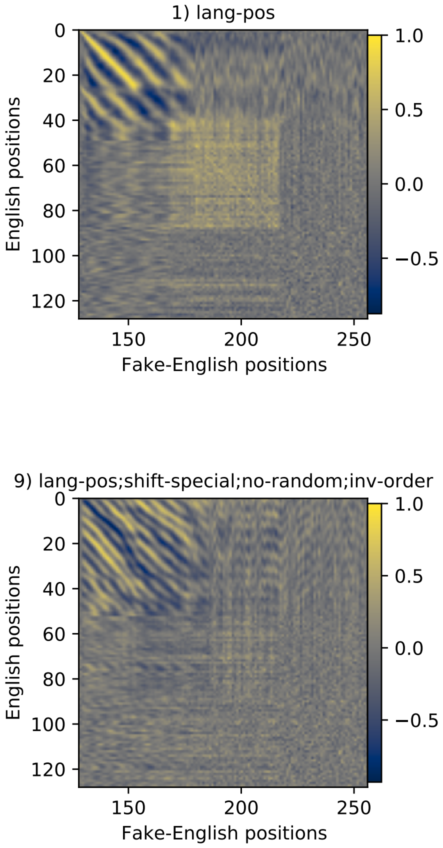

Figure 5: Cosine similarity matrices of position embeddings. The maximum length after tokenization in our experiments is 128. Position embedding IDs 0-127 are used by English, 128-255 by Fake-English.

The **overparameterized** model (ID 15) exhibits lower scores for word translation, but higher ones for retrieval and overall a lower multilinguality score (.58 vs. .70). However, when we add lang-pos (16) or apply all three architectural modifications (17), multilinguality drops to .01 and .00. This indicates that by decoupling languages with the proposed modifications (lang-pos, shift-special, no-random) and greatly increasing the number of parameters (overparam), it is possible to get a well-

---

[5] Perplexities on dev are high because the English of the King James Bible is quite different from that of the Easy-to-Read Bible. Our research question is: which modifications harm BERT's multilinguality without harming model fit (i.e., perplexity). The relative change of perplexities, not their absolute value is important in this context.

performing language model (low perplexity) that is not multilingual. *Conversely, we can conclude that the four architectural properties together are necessary for BERT to be multilingual.*

3.2 Linguistic Properties

Inverting Fake-English (IDs 3, 9) breaks multilinguality almost completely – independently of any architectural modifications. Having a language with the exact same structure (same ngram statistics, vocabulary size etc.), only with inverted order, seems to block BERT from creating a multilingual space. Note that perplexity is almost the same. *We conclude that having a similar word order structure is necessary for BERT to create a multilingual space.* The fact that shared position embeddings are important for multilinguality supports this finding. Our hypothesis is that the drop in multilinguality with inverted word order comes from an incompatibility between word and position encodings: BERT needs to learn that the word at position 0 in English is similar to word at position n in Fake-English. However, n (the sentence length) varies from sentence to sentence. This suggests that relative position embeddings – rather than absolute position embeddings – might be beneficial for multilinguality across languages with high distortion.

To investigate this effect more, Figure 8 shows cosine similarities between position embeddings for models 1, 9. Position IDs 0-127 are for English, 128-255 for Fake-English. Despite language specific position embeddings, the embeddings exhibit a similar structure: in the top panel there is a clear yellow diagonal at the beginning, which weakens at the end. The bottom shows that for a model with inverted Fake-English the position embeddings live in different spaces: no diagonal is visible.

In the range 90–128 (a rare sentence length) the similarities look random. This indicates that smaller position embeddings are trained more than larger ones (which occur less frequently). We suspect that embedding similarity correlates with the number of gradient updates a single position embedding receives. Positions 0, 1 and 128, 129 receive a gradient update in every step and can thus be considered an average of all gradient updates (up to random initialization). This is potentially one reason for the diagonal pattern in the top panel.

3.3 Corpus Comparability

So far we have trained on a parallel corpus. Now we show what happens with a merely comparable corpus. The first half of the training corpus is used for English and the other half for Fake-English. To mitigate the reduced amount of training data we train for twice as many epochs. Table 2 shows that multilinguality indeed decreases as the training cor-

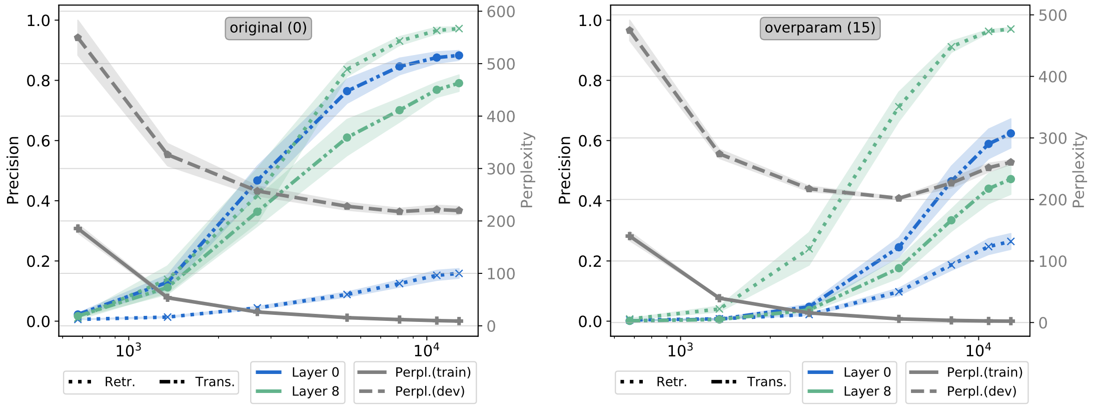

Figure 6: The longer a model is trained, the more multilingual it gets. x-axis shows training steps. Alignment F_1 is not shown as the models use shared position embeddings. Lines show mean and shaded areas show standard deviation across 5 random seed.

pus becomes non-parallel. This suggests that the more comparable a training corpus is across languages the higher the multilinguality. Note, however, that the models fit the training data worse and do not generalize as well as the original model.

3.4 Multilinguality During Training

One central hypothesis is that BERT becomes multilingual at the point at which it is forced to use its parameters efficiently. We argue that this point depends on several factors including the number of parameters, training duration, "complexity" of the data distribution and how easily common structures across language spaces can be aligned. The latter two are difficult to control for. We provided insights that two languages with identical structure but inverted word order are harder to align. Figure 6 analyzes the former two factors and shows model fit and multilinguality for the small and large model settings over training steps.

Generally, multilinguality rises very late at a stage where model fit improvements are flat. In fact, most of multilinguality in the overparameterized setting (15) arises once the model starts to overfit and perplexity on the development set goes up. The original setting (0) has far fewer parameters. We hypothesize that it is forced to use its parameters efficiently and thus multilinguality scores rise much earlier when both training and development perplexity are still going down.

Although this is a very restricted experimental setup it indicates that having multilingual models is a trade-off between good generalization and high degree of multilinguality. By overfitting a model one could achieve high multilinguality. Conneau et al. (2020a) introduced the concept of "curse of multilinguality" and found that the number of parameters should be increased with the number of languages. Our results indicate that too many parameters can also harm multilinguality. However, in practice it is difficult to create a model with so many parameters that it is overparameterized when being trained on 104 Wikipedias.

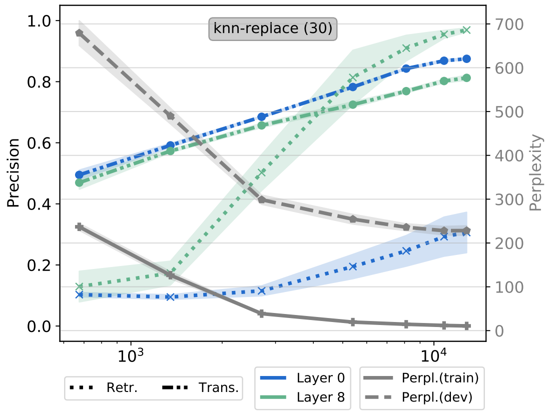

Figure 7: With knn-replace multilinguality rises earlier. Alignment F_1 is not shown as the model uses shared position embeddings.

Rönnqvist et al. (2019) found that current multilingual BERT models may be undertrained. This is consistent with our findings that multilinguality arises late in the training stage.

4 Improving Multilinguality

So far we have tried to break BERT's multilinguality. Now we turn to exploiting our insights for improving it. mBERT has shared position embeddings, shared special tokens and we cannot change linguistic properties of languages. Our results on overparameterization suggest that smaller models become multilingual faster. However, mBERT may already be considered underparameterized given that it is trained on 104 large Wikipedias.

One insight we can leverage for the masking procedure is *no-random*: replacing masked words with random tokens. *We propose to introduce a fourth masking option:* replacing masked tokens with semantically similar words from other languages. To this end we train static fastText embeddings (Bojanowski et al., 2017) on the training set and then project them into a common space using VecMap (Artetxe et al., 2018). We use this crosslingual space to replace masked tokens with nearest neighbors from the other language. Each masked word is then replaced with the probabilities $(p_{[\text{mask}]}, p_{[\text{id}]}, p_{[\text{rand}]}, p_{[\text{knn}]}) = (0.5, 0.1, 0.1, 0.3)$, i.e., in 30% of the cases masked words get replaced with the nearest neighbor from the multilingual static embedding space. Note that this procedure (including VecMap) is fully unsupervised (i.e., no parallel data or dictionary required). We call this method *knn-replace*. Conneau et al. (2020b) performed similar experiments by creating code switched data and adding it to the training data. However, we only replace masked words.

Figure 7 shows the multilinguality score and model fit over training time. Compared to the original model in Figure 6, retrieval and translation have higher scores earlier. Towards the end multilinguality scores become similar, with knn-replace outperforming the original model (see Table 1). This finding is particularly important for training BERT on large amounts of data. Given how expensive training is, it may not be possible to train a model long enough to obtain a high degree of multilinguality. Longer training incurs the risk of overfitting as well. Thus achieving multilinguality early in the training process is valuable. Our new masking strategy has this property.

5 Real Data Experiments

5.1 XNLI

We have presented experiments on a small corpus with English and Fake-English. Now we provide results on real data. Our setup is similar to (K et al., 2020): we train a multilingual BERT model on English, German and Hindi. As training corpora we sample 1GB of data from Wikipedia (except for Hindi, as its size is <1GB) and pretrain the model for 2 epochs/140k steps with batch size 256 and learning rate 1e-4. In this section, we use BERT-base, not BERT-small because we found that BERT-small with less than 1M parameters performs poorly in a larger scale setup. The remaining model and training parameters are the same as before. Each language has its own vocabulary with size 20k. We then evaluate the pretrained models on XNLI (Conneau et al., 2018). We finetune the pretrained models on English XNLI (3 epochs, batch size 32, learning rate 2e-5, following Devlin et al. (2019)). Then the model is evaluated on English. In addition, we do a zero-shot evaluation on German and Hindi.

ID	Description	ENG	DEU	HIN
0-base	original	$\mathbf{.75}_{.00}$	$.57_{.02}$	$.45_{.01}$
3-base	inv-order[DEU]	$\mathbf{.75}_{.00}$	$.41_{.01}$	$.46_{.04}$
8-base	lang-pos;shift-special;no-random	$.74_{.00}$	$.37_{.02}$	$.38_{.02}$
30-base	knn-replace	$.74_{.01}$	$\mathbf{.61}_{.01}$	$\mathbf{.54}_{.00}$
mBERT	Results by (Hu et al., 2020)	.81	.70	.59

Table 3: Accuracy on XNLI test for different model settings. Shown is the mean and standard deviation (subscript) across three random seeds. All models have the same architecture as BERT-base, are pretrained on Wikipedia data and finetuned on English XNLI training data. mBERT was pretrained longer and on much more data and has thus higher performance. Best non-mBERT performance in bold.

Table 3 presents accuracy on XNLI test. Compared to mBERT, accuracy is significantly lower but reasonable on English (.75 vs. .81) – we pretrain on far less data. ID 0 shows high multilinguality with 0-shot accuracies .57 and .45. Inverting the order of German has little effect on HIN, but DEU drops significantly (majority baseline is .33). Our architectural modifications (8) harm both HIN and DEU. The proposed *knn-replace* model exhibits the strongest degree of multilinguality, boosting the 0-shot accuracy in DEU / HIN by 4% / 9%. Note that to accommodate noise in the real world data, we randomly replace with one of the five nearest neighbors (not the top nearest neighbor). This indicates that *knn-replace* is useful for real world data and that our prior findings transfer to larger scale settings.

6 Related Work

There is a range of prior work analyzing the reason for BERT's multilinguality. Singh et al. (2019) show that BERT stores language representations in different subspaces and investigate how subword tokenization influences multilinguality. Artetxe et al. (2020) show that neither a shared vocabulary nor joint pretraining is essential for multilinguality. K et al. (2020) extensively study reasons for multilinguality (e.g., researching depth, number of parameters and attention heads). They conclude that depth is essential. They also investigate language properties and conclude that structural similarity across languages is important, without further defining this term. Last, Conneau et al. (2020b) find that a shared vocabulary is not required. They find that shared parameters in the top layers are required for multilinguality. Further they show that different monolingual BERT models exhibit a similar structure and thus conclude that mBERT somehow aligns those isomorphic spaces. They investigate having separate embedding look-ups per language (including position embeddings and special tokens) and a variant of avoiding cross-language replacements. Their method "extra anchors" yields a higher degree of multilinguality. In contrast to this prior work, we investigate multilinguality in a clean laboratory setting, investigate the interaction of architectural aspects and research new aspects such as overparameterization or inv-order.

Other work focuses on creating better multilingual models. Mulcaire et al. (2019) proposed a method to learn multilingual contextual representations. Conneau and Lample (2019) introduce the translation modeling objective. Conneau et al. (2020a) propose XLM-R. They introduce the term "curse of multilinguality" and show that multilingual model quality degrades with an increased number of languages given a fixed number of parameters. This can be interpreted as the minimum number of parameters required whereas we find indications that models that are too large can be harmful for multilinguality as well. Cao et al. (2020) improve the multilinguality of mBERT by introducing a regularization term in the objective, similar to the creation of static multilingual embedding spaces. Huang et al. (2019) extend mBERT pretraining with three additional tasks and show an improved overall performance. More recently, better multilinguality is achieved by Pfeiffer et al. (2020) (adapters) and Chi et al. (2020) (parallel data). We propose a simple extension to make mBERT more multilingual; it does not require additional supervision, parallel data or a more complex loss function – in contrast to this prior work.

Finally, many papers find that mBERT yields competitive zero-shot performance across a range of languages and tasks such as parsing and NER (Pires et al., 2019; Wu and Dredze, 2019), word alignment and sentence retrieval (Libovický et al., 2019) and language generation (Rönnqvist et al., 2019); Hu et al. (2020) show this for 40 languages and 9 tasks. Wu and Dredze (2020) consider the performance on up to 99 languages for NER. In contrast, Lauscher et al. (2020) show limitations of the zero-shot setting and Zhao et al. (2020) observe poor performance of mBERT in reference-free machine translation evaluation. Prior work here focuses on investigating the degree of multilinguality, not the reasons for it.

7 Conclusion

We investigated which architectural and linguistic properties are essential for BERT to yield crosslingual representations. The main takeaways are: **i)** Shared position embeddings, shared special tokens, replacing masked tokens with random tokens and a limited amount of parameters are necessary elements for multilinguality. **ii)** Word order is relevant: BERT is not multilingual with one language having an inverted word order. **iii)** The comparability of training corpora contributes to multilinguality. We show that our findings transfer to larger scale settings. We experimented with a simple modification to obtain stronger multilinguality in BERT models and demonstrate its effectiveness on XNLI. We considered a fully unsupervised setting without any crosslingual signals. In future work we plan to incorporate crosslingual signals as Vulić et al. (2019) argue that a fully unsupervised setting is hard to motivate.

A Additional Details on Methods

A.1 Word Translation Evaluation

Word translation is evaluated in the same way as sentence retrieval. This section provides additional details.

For each token in the vocabulary $w^{(k)}$ we feed the “sentence” “[CLS] $\{ w^{(k)} \}$ [SEP]” to the BERT model to obtain the embeddings $\mathcal{E}(w^{(k)}) \in \mathbb{R}^{3\times d}$ from the l-th layer of BERT for $k \in \{\text{eng}, \text{fake}\}$. Now, we extract the word embedding by taking the second vector (the one corresponding to $w^{(k)}$) and denote it by $e_w^{(k)}$. Computing cosine similarities between English and Fake-English tokens yields the similarity matrix $R \in \mathbb{R}^{m\times m}$ where $R_{ij} = \text{cosine-sim}(e_i^{(\text{eng})}, e_j^{(\text{fake})})$ for m tokens in the vocabulary of one language (in our case 2048).

Given an English query token $s_i^{(\text{eng})}$, we obtain the retrieved tokens in Fake-English by ranking them according to similarity. Note that we can do the same with Fake-English as query language. We report the mean precision of these directions that is computed as

$$\tau = \frac{1}{2m}\sum_{i=1}^{m} \mathbb{1}_{\arg\max_l R_{il}=i} + \mathbb{1}_{\arg\max_l R_{li}=i}.$$

A.2 inv-order

Assume the sentence “He ate wild honey .” exists in the corpus. The tokenized version is [He, ate, wild, hon, ##e, ##y, .] and the corresponding Fake-English sentence is [::He, ::ate, ::wild, ::hon, ::##e, ::##y, ::.]. If we apply the modification inv-order we always invert the order of the Fake-English sentences, thus the model only receives the sentence [::., ::##y, ::##e, ::hon, ::wild, ::ate, ::He].

A.3 knn-replace

We use the training data to train static word embeddings for each language using the tool fastText. Subsequently we use VecMap (Artetxe et al., 2018) to map the embedding spaces from each language into the English embedding space, thus creating a multilingual static embedding space. We use VecMap without any supervision.

During MLM-pretraining of our BERT model 15% of the tokens are randomly selected and “masked”. They then get either replaced by “[MASK]” (50% of the cases), remain the same (10% of the cases), get replaced by a random other token (10% of the cases) or we replace the token with one of the five nearest neighbors (in the fake-English setup only with the nearest neighbor) from another language (30% of the cases). Among those five nearest neighbors we pick one randomly. In case more than one other language is available we pick one randomly.

B Additional Non-central Results

B.1 Model 17

One might argue that our model 17 in Table 1 of the main paper is simply not trained enough and thus not multilingual. However, Table 10 shows that even when continuing to train this model for a long time no multilinguality arises. Thus in this configuration the model has enough capacity to model the languages independently of each other – and due to the modifications apparently no incentive to try to align the language representations.

B.2 Word Order in XNLI

To verify whether similar word order across languages influences the multilinguality we propose to compute a word reordering metric and correlate this metric with the performance of 0-shot transfer capabilities of mBERT. To this end we consider the performance of mBERT on XNLI. We follow Birch and Osborne (2011) in computing word reordering metrics between parallel sentences (XNLI is a parallel corpus). More specifically we compute the Kendall’s tau metric. To this end, we compute word alignments between two sentences using the Match algorithm by Sabet et al. (2020), which directly yield a permutation between sentences as

Scenario	Runtime
pretrain small BERT model on Easy-to-Read-Bible, 100 epochs	$\sim 35m$
pretrain large BERT model (BERT-base) on Easy-to-Read-Bible, 100 epochs	$\sim 4h$
pretrain large BERT model (BERT-base) on Wikipedia sample, 1 epoch	$\sim 2.5days$

Table 5: Runtime on a single GPU.

Model	Parameters
Standard Configuration ("Small model")	$1M$
BERT-Base / Overparameterized Model / "Large model"	$88M$
Real data model (BERT-Base with larger vocabulary)	$131M$
mBERT	$178M$

Table 6: Number of parameters for our used models.

required by the distance metric. We compute the metric on 2500 sentences from the development data of XNLI and average it across sentences to get a single score per language. The scores and XNLI accuracies are in Table 4.

The Pearson correlation between Kendall's tau metric and the XNLI classification accuracy in a zero-shot scenario (mBERT only finetuned on English and tested on all other languages) is 46% when disregarding English and 64% when including English. Thus there is a some correlation observable. This indicates that zero-shot performance of mBERT might also rely on similar word order across languages. We plan to extend this experiment to more zero-shot results and examine this effect more closely in future work.

B.3 Larger Position Similarity Plots

We provide larger versions of our position similarity plots in Figure 8.

C Reproducibility Information

C.1 Data

Table 7 provides download links to data.

C.2 Technical Details

The number of parameters for each model are in Table 6.

We did all computations on a server with up to 40 Intel(R) Xeon(R) CPU E5-2630 v4 CPUs and 8 GeForce GTX 1080Ti GPU with 11GB memory. No multi-GPU training was performed. Typical runtimes are reported in Table 5.

Used third party systems are shown in Table 8.

C.3 Hyperparameters

We show an overview on hyperparameters in Table 9. If not shown we fall back to default values in the systems.

Name	Languages	Description	Size	Link
XNLI (Conneau et al., 2018)	English, German, Hindi	Natural Language Inference Dataset. We use the English training set and English, German and Hindi test set.	392703 sentence pairs in train, 5000 in test, 2500 in dev per language.	`https://cims.nyu.edu/~sbowman/xnli/`
Wikipedia	English, German, Hindi	We use 1GB of randomly sampled data from a Wikipedia dump downloaded in October 2019.	8.5M sentences for ENG, 9.3M for DEU and 800K for HIN.	`download.wikimedia.org/[X]wiki/latest/[X]wiki-latest-pages-articles.xml.bz2`
Bible (Mayer and Cysouw, 2014)	English	We use the editions Easy-to-Read and King-James-Version.	We use all 17178 sentences in Easy-to-Read (New Testament) and the first 10000 sentences of King-James in the Old Testament.	n/a

On Negative Interference in Multilingual Models: Findings and A Meta-Learning Treatment

Zirui Wang **Zachary C. Lipton** **Yulia Tsvetkov**
Carnegie Mellon University, Pittsburgh, USA
{ziruiw, zlipton, ytsvetko}@cs.cmu.edu

Abstract

Modern multilingual models are trained on concatenated text from multiple languages in hopes of conferring benefits to each (positive transfer), with the most pronounced benefits accruing to low-resource languages. However, recent work has shown that this approach can degrade performance on high-resource languages, a phenomenon known as *negative interference*. In this paper, we present the first systematic study of negative interference. We show that, contrary to previous belief, negative interference also impacts low-resource languages. While parameters are maximally shared to learn language-universal structures, we demonstrate that language-specific parameters do exist in multilingual models and they are a potential cause of negative interference. Motivated by these observations, we also present a meta-learning algorithm that obtains better cross-lingual transferability and alleviates negative interference, by adding language-specific layers as meta-parameters and training them in a manner that explicitly improves shared layers' generalization on all languages. Overall, our results show that negative interference is more common than previously known, suggesting new directions for improving multilingual representations.[1]

1 Introduction

Advances in pretraining language models (Devlin et al., 2018; Liu et al., 2019; Yang et al., 2019) as general-purpose representations have pushed the state of the art on a variety of natural language tasks. However, not all languages enjoy large public datasets for pretraining and/or downstream tasks. Multilingual language models such as mBERT (Devlin et al., 2018) and XLM (Lample and Conneau, 2019) have been proven effective for cross-lingual transfer learning by pretraining a single shared Transformer model (Vaswani et al., 2017) jointly on multiple languages. The goals of multilingual modeling are not limited to improving language modeling in low-resource languages (Lample and Conneau, 2019), but also include zero-shot cross-lingual transfer on downstream tasks—it has been shown that multilingual models can generalize to target languages even when labeled training data is only available in the source language (typically English) on a wide range of tasks (Pires et al., 2019; Wu and Dredze, 2019; Hu et al., 2020).

However, multilingual models are not equally beneficial for all languages. Conneau et al. (2019) demonstrated that including more languages in a single model can improve performance for low-resource languages but hurt performance for high-resource languages. Similarly, recent work (Johnson et al., 2017; Tan et al., 2019; Aharoni et al., 2019; Arivazhagan et al., 2019) in multilingual neural machine translation (NMT) also observed performance degradation on high-resource language pairs. In multi-task learning (Ruder, 2017), this phenomenon is known as *negative interference* or *negative transfer* (Wang et al., 2019), where training multiple tasks jointly hinders the performance on individual tasks.

Despite these empirical observations, little prior work analyzed or showed how to mitigate negative interference in multilingual language models. Particularly, it is natural to ask: (1) Can negative interference occur for low-resource languages also? (2) What factors play an important role in causing it? (3) Can we mitigate negative interference to improve the model's cross-lingual transferability?

In this paper, we take a step towards addressing these questions. We pretrain a set of monolingual and bilingual models and evaluate them on a range of downstream tasks to analyze negative interference. We seek to individually characterize the un-

derlying factors of negative interference through a set of ablation studies and glean insights on its causes. Specifically, we examine if training corpus size and language similarity affect negative interference, and also measure gradient and parameter similarities between languages.

Our results show that negative interference can occur in both high-resource and low-resource languages. In particular, we observe that neither subsampling the training corpus nor adding typologically similar languages substantially impacts negative interference. On the other hand, we show that gradient conflicts and language-specific parameters do exist in multilingual models, suggesting that languages are fighting for model capacity, which potentially causes negative interference. We further test whether explicitly assigning language-specific modules to each language can alleviate negative interference, and find that the resulting model performs better within each individual language but worse on zero-shot cross-lingual tasks.

Motivated by these observations, we further propose to meta-learn these language-specific parameters to explicitly improve generalization of shared parameters on all languages. Empirically, our method improves not only within-language performance on monolingual tasks but also cross-lingual transferability on zero-shot transfer benchmarks. To the best of our knowledge, this is the first work to systematically study and remedy negative interference in multilingual language models.

2 Motivation

Multilingual transfer learning aims at utilizing knowledge transfer across languages to boost performance on low-resource languages. State-of-the-art multilingual language models are trained on multiple languages jointly to enable cross-lingual transfer through parameter sharing. However, languages are heterogeneous, with different vocabularies, morphosyntactic rules, and different pragmatics across cultures. It is therefore natural to ask, *is knowledge transfer beneficial for all languages in a multilingual model?* To analyze the effect of knowledge transfer from other languages on a specific language *lg*, we can compare multilingual models with the monolingual model trained on *lg*. For example, in Figure 1, we compare the performance on a named entity recognition (NER) task of monolingually-trained models vs. bilingual models (trained on *lg* and English) vs. state-of-the-art XLM (Conneau et al., 2019). We can see that monolingual models outperform multilingual models on four out of six languages (See §3.3 for details). This shows that language conflicts may induce negative impacts on certain languages, which we refer to as *negative interference*. Here, we investigate the causes of negative interference (§3.3) and methods to overcome it (§4).

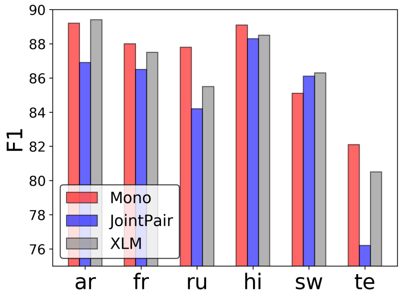

Figure 1: Comparing monolingual vs multilingual models on NER. Lower performance of multilingual models is likely an indicator of negative interference.

3 Investigating the Sources of Negative Interference in Multilingual Models

3.1 Methodology

To study negative interference, we compare multilingual models with monolingual baselines. Without loss of generality, we focus on analyzing bilingual models to minimize confounding factors. For two languages lg_1 and lg_2, we pretrain a single bilingual model and two monolingual models. We then assess their performance on downstream tasks using two different settings. To examine negative interference, we evaluate both monolingual and multilingual models using the **within-language monolingual** setting, such that the pretrained model is finetuned and tested on the same language. For instance, if the monolingual model of lg_1 outperforms the bilingual model on lg_1, we know that lg_2 induces negative impact on lg_1 in the bilingual model. Besides, since multilingual models are trained to enable cross-lingual transfer, we also report their performance on the **zero-shot cross-lingual transfer** setting, where the model is only finetuned on the source language, say lg_1, and tested on the target language lg_2.

We hypothesize that the following factors play important roles in causing negative interference and study each individually:

Training Corpus Size While prior work mostly report negative interference for high-resource lan-

	en	ar	fr	ru	hi	sw	te
corpus size	44.6	8.7	16.2	13.1	0.5	0.2	0.3
NER	✓	✓	✓	✓	✓	✓	✓
POS	✓	✓	✓	✓	✓		✓
QA	✓	✓		✓		✓	✓
XNLI	✓	✓	✓	✓	✓	✓	

Table 1: Language training corpra statitstics and downstream tasks availability. Corpus size measured in millions of sentences.

guages (Conneau et al., 2019; Arivazhagan et al., 2019), we hypothesize that it can also occur for languages with less resources. We study the impact of training data size per language on negative interference. We subsample a high-resource language, say lg_1, to create a "low-resource version". We then retrain the monolingual and bilingual models and compare with results of their high-source counterparts. Particularly, we test if reducing lg_1's training size also reduces negative interference on lg_2.

Language Similarity Language similarity has been shown important for effective transfer in multilingual models. Wu et al. (2019) shows that bilingual models trained on more similar language pairs result in better zero-shot transfer performance. We thus expect it to play a critical role in negative interference as well. For a specific language lg_1, we pair it with languages that are closely and distantly related. We then compare these bilingual models' performance on lg_1 to investigate if more similar languages cause less severe interference. In addition, we further add a third language lg_3 that is similar to lg_1 and train a trilingual model on lg_1-lg_2-lg_3. We compare the trilingual model with the bilingual model to examine if adding lg_3 can mitigate negative interference on lg_1.

Gradient Conflict Recent work (Yu et al., 2020) shows that gradient conflict between dissimilar tasks, defined as a negative cosine similarity between gradients, is predictive of negative interference in multi-task learning. Therefore, we study whether gradient conflicts exist between languages in multilingual models. In particular, we sample one batch for each language in the model and compute the corresponding gradients' cosine similarity for every 10 steps during pretraining.

Parameter Sharing State-of-the-art multilingual models aim to share as many parameters as possible in the hope of learning a language-universal model for all languages (Wu et al., 2019). While prior studies measure the latent embedding similarity between languages, we instead examine model parameters directly. The idea is to test whether model parameters are **language-universal** or **language-specific**. To achieve this, we prune multilingual models for each language using relaxed L_0 norm regularization (Louizos et al., 2017), and compare parameter similarities between languages. Formally, for a model $f(\cdot;\boldsymbol{\theta})$ parameterized by $\boldsymbol{\theta} = \{\theta_i\}_{i=1}^{n}$ where each θ_i represents an individual parameter or a group of parameters, the method introduces a set of binary masks $\mathbf{z}$, drawn from some distribution $q(\mathbf{z}|\boldsymbol{\pi})$ parametrized by $\boldsymbol{\pi}$, and learns a sparse model $f(\cdot;\boldsymbol{\theta}\odot\mathbf{z})$ by optimizing:

$$\begin{aligned} \min_{\boldsymbol{\pi}} \quad & \mathbb{E}_{q(\mathbf{z}|\boldsymbol{\pi})}\left[\frac{1}{N}\sum_{i=1}^{N}\mathcal{L}(f(x_i;\tilde{\boldsymbol{\theta}}), y_i) + \lambda\|\tilde{\boldsymbol{\theta}}\|_0\right] \\ \text{s.t.} \quad & \tilde{\boldsymbol{\theta}} = \boldsymbol{\theta}\odot\mathbf{z}, \end{aligned} \tag{1}$$

where $\odot$ is the Hadamard (elementwise) product, $\mathcal{L}(\cdot)$ is some task loss and λ is a hyper-parameter. We follow the work of (Louizos et al., 2017) and use the Hard Concrete distribution for the binary mask $\mathbf{z}$, such that the above objective is fully differentiable. Then, for each bilingual model, we freeze its pretrained parameter weights and learn binary masks $\mathbf{z}$ for *each* language independently. As a result, we obtain two independent sets of mask parameters $\boldsymbol{\pi}$ which can be used to determine parameter importance. Intuitively, for each parameter group, it is language-universal if both languages consider it important (positive $\boldsymbol{\pi}$ values). On the other hand, if one language assigns positive value while the other assigns negative, it shows that the parameter group is language-specific. We compare them across languages and layers to analyze parameter similarity in multilingual models.

3.2 Experimental Setup

We focus on standard multilingual masked language modeling (MLM) used in mBERT and XLM. We first pretrain models and then evaluate their performance on four NLP benchmarks.

For pretraining, we mainly follow the setup and implementation of XLM (Lample and Conneau, 2019). We focus on monolingual and bilingual models for a more controllable comparison, which we refer to as **Mono** and **JointPair** respectively. In particular, we always include English (En) in bilingual models to compare on zero-shot transfer settings with prior work. Besides, we consider three

Table 2: NER and POS results. We observe negative interference when monolingual models outperform multilingual models. Besides, adding language-specific layers (e.g. ffn) mitigates interference but sacrifices transferability.

high-resource languages {Arabic (Ar), French (Fr), Russian (Ru)} and three low-resource languages {Hindi (Hi), Swahili (Sw), Telugu (Te)} (see Table 1 for their statistics). We choose these six languages based their data availability in downstream tasks. We use Wikipedia as training data with statistics shown in Table 1. For each model, we use BPE (Sennrich et al., 2016) to learn 32k subword vocabulary shared between languages. For multilingual models, we sample language proportionally to $P_i = (\frac{L_i}{\sum_j L_j})^{\frac{1}{T}}$, where L_i is the size of the training corpus for i-th language pair and T is the temperature. Each model is a standard Transformer (Vaswani et al., 2017) with 8 layers, 12 heads, 512 embedding size and 2048 hidden dimension for the feedforward layer. Notice that we specifically consider a smaller model capacity to be comparable with existing models with larger capacity but also include much more (over 100) languages. We use the Adam optimizer (Kingma and Ba, 2014) and exploit the same learning rate schedule as Lample and Conneau (2019). We train each model with 4 NVIDIA V100 GPUs with 32GB of memory. Using mixed precision, we fit a batch of 128 for each GPU and the total batch size is 512. Each epoch contains 10k steps and we train for 50 epochs.

For evaluation, we consider four downstream tasks: named entity recognition (NER), part-of-speech tagging (POS), question answering (QA), and natural language inference (NLI). (See Apendix A for finetuning details.)

NER We use the WikiAnn (Pan et al., 2017) dataset, which is a sequence labelling task built automatically from Wikipedia. A linear layer with softmax classifier is added on top of pretrained models to predict the label for each word based on its first subword. We report the F1 score.

POS Similar to NER, POS is also a sequence labelling task but with a focus on synthetic knowledge. In particular, we use the Universal Dependencies treebanks (Nivre et al., 2018). Task-specific layers are the same and we report F1, as in NER.

QA We choose to use the TyDiQA-GoldP dataset (Clark et al., 2020) that covers typologically diverse languages. Similar to popular QA dataset such as SQuAD (Rajpurkar et al., 2018), this is a span prediction task where task-specific linear classifiers are used to predict start/end positions of the answer. Standard metrics of F1 and Exact Match (EM) are reported.

NLI XNLI (Conneau et al., 2018) is probably the most popular cross-lingual benchmark. Notice that the original dataset only contains training data for English. Consequently, we only evaluate this task on the zero-shot transfer setting while we consider both settings for the rest of other tasks.

3.3 Results and Analysis

In Table 2 and 3, we report our results on NER, POS and QA together with XLM-100, which is trained on 100 languages and contains 827M parameters. In particular, we observe that monolin-

(a) hi (b) sw

Figure 2: Validation perplexity during pretraining.

gual models outperform bilingual models for all languages except Swahili on all three tasks. In fact, monolingual models even perform better than XLM on four out of six languages including *hi* and *te*, despite that XLM is much larger in model sizes and trained with much more resources. This shows that negative interference *can* occur on low-resource languages as well. While the negative impact is expected to be more prominent on high-resource languages, we demonstrate that it may occur for languages with resources fewer than commonly believed. The existence of negative interference confirms that state-of-the-art multilingual models cannot generalize equally well on all languages, and there is still a gap compared to monolingual models on certain languages.

We next turn to dissect negative interference by studying the four factors described in Section 3.1.

Training Corpus Size By comparing the validation perplexity on Swahili and Telugu in Figure 2, we find that while both monolingual models outperform bilingual models in the first few epochs, the Swahili model's perplexity starts to *increase* and is eventually surpassed by the bilingual model in later epochs. This matches the intuition that monolingual models may overfit when training data size is small. To verify this, we subsample French and Russian to 100k sentences to create a "low-resource version" of them (denoted as $\mathrm{fr}_l/\mathrm{ru}_l$). As shown in Table 5, while the performance for both models drop compared to their "high-resource" counterparts, bilingual models indeed outperform monolingual models for $\mathrm{fr}_l/\mathrm{ru}_l$, in contrast for fr/ru. This suggests that multilingual models can stimulate positive transfer for low-resource languages when monolingual models overfit. On the other hand, when we compare bilingual models on English, models trained using different sizes of fr/ru data obtain similar performance, indicating that the training size of the source language has little impact on negative interference on the target language (English in this case). While more training data usually implies larger vocabulary and more diverse linguistic phenomena, negative interference seems to arise from more fundamental conflicts contained in even small training corpus.

Language Similarity As illustrated by Table 5, the in-language performance on English drops as the paired language becomes more distantly related (French vs Russian). This verifies that transferring from more distant languages results in more severe negative interference.

It is therefore natural to ask if adding more similar languages can mitigate negative interference, especially for low-resource languages. We then train two trilingual models, adding Marathi to English-Hindi, and Kannada to English-Telugu. Compared to their bilingual counterparts (Table 4), trilingual models obtain similar within-language performance, which indicates that adding similar languages *cannot* mitigate negative interference.

Model	NER (F1)				POS (F1)				QA (F1/EM)

Table 5: Evaluating effects of training corpus sizes on negative interference.

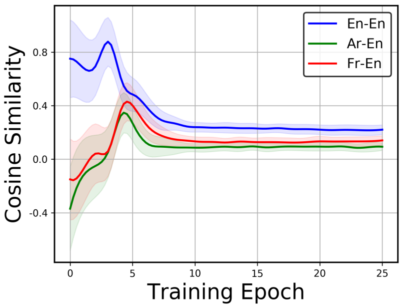

Figure 3: Gradients similarity throughout training. "En-En" refers to gradients of two English batches within the Ar-En model, while "Ar-En" and "Fr-En" refer to gradients of two batches, one from each language, within Ar-En and Fr-En models respectively.

However, they do improve zero-shot cross-lingual performance. One possible explanation is that even similar languages can fight for language-specific capacity but they may nevertheless benefit the generalization of the shared knowledge.

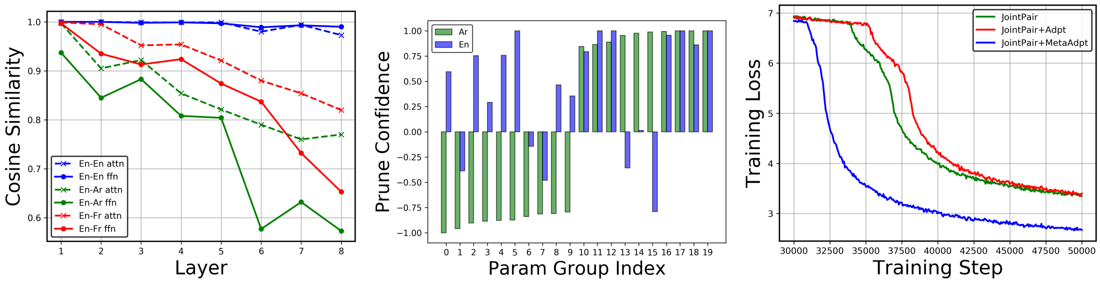
Gradient Conflict In Figure 3, we plot the gradient cosine similarity between Arabic-English and French-English in their corresponding bilingual models over the first 25 epochs. We also plot the similarity within English, measured using two independently sampled batches[2]. Specifically, gradients between two different languages are indeed less similar than those within the same language. The gap is more evident in the early few epochs, where we observe negative gradient similarities for Ar-En and Fr-En while those for En-En are positive. In addition, gradients in Ar-En are less similar than those in Fr-En, indicating that distant language pair can cause more severe gradient conflicts. These results confirm that gradient conflict exists in multilingual models and is correlated to per language performance, suggesting it may introduce optimization challenge that results in negative interference.

Parameter Sharing The existence of gradient conflicts may imply that languages are fighting for capacity. Thus, we next study how language-universal these multilingual parameters are. Figure 4a shows the cosine similarity of mask parameters π across different layers. We observe that within-language similarity (En-En) is near perfect, which validates the pruning method's robustness. The trend shows that model parameters are better shared in the bottom layers than the upper ones. Besides, it also demonstrates that parameters in multi-head attention layers obtain higher similarities than those in feedforward layers, suggesting that attention mechanism might be more language-universal. We additionally inspect π parameters with the highest absolute values and plot those values for Ar (Figure 4b), together with their En counterparts. A more negative value indicates that the parameter is more likely to be pruned for that language and vice versa. Interestingly, while many parameters with positive values (on the right) are language-universal as both languages assign very positive values, parameters with negative values (on the left) are mostly language-specific for Ar as En assigns positive values. We observe similar patterns for other languages as well. These results demonstrate that language-specific parameters do exist in multilingual models.

Having language-specific capacity in shared parameters is sub-optimal. It is less transferable and thus can hinder cross-lingual performance. Moreover, it may also take over capacity budgets for other languages and degrade their within-language performance, i.e., causing negative interference. A natural next question is whether explicitly adding language-specific capacity into multilingual models can alleviate negative interference. We thus train variants of bilingual models that contain language-specific components for each language. Particularly, we consider adding language-specific feedforward layers, attention layers, and residual adapter layers (Rebuffi et al., 2017; Houlsby et al., 2019), denoted as ffn, attn and adpt respectively.

---

[2] Notice that we use gradient accumulation to sample an effectively larger batch of 4096 sentences to calculate the gradient similarity.



(a) (b) (c)

Figure 4: **Left:** Parameter similarity across layers. **Middle:** Normalized pruning variables of highest absolute values for Ar in Ar-En model. 10 parameter groups with most negative values are shown on the left and 10 with most positive values are shown on the right. **Right:** Average MLM training loss after the warm-up stage.

For each type of component, we create two separate copies in each Transformer layer, one designated for each language, while the rest of the network remains unchanged. As shown in Table 2 and 3, adding language-specific capacity does mitigate negative interference and improve monolingual performance. We also find that language-specific feedforward layers obtain larger performance gains compared to attention layers, consistent with our prior analysis. However, these gains come at a cost of cross-lingual transferability, such that their zero-shot performance drops tremendously. Our results suggest a tension between addressing interference versus improving transferability. In the next section, we investigate how to address negative interference in a manner that can improve performance on *both* within-language tasks and cross-lingual benchmarks.

4 Mitigating Negative Interference via Meta Learning

4.1 Proposed Method

In the previous section, we demonstrated that while explicitly adding language-specific components can alleviate negative interference, it can also hinder cross-lingual transferability. We notice that a critical shortcoming of language-specific capacity is that they are **agnostic** of the rest of other languages, since by design they are trained on the designated language only. They are thus more likely to overfit and can induce optimization challenges for shared capacity as well. Inspired by recent work in meta learning (Flennerhag et al., 2019) that utilizes meta parameters to improve gradient geometry of the base network, we propose a novel meta-learning formulation of multilingual models that exploits language-specific parameters to improve generalization of shared parameters.

For a model with some predefined language-specific parameters $\boldsymbol{\phi} = \{\phi_i\}_{i=1}^{L}$, where ϕ_i is designated for the i-th language, and shared parameters $\boldsymbol{\theta}$, our solution is to treat $\boldsymbol{\phi}$ as meta parameters and $\boldsymbol{\theta}$ as base parameters. Ideally, we want $\boldsymbol{\phi}$ to store non-transferable language-specific knowledge to resolve conflicts and improve generalization of $\boldsymbol{\theta}$ in all languages (a.k.a. mitigate negative interference and improve cross-lingual transferability). Therefore, we train $\boldsymbol{\phi}$ based on the following principle: *if $\boldsymbol{\theta}$ follows the gradients on training data for a given $\boldsymbol{\phi}$, the resulting $\boldsymbol{\theta}$ should obtain a good validation performance on all languages*. This implies a bilevel optimization problem (Colson et al., 2007) formally written as:

$$\begin{aligned} \min_{\boldsymbol{\phi}} \quad & \frac{1}{L}\sum_{i=1}^{L}\mathcal{L}_{\text{val}}^{i}(\boldsymbol{\theta}^{*},\phi_i) \\ \text{s.t.} \quad & \boldsymbol{\theta}^{*} = \arg\min_{\boldsymbol{\theta}} \frac{1}{L}\sum_{i=1}^{L}\mathcal{L}_{\text{train}}^{i}(\boldsymbol{\theta},\phi_i), \end{aligned} \tag{2}$$

where $\mathcal{L}_{\text{val}}^{i}$ and $\mathcal{L}_{\text{train}}^{i}$ denote the training and the validation MLM loss for the i-th language. Since directly solving this problem can be prohibitive due to the expensive inner optimization, we approximate $\boldsymbol{\theta}^{*}$ by adapting the current $\boldsymbol{\theta}^{(t)}$ using a single gradient step, similar to techniques used in prior meta-learning methods (Finn et al., 2017). This results in a two-phase iterative training process shown in Algorithm 1 (See Appendix B).

To be specific, at each training step t on the i-th language during pretraining, we first adapt a gradient step on $\boldsymbol{\theta}$ to obtain a new $\boldsymbol{\theta}'$ and update ϕ_i

Algorithm 1 Training XLM with Meta Language-specific Layers

```
Input: Training data
Output: The converged model $\{\boldsymbol{\theta}^*, \boldsymbol{\phi}^*\}$
Initialize model parameters $\{\boldsymbol{\theta}^{(0)}, \boldsymbol{\phi}^{(0)}\}$
while not converged do
    Sample language $i$
    Update language-specific parameters as:
        $\phi_i^{(t+1)} \leftarrow \text{GradientUpdate}(\phi_i^{(t)}, \nabla_{\phi_i^{(t)}} \frac{1}{L} \sum_{j=1}^{L} \mathcal{L}_{\text{val}}^{j}(\theta_i^{(t)} - \beta \nabla_{\boldsymbol{\theta}^{(t)}} \mathcal{L}_{\text{train}}^{i}(\boldsymbol{\theta}^{(t)}, \phi_i^{(t)}), \phi_j^{(t)}))$
    Update shared parameters as:
        $\boldsymbol{\theta}^{(t+1)} \leftarrow \text{GradientUpdate}(\boldsymbol{\theta}^{(t)}, \nabla_{\boldsymbol{\theta}^{(t)}} \mathcal{L}_{\text{train}}(\boldsymbol{\theta}^{(t)}, \boldsymbol{\phi}^{(t+1)}))$
end while
```

based on the $\boldsymbol{\theta}'$'s validation MLM loss:

$$\begin{aligned} \phi_i^{(t+1)} &= \phi_i^{(t)} - \alpha \nabla_{\phi_i^{(t)}} \frac{1}{L} \sum_{j=1}^{L} \mathcal{L}_{\text{val}}^{j}(\boldsymbol{\theta}', \phi_j^{(t)}) \\ \boldsymbol{\theta}' &= \boldsymbol{\theta}^{(t)} - \beta \nabla_{\boldsymbol{\theta}^{(t)}} \mathcal{L}_{\text{train}}^{i}(\boldsymbol{\theta}^{(t)}, \phi_i^{(t)}), \end{aligned} \tag{3}$$

where α and β are learning rates. Notice that $\boldsymbol{\theta}'$ is a function of $\phi_i^{(t)}$ and thus this optimization requires computing the gradient of gradient. Particularly, by applying chain rule to the gradient of $\phi_i^{(t)}$, we can observe that it contains a higher-order term:

$$\left[\nabla^2_{\phi_i^{(t)}, \boldsymbol{\theta}^{(t)}} \mathcal{L}_{\text{train}}^{i}(\boldsymbol{\theta}^{(t)}, \phi_i^{(t)})\right] \cdot \left[\nabla_{\boldsymbol{\theta}'} \frac{1}{L} \sum_{j=1}^{L} \mathcal{L}_{\text{val}}^{j}(\boldsymbol{\theta}', \phi_j^{(t)})\right] \tag{4}$$

This is important, since it shows that ϕ_i can obtain information from other languages through higher-order gradients. In other words, language-specific parameters are **not** agnostic of other languages anymore without violating the language-specific requirement. This is because, in Eq. 3, while $\nabla_{\boldsymbol{\theta}^{(t)}}$ is based on the i-th language only, the validation loss is computed for all languages. Finally, in the second phase, we update $\boldsymbol{\theta}$ based on the new $\boldsymbol{\phi}^{(t+1)}$:

$$\boldsymbol{\theta}^{(t+1)} = \boldsymbol{\theta}^{(t)} - \beta \nabla_{\boldsymbol{\theta}^{(t)}} \mathcal{L}_{\text{train}}(\boldsymbol{\theta}^{(t)}, \boldsymbol{\phi}^{(t+1)}) \tag{5}$$

4.2 Evaluation

While our method is generic, we evaluate it applied on bilingual models with adapter networks. Adapters have been effectively utilized in multilingual models (Bapna et al., 2019), and we choose them for practical consideration of limiting per-language capacity. Unlike prior works that finetune adapters for adaptation, we train them jointly with shared parameters during pretraining. We follow Houlsby et al. (2019) and insert language-specific adapters after attention and feedforward layers. We leave a more thorough investigation of how to better pick language-specific structures for future work. For downstream task evaluation, we finetune all layers. Notice that computing the gradient of gradient in Eq. 3 doubles the memory requirement. In practice, we utilize the finite difference approximation (Appendix B).

By evaluating their performance on the zero-shot transfer settings (Table 2, 3 and 6), we observe that our method, denoted as meta adpt, consistently improves the performance over JointPair baselines, while ordinary adapters (adpt) perform worse than JointPair. This shows that, the proposed method can effectively utilize the added language-specific adapters to improve generalization of shared parameters across languages. At the same time, our method also mitigates negative interference and outperforms JointPair on within-language performance, closing the gap with monolingual models. In particular, it performs better than ordinary adapters in both settings. We hypothesize that this is because it alleviates language conflicts during training and thus converges more robustly. For example, we plot training loss in the early stage in Figure 4c, which shows that ordinary adapters converge slower than JointPair due to overfitting of language-specific adapters while meta adapters converge much faster. For ablation studies, we also report results for JointPair trained with adapters shared between two languages, denoted as share adpt. Unlike language-specific adapters that can hinder transferability, shared adapters improve both within-language and cross-lingual performance with the extra capacity. However, meta adapters still obtain better performance. These results show that mitigating negative interference can improve multilingual representations.

Model	ar	fr	ru	hi	sw	avg
JointPair	67.1	73.5	69.2	61.5	62.3	66.7
+ ffn	42.5	51.4	40.7	36.2	34.8	41.1
+ attn	48.5	50.7	41.2	33.3	35.1	41.8
+ adpt	67.8	73.7	69.5	62.2	59.7	66.6
+ share adpt	67.9	73.4	70.0	61.8	62.2	67.1
+ meta adpt	68.5	74.8	70.2	64.5	61.5	67.9
XLM	68.2	75.2	72.3	65.4	58.1	67.8

5 Related Work

Unsupervised multilingual language models such as mBERT (Devlin et al., 2018) and XLM (Lample and Conneau, 2019; Conneau et al., 2019) work surprisingly well on many NLP tasks without parallel training signals (Pires et al., 2019; Wu and Dredze, 2019). A line of follow-up work (Wu et al., 2019; Artetxe et al., 2019; Karthikeyan et al., 2020) study what contributes to the cross-lingual ability of these models. They show that vocabulary overlap is not required for multilingual models, and suggest that abstractions shared across languages emerge automatically during pretraining. Another line of research investigate how to further improve these shared knowledge, such as applying post-hoc alignment (Wang et al., 2020b; Cao et al., 2020) and utilizing better calibrated training signal (Mulcaire et al., 2019; Huang et al., 2019). While prior work emphasize how to share to improve transferability, we study multilingual models from a different perspective of how to unshare to resolve language conflicts.

Our work is also related to transfer learning (Pan and Yang, 2010) and multi-task learning (Ruder, 2017). In particular, prior work have observed (Rosenstein et al., 2005) and studied (Wang et al., 2019) negative transfer, such that transferring knowledge from source tasks can degrade the performance in the target task. Others show it is important to remedy negative transfer in multi-source settings (Ge et al., 2014; Wang and Carbonell, 2018). In this work, we study negative transfer in multilingual models, where languages contain heavily unbalanced training data and exhibit complex intertask relatedness.

In addition, our work is related to methods that measure similarity between cross-lingual representations. For example, existing methods utilize statistical metrics to examine cross-lingual embeddings such as singular vector canonical correlation analysis (Raghu et al., 2017; Kudugunta et al., 2019), eigenvector similarity (Søgaard et al., 2018), and centered kernel alignment (Kornblith et al., 2019; Wu et al., 2019). While these methods focus on testing latent representations, we directly compare similarity of neural network structures through network pruning. Finally, our work is related to meta learning, which sets a meta task to learn model initialization for fast adaptation (Finn et al., 2017; Gu et al., 2018; Flennerhag et al., 2019), data selection (Wang et al., 2020a), and hyperparameters (Baydin et al., 2018). In our case, the meta task is to mitigate negative interference.

6 Conclusion

We present the first systematic study of negative interference in multilingual models and shed light on its causes. We further propose a method and show it can improve cross-lingual transferability by mitigating negative interference. While prior efforts focus on improving sharing and cross-lingual alignment, we provide new insights and a different perspective on unsharing and resolving language conflicts.

Acknowledgments

We want to thank Jaime Carbonell for his support on the early stage of this project. We also would like to thank Zihang Dai, Graham Neubig, Orhan Firat, Yuan Cao, Jiateng Xie, Xinyi Wang, Ruochen Xu and Yiheng Zhou for insightful discussions. Lastly, we thank anonymous reviewers for their valueable feedbacks.

A Fine-tuning Details

Notice that XNLI only has training data in available in English so we only evaluate zero-shot cross-lingual performance on it. Following (Hu et al., 2020), we finetune the model for 10 epochs for NER and POS, 2 epochs for QA and 200 epochs for XNLI. For NER, POS and QA, we search the following hyperparameters: batch size {16, 32}; learning rate {2e-5, 3e-5, 5e-5}. We use English dev set for zero-shot cross-lingual setting and the target language dev set for within-language monolingual setting. For XNLI, we search for: batch size {4, 8}; encoder learning rate {1e-6, 5e-6, 2e-5}; classifier learning rate {5e-6, 2e-5, 5e-5}. For models with language-specific components, we test freezing these components or finetuning them together. We discover that finetuning the whole network always yields better results. For all experiments, we save checkpoint after each epoch.

B Method Details

Let z_i be the output of the i-th layer of dimension d. The residual adapter network (Rebuffi et al., 2017; Houlsby et al., 2019; Bapna et al., 2019) is a bottleneck layer that first projects z_i to an inner layer with dimension b:

$$h_i = g(W_i^z z_i) \tag{6}$$

where $W_i^z \in \mathbb{R}^{d\times b}$ and g is some activation function such as $relu$. It is then projected back to the original input dimension d with a residual connection:

$$o_i = W_i^h h_i + z_i \tag{7}$$

where $W_i^h \in \mathbb{R}^{b\times d}$. In our experiments, we fix $b = \frac{1}{4}d$. For a bilingual model of lg_1 and lg_2, we inject two langauge-specific adapters after each attention and feedforward layer, one for each language. For example, if the input text is in lg_1, the network will be routed to adapters designated for lg_1. The rest of the network and training protocol remain unchanged.

The injected adapter layers mimic the warp layers interleaved between base network layers in Flennerhag et al. (2019). Warp layers are meta parameters that aim to improve the performance of the base network. They precondition base network gradients to obtain better gradient geometry. In our experiments, we treat language-specific adapters as meta parameters to improve generalization of the shared network. The algorithm is outlined in Algorithm 1. The adapters are updated according to Eq 3, which doubles the memory requirement. In particular, the high-order term in Eq 4 requires computing the gradient of gradient. In practice, we approximate this term using the finite difference approximation as:

$$\frac{\nabla_{\phi_i^{(t)}} \mathcal{L}^i_{\text{train}}(\boldsymbol{\theta}^+, \phi_i^{(t)}) - \nabla_{\phi_i^{(t)}} \mathcal{L}^i_{\text{train}}(\boldsymbol{\theta}^-, \phi_i^{(t)})}{2\epsilon} \tag{8}$$

where $\boldsymbol{\theta}^{\pm} = \boldsymbol{\theta}^{(t)} \pm \epsilon \nabla_{\boldsymbol{\theta}'} \frac{1}{L} \sum_{j=1}^{L} \mathcal{L}^j_{\text{val}}(\boldsymbol{\theta}', \phi_j^{(t)})$ and ϵ is a small scalar. We use the same value for learning rates α and β in Eq 3, to be consistent with standard learning rate schedule used in XLM (Lample and Conneau, 2019).

Abstract

Cross-lingual word embedding (CWE) algorithms represent words in multiple languages in a unified vector space. Multi-Word Expressions (MWE) are common in every language. When training word embeddings, each component word of an MWE gets its own separate embedding, and thus, MWEs are not translated by CWEs. We propose a simple method for word translation of MWEs to and from English in ten languages: we first compile lists of MWEs in each language and then tokenize the MWEs as single tokens before training word embeddings. CWEs are trained on a word-translation task using the dictionaries that only contain single words. In order to evaluate MWE translation, we created bilingual word lists from multilingual WordNet that include single-token words and MWEs, and most importantly, include MWEs that correspond to single words in another language. We show that the pre-tokenization of MWEs as single tokens performs better than averaging the embeddings of the individual tokens of the MWE. We can translate MWEs at a top-10 precision of 30-60%. The tokenization of MWEs makes the occurrences of single words in a training corpus more sparse, but we show that it does not pose negative impacts on single-word translations.

1 Introduction

Cross-lingual word embeddings (CWEs) are real-valued vector representations of words in multiple languages placed in a shared vector space, with the intention that words with closer meanings have closer locations in the vector space. First, monolingual word embeddings are trained based on the hypothesis of distributional semantics (Harris, 1954) that context approximates meaning. They are learned from data in a way that words used in similar contexts have similar vectors. Following that, the monolingual word embeddings are aligned to produce CWEs. CWEs are an essential building block in modern cross-lingual methods and can also be used to induce bilingual lexicons from a small seed dictionary (Mikolov et al., 2013).

An important and overlooked fact is that before CWEs are trained, the corpus is pre-processed by a word tokenizer. This illustrates a clear limitation of the state-of-the-art CWEs: they can only align words that happen to be considered as single tokens by the word tokenizer.

Multi-word expressions (MWEs) are combinations of orthographic words, whose meaning, form, use, or distribution is non-compositional or unpredictable in some way (Sag et al., 2002; Baldwin and Kim, 2010). They come in diverse forms such as compound nouns (*dance floor*), named entities (*United States*), phrasal verbs (*give up*), and connectives (*as well as*). Word tokenizers do not recognize MWEs as single units but rather as a sequence of their components, a deficiency carried into CWE construction.

In this position paper, we argue that the token units of word embeddings should be discussed more carefully, and, in particular, that MWEs should be recognized as single units before training and evaluating word embeddings. In cross-lingual applications, MWEs are particularly important. A single token in one language is often translated into an MWE in another language. So, failure to tokenize MWEs is a critical flaw of CWEs in the task of word translation and presumably in other cross-lingual tasks as well.

Some studies (Iyyer et al., 2015; Shen et al., 2018) have suggested representing phrase and sentence embeddings by taking the average or sum of their component word vectors. However, such a simple approach is not sufficient, as the meaning

November 16–20, 2020.

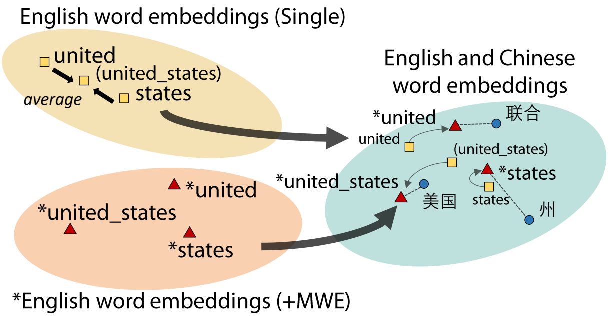

Figure 1: **The effect of MWE tokenization in cross-lingual alignments (Table 1).** English word embeddings trained with single-word tokenization (□) do not have *united states* in the vocabulary, and we represent its embedding by the average embedding. Word embeddings with MWE tokenization (△) assigns a unique embedding to *united_states*, which is better aligned with its Chinese translation 美国. Note that the configuration of single-word embeddings also changes by having MWE embeddings.

of an MWE is often unpredictable from its components, as in *red tape* and *hot dog*. Instead, MWEs should be explicitly modeled during CWE training.

To illustrate the advantage of having MWEs in the CWE vocabulary, we compare the alignments of English-Chinese CWEs with and without MWE tokens (Figure 1). Table 1 shows cosine similarities of English and Chinese words *united* and *states*. The numbers on the left side of each arrow (Single) show the cosine similarities between English and Chinese embeddings trained with standardly pre-tokenized corpora. As the English MWE *United States* is not in the vocabulary, we made an embedding for it by taking the average of the vectors of *united* and *states*. In contrast, we obtained the cosine similarities on the right-hand side of each arrow (+MWE) by combining *United States* into one token before training word embeddings.

With MWE-based tokenization, the single token *united_states* aligns with 美国 (*United States*; *meiguo*) with a high cosine similarity of 0.82. The pre-tokenization of *United States* into a single token solves additional problems as well. When we treat *United States* as two separate tokens, we distort the embeddings of *united* and *states*. On the left sides of the arrows in Table 1, both *united* and *states* have a much higher cosine similarity to 美国 than to their correct translations. Also, *united* and *state* have a higher cosine similarity to each other than they should. Recognizing *United States* as one token before training word embeddings makes it possible to translate a single token to/from an MWE and ameliorates the alignments

Single → +MWE	联合$_{\text{united}}$	州$_{\text{states}}$	美国$_{\text{U.S.}}$
united	.32 → .40	.19 → .10	.57 → .41
states	.32 → .24	.16 → .10	.63 → .44
united_states	.37 → .38	.20 → .18	.69 → .82

Table 1: **Cosine similarities between English and Chinese word embeddings projected in the shared space.** We compare the alignments of embeddings without MWEs (left) and with MWEs (right) here.

of single tokens.[1]

In this study, we employ a simple method to identify MWEs in corpora by using MWE dictionaries instead of automatic detection. Despite the rich body of work (Constant et al., 2017), including methods developed in specialized shared tasks (Schneider et al., 2014; Savary et al., 2017; Ramisch et al., 2018), automatic MWE detection is still a hard problem (Savary et al., 2019). Ramisch et al. (2012) tested several unsupervised discovery methods and reported that they performed poorly in terms of either precision or recall.

A lexicon-based approach to MWE detection comes with another advantage. Supervised methods for MWE detection require annotated texts (Constant et al., 2017), which may not be available for all languages. On the other hand, the high availability of lexical resources containing MWEs in many languages, such as Wiktionary and WordNet, makes a lexicon-based approach for MWE detection possible in many languages.

Our focus in this paper is not to study the automatic extraction of MWEs, but rather to establish that tokenization of MWEs can contribute to improvements in CWE. Since MWE lexicons exist for the languages we are interested in, we have used those for the time being. Of course, using automatically discovered MWEs would be an interesting direction for future research.

To explore the effect of pre-tokenization of MWEs, we evaluate CWEs in the task of word translation between English and 10 languages, Arabic), Bulgarian, Chinese, German, Hebrew, Hindi, Japanese, Russian, Spanish, and Turkish, which span a wide typological variety. We find that our simple lexicon-based tokenization can align embeddings of MWEs at a precision@10 score of 30-60%

---

[1] The reason for the lowering of the cosine similarity between English and Chinese embeddings of *states* would be the fact that the English word *states* is polysemous while the Chinese word *states* almost exclusively means regional states. After the pre-tokenization of MWEs, English *states* no longer appears as the component of *united states*, so its distribution would be dissimilar to that of regional states.

without negative impacts on single word translation. Furthermore, we find some single-token words are correctly translated into MWEs, which are not attested in the common evaluation practice.

In summary, we argue that CWE studies should consider MWEs in development and evaluation. MWEs are pervasive in many languages and should not be ignored when the alignment of words is discussed. We present a lexicon-based method to this end (§3-4) and show its effectiveness in the task of word translation (§5). We have created a new word translation dataset that contains MWEs (§3.2). The dataset is in ten language pairs and contains MWEs in addition to single orthographic tokens.[2]

2 Related Work

2.1 Cross-lingual Word Embeddings

In this study, we experiment with one of the major approaches of learning CWEs, where monolingual embeddings trained in each language are mapped using cross-lingual supervision. Early work by Mikolov et al. (2013) showed that a linear transformation of word embeddings across languages can be trained by a bilingual dictionary. Smith et al. (2017) reported that the linear mapping becomes more accurate and computationally efficient by setting an orthogonal constraint on a transformation matrix. Recent studies (Artetxe et al., 2017; Zhang et al., 2017; Conneau et al., 2018) have further demonstrated that a transformation matrix can be learned by a very small amount of seed translations and even without any supervision.

Another stream of studies on CWEs adopts a joint approach: word embeddings on multiple languages are trained at one time using parallel corpora (Luong et al., 2015; Gouws et al., 2015). It is an interesting future direction to explore how MWEs affect joint detection of CWEs.

2.2 The limitations of CWEs

Besides the problem of word units, several limitations of CWEs have been pointed out in the literature. The majority of such work focuses on the statistical characteristics of word embeddings rather than their linguistic nature. Some studies (Søgaard et al., 2018; Ormazabal et al., 2019) claim that the accuracy of cross-lingual alignments depends on the similarity of word embeddings spaces of different languages, and this similarity in turn depends on the similarity between the training corpora. Kementchedjhieva et al. (2019), illustrating an issue related to evaluation of CWEs, argues that proper nouns constitute a quarter of the MUSE dataset, rendering it not ideal for word translation.

Using a word translation task for the intrinsic evaluation of CWEs presupposes a correlation between its performance with the performance of CWEs in downstream tasks, which has been questioned by several studies. Ammar et al. (2016), Glavaš et al. (2019) and Fujinuma et al. (2019) show low correlation between word translation accuracy and the performance of downstream tasks such as document classification, natural language inference, and dependency parsing. A specific problem may be that underfitting to the training data in order to better handle unseen words in the test set hinders downstream tasks that rely on words from the training dictionary (Zhang et al., 2020). In this study, we primarily examine the transferrability of MWEs in a word translation task, although it is possible that the better treatment of MWEs is also effective in downstream tasks.

2.3 Multi-word Expressions

MWEs have been studied in the context of syntactic analysis (Rosén et al., 2016; Kahane et al., 2017) and semantic analysis (Tratz and Hovy, 2010; Cordeiro et al., 2019). The discovery and identification of MWEs in corpora are important problems in this area (Sag et al., 2002), and much effort has been devoted to the development of methods (Constant et al., 2017) and annotated resources (Losnegaard et al., 2016). The universal dependencies (UD) project (Nivre et al., 2016) covers a wide range of languages but uses just a few dependency relations to annotate MWEs, namely *fixed*, *flat*, and *compound*. The DiMSUM shared task (Schneider et al., 2016) aims to detect English MWEs in texts. The PARSEME project (Savary et al., 2017; Ramisch et al., 2018) targets verbal MWEs and has constructed benchmark datasets in several–mostly European–languages for training automatic MWE taggers. However, such training resources are available only in a limited number of languages, and even with such resources, the automatic analysis of MWEs is known to be very difficult. Savary et al. (2019) argues the importance of syntactic MWE lexicons for further development in this area.

Another line of work analyzes the interpretation of MWEs such as noun compounds (Tratz

---

[2] Available at `https://github.com/llab-cmu/emnlp2020-mwe-pretokenization`.

and Hovy, 2010). Some studies exploit word embeddings to build a classifier (e.g., Shwartz and Waterson, 2018). Several studies tokenize MWEs before training word embeddings (Baldwin et al., 2003; Salehi et al., 2015; Cordeiro et al., 2019). Although the major target of these studies is monolingual, our focus is on the cross-lingual mapping of MWEs by CWEs.

3 Data Creation

This section describes the methods we used for creating the data that we are releasing with this paper: (1) monolingual lists of MWEs in eleven languages for pre-tokenizing MWEs in corpora and (2) bilingual dictionaries (ten languages each paired with English) for evaluating the resulting MWE embeddings in the word translation task. The languages are Arabic (ar), Bulgarian (bg), Chinese (zh), English (en), German (de), Hebrew (he), Hindi (hi), Japanese (ja), Russian (ru), Spanish (es), and Turkish (tr)

3.1 Monolingual MWE Lists for Pre-tokenization

For each of the eleven languages, we compiled a list of MWEs from publicly available resources listed below. We examined each lexical unit in each resource and selected those with multiple tokens. We treat all lexical units that are divided into two or more tokens as MWEs in our study, assuming they are fixed semantic units in some way.

eomw: Entries of the Extended Open Multilingual Wordnet (EOMW; Bond and Foster, 2013) consist of a WordNet synset identifier, a language identifier, and a lexical unit in that language. EOMW includes all WordNet synsets and additional synsets drawn from Wiktionary and the Unicode Common Locale Data Repository.[3] Most entries are nominals, but this resource also contains other types of MWEs like verbal phrases and connectives.

parseme: Parseme is multilingual corpus in which Verbal MWEs are annotated for the PARSEME shared task 1.1 (Ramisch et al., 2018). Types of verbal MWEs include light verb constructions (e.g., *give a speech*), verb-particle constructions (e.g., *wake up*), verbal idioms, etc. They can be commonly observed in many languages even though the category distributions vary from language to language.

	eomw		eomw	parseme
ar	1,608	bg	1,022	3,255
ja(i)	5,006	de	1,092	2,705
ja(u)	3,897	en	8,552	8,982
ru	3,887	es	3,079	4,485
zh	6,927	he	934	2,454
		hi	454	878
		tr	1,959	4,240

Table 2: **MWE lists (lemma) used for MWE identification.** eomw=Extended Multilingual Open Wordnet, i=IPADIC u=UniDic

Table 2 shows the sizes of our lexicons. Note that not all MWEs in our lists are included in our word embeddings as some of them do not exist in our training corpora.

3.2 Bilingual Dictionaries for the Word Translation Task

Next, we built bilingual dictionaries that have MWEs for each of the pairs between English and the ten languages. To the best of our knowledge, there is no public benchmark dataset including translations between MWEs. We again used EOMW, linking lexical units in different languages with the same WordNet synset identifiers. We call the resulting bilingual dictionaries EOMW-MWE BENCHMARK, hereafter. In the EOMW-MWE benchmark, source words are all MWEs, while target words could be both single words or MWEs. We limited source words to be MWEs to ensure an MWE is always involved in translation. The number of source words varies in different language pairs. For example, zh-en has the largest number of source (zh) words, 4,813, while hi-en has 274. We report the number of source words in Table 4 (§5).

3.2.1 Annotation of MWE types

We annotated the 1.5k English MWEs in our bilingual dictionaries for the purpose of error analysis.[4] We manually POS-tagged the English MWEs with the six tags **adj** (adjective phrases), **adv** (verbal and clausal adverbs), **noun** (noun phrases), **prep** (prepositional phrases), **verb** (verb phrases) and **misc** (anything else). We also classified the English

---

[3] We use subsets of Arabic (Elkateb and Black, 2006), Chinese (Wang and Bond, 2013), English (Fellbaum, 1998), Japanese (Isahara et al., 2008), Spanish (Gonzalez-Agirre et al., 2012), Bulgarian, Russian, German, Hebrew, Hindi, and Turkish (Bond and Foster, 2013).

[4] NO, SO, XZ and LL annotated English MWEs. LL is a professor who is a native speaker of English and has expertise in theoretical and computational linguistics. The others are non-native speakers studying computational linguistics and NLP in the US. SO also has a background in theoretical linguistics.

MWEs into four categories, **synphrase (s)**, **proper-name (pn)**, **compound (c)** and **flat+fixed+idiom (ffi)**. Below we list the definition and a prototypical example for each of the four categories.

synphrase (s) A semantically compositional multi-word entry from EOMW , e.g. *cease to be*.

proper-name (pn) A MWE that non-deictically refers to a unique or identifiable referent. Most of these are PER, LOC, GPE, or ORG in a simple NER annotation scheme. e.g. *Pacific Ocean*.

compound (c) We included noun-noun compounds as well as adjective-noun pairs, which are often hard to distinguish from noun-noun compounds. e.g. *opera house*, *nuclear weapon*. Most are syntactically endocentric (headed) and semantically endocentric (a hyponym of its head).

flat+fixed+idiom (ffi) A MWE that is one of the following: (1) A fixed grammaticalized expression that behaves like a function word or adverbial, e.g. *that is to say*; (2) A verbal idiom (e.g. *let loose*), verb-particle construction (e.g. *hang up*) or multi-verb construction (e.g. *let go*) as defined by PARSEME, and fixed collocation constructions like *take a step*, *make a decision*; (3) Any other idiomatic MWE, e.g. *bread and butter*.

We defined our own categories rather than use an existing annotation scheme. **Synphrase** was necessary because our dataset contained certain MWEs such as *other side*, *cease to be* that are frequent enough to appear in an MWE lexicon but were semantically compositional. We gave proper name its own category (**proper-name**) because proper names are uniquely nouns unlike other unheaded MWEs, which are dates, complex numerals and foreign phrases that span a wide variety of POS.

We annotated 1.5k English MWEs containing 61 s, 969 c, 215 pn, and 237 ffi. Of these 1285 are nouns, 98 verbs, 53 adjective, 52 adverb, 6 preposition, and 3 misc.[5] We excluded 18 MWEs that were numbers or contained tokenization errors.

4 Training CWEs: Components

This section describes our pipeline for training CWEs, including the following three steps (Figure 2): (1) identifying MWEs in a corpus, (2) training monolingual word embeddings, and (3) aligning embeddings across languages.

4.1 Monolingual MWE Identification

We first prepare a monolingual corpus for training word embeddings for each of the eleven languages included in this study. We take a simple lexicon-based approach to combine MWEs into one token. Suppose we have the tokenized sentence below.

(1) freedom fries was a political euphemism for french fries in the united states .

Using an MWE lexicon which includes *french fries* and *united states*, we combine tokens with underscores and obtain the following sentence.

(2) freedom fries was a political euphemism for french_fries in the united_states .

With this approach we cannot identify MWEs that do not exist in the lexicon like *freedom fries*, but there is an advantage: we do not need an annotated corpus of MWEs. Such corpora are difficult to obtain in more than a few languages.

Based on the lexicons that we compiled for each language (§3.1), we tokenize MWEs in a corpus with `mwetoolkit3` (Ramisch, 2015). To increase the recall, we use lemmas for string matching.[6] We do not consider discontinuous MWEs.

4.2 Monolingual Word Embeddings

We train monolingual embeddings on tokenized texts with off-the-shelf word embedding algorithms. We adopt fastText with CBOW (Bojanowski et al., 2017). MWEs processed in the previous step are treated as one token and given an individual vector. For example, *french_fries* has a different vector from those of *french* and *fries*.

4.3 Cross-lingual Mapping of Embeddings

Now we take two sets of word embeddings from two different languages and align the source embeddings to the target embeddings using an existing supervised method based on a bilingual dictionary. Suppose we have n pairs of source and target words. We denote the embeddings of those words $X \in \mathbb{R}^{n\times d}$ and $Y \in \mathbb{R}^{n\times d}$, respectively, where d is the dimension of the embeddings. We learn a $d \times d$ matrix W so that XW is close to Y in terms of Frobenius norm (Mikolov et al., 2013).

---

[5] Note that some MWEs have multiple possible parts-of-speech. For example, *cross over* (noun and verb).

[6] In Appendix A, we show our attempt at using unsupervised co-occurrence measures for automatic detection of MWEs for this study. We found that the vast majority of true MWEs in our evaluation lexicons had low Dice coefficient scores, which means that the automatic detection method did not predict them to have high chances of being MWEs. Thus, we were unable to find a good threshold for Dice coefficient at which precision and recall would both be adequate.

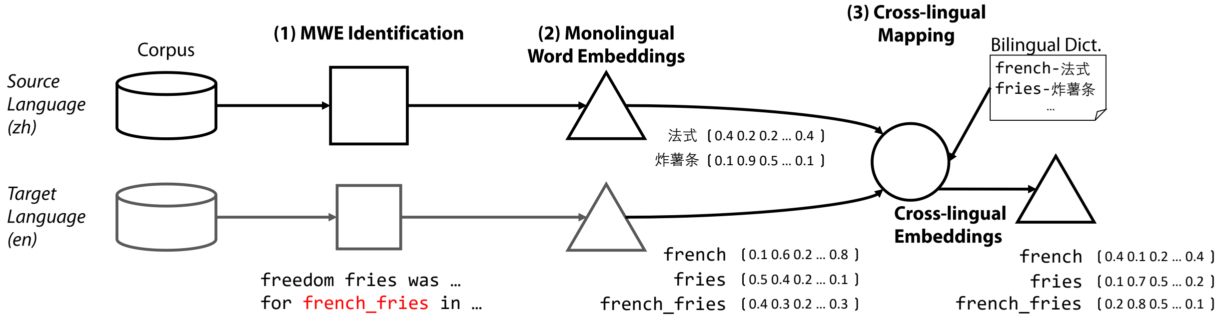

Figure 2: **Pipeline for training CWEs with MWEs.**

$$\min_W |XW - Y|_{\mathrm{F}}$$

We follow Xing et al. (2015) and impose an orthogonality constraint on W, namely $W^TW = I$ as this constraint is known to improve the accuracy of word translation. We then refine W using an iterative bootstrapping method proposed by Conneau et al. (2018). Specifically, we produce pseudo translation pairs for training by retrieving nearest neighbors in terms of cross-domain similarity local scaling (CSLS). Finally, we translate all embeddings in the source language into the vector space in the target language by W.

5 Experiments

To examine the effect of pre-tokenization of MWEs, we conduct the task of word translation between each of the ten languages and English, in both directions. A word embedding in a source language is projected into the embedding space of a target language using a trained linear mapping W (§4.3). The translation candidates of the source word are retrieved by k-nearest neighbor search in terms of CSLS. The performance is measured by top-k precision (Precision@k).[7]

Our evaluation involves two tasks. In the first task, we focused on the translation of MWEs using our new evaluation dictionaries that contain tokenized MWEs (§3.2). In the second task, we evaluated the translation of single words on the existing benchmark, MUSE (Conneau et al., 2018) to investigate the influence on single word embeddings of pre-tokenizing MWEs.

5.1 Corpora

We focus on the translation between en and ten languages: ar, bg, es, de, he, hi, ja, ru, tr, and zh. These languages represent both Indo-European and non-Indo-European languages with a wide variety of morphological features and have sufficient Wikipedia texts for training embeddings. We report results using two Japanese segmentation schemes, IPADIC (Asahara and Matsumoto, 2000) and UniDic (Den et al., 2008). Both of these break Japanese utterances down into relatively small units, sometimes corresponding to morphemes. For this reason, the Japanese texts we trained on have fewer types than the other languages despite the fact that Japanese is highly agglutinative.

Language	Sentence	Token	Type
ar	1,962,738	91,097,526	1,990,665
bg	2,739,946	56,871,914	1,643,486
de	4,961,118	98,123,008	3,439,237
en	4,174,043	1,00,000,031	1,764,082
es	3,729,100	99,733,231	1,869,469

zh	3,688,280	100,000,003	2,411,269

Table 3: **Statistics of Wikipedia corpora.**

For training monolingual embeddings, we sampled 100M tokens for each language[8] from the publicly available Wikipedia corpora (Ginter et al., 2017), which were automatically annotated with UDPipe. Table 3 shows the corpus statistics. We then used `mwetoolkit3` to annotate MWEs. Note that the PARSEME dataset does not cover Arabic[9], Japanese, Russian, and Chinese.

---

[7] We used an evaluation script provided with the MUSE dictionary.

[8] Except for bg, he, hi, and tr, whose tokenized Wikipedia dumps only had 57M, 85M, 24M, and 57M tokens, respectively. We used all the texts in these languages.

[9] The PARSEME shared task covers Arabic, but the resource is not publicly available.

Table 4: **Precision@10 on EOMW-MWE in Task 1.**

5.2 Experimental Settings

Task 1: In the first task, we use our EOMW-MWE dataset to evaluate the translatability of MWE embeddings obtained by lexicon-based tokenization. For some languages, the EOMW-MWE dataset has a small number of source words due to the coverage of multilingual WordNet, leaving not enough data for both training and testing. Therefore, for all languages, we used the entire EOMW-MWE dataset for testing word translation accuracy. For training, the dictionaries do not contain MWEs. The training dictionaries consist only of 5k word pairs from the common word translation benchmark, MUSE. If the cross-lingual mapping could learn a proper transformation matrix based on single word dictionaries, it should also be able to transform MWE embeddings to the shared vector space properly.

Task 2: We also study whether the inclusion of MWEs in cross-lingual embedding space adversely affects the alignments between single words. We use MUSE for training and evaluation in Task 2. For each language pair, we train and test cross-lingual mappings by the first 5k and next 1.5k unique source words[10] in the bilingual dictionary, respectively.

Parameters: We trained CBOW fastText models of 300 dimensions with the parameters suggested by Grave et al. (2018). We used the implementation by (Conneau et al., 2018) to align monolingual embeddings by the method described in §4.[11] To fairly compare between the baseline (tokenization without MWEs) and the experimental condition (tokenization with MWEs), we uses the same set of candidate words from which we are going to pick the k best. The candidate set does not include MWEs in Task 2. For the baseline in Task 1, MWEs are represented by the average of the embeddings of the individual words. We used larger vocabulary sizes (e.g, 300-600k) for the candidate set than typical sizes in related studies (e.g. 200k). We describe the details of implementation and hyperparameters in Appendix C and D.

5.3 Task 1: MWE Translation

As a baseline method, we tokenize the corpus without MWEs and represent the embedding of each MWE as the average of the single-word embeddings of its components. The baseline and our MWE embeddings were trained on the same single-word dictionaries. We report results of a word translation task on the EOMW-MWE in Table 4.

Despite the absence of MWEs in training dictionaries, our CWEs aligned English MWEs with their correct translation with Precision@10 as high as 30-60%. Our method clearly outperforms the baseline method in most language pairs. This fact shows the importance of learning MWE embeddings directly from a corpus to establish cross-lingual alignments.

We broke down English–*L2* MWEs translation results based on our annotated 1.5k English MWEs (§3) in Table 5. In terms of MWE types, compound (c) was the easiest category to translate (success rate of 60.22%), and flat+fixed+idiom (ffi), which includes various idiomatic expressions, was the hardest (25.52%). In terms of parts-of-speech of MWEs, it turned out that verbal MWEs were much more difficult to translate (21.01%) than nominal MWEs (48.06%). This is consistent with the observation of the PARSEME shared tasks on verbal MWE identification. Interestingly, the translation of adverbial MWEs was very accurate (40.3%). This may indicate that adverbial/adpositional phrases tend to

---

[10] Source words are sorted by frequencies by Conneau et al.

[11] We also experimented with VecMap (Artetxe et al., 2018) and observed a similar result (Appendix E).

be used in similar contexts (i.e., words in specific semantic/grammatical classes) across languages.

In Table 8, we show some correct translations retrieved by nearest neighbor search. While stop words such as "in" and "a" are usually not aligned with significant words, the inclusion of these words in MWEs (e.g., *in_vain* and *a_bit*) establishes meaningful relationships across languages.

5.4 Task 2: Single Word Translation

Table 6 shows the results of single-word translation on the MUSE benchmark.[12] We excluded MWEs from the embeddings in the target language as the benchmark only contains single words.

---

[12] We also broke down the precision scores in five language pairs based on POS of source words annotated by Kementchedjhieva et al. (2019) but did not observe meaningful patterns (Appendix E).

We were concerned that, keeping the amount of training data unchanged, the inclusion of MWEs may decrease single-word performance as it makes the occurrence of single words sparse, and it might degrade the quality of monolingual word embeddings. However, the difference in the performance of the single word translation in the other language pairs was not statistically significant.[13]

Our method might align a single word in one language with an MWE in another language, which is not attested in the common evaluation practice. To examine this, we included MWE embeddings in evaluation and observed nearest neighbors. Interestingly, our method retrieved MWEs that are correct translations but absent from the MUSE dictionaries. In particular, we show characteristic examples in English-Japanese (IPADIC) translations in Table 7. The first example illustrates a common construction using *-nin* (person), which is segmented into two words. The benchmark tends to contain transcriptions of foreign words like *shefu* as they are often single tokens. The second example shows verbalization, which is again segmented into noun + *suru* (do). These examples exemplify the limitation of evaluations restricted by single words, and may explain the difficulty of English-Japanese word translations reported in a previous study (Hoshen and Wolf, 2018).

6 Conclusion

We studied the impact of pre-tokenizing MWEs on cross-lingual alignments of word embeddings. We found that simple lexicon-based tokenizations can align embeddings of MWEs at a high precision without breaking alignments of single-words. We believe our results will motivate researchers to pay more attention to the existence of MWEs and how they are aligned across languages.

A Automatic MWE Discovery

In this study, we compiled MWE lists from existing lexical resources. Although MWEs can also be harvested from corpora without relying on lexical units, we found in our preliminary experiments that unsupervised methods cannot distinguish between MWEs and non-MWE phrases accurately. We tested word association measures based on word co-occurrences (Ramisch et al., 2012).

Method: Given tokenized texts, we extract and filter MWEs as follows:

1. We use syntactic patterns to extract candidates of MWEs. We define the following patterns based on part-of-speech (POS) tags.

   Nominal compounds:

   `(Adjective|Noun)+Noun`

   Verb-particle constructions:

   `Verb.{0,5}(up|down|on|off|in|out|away)`

   Here, $|$ denotes an OR condition, . denotes any POS tags, + denotes 1 or more repetitions, and $\{m, n\}$ denotes from m to n repetitions.

2. We count occurrences of MWE candidates and components of them.

3. We calculate association scores of the components of each MWE candidate by Dice coefficients, PMI, and maximum likelihood estimates (Ramisch et al., 2012).

4. We filter MWEs by setting a threshold on the association score.

Ideally, the real MWEs have higher scores, and non-MWE phrases have lower scores. Examining this, however, is not easy. It is very expensive to manually check all the candidates in Step 1. So, in our experiments, we aimed to obtain a rough estimate using the MWE lists we compiled. The phrases in our lists are true positives and should be assigned high association scores.

Figure 3 shows the results. The horizontal axis denotes the Dice coefficients calculated in Step 3, and the vertical axis shows the number of MWEs in each bin of Dice coefficients. The orange bars shows the number of MWEs that exist in our eomw+parseme lexicon, which are true positives. This result gives us two important implications.

1. The Dice coefficients are not indicative of MWE-ness. There are many true MWEs among the candidates with very low association scores. For example, the Dice coefficient of *french_fry* was only 0.000173.

2. The distribution of the scores is highly skewed, and it is difficult to set a threshold. If we set a lower threshold, the results contain many false MWEs, and if we set a high threshold, we can only obtain a few MWEs.

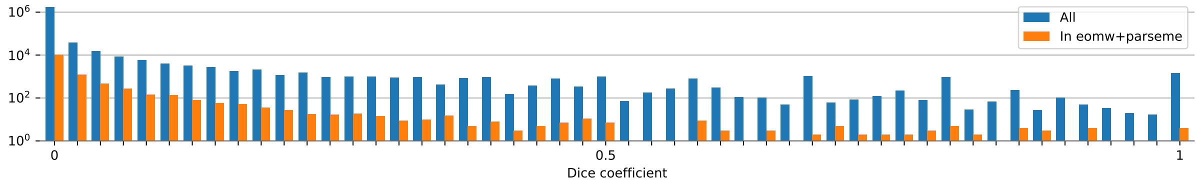
We observed very similar results in association measures other than the Dice coefficients.

B Corpus Preprocessing

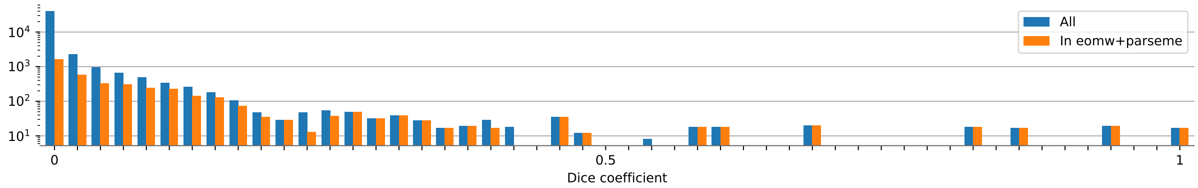
We trained word embeddings on the sentences collected and torkenized following UD version 2 (Ginter et al., 2017). We lowercased texts as the tokens in MUSE dictionaries are all lowercase. The used OpenCC[14] and simplified Chinese characters. For Japanese, we tokenized plain texts provided

---

[14] `https://github.com/BYVoid/OpenCC`



(a) Nominal compounds (`(Adjective|Noun)+Noun`).



(b) Verb-particle constructions (`Verb.{0,5}(up|down|on|off|in|out|away)`).

Figure 3: Distribution of Dice coefficient scores assigned to English MWEs automatically discovered from the Wikipedia corpus. The vertical axis denotes log frequencies.

with the tokenized Wikipedia dump by MeCab with IPADIC[15]. We then sampled sentences with 100M tokens or extracted full texts. We used GNU Parallel (Tange, 2018) to speed up the preprocessing.

C Monolingual Word Embeddings

We trained CBOW fastText models of 300 dimensions with the parameters suggested by Grave et al. (2018). Specifically, we set hyperparameters as follows:

- Dimension of word embeddings (`dim`): 300
- Minimum length of char N-gram (`minn`): 5
- Maximum length of char N-gram (`maxn`): 5
- Number of epochs (`epoch`): 10
- We set the other parameters to the default values of the fastText software v0.9.1[16].

Table 9 shows the vocabulary sizes of monolingual word embeddings. Note that the vocabulary sizes of Single are smaller than word type counts listed in Table 3 as we follow the default hyperparameters and set the minimal number of word occurrences for assigning word embeddings to 5.

D Cross-lingual Word Embeddings

We used the supervised algorithms implemented in the MUSE library[17] and VecMap library[18] to align monolingual embeddings.

Table 9: **Vocabulary sizes of word embedding models.** We report the number of MWEs (the left hand side of each slash) for the MWE tokenization.

MUSE: We normalized word embeddings into unit vectors before training. We set the number of refinements to 1 as most of the bootstrapped word pairs were found in the first iteration.

VecMap: We followed the hyperparameter setting used by Artetxe et al. (2018).

E Experimental Results

Table 10 and Table 11 show the results of Task 1 and Task 2 with supervised VecMap, respectively. The precision scores are slightly better than those of the supervised alignment with iterative refinements by Conneau et al. (2018), but the overall tendency is very similar to the result in Section 5.

Table 12 shows the result of Task 2 broken down based on the categorizations made by Kementchedjhieva et al. (2019). In some languages, the pre-tokenization of MWEs improved the translation ac-

Abstract

We propose a novel adapter layer formalism for adapting multilingual models. They are more parameter-efficient than existing adapter layers while obtaining as good or better performance. The layers are specific to one language (as opposed to bilingual adapters) allowing to compose them and generalize to unseen language-pairs. In this zero-shot setting, they obtain a median improvement of +2.77 BLEU points over a strong 20-language multilingual Transformer baseline trained on TED talks.

1 Introduction

Of the many virtues of multilingual neural machine translation (MNMT), arguably the most attractive is the promise of improving performance in the low resource setting (Johnson et al., 2017; Arivazhagan et al., 2019; Dabre et al., 2020). These models even allow for the extreme of these cases, namely to translate in language pair directions which are unseen at training time (*zero-shot setting* in this paper). Unfortunately, while performance in the low-resource setting indeed increases significantly, their zero-shot performance remains very low (Johnson et al., 2017). In this paper, we propose a neural architecture that allows to translate from any of the source languages towards any of the target languages seen in the training data, regardless of the presence of that specific language direction during training. For that, we build upon the recently proposed *adapter layers* for NMT (Bapna and Firat, 2019), by using *monolingual* (language-specific) adapter layers, instead of *bilingual* (language-pair specific) ones. This design difference improves their compositionality, permitting to combine any encoder adapter with other decoder adapters. Monolingual adapter layers perform as good as bilingual adapter layers in the non–zero-shot setting, are effective in the zero-shot setting and have the additional advantage of requiring fewer parameters.

2 Related Work

Zero-shot translation is direct translation in a language pair unseen during training. Aharoni et al. (2019) analyze the zero-shot performance of MNMT models as a function of the number of language pairs. They observe that having more languages results in better zero-shot performance. However, several artifacts arise, as described by Dabre et al. (2020); Zhang et al. (2020); Aharoni et al. (2019); Arivazhagan et al. (2019), like off-target translation and insufficient modeling capacity of the MNMT models. Zhang et al. (2020) use language-aware layer normalization and linear transformation to improve some drawbacks of MNMT; they also rely massively on back-translation to improve zero-shot translation.

Adaptation to a new language pair may be addressed by training a multilingual model then fine-tuning it with parallel data in the language pair of interest (Neubig and Hu, 2018; Variš and Bojar, 2019; Stickland et al., 2020). Escolano et al. (2020) propose plug-and-play encoders and decoders per language, which take advantage of a single representation in each language but at the cost of larger model sizes. In order to add only a few trainable parameters per task, adapter modules – initially introduced for computer vision (Rebuffi et al., 2017, 2018) – were proposed for language modeling by Houlsby et al. (2019). Bapna and Firat (2019) used them for parameter-efficient adaptation in MNMT. The parameters of the original MNMT network (the *parent* model) remain fixed, which permits a high degree of parameter sharing. The final multilingual model (the *adapted* model) is just slightly larger than the original one. (Bapna

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4465–4470,
November 16–20, 2020.

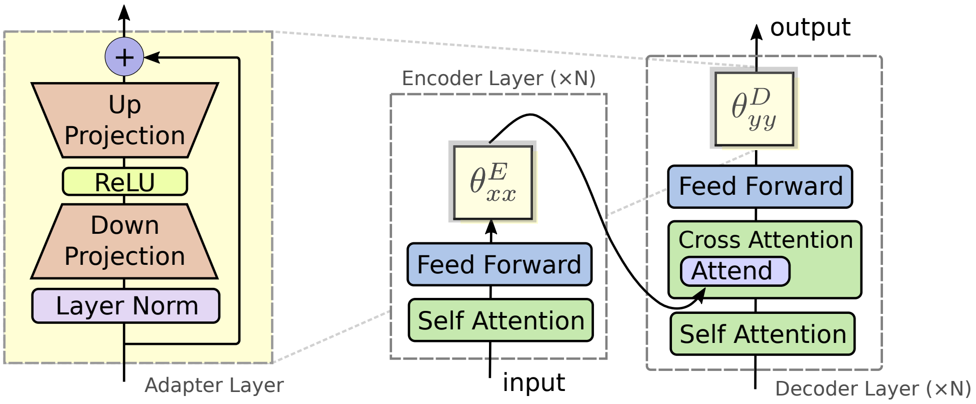

Figure 1: Proposed modification of the adapter layers from Bapna and Firat (2019). We use languages as the tasks in the encoder and in the decoder. *xx* and *yy* denote source and target languages respectively.

and Firat, 2019) show that adapters mitigate one major problem of MNMT models: performance drop in high-resource languages.

The motivation of that work was not zero-shot, and it is not obvious how to use them in such a scenario as the adapter layers are *language-pair* specific. While in Section 5 we propose a way of using those adapters through pivoting adapter layers, the main contribution of this paper is monolingual adapters which allow combining any encoder adapter with other decoder adapters.

3 Monolingual adapters

Adapter modules (Rebuffi et al., 2017; Houlsby et al., 2019) were formulated for NMT by Bapna and Firat (2019): lightweight adapter layers are transplanted between the layers of a pre-trained network and fine-tuned on the adaptation corpus. As shown in Figure 1 (left), an adapter layer is a down projection to a bottleneck dimension followed by an up projection to the initial dimension. The bottleneck allows to limit the number of parameters of the adapter module. The residual connection coupled with a near-identity initialization enables a pass-through and allows keeping at least the performance of the parent model. In their initial formulation, Bapna and Firat (2019) proposed adapters for each *language pair* (bilingual adapters), while we propose monolingual adapters.

We illustrate the mechanism in Figure 1: our monolingual-adapter layers are inserted into each of the transformer encoder and decoder layers. When translating from language *xx* to language *yy*, we only activate the encoder adapter layers for *xx*, denoted by θ^E_{xx}; and the decoder adapter layers for *yy*, denoted by θ^D_{yy}.

adapt	#tasks	+ params/task	zero-shot
FT	$\mathcal{O}(n^2)$	$\mathcal{O}(K)$	✗
biling.	$\mathcal{O}(n^2)$	$\mathcal{O}(k)$	✓(pivot)
mono.	$\mathcal{O}(n)$	$\mathcal{O}(k)$	✓

Table 1: Number of parameters required for different adaptation techniques. FT denotes fine-tuning. K is the total number of model parameters, k is the number of parameters per set of adapter layers (with $k \ll K$), and n is the number of languages.

Our formulation is different from Bapna and Firat (2019), who propose adapter layers for each language direction ($\theta_{xx \rightarrow yy}$). In a multiparallel setting (*i.e.*, where parallel data is available for all language pairs), this requires training $n(n-1)$ sets of layers, where n is the number of languages. Our monolingual (language-specific) adapters only require $2n$ layers. Table 1 summarizes the amount of parameters needed for adaptation with regular fine-tuning (FT), bilingual adapters (Bapna and Firat, 2019) and our proposed monolingual adapters. In our setting of 20 languages, fine-tuning would multiply the number of parameters by 380 (20×19). As the bottleneck dimension determines the increase of parameters, we experiment with both 64 (used in past work) and 1024, which matches the total number of parameters for bilingual adapters (see Table 2).

4 Experimental Setup

4.1 Datasets

We use the TED talks (Qi et al., 2018) in all our experiments, and all the numbers are BLEU scores

type	FT	mono.	biling.	mono.
bottleneck	–	64	64	1024
increase	×380	×1.47	×4.53	×3.73

Table 2: Increase in parameters over all tasks (380 language directions). FT denotes fine-tuning. The number of parameters of the parent model in this work is 68M. These parameter counts include the embeddings.

over the test set.[1] The TED talks dataset is multiparallel, *i.e.*, each English sentence has translations in multiple languages. Here, we restrict to the top 20 languages,[2] resulting in training corpora ranging between 108k and 214k parallel sentences. We use the dataset as a full multiparallel corpus (data aligned in all directions) and simulate an English-centric setting by using only parallel corpora with English as one of the languages.

4.2 Training

Architecture We use the Transformer architecture (Vaswani et al., 2017), implemented in `fairseq` (Ott et al., 2019), which we modify to include monolingual and bilingual adapters. We train a joint BPE model (Sennrich et al., 2016) on all languages, with inline casing (Berard et al., 2019) and 64k merge operations (resulting in a 70k vocabulary size). The Transformer architecture used in this work[3] has 4 attention heads, 6 encoder layers, 6 decoder layers, an embedding size of 512 and a feed-forward dimension of 1024.

MNMT Training We train a standard MNMT model following similar settings as Johnson et al. (2017). A single many-to-many model is trained on all the data English-centric data, using a source-side control token to indicate the target language. This model, which we call "parent", serves as an initialization for our adapter-enabled models. We use Adam (Kingma and Ba, 2015) with an inverse square root schedule, with 4000 warmup updates and a maximum learning rate of 0.0005. We set the maximum batch size per GPU to 4000 tokens, and train on 4 GPUs with mixed-precision (Ott et al., 2018). We apply dropout with a rate of 0.3, and label smoothing with a rate of 0.1. Like Arivazhagan et al. (2019), we mitigate the training size imbalance between language pairs by following a temperature-based sampling strategy with $T = 5$. To ensure all languages are represented adequately in the vocabulary, we use the same temperature-based sampling strategy for training the BPE model. This MNMT model is trained for 120 epochs over all the English-centric training data (38 language pairs). As shown in Table 3, it is a strong MNMT baseline.

Adapter Variations With monolingual adapters enabled, we optimize the adapter parameters for an additional 60 epochs with the same English-centric data. This setting lets us study the zero-shot capabilities of monolingual adapters. We also consider an "adaptation" setting where the monolingual adapters see data in all language pairs (380). In this setting, we only optimize adapter parameters for 10 epochs due to the increase of training time owing to more data. We use a bottleneck dimension of 64 for bilingual adapters, and try two values for the monolingual adapters: 64 and 1024. Table 2 shows how many extra parameters are added in each setting.

To train the adapters, we use the same settings as the parent MNMT model but reset the learning rate schedule and freeze all model parameters except the new adapter parameters. We train the 380 sets of bilingual adapters sequentially, as they are independent from each other. However, the monolingual adapters are trained all at once. To do so, we aggregate the training data for all language directions, using the same temperature-based sampling strategy as the parent model. For ease of implementation, we build homogeneous batches (*i.e.*, only containing sentences for one language direction) and only activate corresponding adapters. An epoch consists in a pass over the training data in all language directions (≈ 160k line pairs × 380 lang dirs ≈ 62M examples in the adaptation case, and ≈ 7.1M examples in the zero-shot case).

5 Results and Discussion

We evaluate the effectiveness of monolingual adapters in two settings: adaptation, where multiparallel training data is available for the adapters; and in the zero-shot setting where translation is done on unseen language pairs.

Table 3: BLEU scores of our models on the TED test sets compared to the literature. (1) Bilingual models. (2) Many-to-many MNMT models. The best model for each case is highlighted in italics and the best overall is in bold. Note that "(2) Aharoni et al. (2019)" is a 58-language model. "Parent" is our MNMT model trained on English-centric data. "Parent adaptation" is the same model fine-tuned for 10 epochs on the full multiparallel corpus (similar setting as "Mono-1024 adaptation", but without adapters). "Bilingual baselines" are models trained on one language direction only, with the same architecture as "Parent". Pivot-translating through English with "Parent" gives an average zero-shot performance ($xx \rightarrow yy$) of 14.39 BLEU.

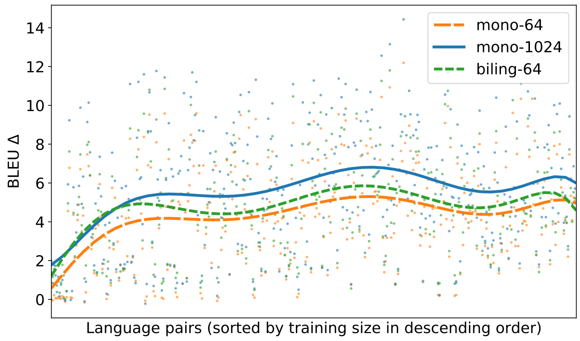

Figure 2: Comparison of bilingual adapters and monolingual adapters on the TED test sets in the adaptation setting, over 380 language pairs (sorted by available data). The y-axis shows the absolute BLEU differences with the parent model (trained on English-centric data only). The trendlines are obtained by interpolating a polynomial of degree 7 over the individual points.

5.1 Adaptation

In this setting, the adapter layers are trained on multiparallel data in 380 language pairs. Figure 2 shows the absolute difference in BLEU with the parent model, trained on English-centric data only, on each language pair. We compare bilingual adapters of dimension 64 with monolingual adapters of dimension 1024 or 64. As can be seen from the trendlines, while *mono-64* performs slightly (but consistently) worse than *biling-64*, *mono-1024* (which has a lower parameter budget than *biling-64*) obtains even better results, ranging from an absolute difference of -0.22 to +14.43, with a median of +5.59.

Because multilingual models are known to degrade performance on high-resource language directions, we study specifically translation to and from English. For *en*→*yy*, *mono-1024* (median +1.65) consistently outperforms *biling-64* (+1.24) and *mono-64* (+0.48) over the 19 language pairs. For *xx*→*en* however, *biling-64* adapters are slightly superior to both *mono-64* and *mono-1024* (+1.08 vs +0.09 and +0.50 respectively).

5.2 Zero-shot

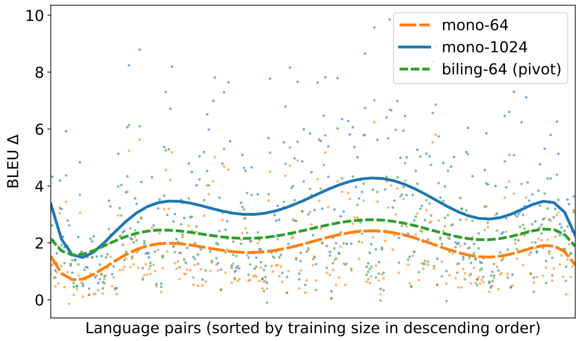

Figure 3: Comparison of bilingual adapters and monolingual adapters on the TED test sets in the zero-shot setting. The parent model and adapter-enabled models have only seen *xx*→*en* and *en*→*yy* data, and are tested on the remaining 342 pairs. The y-axis shows the absolute BLEU differences with the parent model.

Monolingual adapters can be naturally used for zero-shot translation, where a new language pair is provided at inference time. For this, we simply use the encoder adapters of the source language and the decoder adapters of the target language. To evaluate zero-shot translation, we use the adapter-enabled models trained on English-centric data and translate the test sets in the 342 language pairs not involving English (19×18).

Absolute improvements in BLEU scores of the adapter-enabled models over the MNMT parent model are shown in Figure 3. A median improvement of +1.26 is observed in the *mono-64* setting, while the *mono-1024* setting brings a median improvement of +2.77. The smallest difference (over the parent model) observed in each case was -0.14 and +0.30 respectively, indicating near-systematic improvement by using monolingual adapter layers. These results demonstrate the compositionality property of our monolingual adapters.

Because of the English-centric nature of TEDx, we also apply bilingual adapters to the zero-shot setting. We do this by composing the encoder and decoder adapter layers through a pivot language. That is, to translate *xx*→*yy*, we choose the bilingual adapter corresponding to *xx*→*en* in the encoder and *en*→*yy* in the decoder. As can be seen in Figure 3, this slightly outperforms *mono-64* but not *mono-1024*.

6 Ablation Study

We investigate the individual contribution of the encoder and decoder adapter layers at inference time. We compare the full model using *mono-1024* adapters against the two options of activating (1) only encoder adapters (2) only decoder adapters.

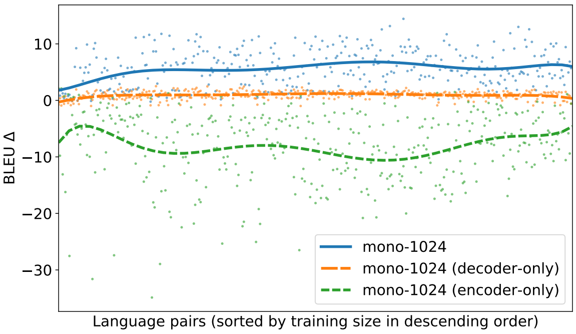

Figure 4: Ablation study for the adaptation setting, where we compare the full model using *mono-1024* adapter against its degraded versions with (1) only encoder adapters (2) only decoder adapters.

The interpolated curves for all language pairs are in Figure 4 for the adaptation setting and in Figure 5 for the zero-shot setting. In the adaptation setting, enabling only the decoder layers brings a median improvement of +1.03 over the parent model, while enabling only the encoder gives -7.00 BLEU (versus +5.59 when both encoder and decoders are enabled). In the zero-shot setting, the contribution of the encoder is larger (+1.69) than the decoder (+0.63), compared to +2.77 when both encoder and decoder adapters are enabled.

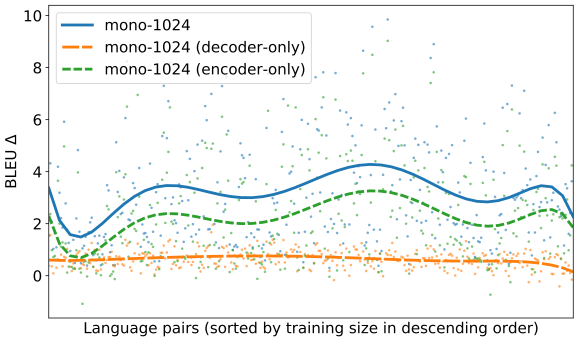

Figure 5: Ablation study for the zero-shot setting, where we compare the full model using *mono-1024* adapter against its degraded versions with (1) only encoder adapters (2) only decoder adapters.

We have seen that in the adaptation case, using the encoder adapter layers alone leads to a severe drop in performance. This might indicate that – at least during the adaptation – important information is captured in the encoder's adapter layer (in line with previous reports by Kudugunta et al., 2019) or that the decoder adaptation grows dependent on the encoder adapters, to the point where dropping the latter degrades the system. However, further analysis would be needed to confirm either of these hypotheses.

7 Conclusion

This work investigated adapter modules and their compositionality for MNMT, in particular in the zero-shot setting. We introduced *monolingual adapters* and compared them to *bilingual adapters*, which we also applied to zero-shot translation. Our adaptation experiments show the potential of the proposed monolingual adapters, which outperform bilingual adapters while having fewer parameters. In a zero-shot setting, we naturally compose our monolingual adapters and obtain a median improvement of +2.77 BLEU points over a strong MNMT model. Future work will investigate the compositional capability of these adapters, and combine domain and monolingual adapters for NMT.

More generally, this work adds to the growing evidence of the flexibility of adapter layers (Pfeiffer et al., 2020a), and their potential for lightweight fine-tuning, including in zero-shot scenarios (Pfeiffer et al., 2020b) and in a variety of tasks (Üstün et al., 2020).

Do Explicit Alignments Robustly Improve Multilingual Encoders?

Shijie Wu and **Mark Dredze**

Abstract

Multilingual BERT (Devlin et al., 2019, mBERT), XLM-RoBERTa (Conneau et al., 2019, XLMR) and other unsupervised multilingual encoders can effectively learn cross-lingual representation. Explicit alignment objectives based on bitexts like Europarl or MultiUN have been shown to further improve these representations. However, word-level alignments are often suboptimal and such bitexts are unavailable for many languages. In this paper, we propose a new contrastive alignment objective that can better utilize such signal, and examine whether these previous alignment methods can be adapted to noisier sources of aligned data: a randomly sampled 1 million pair subset of the OPUS collection. Additionally, rather than report results on a single dataset with a single model run, we report the mean and standard derivation of multiple runs with different seeds, on four datasets and tasks. Our more extensive analysis finds that, while our new objective outperforms previous work, overall these methods do not improve performance with a more robust evaluation framework. Furthermore, the gains from using a better underlying model eclipse any benefits from alignment training. These negative results dictate more care in evaluating these methods and suggest limitations in applying explicit alignment objectives.

1 Introduction

Unsupervised massively multilingual encoders including multilingual BERT (Devlin et al., 2019, mBERT) and XLM-RoBERTa (Conneau et al., 2019, XLMR) are now standard tools for zero-shot cross-lingual transfer for NLP tasks (Wu and Dredze, 2019; Xia et al., 2020). While almost all encoders are pretrained without explicit cross-lingual objective, i.e. enforcing similar words from different languages have similar representation, improvements can be attained through the use of explicit cross-lingually linked data during pretraining, such as bitexts (Conneau and Lample, 2019; Huang et al., 2019; Ji et al., 2019) and dictionaries (Wu et al., 2019). As with cross-lingual embeddings (Ruder et al., 2019), these data can be used to support explicit alignment objectives with either linear mappings (Wang et al., 2019, 2020; Wu et al., 2019; Liu et al., 2019) or fine-tuning (Cao et al., 2020).

However, as word-level alignments from an unsupervised aligner are often suboptimal, we develop a new cross-lingual alignment objective for training our model. We base on our objective on contrastive learning, in which two similar inputs – such as from a bitext – are directly optimized to be similar, relative to a negative set. These methods have been effective in computer vision tasks (He et al., 2019; Chen et al., 2020a). Additionally, most previous work on contextual alignments consider high-quality bitext like Europarl (Koehn, 2005) or MultiUN (Eisele and Chen, 2010). While helpful, these resources are unavailable for most languages for which we seek a zero-shot transfer. To better reflect the quality of bitext available for most languages, we additionally use OPUS-100 (Zhang et al., 2020), a randomly sampled 1 million subset (per language pair) of the OPUS collection (Tiedemann, 2012).

We show that our new contrastive learning alignment objectives outperform previous work (Cao et al., 2020) when applied to bitext from previous works or the OPUS-100 bitext. However, our experiments also produce a negative result. While previous work showed improvements from alignment-based objectives on zero-shot cross-lingual transfer for a single task (XNLI) with a single random seed, our more extensive analysis tells a different story. We report the mean and standard derivation of multiple runs with the same hyperparam-

November 16–20, 2020.

eters and different random seeds. We find that previously reported improvements disappear, even while our new method shows a small improvement. Furthermore, we extend the evaluation to multiple languages on 4 tasks, further supporting our conclusions. Finally, we evaluate XLMR$_{\text{large}}$ on these tasks, which dominate the results obtained from the alignment objectives. We conclude that explicit alignments do not improve cross-lingual representations under a more extensive evaluation with noisier bitexts, and improvements are lost when compared to larger models. This negative result shows the limitation of explicit alignment objective with larger-scale bitext and encoders.

2 Explicit Alignment Objectives

We begin with a presentation of objective functions that use parallel data across languages for training multilingual encoders. These objectives assume multilingual data in the form of word pairs in parallel sentences. Since gold word alignments are scarce, we use an unsupervised word aligner. Let $\mathbf{S}$ and $\mathbf{T}$ be the contextual hidden state matrix of corresponding words from a pretrained multilingual encoder. We assume $\mathbf{S}$ is English while $\mathbf{T}$ is a combination of different target languages. As both mBERT and XLMR operate at the subword level, we use the representation of the first subword, which is consistent with the evaluation stage. Each s_i and t_i are a corresponding row of $\mathbf{S}$ and $\mathbf{T}$, respectively. $\mathbf{S}$ and $\mathbf{T}$ come from the final layer of the encoder while $\mathbf{S}^l$ and $\mathbf{T}^l$ come from the l^{th}-layer.

Linear Mapping If $\mathbf{S}$ and $\mathbf{T}$ are static feature (such as from ELMo (Peters et al., 2018)) then $\mathbf{T}$ can be aligned so that it is close to $\mathbf{S}$ via a linear mapping (Wang et al., 2019, 2020; Wu et al., 2019; Liu et al., 2019), similar to aligning monolingual embeddings to produce cross-lingual embeddings. For feature $\mathbf{S}^l$ and $\mathbf{T}^l$ from layer l, we can learn a mapping $\mathbf{W}^l$.

$$\mathbf{W}^{l*} = \arg\min_{\mathbf{W}^l} \|\mathbf{S}^l - \mathbf{T}^l\mathbf{W}^l\|_2^2 \tag{1}$$

When $\mathbf{W}^l$ is orthogonal, Eq. (1) is known as Procrustes problem (Smith et al., 2017) and can be solved by SVD. Alternatively, Eq. (1) can also be solved by gradient descent, without the need to store in memory huge matrices $\mathbf{S}$ and $\mathbf{T}$. We adopt the latter more memory efficient approach. Following Lample et al. (2018), we enforce the orthogonality by alternating the gradient update and the following update rule

$$\mathbf{W} \leftarrow (1+\beta)\mathbf{W} - \beta(\mathbf{W}\mathbf{W}^T)\mathbf{W} \tag{2}$$

with $\beta = 0.01$. Note we learn different $\mathbf{W}^l$ for each target language.

This approach has yielded improvements in several studies. Wang et al. (2019) used mBERT and 10k parallel sentences from Europarl to improve dependency parsing. Wang et al. (2020) used mBERT and 30k parallel sentences from Europarl to improve named entity recognition (NER) on Spanish, Dutch, and German. Wu et al. (2019) used bilingual BERT and 10k parallel sentences from XNLI (Conneau et al., 2018) to improve dependency parsing (but not NER) on French, Russian, and Chinese. Liu et al. (2019) did not evaluate on cross-lingual transfer tasks.

L2 Alignment Instead of using $\mathbf{S}$ and $\mathbf{T}$ as static features, Cao et al. (2020) proposed fine-tuning the entire encoder

$$\mathcal{L}_{\text{L2}}(\theta) = \text{mean}_i(\|s_i - t_i\|_2^2) \tag{3}$$

where θ is the encoder parameters. To prevent a degenerative solution, they additionally use a regularization term

$$\mathcal{L}_{\text{reg-hidden}}(\theta) = \|\bar{\mathbf{S}} - \bar{\mathbf{S}}_{\text{pretrained}}\|_2^2 \tag{4}$$

where $\bar{\mathbf{S}}$ denote **all** hidden states of the source sentence including unaligned words, encouraging the source hidden states to stay close to the pretrained hidden states. With mBERT and 20k to 250k parallel sentences from Europarl and MultiUN, Cao et al. show improvement on XNLI but not parsing.[1]

In preliminary experiments, we found constraining parameters to stay close to their original pretrained values also prevents degenerative solutions

$$\mathcal{L}_{\text{reg-param}}(\theta) = \|\theta - \theta_{\text{pretrained}}\|_2^2 \tag{5}$$

while being more efficient than Eq. (4). As a result, we adopt the following objective (with $\lambda = 1$):

$$\mathcal{L}(\theta) = \mathcal{L}_{\text{L2}}(\theta) + \lambda\mathcal{L}_{\text{reg-param}}(\theta) \tag{6}$$

2.1 Contrastive Alignment

Inspired by the contrastive learning framework of Chen et al. (2020a), we propose a contrastive loss to align $\mathbf{S}$ and $\mathbf{T}$ by fine-tuning the encoder. Assume in each batch, we have corresponding (s_i, t_i)

---

[1] The authors state they did not observe improvements on parsing in the NLP Hightlights podcast (#112) (AI2, 2020).

where $i \in \{1, \ldots, B\}$. Instead of optimizing the absolute distance between s_i and t_i like Eq. (1) or Eq. (3), contrastive loss allows more flexibility by encouraging s_i and t_i to be closer as compared with any other hidden state. In other words, our proposed contrastive alignment optimizes the relative distance between s_i and t_i. As the alignment signal is often suboptimal, our alignment objective is more robust to errors in unsupervised word-level alignment. Additionally, unlike previous works, we select different sets of negative examples to enforce different levels of cross-lingual alignment. Finally, it naturally scales to multiple languages.

Weak alignment When the negative examples only come from target languages, we enforce a weak cross-lingual alignment, i.e. s_i should be closer to t_i than any other $t_j, \forall j \neq i$. The same is true in the other direction. The loss of a batch is

$$\begin{aligned}&\mathcal{L}_{\text{weak}}(\theta)\\ =&\frac{1}{2B}\sum_{i=1}^{B}\Big(\log\frac{\exp(\text{sim}(s_i,t_i)/T)}{\sum_{j=1}^{B}\exp(\text{sim}(s_i,t_j)/T)}\\ &+\log\frac{\exp(\text{sim}(s_i,t_i)/T)}{\sum_{j=1}^{B}\exp(\text{sim}(s_j,t_i)/T)}\Big) \quad (7)\end{aligned}$$

where $T = 0.1$ is a temperature hyperparameter and $\text{sim}(a, b)$ measures the similarity of a and b.

We use a learned cosine similarity $\text{sim}(a, b) = \cos(f(a), f(b))$ where f is a feed-forward feature extractor with one hidden layer (768-768-128) and ReLU. It can learn to discard language-specific information and only align the align-able information. Chen et al. (2020a) find that this similarity measure learns better representation for computer vision. After alignment, f is discarded as most cross-lingual transfer tasks do not need this feature extractor, though tasks like parallel sentence retrieval might find it helpful. This learned similarity cannot be applied to an absolute distance objective like Eq. (3) as it can produce degenerate solutions.

Strong alignment If the negative examples include both source and target languages, we enforce a strong cross-lingual alignment, i.e. s_i should be closer to t_i than any other $t_j, \forall j \neq i$ and $s_j, \forall j \neq i$.

$$\begin{aligned}&\mathcal{L}_{\text{strong}}(\theta)\\ =&\frac{1}{2B}\sum_{h\in\mathcal{H}}\log\frac{\exp(\text{sim}(h,\text{aligned}(h))/T)}{\sum_{h'\in\mathcal{H},h'\neq h}\exp(\text{sim}(h,h')/T)}\end{aligned} \quad (8)$$

where $\text{aligned}(h)$ is the aligned hidden state of h and $\mathcal{H} = \{s_1, \ldots, s_B, t_1, \ldots, t_B\}$.

For both weak and strong alignment objectives, we add a regularization term Eq. (5) with $\lambda = 1$.

3 Experiments

Multilingual Alignment We consider alignment and transfer from English to 8 target languages: Arabic, German, English, Spanish, French, Hindi, Russian, Vietnamese, and Chinese. We use two sets of bitexts: (1) bitext used in previous works (Conneau and Lample, 2019) and (2) the OPUS-100 bitext (Zhang et al., 2020). (1) For bitext used in previous works, we use MultiUN for Arabic, Spanish, French, Russian or Chinese, EUBookshop (Skadiņš et al., 2014) for German, IIT Bombay corpus (Kunchukuttan et al., 2018) for Hindi and OpenSubtitles (Lison et al., 2018) for Vietnamese. We sample 1M bitext for each target language. (2) The OPUS-100 covering 100 languages with English as the center, and sampled from the OPUS collection randomly, which better reflects the average quality of bitext for most languages. It contains 1M bitext for each target language, except Hindi (0.5M).

We tokenize the bitext with Moses (Koehn et al., 2007) and segment Chinese with Chang et al. (2008). We use `fast_align` (Dyer et al., 2013) to produce unsupervised word alignments in both direction and symmetrize with the *grow-diag-final-and* heuristic. We only keep one-to-one alignment and discard any trivial alignment where the source and target words are identical.

We train the L2, weak, and strong alignment objectives in a multilingual fashion. Each batch contains examples from all target languages. Following Devlin et al. (2019), we optimize with Adam (Kingma and Ba, 2014), learning rate `1e-4`, 128 batch size, 100k total steps (≈ 2 epochs), 4k steps linear warmup and linear decay. We use 16-bit precision and train each model on a single RTX TITAN for around 18 hours. We set the maximum sequence length to 96. For linear mapping, we use a linear decay learning rate from `1e-4` to 0 in 20k steps (≈ 3 epochs), and train for 3 hours for each language pairs.

Evaluation We consider zero-shot cross-lingual transfer with XNLI (Conneau et al., 2018), NER (Pan et al., 2017), POS tagging and dependency

(b) Alignment with the OPUS-100 bitext

Table 1: Zero-shot cross-lingual transfer result, average over 9 languages. Breakdown can be found in App. B. Blue or orange indicates the mean performance is one standard derivation above or below the mean of baseline. While mBERT benefits from alignment in some cases, extra alignment does not improve XLMR.

parsing (Zeman et al., 2020).[2] We evaluate XNLI and POS tagging with accuracy (ACC), NER with span-level F1, and parsing with labeled attachment score (LAS). For the task-specific layer, we use a linear classifier for XNLI, NER, and POS tagging, and use Dozat and Manning (2017) for dependency parsing. We fine-tune all parameters on English training data and directly transfer to target languages. We optimize with Adam, learning rate `2e-5` with 10% steps linear warmup and linear decay, 5 epochs, and 32 batch size. For the linear mapping alignment, we use an ELMo-style feature-based model[3] with 4 extra Transformer layers (Vaswani et al., 2017), a CRF instead of a linear classifier for NER, and train for 20 epochs, a batch size of 128 and learning rate `1e-3` (except NER and XNLI with `1e-4`). All token level tasks use the first subword as the word representation for task-specific layers following previous work (Devlin et al., 2019; Wu and Dredze, 2019). Model selection is done on the English dev set. We report the mean and standard derivation of test performance of 5 evaluation runs with different random seeds[4] and the same hyperparameters. Additional experiments detail can be found in App. A.

4 Result

Robustness of Previous Methods With a more robust evaluation scheme and 1 million parallel sentences (4× to 100× of previously considered data), the previously proposed Linear Mapping or L2 Alignment does not consistently outperform a no alignment setting more than one standard derivation in all cases (Tab. 1). With mBERT, L2 Alignment performs comparably to no alignment on all 4 tasks (XNLI, NER, POS tagging, and parsing). Compared to no alignment, Linear Mapping performs much worse on NER, performs better on POS tagging and parsing, and performs comparably on XNLI. While previous work observes small improvements on selected languages and tasks, it likely depends on the randomness during evaluation. Based on a more comprehensive evaluation including 4 tasks and multiple seeds, the previously proposed methods do not consistently perform better than no alignment with millions of parallel sentences.

Contrastive Alignment In Tab. 1, with mBERT, both proposed contrastive alignment methods consistently perform as well as no alignment while outperforming more than 1 standard derivation on POS tagging and/or parsing. This suggests the proposed methods are more robust to suboptimal alignments. We hypothesize that learned cosine similarity and contrastive alignment allow the model to recover from suboptimal alignments. Both weak and strong alignment perform comparably. While preliminary experiments found that increasing the batch size by 1.5× does not lead to better performance, future work could consider using a memory bank to greatly increase the number of negative examples (Chen et al., 2020b), which has been shown to be beneficial for computer vision tasks.

---

[2] We use the following treebanks: Arabic-PADT, German-GSD, English-EWT, Spanish-GSD, French-GSD, Hindi-HDTB, Russian-GSD, Vietnamese-VTB, and Chinese-GSD.

[3] We take the weighted average of representations in all layers of the encoder.

[4] We pick 5 random seeds before the experiment and use the same seeds for each task and model.

Alignment with XLMR XLMR, trained on 2.5TB of text, has the same number of transformer layers as mBERT but larger vocabulary. It performs much better than mBERT. Therefore, we wonder if an explicit alignment objective can similarly lead to better cross-lingual representations. Unfortunately, in Tab. 1, we find all alignment methods we consider do not improve over no alignment. Compared to no alignment, Linear Mapping and L2 Alignment have worse performance in 3 out of 4 tasks (except POS tagging). In contrast to previous work, both contrastive alignment objectives perform comparably to no alignment in all 4 tasks.

Impact of Bitext Quality Even though the OPUS-100 bitext has lower quality compared to bitext used in previous works (due to its greater inclusion of bitext from various sources), it has minimum impact on each alignment method we consider. This is good news for the lower resource languages, as not all languages are covered by MultiUN or Europarl.

Model Capacity vs Alignment $\text{XLMR}_{\text{large}}$ has nearly twice the number of parameters as $\text{XLMR}_{\text{base}}$. Even trained on the same data, it performs much better than $\text{XLMR}_{\text{base}}$, with or without alignment. This suggests increasing model capacity likely leads to better cross-lingual representations than using an explicit alignment objective. Future work could tackle the curse of multilinguality (Conneau et al., 2019) by increasing the model capacity in a computationally efficient way (Pfeiffer et al., 2020).

5 Discussion

Our proposed contrastive alignment objective outperforms L2 Alignment (Cao et al., 2020) and consistently performs as well as or better than no alignment using various quality bitext on 4 NLP tasks under a comprehensive evaluation with multiple seeds. However, to our surprise, previously proposed methods do not show consistent improvement over no alignment in this setting. Therefore, we make the following recommendations for future work on cross-lingual alignment or multilingual representations: 1) Evaluations should consider average quality data, not exclusively high-quality bitext. 2) Evaluation must consider multiple NLP tasks or datasets. 3) Evaluation should report **mean and variance over multiple seeds**, not a single run. More broadly, the community must establish a robust evaluation scheme for zero-shot cross-lingual transfer as a single run with one random seed does not reflect the variance of the method (especially in a zero-shot or few-shot setting).[5] While Keung et al. (2020) advocate using oracle for model selection, we instead argue reporting the variance of test performance, following the few-shot learning literature. Additionally, no alignment methods improve XLMR and larger $\text{XLMR}_{\text{large}}$ performs much better, and raw text is easier to obtain than bitext. Therefore, scaling models to more raw text and larger capacity models may be more beneficial for producing better cross-lingual models.

A Additional Experiments Detail

Evaluation Detail We set the maximum sequence length to 128 during fine-tuning. For NER and POS tagging, we additionally use a sliding window of context to include subwords beyond the first 128. At test time, we use the same maximum sequence length except for parsing. At test time for parsing, we only use the first 128 words of a sentence instead of subwords to make sure we compare different models consistently. We ignore words with POS tags of `SYM` and `PUNCT` during parsing evaluation. We rewrite the `BIO` label, similar to an unbiased structure predictor, to make sure a valid span is produced during NER evaluation. As the supervision on Chinese NER is on character-level, we segment the character into word using the Stanford Word Segmenter and realign the label.

All datasets we used are publicly available: NER[6], XNLI[7][8], POS tagging and dependency parsing[9]. Data statistic can be found in Tab. 2.

	XNLI	NER	POS tagging Parsing
en-train	392703	20000	12543
en-dev	2490	10000	2002

Abstract

Massively multilingual transformers (MMTs) pretrained via language modeling (e.g., mBERT, XLM-R) have become a default paradigm for zero-shot language transfer in NLP, offering unmatched transfer performance. Current evaluations, however, verify their efficacy in transfers (a) to languages with sufficiently large pretraining corpora, and (b) between close languages. In this work, we analyze the limitations of downstream language transfer with MMTs, showing that, much like cross-lingual word embeddings, they are substantially less effective in resource-lean scenarios and for distant languages. Our experiments, encompassing three lower-level tasks (POS tagging, dependency parsing, NER) and two high-level tasks (NLI, QA), empirically correlate transfer performance with linguistic proximity between source and target languages, but also with the size of target language corpora used in MMT pretraining. Most importantly, we demonstrate that the inexpensive few-shot transfer (i.e., additional fine-tuning on a few target-language instances) is surprisingly effective across the board, warranting more research efforts reaching beyond the limiting zero-shot conditions.

1 Introduction and Motivation

Labeled datasets of sufficient size support supervised learning in NLP. The notorious tediousness, subjectivity, and cost of linguistic annotation (Dandapat et al., 2009; Sabou et al., 2012; Fort, 2016), coupled with plethora of structurally different NLP tasks, lead to existence of such datasets only for a handful of resource-rich languages (Bender, 2011; Ponti et al., 2019; Joshi et al., 2020). This data scarcity renders the need for effective *cross-lingual transfer* strategies: how can we exploit abundant labeled data from resource-rich languages to make predictions in resource-lean languages? In the most extreme scenario, termed *zero-shot cross-lingual transfer*, not a single labeled instance exists for a target language. Recent work has placed much emphasis on this scenario exactly; in theory, it offers the widest portability across the world's 7,000+ languages (Pires et al., 2019; Artetxe et al., 2020b; Lin et al., 2019; Cao et al., 2020; Hu et al., 2020).

The current mainstay of cross-lingual transfer in NLP are approaches based on continuous cross-lingual representation spaces such as cross-lingual word embeddings (CLWEs) (Ruder et al., 2019) and, most recently, massively multilingual transformer networks (MMTs), pretrained on multilingual corpora with language modeling (LM) objectives (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020). The latter have *de facto* become the default language transfer paradigm, with multiple studies reporting their unparalleled transfer performance (Pires et al., 2019; Wu and Dredze, 2019; Rönnqvist et al., 2019; Karthikeyan et al., 2020; Wu et al., 2020).

Key Questions and Contributions. In this work, we dissect the current state-of-the-art MMT-based approach to (zero-shot) cross-lingual transfer, and analyze a variety of conditions and factors that critically impact or limit effective cross-lingual transfer. Our aim is to provide answers to the following crucial questions.

(Q1) *What is the role of language (dis)similarity and language-specific corpora size in pretraining?*

Current cross-lingual transfer via MMTs is still primarily focused on either (1) languages that are typologically or etymologically close to English (e.g., German, Scandinavian languages, French, Spanish), or (2) languages with large monolingual corpora, well-represented in the multilingual pretraining corpora (e.g., Arabic, Hindi, Chinese). Wu et al. (2020) suggest that LM-pretrained transform-

November 16–20, 2020.

ers, much like static word embeddings models, produce topologically similar representation spaces that can easily be aligned between languages, offering this as explanation of language transfer efficacy of MMTs. However, transfer with static CLWEs has been shown ineffective between dissimilar languages (Søgaard et al., 2018; Vulić et al., 2019) or languages with small corpora (Vulić et al., 2020).

We thus scrutinize MMTs in diverse zero-shot transfer settings and find, in line with prior work on CLWEs, that MMTs' transfer performance critically depends on (1) linguistic (dis)similarity between the source and target language and (2) size of the pretraining corpus of the target language.

(Q2) *What is the role of a particular task in consideration for transfer performance?*

We conduct all analyses across five different tasks, which we roughly divide into two groups: (1) "low-level" tasks (POS-tagging, dependency parsing, and NER); and (2) "high-level" language understanding (LU) tasks (NLI and QA). We show that transfer performance in both zero-shot and few-shot scenarios largely depends on the "task level".

(Q3) *Can we (even) predict transfer performance?*

Running a simple regression on available transfer results, we show that we can (roughly) predict the transfer performance from (1) language proximity (Littell et al., 2017) for low-level tasks; (2) combination of language proximity and size of target-language pretraining corpora for high-level tasks.

(Q4) *Should we focus more on few-shot transfer scenarios and quick annotation cycles?*

Complementing the efforts on improving zero-shot transfer (Cao et al., 2020), we point to few-shot transfer as a very effective mechanism for improving target-language performance. Similar to the seminal "pre-neural" work of Garrette and Baldridge (2013), our results suggest that only several hours (or even minutes) of annotation work can "buy" substantial performance gains for low-resource targets. For all five tasks in our study, we obtain substantial (and in some cases surprisingly large) improvements with minimal annotation effort. For instance, we improve dependency parsing for some target languages up to 40 UAS points with as few as 10 target language sentences. Crucially, the few-shot gains are most pronounced exactly where zero-shot transfer fails: for distant target languages with small monolingual corpora.

2 Background and Related Work

For completeness, we provide a brief overview of **1)** cross-lingual transfer approaches, with a focus on **2)** massively multilingual transformer (MMT) models, and then **3)** position our work w.r.t. other studies that examine different properties of MMTs.

2.1 Cross-Lingual Transfer Paradigms

Language transfer entails representing texts from both the source and target language in a shared cross-lingual space. Transfer paradigms based on discrete text representations include *machine translation* (MT) of target language text to the source language (or vice-versa) (Mayhew et al., 2017; Eger et al., 2018), and grounding texts from both languages in *multilingual knowledge bases* (KBs) (Navigli and Ponzetto, 2012; Lehmann et al., 2015). While reliable MT hinges on availability of large parallel corpora, transfer via multilingual KBs (Camacho-Collados et al., 2016; Mrkšić et al., 2017) is impaired by the limited KB coverage and inaccurate entity linking (Moro et al., 2014; Raiman and Raiman, 2018).

Therefore, recent years have seen a surge of language transfer methods based on continuous representation spaces. The previous state-of-the-art, cross-lingual word embeddings (CLWEs) (Mikolov et al., 2013; Ammar et al., 2016; Artetxe et al., 2017; Smith et al., 2017; Glavaš et al., 2019; Vulić et al., 2019) and sentence embeddings (Artetxe and Schwenk, 2019), have most recently been replaced by massively multilingual transformers (MMTs) pretrained with LM objectives (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020).

2.2 Massively Multilingual Transformers

Multilingual BERT (mBERT). At BERT's (Devlin et al., 2019) core is a multi-layer transformer network (Vaswani et al., 2017), parameters of which are pretrained using masked language modeling (MLM) and next sentence prediction (NSP). In MLM, some tokens are masked out and they need to be recovered from the context; NSP predicts adjacency of sentences in text, informing the transformer of longer dependencies, beyond sentence boundaries. Liu et al. (2019) introduce RoBERTa, a more robust instance of BERT trained on larger corpora using only the MLM objective. Multilingual BERT (mBERT) is an instance of BERT trained on concatenation of 104 largest Wikipedias. The effects of underfitting for languages with small Wikipedias and overfitting to languages with large Wikipedias, are respectively attenuated with exponentially smoothed up-sampling and down-sampling.

XLM on RoBERTa (XLM-R). XLM-R (Conneau et al., 2020) is an instance of RoBERTa, robustly trained on a large multilingual CommonCrawl-100 (CC-100) corpus (Wenzek et al., 2019) covering 100 languages. mBERT's corpus and CC-100 share 88 languages, with corresponding CC-100's portions being much larger than mBERT's Wikipedias.

The "Curse of Multilinguality". For XLM-R, Conneau et al. (2020) observe that for a fixed model capacity, downstream cross-lingual transfer improves with more pretraining languages up to a point after which adding more pretraining languages hurts downstream transfer. This effect, termed the "curse of multilinguality", can be mitigated by increasing model's capacity (Artetxe et al., 2020b) or additional training for particular language pairs (Pfeiffer et al., 2020). This points to MMTs' capacity (i.e., computational budgets), as a critical factor for effective zero-shot transfer.

In contrast, we identify few-shot transfer as a much more cost-effective strategy for improving downstream target language performance (§4). We show for a number of target languages and downstream tasks, that one can obtain large performance gains at very small annotation cost, without having to pretrain from scratch an MMT of larger capacity.

2.3 Cross-Lingual Transfer with MMTs

A body of recent work probed the knowledge encoded in MMTs, primarily mBERT. Libovickỳ et al. (2020) analyze language-specific versus language-universal knowledge encoded in mBERT. Pires et al. (2019) demonstrate mBERT to be effective for POS-tagging and NER zero-shot transfer between related languages. Wu and Dredze (2019) extend this analysis to more tasks and languages, and show that mBERT-based transfer is on a par with the best task-specific zero-shot transfer approaches. Similarly, Karthikeyan et al. (2020) prove mBERT to be effective for NER and NLI transfer to Hindi, Spanish, and Russian.[1] Importantly, they show that transfer effectiveness does not depend on the vocabulary overlap between the languages.

In most recent work, concurrent to this, Hu et al. (2020) introduce XTREME, a benchmark for evaluating multilingual encoders encompassing 9 tasks and 40 languages.[2] While the primary focus is a large-scale zero-shot transfer evaluation, they also experiment with target-language fine-tuning (1,000 instances for POS and NER). While Hu et al. (2020) focus on the evaluation aspects and protocols, in this work, we provide a more detailed analysis of the factors that hinder effective zero-shot transfer across several tasks.[3] We also put more emphasis on few-shot transfer, and approach it differently: by sequentially fine-tuning MMTs, first on (larger) source language training data and then on few target-language instances.

Artetxe et al. (2020b) and Wu et al. (2020) analyze different monolingual BERTs to explain transfer efficacy of mBERT. They find topological similarities between monolingual spaces, suggesting these are responsible for effective language transfer with MMTs. In essence, their work recasts the well-known assumption of approximate isomorphism of monolingual representation spaces (Søgaard et al., 2018). For CLWEs, this assumption does not hold for distant languages (Søgaard et al., 2018; Vulić et al., 2019), and in face of monolingual corpora of small size (Vulić et al., 2020). We demonstrate that the same is the case for zero-shot language transfer with MMTs: target-language performance drastically decreases as we move to more distant target languages with smaller pretraining corpora.

3 Zero-Shot Transfer: Analyses

We first address Q1 and Q2 (see §1): we conduct zero-shot language transfer experiments for five different tasks and analyze the factors behind the varying performance drops across target languages.

3.1 Experimental Setup

Tasks and Languages. We experiment with – **a)** low-level structured prediction tasks: POS-tagging, dependency parsing, and NER and **b)** high-level language understanding (LU) tasks: NLI and QA. We investigate if the factors that drive transfer performance differ between the two task groups.

Dependency Parsing (DEP). We use Universal Dependency treebanks (UD, Nivre et al., 2017) for English and following target languages (from 8 language families): Arabic (AR), Basque (EU), (Man-

---

[1] Note that all three are high-resource Indo-European languages with large Wikipedias.

[2] Note that none of the individual tasks in XTREME covers all 40 languages, but much smaller language subsets.

[3] We leave an even more general analysis that combines transfer both across tasks (Pruksachatkun et al., 2020; Glavaš and Vulić, 2020) *and* across languages for future work.

darin) Chinese (ZH), Finnish (FI), Hebrew (HE), Hindi (HI), Italian (IT), Japanese (JA), Korean (KO), Russian (RU), Swedish (SV), and Turkish (TR).

Part-of-speech Tagging (POS). Again, we use UD and obtain the Universal POS-tag (UPOS) annotations from the same treebanks as with DEP.

Named Entity Recognition (NER). We resort to the NER WikiANN dataset from Rahimi et al. (2019). We experiment with the same set of 12 target languages as in DEP and POS.

Cross-lingual Natural Language Inference (XNLI). We evaluate on the XNLI corpus (Conneau et al., 2018) created by translating dev and test portions of the English Multi-NLI dataset (Williams et al., 2018) into 14 languages by professional translators (French (FR), Spanish (ES), German (DE), Greek (EL), Bulgarian (BG), Russian (RU), Turkish (TR), Arabic (AR), Vietnamese (VI), Thai (TH), Chinese (ZH), Hindi (HI), Swahili (SW), and Urdu (UR)).

Cross-lingual Question Answering (XQuAD). We rely on the XQuAD dataset (Artetxe et al., 2020b), created by translating the 240 dev paragraphs (from 48 documents) and corresponding 1,190 QA pairs of SQuAD v1.1 (Rajpurkar et al., 2016) to 11 languages (ES, DE, EL, RU, TR, AR, VI, TH, ZH, and HI). In order to allow for a comparison between zero-shot and few-shot transfer (see §4), we reserve 10 documents as the development set for our experiments and evaluate on the remaining 38 articles.[4]

Fine-tuning. For higher-level tasks, we perform standard downstream fine-tuning of LM-pretrained mBERT and XLM-R. For lower-level tasks, we instead freeze the transformer and train only task-specific classifiers.[5,6]

We add the following task-specific architectures on top of MMTs: for DEP we add the biaffine parsing head (Dozat and Manning, 2017; Kondratyuk and Straka, 2019); for POS, we attach a simple feed-forward token-level classifier; for NER, we feed MMT's token-level outputs to a CRF classifier, similar to Peters et al. (2017). For XNLI, we apply a simple softmax classifier on the vector of the sequence start token (`[CLS]` for mBERT; `<s>` for XLM-R); for XQuAD, we pool MMT's representations of all subwords and input it to a span classification head – a linear layer computing the start and the end of the answer.

Training and Evaluation Details. We experiment with mBERT *Base cased* and XLM-R *Base*, both with $L = 12$ transformer layers, hidden state size of $H = 768$, and $A = 12$ self-attention heads.

For XNLI, we limit the inputs to $T = 128$ subword tokens and train in batches of 32 instances. For XQuAD, we limit paragraphs to $T = 384$ tokens and questions to $Q = 64$ tokens. We slide over paragraphs with a window of 128 tokens and train in batches of size 12. For XNLI and XQuAD, we search the following hyperparameter grid: learning rate $\lambda \in \{5 \cdot 10^{-5}, 3 \cdot 10^{-5}\}$; training epochs $n \in \{2, 3\}$. For DEP, POS and NER, we fix the number of training epochs to 20. We train in batches of 32 sentences, with maximal length of $T = 512$ subword tokens. We optimize all models with Adam (Kingma and Ba, 2015).

We report DEP performance in terms of Unlabeled Attachment Scores (UAS).[7] For POS, NER, and XNLI we report accuracy, and for XQuAD, we report the Exact Match (EM) score.

3.2 Results and Preliminary Discussion

A summary of the zero-shot cross-lingual transfer results, per target language, is provided in Table 1. As expected, we observe drops in performance for all tasks and all target languages w.r.t. reference EN performance. However, the drops vary greatly across languages. For example, NER (mBERT) drops mere 2.6% for IT, but enormous 32% for AR; XNLI transfer (XLM-R) yields a moderate 6.1% drop for FR, but a large 20% drop for SW, etc.

At first glance, it appears – as suggested in prior work – that the transfer drops primarily correlate with language proximity: they are more pronounced for languages that are more distant from EN (e.g., JA, ZH, AR, TH, SW). While we see no notable exception to this in the three lower-level tasks, language proximity alone does not explain many

---

[4] As a general note, while the effects of "translationese" might have some impact on the absolute numbers (Artetxe et al., 2020a), they are not prominent enough to have any impact on the relative trends in the reported results (e.g., zero-shot vs. few-shot performance). For both XNLI and XQuAD, the translations were done completely manually and not via post-editing of MT (which would pose a higher "translationese" risk). Moreover, having an independently created test set in each language would impede comparability across languages.

[5] This gave slightly better performance than fine-tuning.

[6] We tokenize the input for each model with the corresponding pretrained fixed-vocabulary tokenizer: WordPiece tokenizer (Wu et al., 2016) with the vocabulary of 110K tokens for mBERT, and the SentencePiece BPE tokenizer (Sennrich et al., 2016) with the vocabulary of 250K tokens for XLM-R.

[7] Using Labeled Attachment Score (LAS) would make differences in annotation schemes between languages a confounding factor and impede our analysis of effects of language proximity and size of the target language corpora.

Table 1: Zero-shot cross-lingual transfer performance on five tasks (DEP, POS, NER, XNLI, and XQuAD) with mBERT (B) and XLM-R (X). We show the monolingual EN performance and report drops in performance relative to EN for all target languages. Numbers in bold indicate the largest zero-shot performance drops for each task.

of the XNLI and XQuAD results. For instance, RU XNLI (for both mBERT and XLM-R) is comparable to that of ZH, and lower than that for HI and UR: this is despite the fact that, as Indo-European languages, RU, HI, and UR are linguistically closer to EN than ZH. Similarly, we observe comparable performance on XQuAD for TH, RU, and ES.

3.3 Analysis

For each task, we now analyze the correlations between transfer performance and **a)** several measures of linguistic proximity (i.e., similarity) between languages and **b)** the size of MMT pretraining corpora of each target language.

Language Vectors and Corpora Sizes. For estimates of linguistic similarity, we rely on language vectors from LANG2VEC, which encode various linguistic features from the URIEL database (Littell et al., 2017). We consider the following LANG2VEC vectors: `syntax` (SYN) vectors encode syntactic properties, e.g., if a subject appears before or after a verb; `phonology` (PHON) vectors encode phonological properties such as the consonant-vowel ratio; `inventory` (INV) vectors denote presence or absence of natural classes of sounds (e.g., voiced uvulars); FAM vectors encode memberships in `language families`; and GEO vectors express orthodromic distances for languages w.r.t. fixed points on the Earth's surface. Language proximity is computed as cosine similarity between the languages' corresponding LANG2VEC vectors: each vector type (e.g., SYN) produces one similarity score (i.e., feature). We couple LANG2VEC features with the z-normalized size of the target language corpus used in MMT pretraining (SIZE).[8]

Correlation Analysis. We first correlate individual features with the zero-shot transfer scores for each task and show the results in Table 2. Quite intuitively, the zero-shot performance for low-level syntactic tasks – POS and DEP – highly correlates with syntactic language similarity (SYN). SYN also correlates well with transfer results for high-level tasks (except with XLM-R results on XQuAD). Somewhat surprisingly, the phonological language similarity (PHON) correlates best with transfer performance with XLM-R, for all tasks except XNLI, and also for mBERT on POS. For both high-level tasks and both MMTs, we observe very high correlations between transfer performance and size of pretraining corpora of the target language (SIZE). In contrast, SIZE exhibits lower correlations for lower-level tasks (DEP, POS, NER). We believe that this reflect the fact that high-level LU tasks rely on rich representations of semantic phenomena of a language, whereas low-level tasks require simpler structural representation of a language – it simply takes more distributional data to acquire the former than the latter.

Meta-Regression. Across the tasks, we observe high correlations between zero-shot transfer results and several features (e.g., SYN, PHON and SIZE). We next test if we can predict the transfer performance for a new language, by (linearly) combining individual features. For each task, we fit a linear regression using transfer results for target languages as labels. With only between 11 and 14 target languages (i.e., instances for fitting the regressor) per task, we resort to leave-one-out cross-validation (LOOCV) to obtain correlations for feature com-

---

[8] For XLM-R, we take reported sizes of language-specific CC-100 portions (Conneau et al., 2020); for mBERT, we work with sizes of language-specific Wikipedias.

	B	SYN (.35); SIZE (.34), FAM (.31)	0.89	0.90	2.78
XQuAD	X	PHON (.99)	0.95	0.83	2.89
	B	SIZE (.99)	0.89	0.93	4.76

Table 3: Results of the meta-regression analysis, i.e., predicting zero-shot transfer performance for mBERT (B) and XLM-R (X). For each task-model pair we list only features with weights ≥ 0.01. P=Pearson; S=Spearman; MAE=Mean Absolute Error.

binations. We perform greedy forward feature selection: in each iteration we add the feature which boosts correlation (obtained via LOOCV) the most; we stop when none of the remaining features further improves the Pearson correlation.

We summarize the results of this meta-regression analysis in Table 3. For each task-model pair, we list features selected with the greedy feature selection and show (normalized) weights assigned to each feature. Except for NER, combinations of features manage to yield higher correlations with zero-shot transfer results than any of the features on their own. These results empirically confirm our previous intuition that linguistic proximity between the source and target language only partially explains zero-short transfer performance. On XNLI, transfer performance is best explained with the combination of structural similarity between languages (SYN) and the size of the target-language pretraining corpora (SIZE); on XQuAD with mBERT, SIZE alone best explains zero-short transfer scores. Note that the features are mutually quite correlated as well (e.g., languages closer to EN also tend to have larger pretraining corpora): thus if the regressor selects only one feature, this does not mean that other features do not correlate with transfer performance (as shown by Table 2).

The coefficients in Table 3 again indicate the importance of SIZE for the language understanding tasks and highlight our core finding: pretraining corpora sizes are stronger features for predicting zero-shot performance in higher-level tasks, whereas the results in lower-level tasks are more affected by typological language proximity.

4 From Zero to Hero: Few-Shot

Motivated by the low zero-shot transfer performance for many tasks and languages obtained in §3, we now investigate Q4 from §1: we aim to mitigate transfer losses with inexpensive few-shot cross-lingual transfer.

Experimental Setup. We rely on the same models, tasks, and evaluation protocols as described in §3.1. However, instead of fine-tuning the MMTs on task-specific data in EN only, we continue the fine-tuning process by feeding k additional training examples randomly chosen from reserved target language data portions, disjoint with the test sets.[9]

---

[9] Note that for XQuAD, we performed the split on the article level to avoid topical overlap. Consequently, for XQuAD

Table 4: Results of the few-shot experiments with varying numbers of target-language examples k. For each k, we report performance averaged across languages and the difference (Δ) with respect to the zero-shot setting.

For our low-level tasks, we compare three sampling methods: (i) random sampling (RAND) of k target language sentences, (ii) selection of the k shortest (SHORTEST) and (iii) the k longest (LONGEST) sentences.[10] For XNLI and XQuAD, we run the experiments five times and report the average scores.

4.1 Results and Discussion

The results on each task, conditioned on the number of examples k and averaged across all target languages, are presented in Table 4. We note substantial improvements in few-shot learning setups for all tasks. However, the results also reveal notable differences between different types of tasks. For higher-level language understanding tasks the improvements are less pronounced; the maximum gains for XNLI and XQuAD after seeing $k = 1,000$ target-language instances and 10 articles, respectively, are between 2.52 (XLM-R) and 4.57 points (mBERT). On the other hand, the average gains for the lower-level tasks are massive: between 10 (NER) and 30 (DEP) points for mBERT and 8 (NER) and 35 (DEP) points for XLM-R. Moreover, the gains in all lower-level tasks are substantial even when we add only 10 annotated sentences in the target language (on average, up to 17 points on DEP, and 15 points on POS). What is more, our additional experiments (omitted for brevity) show substantial gains for DEP and POS even with fewer than 5 annotated target language sentences. A comparison of different sampling strategies for the lower-level tasks is shown in Figure 1 for mBERT.[11] For DEP and POS, the pattern is very clear and quite expected – adding longer sentences results in better scores. For NER, however, random sampling (RAND) appears to perform best: we hypothesize that this is because: (i) very long sentences are relatively sparse with named entities, resulting in our model seeing mostly negative examples; (ii) shorter sentences contribute less than for DEP and POS because they typically consist of (confirmed by manual inspection) a single named entity mention, without any non-NE tokens.

Figure 2 illustrates few-shot performance for individual languages on two lower-level (DEP, NER) and two higher-level tasks (XNLI, XQuAD), for different values of k.[12] Across languages, we see a clear trend – more distant target languages benefit much more from the few-shot data. Observe, e.g., SV for DEP or DE for XQuAD. Both are closely related to EN, exhibit high zero-shot transfer performance, and benefit only marginally from few in-language instances. We hypothesize that for such closely related languages, with enough pretraining data, MMT is able to extrapolate the missing language-specific knowledge from few in-language examples; its priors for languages close to EN are already quite sensible and *a priori* offer less room for improvements. In stark contrast, KO (DEP, a) and TH (XQuAD, b), for example, both exhibit poor zero-shot performance and understandably so, given their linguistic distance to EN. Given in-language data, however, both see rapid leaps in performance, displaying gains of almost 40% UAS on

---

k refers to the number of articles.

[10] In all three cases, we only choose between sentences with ≥ 3 and ≤ 50 tokens.

[11] A similar analysis for XLM-R is in the supplementary.

[12] We show per-language scores for POS with mBERT, and all tasks with XLM-R in the Appendix.

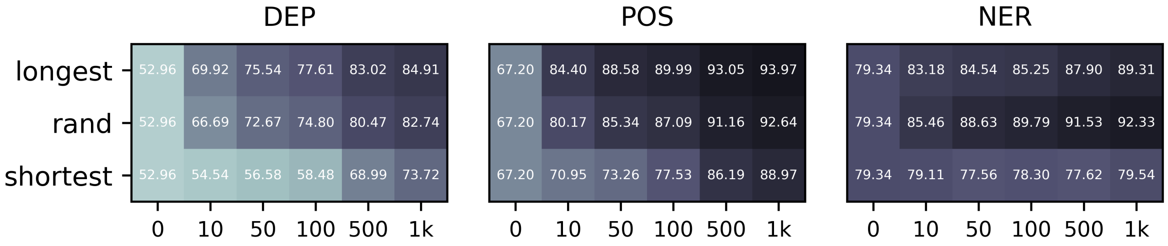

Figure 1: Heatmap of performance gains for low-level tasks from few-shot transfer with mBERT for different sampling strategies. X-axis: number of target-language instances k; Y-axis: sampling strategy.

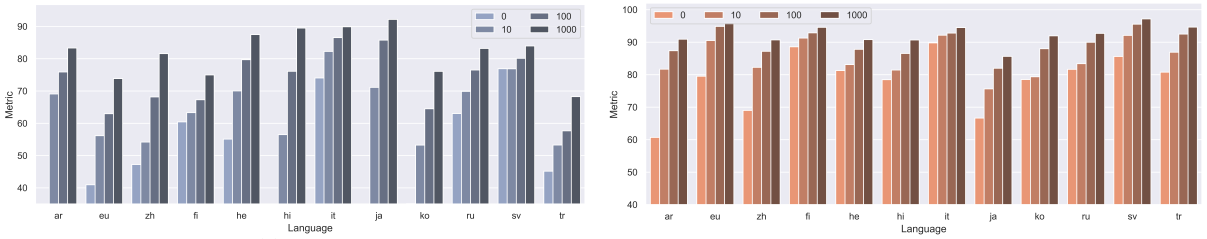
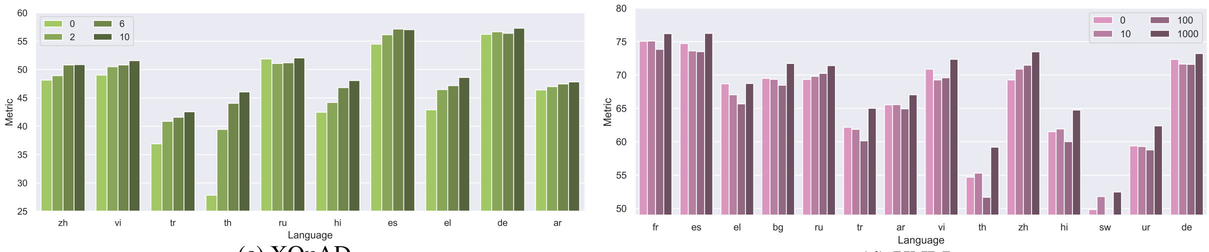


(a) DEP

(b) NER



(c) XQuAD

(d) XNLI

Figure 2: Few-shot transfer results with mBERT for each language with varying k for two low-level tasks: a) DEP, b) NER, and two higher-level tasks: c) XQuAD, d) XNLI. For DEP, NER, and XNLI k denotes the number of sampled sentences, for XQuAD, the number of sampled articles.

DEP (KO), and almost 5% on XQuAD (TH). This can be seen as MMTs' ability to rapidly learn to utilize the multilingual space to adjust its task-specific knowledge for the target language. Other interesting patterns emerge. Particularly interesting are DEP results for JA and AR, where we observe massive UAS improvements with only 10 annotated sentences. For XQuAD, we observe a substantial improvement from only 2 in-language documents for TH. In sum, we see the largest gains from few-shot transfer exactly for languages for which the zero-shot transfer setup yields largest performance drops: languages distant from EN and represented with small corpora in MMT pretraining.

Direct Target Language Few-Shot Fine-Tuning. We have additionally run a set of control experiments in which we bypass the task-specific fine-tuning on the Enhlish data and directly fine-tune the MMTs on the few target language instances. Expectedly, for high-level LU tasks, fine-tuning the MMTs with only a handful of target language examples (i.e., *without* prior fine-tuning in English) yields subpar performance w.r.t. the corresponding model variant that had been previously fine-tuned on English data. For instance, direct few-shot target language fine-tuning of mBERT yields the average XNLI performance of 33.95 for $k = 100$ and 40.19 for $k = 1,000$, respectively (compared to 64.92 and 68.16, respectively, when prior fine-tuning on English data is performed). These findings suggest that fine-tuning with abundant (English) in-task data plus fine-tuning with scarce in-language in-task data yields a truly synergistic effect for higher-level language understanding tasks: the small number of examples in the target language is not sufficient to adapt the MMT directly, but they can provide a substantial edge over fine-tuning only on the English data (i.e., zero-shot transfer).

Somewhat surprisingly, however, for the simpler lower-level tasks, omitting task-specific fine-

Task	#inst.	Cost est.	Δ mBERT	Δ XLM-R
POS	1K sents	$73	+25.4	+27.3
DEP	1K sents	$280	+29.8	+34.7
NER	1K sents	$60	+10	+8.4
NLI	1K sent. pairs	$10	+2.24	+2.54
QA	10 docs	$30	+4.5	+2.1

Table 5: Conversion rates between target language annotation costs and corresponding average performance gains from MMT-based few-shot language transfer.

tuning on the English data and fine-tuning only on few target language instances does not lead to the major deterioration of performance (in fact, in some cases, omitting to fine-tune the MMTs on English data even slightly improves the results): for NER (mBERT) we obtain the average performance of 82.89 and 89.76 for $k = 100$ and $k = 1,000$ respectively, compared to 85.25 and 89.31 obtained respectively with prior English fine-tuning; for POS, the direct few-shot target language fine-tuning yields 87.08 ($k = 100$) and 92.64 ($k = 1,000$). We observe the same trends for the remaining tasks and with XLM-R. This suggests that MMTs can be fine-tuned for lower-level (i.e., simpler) tasks with only a handful of instances.

4.2 Cost of Language Transfer Gains

As shown in §4.1, moving to few-shot transfer can massively improve performance and reduce the gaps observed with zero-shot transfer, especially for low-resource languages. While additional fine-tuning on few target-language examples is computationally cheap, data annotation may be expensive, especially for minor languages. What are the annotation costs, and how do they translate into performance gains? Table 5 provides ballpark estimates for our five evaluation tasks; the estimates are based on annotation costs from the literature (Hovy et al., 2014; Tratz, 2019; Bontcheva et al., 2017; Marelli et al., 2014; Rajpurkar et al., 2016). We explain these cost-to-gain conversion estimates in more detail in Appendix C).

A provocative high-level question that calls for further discussion in future work can be framed as: are GPU hours effectively more costly[13] than data annotations are in the long run? While MMTs are extremely useful as general-purpose models of language, their potential for some (target) languages can be quickly unlocked by pairing them with a small number of annotated target-language examples. Effectively, this suggests leveraging the best of both worlds, i.e., coupling knowledge encoded in large MMTs with a small annotation effort.

5 Conclusion

Research on zero-shot language transfer in NLP is motivated by inherent data scarcity: the fact that most languages have no annotated data for most NLP tasks. Massively multilingual transformers (MMTs) have recently been praised for their zero-shot transfer capabilities that mitigate the data scarcity issue. In this work, we have demonstrated that, similar to earlier language transfer paradigms, MMTs perform poorly in zero-shot transfer to distant target languages, and to languages with smaller monolingual corpora available for exploitation in MMT pretraining. We have presented a detailed empirical analysis of factors affecting zero-shot transfer performance of MMTs across diverse tasks and languages. Our results have revealed that structural language similarity determines the transfer success for lower-level tasks like POS-tagging and dependency parsing; on the other hand, the pretraining corpora size of the target language is crucial for explaining transfer results for higher-level language understanding tasks, such as question answering and natural language inference.

Finally and most importantly, we have shown that the MMT potential on distant and low-resource target languages can be quickly unlocked if they are provided a handful of annotated instances in the target language. This finding provides a strong incentive for intensifying future research efforts that focus on cheap or naturally occurring supervision (Vulić et al., 2019; Artetxe et al., 2020c; Marchisio et al., 2020), quick and simple annotation procedure, and the more effective few-shot transfer learning setups.

A Reproducibility

We first provide details on where to obtain datasets and code used in this work.

Code and Dependencies. Our code can be obtained from `https://www.dropbox.com/s/o5cxyy92re48xmu/zerohero_code.zip?dl=0`. The code is separated in two parts: for experiments related to low-level tasks (DEP, POS, NER) the code is based on the AllenNLP framework; for the experiments on high-level tasks (XNLI, XQuAD), our code directly builds on top of the HuggingFace Transformers framework (Wolf et al., 2019). We provide links to code dependencies and pretrained models in Table 6.

Datasets. Table 7 provide links to all datasets that we used in our study, for each of the five tasks (low-level tasks: DEP, POS, NER; high-level tasks: XNLI, XQuAD).

B Full Per-Language Few-Shot Results

We show full per-language few-shot transfer results for all five tasks (DEP, POS, NER, XNLI, XSQuAD) for mBERT and XLM-R in Tables 8 and 9, respectively. We visually illustrate the gains from few-shot transfer for individual languages, for mBERT (for the POS task not covered in the main paper) in Figure 3 and for XLM-R (for all five tasks) in Figure 4. Finally, we show how the few-shot transfer results with XLM-R for lower-level tasks (DEP, POS, NER) depend on the instance sampling strategy (RAND, SHORTEST, LONGEST) in Figure 5.

C Few-Shot Transfer: Annotation Costs versus Performance Gains

We now present the more detailed explanations for the conversion between the annotation costs and few-shot transfer performance gains, summarized in Table 5 in the main paper.

Natural Language Inference. Marelli et al. (2014) reportedly paid $\$2,030$ for 200k judgements, which would amount to $0.01015 per NLI instance and, in turn, to $\$10.15$ for $1,000$ annotations. In our few-shot experiments this would yield an average improvement of 2.24 and 2.52 accuracy points for mBERT and XLM-R, respectively. It is also possible to translate the English data directly via professional translation services as done with the XNLI dataset and XQuAD: the platforms for hiring professionals such as Upwork show that it is possible to find qualified translators even for lower-resource languages: e.g., the translation cost estimate for Zulu is $12.5-$16/h, or $19/h for the Basque language.

Question Answering. Rajpurkar et al. (2016) report a payment cost of $9 per hour and a time effort of 4 minutes per paragraph. With an average of 5 paragraphs per article, our few-shot scenario (10 articles) roughly requires 50 paragraphs-level annotations, i.e., 200 minutes of annotation effort and would in total cost around $30 (for respective performance improvements of 4.6 and 2.1 points for mBERT and XLM-R).

On the one hand, compared to language understanding tasks, our lower-level (DEP, POS) tasks are presumably more expensive to annotate, as they require some linguistic knowledge and annotation training. On the other hand, as shown in our few-shot experiments, we typically need much fewer annotated instances (i.e., we observe high gains with already 10 target language sentences) for substantial gains in these tasks.

Dependency Parsing. Tratz (2019) provide an overview of crowd-sourcing annotations for dependency parsing; they report obtaining a fully correct dependency tree from at least one annotator for 72% of sentences. At the reported cost of $0.28 per sentence this amounts to spending $280 for annotating $1,000$ sentences. Somewhat shockingly, annotating 10 sentences with dependency trees – which for particular target languages like AR and JA corresponds to performance gains of 30-40 UAS points (see Figure 2) – amounts to spending merely $3-5.

Part-of-Speech Tagging. Hovy et al. (2014) measure agreement of crowdsourced POS annotations with expert annotations; they crowdsource annotations for 1,000 tweets, at a cost of $0.05 for every 10 tokens. With a total of $14,619$ tokens in the corpus, this amounts to approximately $73 for $1,000$ tweets, which is $\geq 1,000$ sentences.[14] Based on Table 4, 2 hours of POS annotation work translates to gains of up to 20-22 points on average over zero-shot transfer methods.

---

[14] Note, however, that lower-level tasks do come with an additional risk of poorer quality annotation, due to crowdsourced annotators not being experts. Garrette and Baldridge (2013) report that even for truly low-resource languages (e.g., Kinyarwanda, Malagasy), it is possible to obtain ≈ 100 POS-annotated sentences in 2 hours.

(a) POS

Figure 3: Graphical illustration of few-shot transfer gains for each language with mBERT, for the remaining task not covered in the main paper: POS.

Named Entity Recognition. Bontcheva et al. (2017) provide estimates for crowdsourcing annotation for named entity recognition; they pay \$0.06 per sentence, resulting in \$60 cost for $1,000$ annotated sentences. At a median pay of \$11.37/hr, this amounts to around 190 sentences annotated in an hour. In other words, in less than 3 hours, we can collect more than 500 annotated examples. According to Table 4, this can result in gains of 8+ points on average, and even more for some languages (e.g., 27 points for AR).

Distilling Multiple Domains for Neural Machine Translation

Anna Currey **Prashant Mathur** **Georgiana Dinu**

Abstract

Neural machine translation achieves impressive results in high-resource conditions, but performance often suffers when the input domain is low-resource. The standard practice of adapting a separate model for each domain of interest does not scale well in practice from both a quality perspective (brittleness under domain shift) as well as a cost perspective (added maintenance and inference complexity). In this paper, we propose a framework for training a single multi-domain neural machine translation model that is able to translate several domains without increasing inference time or memory usage. We show that this model can improve translation on both high- and low-resource domains over strong multi-domain baselines. In addition, our proposed model is effective when domain labels are unknown during training, as well as robust under noisy data conditions.

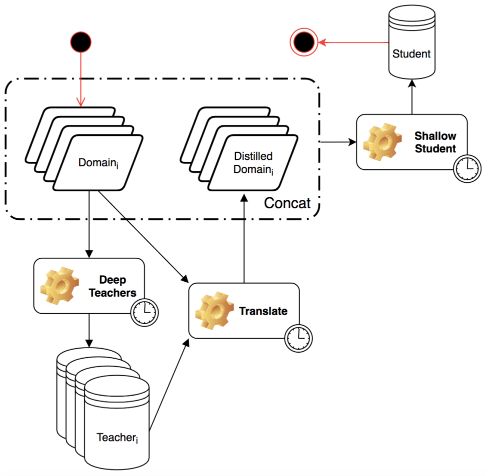

Figure 1: Overview of the multi-domain knowledge distillation (MDKD) method. A single multi-domain model is trained on data that is distilled from high-performance deep teachers. MDKD trains *multiple* deep teachers, each an expert in a specific domain.

1 Introduction

Neural machine translation (NMT) (Bahdanau et al., 2015; Cho et al., 2014; Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014) can achieve high quality when trained using deep architectures on large amounts of relevant data (Barrault et al., 2019). However, training data for generic translation models is typically not balanced or diverse with respect to domain. As a result, translation quality can be inconsistent across domains, with lower-quality outputs for low-resource domains such as chat compared to high-resource domains such as news (Koehn and Knowles, 2017).

One way to address this is by building domain-adapted models (Freitag and Al-Onaizan, 2016; Chu and Wang, 2018) that target a specific domain. In this case, in-domain data is used to specialize the machine translation (MT) model for the target domain, for example by fine-tuning a generic model on this data (Freitag and Al-Onaizan, 2016; Luong and Manning, 2015; Sennrich et al., 2016a; Servan et al., 2016). This yields "expert" models that are better than models trained on the in-domain data alone and more specialized than a generic translation system. However, for an MT application that needs to translate multiple domains, this approach would require maintaining and running separate expert systems for each domain, which becomes prohibitively expensive as the number of domains increases. Additionally, in a real-world scenario, the domain of the input text might be unknown at inference time, adding the complexity of detecting which system should be used for a given input.

One alternative to expert models are multi-domain MT systems (Britz et al., 2017; Farajian et al., 2017; Kobus et al., 2017; Pham et al., 2019; Sajjad et al., 2017). Specifically, the goal of a multi-domain method is to obtain a *single* NMT model that approaches the performance obtained through

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4500–4511,
November 16–20, 2020.

multiple expert models. Under this framework, access to several domain-specific corpora is assumed at training time, but the domain information is not known at inference time.

In this paper, we address the problem of multi-domain MT. Our goal is to exploit knowledge about the heterogeneous nature of the data to train a single *fixed-capacity* model that approaches the quality of the experts across all domains. Achieving high quality on each domain without damaging quality on other domains and without increasing the model complexity is an ambitious goal that matches the setup of many user-facing MT systems (Britz et al., 2017; Crego et al., 2016).

The main contributions of the paper are:

1. We show empirically that even though a single multi-domain NMT model can yield good performance across multiple diverse domains, there is still a performance gap between such a model and separate experts when the domains are well-defined and clearly separated.
2. We propose a new architecture-agnostic multi-domain framework. This method transforms the training data so that it contains outputs obtained through sequence-level knowledge distillation (Kim and Rush, 2016). Crucially, the distilled output is obtained from *multiple* high-capacity domain experts that individually achieve very good performance on their target domains. This allows our approach (multi-domain knowledge distillation, or MDKD) to distill the gains from domain-specific models into a parameter-efficient model that outperforms other multi-domain approaches.
3. We perform experiments that show that the quality of domain expert models is highly dependent on the quality of the domain labels. We show that our MDKD method is robust to low-quality domain labels and outperforms the baselines even when the domain experts themselves are of low quality. We follow up to show that domain labels are not needed and that similar results can be obtained through clustering the input data.

2 Multi-Domain Distillation for MT

We assume our training data $\mathcal{D}^{tr}$ is composed of n disjoint labeled domains $\mathcal{D}_i$ ($i \in \{1, \dots, n\}$) containing parallel sentences (s, t):

$$\mathcal{D}^{tr} = \mathcal{D}_1^{tr} + \mathcal{D}_2^{tr} + \ldots + \mathcal{D}_n^{tr}$$

$$\mathcal{D}_i^{tr} = \{(s_1, t_1), \ldots, (s_{m_i}, t_{m_i})\}$$

The goal is to build a fixed-capacity model that performs well across all n domains. In this work, we assume that all domains are equally important and we measure performance as the unweighted average across all domain-specific test sets $\mathcal{D}_i^{tst}$. However, it is desirable for a multi-domain model to not trade improved performance on one domain with degradation on another. For this reason, we also evaluate performance drop across all domains w.r.t. a baseline model trained on $\mathcal{D}^{tr}$.

Our approach builds on several observations made in previous work. Hinton et al. (2015) showed that knowledge distillation using an increased capacity *teacher* model is an effective method for reducing the complexity of training data. Although the exact mechanisms are still not well understood (Gordon and Duh, 2019; Phuong and Lampert, 2019; Zhou et al., 2020), smaller-sized *student* models trained on the output of the teacher perform better than the same models trained on the original data. Their performance is on par with that of the very large teacher model, which is impractical to use in practice.

In multi-domain MT, increased depth alone does not generally provide the best performance, and increasing capacity through *specialization* of networks, either as completely separate neural models or stacked models, is the optimal strategy in practice (Sajjad et al., 2017). We exploit this intuition and generalize the sequence-level knowledge distillation approach of Kim and Rush (2016) to the multi-domain case by distilling the output of *multiple* domain-specific teachers. This technique is referred to as multi-domain knowledge distillation (MDKD; Figure 1), and it consists of three steps:

1. Train domain-specific teacher models The goal of the first step is to train multiple expert models, each achieving high performance on its target domain. To train the deep domain-specific teacher models, we follow the fine-tuning framework that has proven successful in NMT domain adaptation (Freitag and Al-Onaizan, 2016; Luong and Manning, 2015; Sennrich et al., 2016a; Servan et al., 2016). First, we train a deep domain-general NMT model on the generic training corpus $\mathcal{D}^{tr}$ containing the concatenation of all domains. Then, for each domain i, we create a separate domain-specific teacher model by fine-tuning the generic model on the domain-specific data $\mathcal{D}_i^{tr}$. These teacher models are only used to generate training data and we therefore have fewer limitations on their size. In this paper, we train teachers that are twice the depth of the student model.

2. In-domain distillation The goal of the distillation step is to reduce the complexity of the original training data $\mathcal{D}^{tr}$. Instead of achieving this with a single deep teacher as in Kim and Rush (2016) and Kim et al. (2019), we use the multiple domain-specific teachers trained in step 1. Each training set $\mathcal{D}_i^{tr}$ is translated with its corresponding deep teacher, resulting in a distilled version $\mathcal{D}_i^{dist(tr)}$ of that set. We also distill the domain-specific validation sets $\mathcal{D}_i^{dev}$ to $\mathcal{D}_i^{dist(dev)}$. During distillation, we use beam search and take a single output for each input sentence. We do not perform any filtering on the distilled data.

3. Train a final multi-domain student model To train the final multi-domain model, we create the student training corpus by combining the original training data $\mathcal{D}_i^{tr}$ and the distilled training data $\mathcal{D}_i^{dist(tr)}$ from each domain i (as recommended by Gordon and Duh, 2019), and likewise for the development data. The student model is then trained from scratch on this data. Unlike for the teacher models, we cannot use an arbitrarily large student model, since this would increase memory usage and latency at inference. Thus, our student model is shallower than the teacher models (see section 3.3 for exact configurations).

3 Experiments

3.1 Data

We evaluate our models on two language pairs: German (DE) → English (EN) and EN → French (FR). For both pairs, we draw from a diverse set of domains to create the training and evaluation data. For DE→EN, we use the following data sources:

- **Europarl**: European parliamentary proceedings (Koehn, 2005)
- **law**: JRC-Acquis corpus
- **medical**: EMEA corpus
- **IT**: GNOME, KDE, PHP, Ubuntu, and OpenOffice corpora (combined following Koehn and Knowles, 2017)

The law, medical, and IT corpora are from OPUS (Tiedemann, 2012). From each domain, we randomly sample 3k sentences for the development set and 3k sentences for the test set.

Our EN→FR data comes from:

	domain	training sentences
DE→EN	Europarl	1.9M
	law	500k
	medical	360k
	IT	260k
EN→FR	Europarl	2.0M
	news	180k
	biomedical	690k
	Reddit	36k
	TED	230k

Table 1: Training corpus size for each domain.

- **Europarl**: European parliamentary proceedings (Koehn, 2005)
- **news**: news commentary corpus from WMT14 (Bojar et al., 2014)
- **biomedical**: from the WMT19 biomedical shared task (Bawden et al., 2019)
- **Reddit**: the parallel portion of the MTNT corpus (Michel and Neubig, 2018b)
- **TED talks**: from the IWSLT 2017 shared task (Cettolo et al., 2012)

For all domains except Europarl, we use existing dev and test sets from the corresponding shared task. For Europarl, we hold out 2k sentences each as dev and test sets. Table 1 shows the amount of training data for each domain and language pair.

3.2 Baselines and Evaluation

We evaluate all models using BLEU (Papineni et al., 2002), implemented in SacreBLEU (Post, 2018). Statistical significance is measured using bootstrap resampling (Koehn, 2004).

For both language pairs, there is a large disparity in the amount of training data for each domain (see Table 1). All the models we implement can use the data in an *unbalanced* way (keeping the existing distribution of domains) as well as *upsampling* the data (so that each domain has the same amount of training data). It is difficult to know a priori which of the two data settings leads to the best performance across all domains, and therefore we experiment with both unbalanced and upsampled variants of all the models.

We have three classes of models overall:

1. Multi-domain baselines

- **multi-un**: model trained on the concatenation of all training data from all domains. This is the basic way of training on heterogeneous data without any notion of domains.

- **multi-up**: model trained on the concatenation of all the training data, with each domain upsampled to the size of the largest domain.
- **fine-tune**: fine-tune the multi-un baseline with the upsampled data. This is a multi-domain extension of mixed fine-tuning (Chu et al., 2017) that combines the advantages of the multi-un and multi-up baselines.
- **multi-tgt-tok**: same as multi-un, with the model additionally predicting a domain token at the beginning of each target sentence. This was introduced by Britz et al. (2017).

2. MDKD (proposed)

- **MDKD-un**: concatenates the domain-specific corpora $\mathcal{D}_i^{tr}$ and $\mathcal{D}_i^{dist(tr)}$ without changing the domain distribution.
- **MDKD-up**: balances both $\mathcal{D}_i^{tr}$ and $\mathcal{D}_i^{dist(tr)}$ by upsampling sentences from the smaller corpora so that each domain has the same number of training sentences as the largest domain.

3. Deep teacher models (oracle) To further understand the performance of the multi-domain knowledge distillation models, we compare them to an oracle consisting of the deep, domain-specific teacher models that are used to create the MDKD students.

3.3 Experimental Setup

All models are Transformers (Vaswani et al., 2017) implemented in Sockeye (Hieber et al., 2017). Models are trained on 4 GPUs across a single machine. We do not perform a hyperparameter search, and instead follow the *Transformer-base* settings unless otherwise noted. We perform perplexity-based early stopping on the development set for all models. Before training, we tokenize the data and split it into a shared subword vocabulary using byte pair encoding (Sennrich et al., 2016b) with 32k merge operations. We also deduplicate the data on the sentence level and remove any empty lines.

Following Müller et al. (2019), we turn off label smoothing for knowledge distillation models as it causes loss of information in the logits and in turn diminishes the effect of knowledge distillation. For teacher models, we use 12 encoder and 12 decoder layers; for student models and baselines, we use 6 encoder and 6 decoder layers. The teacher models have roughly 100M parameters, and the other models have roughly 60M parameters. When generating the distilled training and development data, we use a beam size of 10. At inference time, we use a beam size of 5 unless otherwise noted.

BLEU	**avg**	**parl**	**law**	**med**	**IT**
multi-un	48.4	38.9	57.7	54.8	42.1

oracle	51.0	38.8	60.4	59.8	45.0

Table 2: BLEU scores (macro-averaged and per-domain) for the baselines and proposed multi-domain knowledge distillation models on the DE→EN test data. Best results (besides oracle) are in bold. Statistically significant improvements of MDKD models over the fine-tune baseline are marked with † ($p < 0.01$).

4 Results

4.1 German→English Results

The BLEU scores for the DE→EN models on each test set, as well as unweighted average BLEU, are shown in Table 2. As hypothesized, the oracle model, which builds separate deep teachers for each domain, is the best performing method overall. This shows that deep specialized models are indeed difficult to outperform with single shallow models.

Among the baselines, the fine-tune baseline yields slightly higher quality than the other methods on average, although not significantly better than the simple multi-un setting. Both MDKD models achieve higher BLEU scores overall than all the baselines; the MDKD-upsampled model, in particular, gains 1.1 BLEU over the best baseline (fine-tune), while the MDKD-unbalanced model gains 0.9 BLEU over that baseline and does not show significant performance degradation on any domain, which is a very desirable property for a multi-domain model. In Appendix A, we give some examples of translation outputs from the models.

For all domains, the best non-oracle model is one of the multi-domain knowledge distillation models. Additionally, the MDKD systems are able to reduce the gap between baselines and oracle by a large margin, scoring on average only 1 BLEU point lower than the oracle. The MDKD-unbalanced model also surpasses the oracle on the Europarl domain; Europarl represents two-thirds of the training corpus, which could be why the Europarl expert does not do much better than multi-domain models.

Unbalanced vs. upsampled performance Unsurprisingly, the MDKD-unbalanced model yields higher BLEU than the upsampled model on the higher-resource domains (Europarl and law),

BLEU	avg	Europarl	news	biomedical	Reddit	TED
multi-un	38.6	**36.7**	35.9	**45.4**	34.8	40.1
multi-up	36.9	34.5	33.4	44.5	33.5	38.5
fine-tune	38.7	36.3	35.8	45.1	**35.7**	40.5
multi-tgt-tok	38.4	36.4	35.5	44.6	35.3	40.2
MDKD-un	**38.9**‡	**36.7**‡	**36.4**†	44.9	35.5	**40.8**
MDKD-up	37.5	35.1	34.2	44.9	33.7	39.8
oracle	37.1	**36.7**	33.4	41.8	34.2	39.2

Table 3: BLEU scores (macro-averaged and per-domain) for the baselines and proposed multi-domain knowledge distillation (MDKD) models on the EN→FR multi-domain data. Best results are in bold. Statistically significant improvements between MDKD models and the fine-tune baseline are marked with † ($p < 0.01$) and ‡ ($p < 0.05$).

whereas the upsampled model yields higher BLEU on the lower-resource domains (medical and IT). This trend also largely holds for the unbalanced and upsampled baselines. Thus, the two MDKD models are effective in different scenarios. The unbalanced model is better when performance on the largest domain needs to be maintained, while the upsampled model is better when we can afford to sacrifice some quality on large domains in order to improve low-resource domains.

4.2 English→French Results

Table 3 shows the results on the English→French multi-domain corpus. For both the baselines and the MDKD models, upsampling the data causes an important loss in quality; this might be due to the difference in size between the largest training corpus (Europarl, 2M sentences) and the smallest corpus (Reddit, 36k sentences). In addition, the MDKD-unbalanced model shows only a slight improvement over the baselines: +0.2 BLEU compared to the best baseline (fine-tune). This is in contrast to the DE→EN results where the MDKD framework yielded a large increase in BLEU score.

The oracle results point to an explanation: although the oracle should be made up of domain experts, it in fact performs worse than the generic multi-un baseline. Since these are the teacher models used to train the MDKD students, it makes sense that the MDKD models do not improve much over the baselines. In fact, MDKD proves to be surprisingly robust to this adverse setting, given that is it trained to mimic low-quality teachers.

Quality of domain labels In order to investigate the unexpected low performance of the in-domain teachers, we perform additional experiments probing potential domain mismatches that may explain these results. Possible explanations that can be easily tested include 1) heterogeneous domains that are not suitable to be learned by individual specialized models or 2) mismatch in domain labels between training and test data. We evaluate these possibilities using the multi-tgt-tok baseline model.

	domain	train	test	Δ
DE→EN	Europarl	99.8%	99.4%	- 0.4
	law	98.7%	96.7%	- 2.0
	medical	97.9%	97.2%	- 0.7
	IT	99.0%	98.4%	- 0.6
EN→FR	Europarl	98.7%	98.9%	+ 0.2
	news	78.2%	28.0%	- 50.2
	biomed	99.2%	77.7%	- 21.5
	Reddit	81.8%	70.2%	- 11.6
	TED	91.5%	88.2%	- 3.3

Table 4: Domain classification accuracy of the multi-tgt-tok baseline on the training and test sets. Unlike DE→EN domains, EN→FR domains are more difficult to learn (lower train accuracy) and exhibit train/test mismatches for some domains (lower test accuracy).

The multi-tgt-tok baseline (Britz et al., 2017) is trained to simultaneously translate the source sentence and predict its domain. In order to understand the separability of the training domains and the similarity between training and testing domains, we calculate the domain classification accuracy of this model on a subset of the training data (3k randomly sampled sentences per domain) and on the test data for each language pair. The accuracies for DE→EN and EN→FR are shown in Table 4.

For the DE→EN corpus, the domains in the training data are well-defined, as indicated by the high classification accuracy on the training data. Additionally, the test set classification accuracy is very high, indicating that there is no mismatch between train and test domain labels.

On the other hand, for the EN→FR corpus, the lower accuracies on the training data indicate

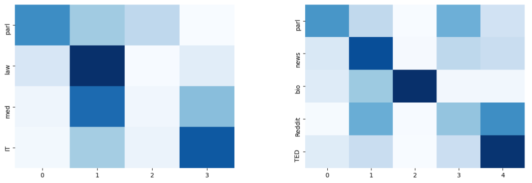

Figure 2: Cluster–domain correlations (darker means higher number of segments associated with the respective domain/cluster cell) for the DE→EN 4-cluster (left) and EN→FR 5-cluster (right) settings.

BLEU	avg	parl	law	med	IT
gold labels	**49.8**	39.3	**59.5**	**57.1**	**43.2**
3 clusters	49.2	**39.4**	58.6	55.8	42.8
4 clusters	49.1	39.0	58.7	55.8	42.9
5 clusters	49.3	39.1	58.9	56.1	42.9

Table 5: DE→EN BLEU scores for the MDKD-unbalanced model when clustering the training data into different numbers of clusters, compared to using gold domain labels.

that the domains are less easily separable than for DE→EN, especially for the news and Reddit domains. The large difference in training and test accuracy for the news, biomedical, and Reddit domains also points to a drift in domains between the training and test data. Thus, both of these issues likely contributed to the lower quality of the EN→FR domain-specific teacher models. Since we cannot take the accuracy of corpus-level domain labels for granted, section 5 considers the possibility of inducing sentence-level labels instead.

5 MDKD Using Unsupervised Clusters

The MDKD framework works well when the domain-labeled training corpus contains domains that are well-defined, since high-quality deep domain experts can be trained. However, as noted in the previous section, domain labels may not always correspond to consistent, separable domains. In addition, in many cases, domain labels might not be available at all.

In this section, we investigate whether the MDKD technique can be used to improve the multi-domain performance of a single model without knowing domain labels at test *or* training time. Instead of relying on corpus-level domain labels, we cluster the heterogeneous training data at the sentence level and treat the clusters obtained as regular domains.

Clustering the training data To cluster the training data, we first compute sentence embeddings of all the source training sentences using the multilingual variant of BERT (mBERT; Devlin et al., 2018), which has 768 dimensions and is trained on Wikipedia data from 104 languages. We then apply k-means clustering (MacQueen, 1967) to compute the clusters on the inferred sentence embeddings. Different numbers of clusters are computed: for DE→EN, we have four domains, so we compute models using 3, 4, and 5 clusters. Similarly, for EN→FR, we compute models with 4, 5, and 6 clusters. We leave finding the optimal number of clusters as future work; in preliminary experiments, the method we employed to automatically compute this number led to a prohibitively large amount of clusters (more in Appendix B.3). Cluster classifications for each domain in the test set are shown as heat maps in Figure 2. Interestingly, the unsupervised clusters do not overlap strongly with the gold domain labels, even for the DE→EN case.

German→English results Table 5 shows the BLEU scores on the DE→EN test set for different numbers of clusters for the MDKD-unbalanced model. For computing domain-level scores and the macro-average scores, domains are defined as the gold domain labels. The unsupervised clusters do slightly worse than the gold domain labels (-0.5 to -0.7 BLEU), showing that the MDKD model can be effective without gold domain labels; however, gold labels are preferable if they are of high quality.

English→French results The previous EN→FR experiments showed that no method significantly outperformed a basic baseline; even the domain-specific teachers performed worse than this baseline. The domains themselves were more difficult to separate, motivating the use of pseudo-domains obtained through clustering.

Table 6 shows the results for the EN→FR MDKD-unbalanced model with both gold and cluster-based domain labels. Unlike for DE→EN, for EN→FR we do not see any loss in quality from the clusters compared to the gold labels. However, we do not observe any large gains over gold labels, showing that this method has not overcome the noisy domain separation. In the future, we will investigate additional clustering methods to address this problem.

BLEU	avg	parl	news	bio	Red	TED
gold labels	38.9	36.7	36.4	44.9	35.5	**40.8**
4 clusters	39.0‡	36.8	36.5	45.6‡	**35.9**	40.4
5 clusters	38.9	36.6	**36.7**‡	45.5‡	35.3	40.3
6 clusters	**39.1**‡	**36.9**	36.6	**45.7**‡	35.5	40.6

Table 6: EN→FR BLEU scores for the MDKD-unbalanced model when clustering the training data into different numbers of clusters, compared to using gold domain labels. Statistically significant improvements ($p < 0.05$) over the model trained with gold labels are marked with ‡.

BLEU	avg	parl	law	med	IT
multi-un	48.3	38.9	57.7	54.8	42.1
multi-up	48.6	36.7	57.1	56.8	43.9
KD-un	49.1	**39.3**	58.7	55.7	42.6

Table 7: BLEU scores on the DE→EN test data for the unbalanced and upsampled baselines, knowledge distillation (KD) models with a single teacher, and our multi-domain knowledge distillation (MDKD) models.

6 Ablations

6.1 Improvements Due to Distillation

Our proposed multi-domain knowledge distillation models train deep in-domain teachers and distill these teachers into the shallower students. In this section, we aim to understand how much of the gains seen from the MDKD models can be attributed to the knowledge distillation component. To this end, we train a knowledge distillation baseline model that builds a single deep teacher for the entire data. The training data is distilled using this teacher model and a student is trained on the concatenation of the distilled data and the original data, similarly to the MDKD models. We train unbalanced and upsampled teachers, from which we distill unbalanced and upsampled students, respectively.

Table 7 shows the BLEU scores on the DE→EN multi-domain test set for these single-domain knowledge distillation models, as well as for the MDKD models and the unbalanced and upsampled baselines. For both the unbalanced and upsampled cases, the single-domain knowledge distillation approach yields improvements in quality over the baseline, and the multi-domain knowledge distillation models give further improvements. This trend also broadly holds across individual domains. Thus, we attribute the improved quality of the MDKD models partially but not completely to the knowledge distillation component of the models.

BLEU	beam	greedy	Δ
multi-un	48.4	47.6	- 0.8
multi-up	48.6	47.8	- 0.8
fine-tuned	48.9	48.1	- 0.8
multi-tgt-tok	48.5	47.6	- 0.9
MDKD-un	49.8	49.2	- 0.6
MDKD-up	**50.0**	**49.4**	- 0.6

Table 8: BLEU scores for the DE→EN baselines and multi-domain knowledge distillation (MDKD) models using beam search (beam size 5) and greedy search during inference.

6.2 Inference Beam Size

Kim and Rush (2016) observed that student models trained using sequence-level knowledge distillation were able to use greedy search during inference time without loss in BLEU compared to beam search. In this section, we evaluate our DE→EN MDKD models and the baselines using both beam search (beam size 5) and greedy search. The results for these evaluations are in Table 8.

For baselines and for multi-domain knowledge distillation models, reducing beam size to 1 results in a drop in quality as measured by BLEU. However, that drop is slightly smaller for the knowledge distillation models (0.6 BLEU, as opposed to 0.8–0.9 BLEU), and the MDKD models with greedy search still outperform the baselines with beam search. For all models, beam search inference takes an average of 0.51 seconds per sentence on a single CPU while greedy search takes 0.30 seconds per sentence. Thus, greedy inference can be a viable setting for MDKD when there are strict latency requirements.

7 Related Work

Knowledge distillation was first introduced for classification tasks as a way to compress large networks or ensembles of networks into smaller models that achieve similar performance (Buciluă et al., 2006; Hinton et al., 2015). Kim and Rush (2016) extended this to neural machine translation, and since then many researchers have proposed further applications of sequence-level knowledge distillation for NMT, for example for non-autoregressive translation models (Gu et al., 2018; Zhou et al., 2020).

Most prior approaches to multi-domain neural machine translation (see Chu and Wang, 2018 for a survey) require knowledge of the input domain at test time. Kobus et al. (2017) used word-level and sentence-level domain tags on the source sentence. Similarly, Pham et al. (2019) performed multi-domain NMT by breaking the word embeddings into generic and domain-specific components. Michel and Neubig (2018a) trained speaker-specific NMT models by treating each speaker as a domain and adapting the softmax bias term for each domain. These models work well when the domain is known at training and inference time, but requiring labeled data at inference time is a major limitation in a real-world setting.

Britz et al. (2017) introduced the setup that we follow in this paper, where domains are known at training but not at inference. In addition to the target token approach evaluated in this paper, they trained a second model that adds a domain classifier on top of the NMT encoder; this achieved similar BLEU scores but is less parameter-efficient than their target token model. Farajian et al. (2017) considered a case where no domain labels are used at all; instead, a generic model is adapted on the fly using similar training sentences to the input. Our multi-domain knowledge distillation technique is architecture-agnostic and thus complementary to these approaches, since it can be combined with any multi-domain NMT model.

Knowledge distillation has been applied to NMT domain adaptation by Gordon and Duh (2020), who used a domain-specific teacher and a generic teacher to improve domain-adapted expert models. Most similar to our MDKD approach is the application of knowledge distillation to multilingual NMT by Tan et al. (2019), who trained single-language teacher models and then distilled these models to a multilingual student model. Knowledge distillation has also been previously applied to domain-aware NMT by Gwinnup et al. (2017). However, unlike our work, they did not train domain-specific teachers; instead, they used source factors like domain and casing information to inform a single teacher model. Concurrently to our work, Mghabbar and Ratnamogan (2020) also proposed multi-domain knowledge distillation using domain-specific teachers and a domain-agnostic student. Their method differs from ours in several aspects, including our use of sequence-level knowledge distillation, domain-specific distillation data, and single-best distillation outputs for each training sentence. Our work and Mghabbar and Ratnamogan (2020) are complementary, as both propose different effective approaches for leveraging knowledge distillation to train multi-domain NMT.

8 Conclusions

We have introduced multi-domain knowledge distillation, a new method for multi-domain NMT that distills multiple expert models into a single student that shows high quality across all domains. We have kept both model architecture and capacity fixed and shown that MDKD leads to significantly better multi-domain models without any increase in translation time or memory usage. Since the approach is architecture-independent, it is easy to combine with other multi-domain NMT models. In this paper, we have fixed the depth and the architecture of the teachers; however, improving the teachers using different architectures may also lead to better empirical results.

Our experiments have covered two data quality conditions: when the domains are well-defined and separable, individually trained deep domain experts outperform all the multi-domain baselines and MDKD bridges a large portion of the gap between these baselines and the deep experts. A second set of experiments has revealed a dataset for which the domains were not clearly separable and some domains exhibited train/test mismatches. In this setting, training domain-specific expert models is not a robust strategy, as the expert models performed significantly worse that the baselines. Despite using distillation from these experts, MDKD was very robust to this noisy setting: not only was there no quality degradation, but we even observed modest improvements over the baselines.

Finally, we performed experiments in which we assumed that the domain labels are unknown and are obtained through clustering of the train data. The resulting MDKD models outperformed the baselines again, showing that gold domain labels are not strictly needed. For future work, we plan to expand the automatic domain induction methods and test the MDKD framework on generic MT with data exhibiting varying degrees of heterogeneity: as MDKD distills domain-specific models to create multiple simpler data distributions, we want to investigate if inducing train-time specializations and using them for distillation through MDKD can lead to better quality.

Acknowledgments

We would like to thank Miguel Ballesteros, Benjie Genchel, Steve Sloto, and Yogarshi Vyas for their valuable feedback on this paper. We also thank the anonymous reviewers for their helpful comments and suggestions.

A Sample MDKD Outputs

When manually comparing the outputs of the multi-unbalanced baseline system and the MDKD-unbalanced system, we noticed that the MDKD-unbalanced system had a tendency to translate domain-specific words and collocations more accurately. Table 9 shows two examples of this phenomenon, one from the law domain and the other from the medical domain. For the law domain, *specifically prohibited* is much more common than *expressly prohibited* in the in-domain training data, but this trend reverses for the unbalanced training data as a whole. This similarly holds for the medical domain, where *coronary* and *artery* are more common in the in-domain data than in the whole unbalanced training corpus, whereas *heart* and *vessels* are more common in the whole training corpus. In the future, we would like to analyze this in a systematic way to see whether our observation that the MDKD models improve translation of domain-specific vocabulary holds on a larger scale.

B Additional Ablation Experiments

B.1 Effect of the Quality of the Distilled Data

In sections 4 and 5, we generate the distilled data from the teacher models by running inference with a beam of size 10. This is a relatively costly step in training the multi-domain knowledge distillation models. Therefore, we would like to better understand how the quality of the distilled data affects the student model translation quality, and in particular whether it is possible to achieve similar results with smaller beam size during distillation.

For each of the DE→EN single-domain teachers, we distill the in-domain training data with greedy search (beam size 1) and with beam sizes 5 and 10. We then train MDKD-unbalanced and MDKD-upsampled student models with this distilled data (concatenated with the original data).

The average BLEU scores over the test data for each of these student models are shown in Table 10. Decreasing the beam size when generating the distilled data generally results in a small decrease in BLEU score for the student model trained on that distilled data: 0.2–0.4 BLEU when going from a beam size of 10 to greedy search. However, the improvement in quality from a larger beam comes with a trade-off in training time, since inference with beam size 10 takes longer than with beam size 1. In our experiments, distillation with beam size 10 took roughly six times as long as greedy distillation.

B.2 Tagging Original vs. Distilled Data

Caswell et al. (2019) showed that when using back-translated data it is beneficial to prepend

	domain: law
source	Sofern in dem obengenannten Abkommen nicht **ausdrücklich untersagt** (. . .)
baseline	Unless **expressly prohibited** in the abovementioned Agreement (. . .)
MDKD	Unless **specifically prohibited** in the abovementioned Agreement (. . .)
reference	Unless **specifically prohibited** in the Agreement referred to above (. . .)

	domain: medical
source	Stabile Erkrankung der **Herzkranzgefäße**
baseline	Stable disease of the **heart vessels**
MDKD	Stable **coronary artery** disease
reference	Stable **coronary artery** disease

Table 9: Translation outputs from the unbalanced baseline model and the MDKD-unbalanced model for two sample sentences from the EN→DE test set.

dist. beam	MDKD-un	MDKD-up
1	49.4	49.8
5	49.5	**50.1**
10	**49.8**	50.0

Table 10: Unweighted average BLEU scores on the test data for DE→EN MDKD models. We show results for different beam sizes used to generate the distilled data that is used to train the student models.

train tags?	inference tag	BLEU
no	N/A	**49.8**
yes	original	**49.8**
yes	distilled	49.5

Table 11: Unweighted average BLEU scores on the test data for DE→EN MDKD unbalanced model trained with and without source-side tags indicating whether the data is original or distilled. For the model trained with source tags, we run inference both by marking the source data as "original" (row 2) and by marking it as "distilled" (row 3).

tags to the source training sentences indicating whether they are back-translated. Since our multi-domain student models are trained on both original and distilled (forward-translated) data, we evaluate whether tagging the training data as original/distilled leads to improvements in quality.

We evaluate source-side original/distilled data tags on our DE→EN MDKD-unbalanced model. During training, we tag all data as either original or distilled. We run inference both by tagging the source test data as "original" and by tagging it as "distilled."

The results for these experiments are in Table 11. Tagging the student model training data does not result in a significant difference in BLEU. Thus, in our main experiments, we did not tag the training data.

B.3 Optimal Number of Clusters

For cases where we are given a large-scale heterogeneous training corpus with no domain labels, the ideal number of clusters is unclear. We did an initial clustering experiment with a hierarchical DBScan (HDBScan) algorithm (Campello et al., 2013) on the training data without defining number of clusters for EN→FR. Once trained on the sentence embeddings from mBERT, HDBScan created 342 clusters. It is computationally expensive to build 342 teacher models (one for each cluster), so we leave the exploration of optimal number of clusters for MDKD as future work.

Making Monolingual Sentence Embeddings Multilingual using Knowledge Distillation

Nils Reimers and Iryna Gurevych
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technische Universität Darmstadt
`www.ukp.tu-darmstadt.de`

Abstract

We present an easy and efficient method to extend existing sentence embedding models to new languages. This allows to create multilingual versions from previously monolingual models. The training is based on the idea that a translated sentence should be mapped to the same location in the vector space as the original sentence. We use the original (monolingual) model to generate sentence embeddings for the source language and then train a new system on translated sentences to mimic the original model. Compared to other methods for training multilingual sentence embeddings, this approach has several advantages: It is easy to extend existing models with relatively few samples to new languages, it is easier to ensure desired properties for the vector space, and the hardware requirements for training are lower. We demonstrate the effectiveness of our approach for 50+ languages from various language families. Code to extend sentence embeddings models to more than 400 languages is publicly available.[1]

1 Introduction

Mapping sentences or short text paragraphs to a dense vector space, such that similar sentences are close, has wide applications in NLP. However, most existing sentence embeddings models are monolingual, usually only for English, as applicable training data for other languages is scarce. For multi- and cross-lingual scenarios, only few sentence embeddings models exist.

In this publication, we present a new method that allows us to extend existing sentence embeddings models to new languages. We require a teacher model M for source language s and a set of parallel (translated) sentences $((s_1, t_1), ..., (s_n, t_n))$ with t_i the translation of s_i. Note, the t_i can be in different languages. We train a new student model $\hat{M}$ such that $\hat{M}(s_i) \approx M(s_i)$ and $\hat{M}(t_i) \approx M(s_i)$ using mean squared loss. We call this approach **multilingual knowledge distillation**, as the student $\hat{M}$ distills the knowledge of the teacher M in a multilingual setup. We demonstrate that this type of training works for various language combinations as well as for multilingual setups. We observe an especially high improvement of up to 40 accuracy points for low resource languages compared to LASER (Artetxe and Schwenk, 2019b).

The student model $\hat{M}$ learns a multilingual sentence embedding space with two important properties: 1) Vector spaces are aligned across languages, i.e., identical sentences in different languages are close, 2) vector space properties in the original source language from the teacher model M are adopted and transferred to other languages.

The presented approach has various advantages compared to other training approaches for multilingual sentence embeddings. LASER (Artetxe and Schwenk, 2019b) trains an encoder-decoder LSTM model using a **translation task**. The output of the encoder is used as sentence embedding. While LASER works well for identifying exact translations in different languages, it works less well for assessing the similarity of sentences that are not exact translations.

Multilingual Universal Sentence Encoder (mUSE) (Chidambaram et al., 2019; Yang et al., 2019) was trained in a multi-task setup on SNLI (Bowman et al., 2015) and on over a billion question-answer pairs from popular online forums and QA websites. In order to align the cross-lingual vector spaces, mUSE used a **translation ranking task**. Given a translation pair (s_i, t_i) and various alternative (incorrect) translations, identify the correct translation. First, multi-task learning is difficult since it can suffer from catastrophic forgetting and balancing multiple

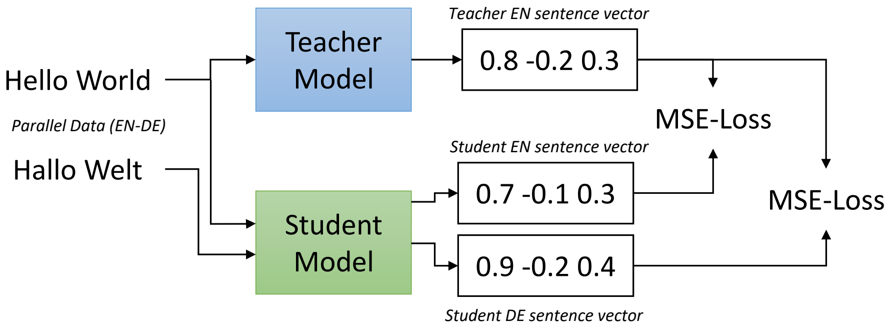

Figure 1: Given parallel data (e.g. English and German), train the student model such that the produced vectors for the English and German sentences are close to the teacher English sentence vector.

tasks is not straight-forward. Further, running the *translation ranking task* is complex and results in a huge computational overhead. Selecting random alternative translations usually leads to mediocre results. Instead, *hard negatives* (Guo et al., 2018) are required, i.e., alternative incorrect translations that have a high similarity to the correct translation. To get these hard negatives, mUSE was first trained with random negatives samples, then, this preliminary sentence encoder was used to identify hard negative examples. They then re-trained the network.

In this work, we use Sentence-BERT (SBERT) (Reimers and Gurevych, 2019), which achieves state-of-the-art performance for various sentence embeddings task. SBERT is based on transformer models like BERT (Devlin et al., 2018) and applies mean pooling on the output. In our experiments we use XLM-R (Conneau et al., 2019), a pre-trained network on 100 languages, as student model. Note, the described approach is not limited to be used with transformer models and should also work with other network architectures.

2 Training

We require a teacher model M, that maps sentences in one or more source languages s to a dense vector space. Further, we need parallel (translated) sentences $((s_1, t_1), ..., (s_n, t_n))$ with s_i a sentence in one of the source languages and t_i a sentence in one of the target languages.

We train a student model $\hat{M}$ such that $\hat{M}(s_i) \approx M(s_i)$ and $\hat{M}(t_i) \approx M(s_i)$. For a given mini-batch $\mathcal{B}$, we minimize the mean-squared loss:

$$\frac{1}{|\mathcal{B}|}\sum_{j\in\mathcal{B}}\left[(M(s_j)-\hat{M}(s_j))^2+(M(s_j)-\hat{M}(t_j))^2\right]$$

$\hat{M}$ could have the structure and the weights of M, or it can be a different network architecture. This training procedure is illustrated in Figure 1. We denote trained models with $\hat{M} \leftarrow M$, as the student model $\hat{M}$ learns the representation of the teacher model M.

In our experiments, we mainly use an English SBERT model as teacher model M and use XLM-RoBERTa (XLM-R) as student model $\hat{M}$. The English BERT models have a wordpiece vocabulary size of 30k mainly consisting of English tokens. Using the English SBERT model as initialization for $\hat{M}$ would be suboptimal, as most words in other latin-based languages would be broken down to short character sequences, and words in non-latin alphabets would be mapped to the `UNK` token. In contrast, XLM-R uses SentencePiece[2], which avoids language specific pre-processing. Further, it uses a vocabulary with 250k entries from 100 different languages. This makes XLM-R much more suitable for the initialization of the multilingual student model.

3 Training Data

In this section, we evaluate the importance of training data for making the sentence embedding model multilingual. The OPUS website[3] (Tiedemann, 2012) provides parallel data for hundreds of language pairs. In our experiments, we use the following datasets:

- **GlobalVoices:** A parallel corpus of news stories from the web site Global Voices.
- **TED2020:** We crawled the translated subti-

---

[2] `https://github.com/google/sentencepiece`

[3] `http://opus.nlpl.eu/`

tles for about 4,000 TED talks, available in over 100 languages. This dataset is available in our repository.

- **NewsCommentary:** Political and economic commentary crawled from the web site Project Syndicate, provided by WMT.
- **WikiMatrix:** Mined parallel sentences from Wikipedia in different languages (Schwenk et al., 2019). We only used pairs with scores above 1.05, as pairs below this threshold were often of bad quality.
- **Tatoeba:** Tatoeba[4] is a large database of example sentences and translations to support language learning.
- **Europarl:** Parallel sentences extracted from the European Parliament website (Koehn, 2005).
- **JW300:** Mined, parallel sentences from the magazines *Awake!* and *Watchtower* (Agić and Vulić, 2019).
- **OpenSubtitles2018:** Translated movie subtitles from opensubtitles.org (Lison and Tiedemann, 2016).
- **UNPC:** Manually translated United Nations documents from 1994 - 2014 (Ziemski et al., 2016).

Getting parallel sentence data can be challenging for some low-resource language pairs. Hence, we also experiment with bilingual dictionaries:

- **MUSE:** MUSE[5] provides 110 large-scale ground-truth bilingual dictionaries created by an internal translation tool (Conneau et al., 2017b).
- **Wikititles:** We use the Wikipedia database dumps to extract the article titles from cross-language links between Wikipedia articles. For example, the page "United States" links to the German page "Vereinigte Staaten". This gives a dictionary covering a wide range of topics.

The data set sizes for English-German (EN-DE) and English-Arabic (EN-AR) are depicted in Table 5. For training, we balance the data set sizes by drawing for a mini batch roughly the same number of samples from each data set. Data from smaller data sets is repeated.

We trained XLM-R as our student model and used SBERT fine-tuned on English NLI and STS data[6] as our teacher model. We trained for a maximum of 20 epochs with batch size 64, 10,000 warm-up steps, and a learning rate of 2e-5. As development set, we measured the MSE loss on hold-out parallel sentences.

In (Reimers and Gurevych, 2017, 2018), we showed that the random seed can have a large impact on the performances of trained models, especially for small datasets. In the following experiments, we have quite large datasets of up to several million parallel sentences and we observed rather minor differences ($\sim$ 0.3 score points) between random seeds.

4 Experiments

In this section, we conduct experiments on three tasks: Multi- and cross-lingual semantic textual similarity (STS), bitext retrieval, and cross-lingual similarity search. STS assigns a score for a pair of sentences, while bitext retrieval identifies parallel (translated) sentences from two large monolingual corpora.

Note, evaluating the capability of different strategies to align vector spaces across languages is non-trivial. The performance for cross-lingual tasks depends on the ability to map sentences across languages to one vector space (usually the vector space for English) as well as on the properties this source vector space has. Differences in performance can then be due to a better or worse alignment between the languages or due to different properties of the (source) vector space.

We evaluate the following systems:

SBERT-nli-stsb: The output of the BERT-base model is combined with mean pooling to create a fixed-sized sentence representation (Reimers and Gurevych, 2019). It was fine-tuned on the English AllNLI (SNLI (Bowman et al., 2015) and Multi-NLI (Williams et al., 2018)) dataset and on the English training set of the STS benchmark (Cer et al., 2017) using a siamese network structure.

---

[6] bert-base-nli-stsb-mean-tokens model from our repository

mBERT / XLM-R mean: Mean pooling of the outputs for the pre-trained multilingual BERT (mBERT) and XLM-R model. These models are pre-trained on multilingual data and have a multilingual vocabulary. However, no parallel data was used.

mBERT- / XLM-R-nli-stsb: We fine-tuned XLM-R and mBERT on the (English) AllNLI and the (English) training set of the STS benchmark.

LASER: LASER (Artetxe and Schwenk, 2019b) uses max-pooling over the output of a stacked LSTM-encoder. The encoder was trained in an encoder-decoder setup (machine translation setup) on parallel corpora over 93 languages.

mUSE: Multilingual Universal Sentence Encoder (Chidambaram et al., 2019) uses a dual-encoder transformer architecture and was trained on mined question-answer pairs, SNLI data, translated SNLI data, and parallel corpora over 16 languages.

LaBSE: Language-agnostic BERT Sentence Embedding (LaBSE) (Feng et al., 2020) was trained similar to mUSE with a dual-encoder transformer architecture based on BERT with 6 Billion translation pairs for 109 languages.

mBERT- / DistilmBERT- / XLM-R ← SBERT-nli-stsb: We learn mBERT, DistilmBERT, and XLM-R to imitate the output of the English SBERT-nli-stsb model.

XLM-R ← SBERT-paraphrases: We train XLM-R to imitate SBERT-paraphrases, a RoBERTa model trained on more than 50 Million English paraphrase pairs.

For our multi-lingual knowledge distillation experiments, we trained a single model with parallel data for 50 languages[7].

4.1 Multilingual Semantic Textual Similarity

The goal of semantic textual similarity (STS) is to assign for a pair of sentences a score indicating their semantic similarity. For example, a score of 0 indicates *not related* and 5 indicates *semantically equivalent*.

The multilingual STS 2017 dataset (Cer et al., 2017) contains annotated pairs for EN-EN, AR-AR, ES-ES, EN-AR, EN-ES, EN-TR. We extend this dataset by translating one sentence of each pair in the EN-EN dataset to German. Further, we use Google Translate to create the datasets EN-FR, EN-IT, and EN-NL. Samples of these machine translated versions have been checked by humans fluent in that language.

For the generate sentence embeddings we compute cosine similarity and, as recommended in (Reimers et al., 2016), compute the Spearman's rank correlation ρ between the computed score and the gold score.

Table 1 shows the results for the monolingual setup and Table 2 the cross-lingual setup.

As shown before (Reimers and Gurevych, 2019), using mBERT / XLM-R without fine-tuning yields rather poor performance. Training on English NLI & STS data (*mBERT/XLM-nli-stsb*) significantly improves the performance also for the other languages. While in the monolingual setup (Table 1) the performance is quite competitive, we observe a significant drop for the cross-lingual setup (Table 2). This indicates that the vectors spaces are not well aligned across languages.

Using our multilingual knowledge distillation approach, we observe state-of-the-art performances for mono- as well as for the cross-lingual setup, significantly outperforming other state-of-the-art models (LASER, mUSE, LaBSE). Even though *SBERT-nli-stsb* was trained on the STSbenchmark train set, we observe the best performance by *SBERT-paraphrase*, which was not trained with any STS dataset. Instead, it was trained on a large and broad paraphrase corpus, mainly derived from Wikipedia, which generalizes well to various topics.

In our experiments, XLM-R is slightly ahead of mBERT and DistilmBERT. mBERT and DistilmBERT use different language-specific tokenization tools, making those models more difficult to be used on raw text. In contrast, XLM-R uses a SentencePiece model that can be applied directly on raw text data for all languages. Hence, in the following experiments we only report results for XLM-R.

4.2 BUCC: Bitext Retrieval

Bitext retrieval aims to identify sentence pairs that are translations in two corpora in different languages. Guo et al. (2018) showed that computing the cosine similarity of all sentence embeddings and to use nearest neighbor retrieval with a threshold has certain issues.

For our experiments, we use the BUCC bitext

Table 2: Spearman rank correlation ρ between the cosine similarity of sentence representations and the gold labels for STS 2017 dataset. Performance is reported by convention as $\rho \times 100$.

retrieval code from LASER[8] with the scoring function from Artetxe and Schwenk (2019a):

$$\text{score}(x, y) = \text{margin}(\cos(x, y),$$
$$\sum_{z \in \text{NN}_k(x)} \frac{cos(x, z)}{2k} + \sum_{z \in \text{NN}_k(y)} \frac{cos(y, z)}{2k}$$

with x, y the two sentence embeddings and $\text{NN}_k(x)$ denoting the k nearest neighbors of x in the other language[9]. As margin function, we use $\text{margin}(a, b) = a/b$.

We use the dataset from the BUCC mining task (Zweigenbaum et al., 2017, 2018), with the goal of extracting parallel sentences between an English corpus and four other languages: German, French, Russian, and Chinese. The corpora consist of 150K - 1.2M sentences for each language with about 2-3% of the sentences being parallel. The data is split into training and test sets. The training set is used to find a threshold for the score function. Pairs above the threshold are returned as parallel sentences. Performance is measured using F_1 score.

Results are shown in Table 3. Using mean pooling directly on mBERT / XLM-R produces low scores. While training on English NLI and STS data improves the performance for XLM-R (XLM-R-nli-stsb), it reduces the performance for mBERT. It is unclear why mBERT mean and XLM-R mean produce vastly different scores and why training on NLI data improves the cross-lingual performance for XLM-R, while reducing the performance for mBERT. As before, we observe that mBERT / XLM-R do not have well aligned vector spaces and training only on English data is not sufficient.

Using our multilingual knowledge distillation method, we were able to significantly improve the performance compared to the mBERT / XLM-R model trained only on English data.

While LASER and LaBSE only achieve mediocre results on the STS 2017 dataset, they

achieve state-of-the-art performances on BUCC outperforming mUSE and our approach. LASER and LaBSE were specifically designed to identify perfect translations across languages. However, as the STS 2017 results show, these models have issues assigning meaningful similarity scores for sentence pairs that don't have identical meaning.

In contrast, mUSE and our approach creates vector spaces such that semantically similar sentences are close. However, sentences with similar meanings must not be translations of each other. For example, in the BUCC setup, the following pair is not labeled as parallel text:

- Olympischen Jugend-Sommerspiele fanden vom 16. bis 28. August 2014 in Nanjing (China) statt. (en: *Summer Youth Olympic Games took place from August 16 to 28, 2014 in Nanjing (China)*)
- China hosted the 2014 Youth Olympic Games.

Both sentences are semantically similar, hence our model and mUSE assign a high similarity score. But the pair is not a translation, as some details are missing (exact dates and location).

These results stress the point that there is no single sentence vector space universally suitable for every application. For finding translation pairs in two corpora, LASER and LaBSE would be the best choice. However, for the task of finding semantically similar sentence pairs, our approach and mUSE would be the better choices.

We noticed that several positive pairs are missing in the BUCC dataset. We analyzed for SBERT, mUSE, and LASER 20 false positive DE-EN pairs each, i.e., we analyzed pairs with high similarities according to the embeddings method but which are not translations according to the dataset. For 57 out of 60 pairs, we would judge them as valid, high-quality translations. This issue comes from the way BUCC was constructed: It consists of a parallel part, drawn from the News Commentary dataset, and sentences drawn from Wikipedia, which are judged as non-parallel. However, it is not ensured that the sentences from Wikipedia are in fact non-parallel. The systems successfully returned parallel pairs from the Wikipedia part of the dataset. Results based on the BUCC dataset should be judged with care. It is unclear how many parallel sentences are in the Wikipedia part of the dataset and how this affects the scores.

4.3 Tatoeba: Similarity Search

In this section, we evaluate the strategy for lower resource languages, where it can be especially challenging to get well-aligned sentence embeddings. For evaluation, we use the Tatoeba test setup from LASER (Artetxe and Schwenk, 2019b): The dataset consists of up to 1,000 English-aligned sentence pairs for various languages. Evaluation is done by finding for all sentences the most similar sentence in the other language using cosine similarity. Accuracy is computed for both directions (English to the other language and back).

As before, we fine-tune XLM-R with SBERT-nli-stsb as teacher model. As training data, we use JW300, which covers over 300 languages. To make our results comparable to LASER, we reduce the training data to the same amount as used by LASER. We selected four languages with rather small parallel datasets: Georgian (KA, 296k parallel sentence pairs), Swahili (SW, 173k), Tagalog (TL, 36k), and Tatar (TT, 119k). Tagalog and Tatar were not part of the 100 languages XLM-R was pre-trained for, i.e., XLM-R has no specific vocabulary and the language model was not tuned for these languages.

As Table 4 shows, we observe a significant accuracy improvement compared to LASER, indicating

Model	KA	SW	TL	TT
LASER				
en → xx	39.7	54.4	52.6	28.0
xx → en	32.2	60.8	48.5	34.3
XLM-R ← SBERT-nli-stsb				
en → xx	73.1	85.4	86.2	54.5
xx → en	71.7	86.7	84.0	52.3

Table 4: Accuracy on the Tatoeba test set in both directions (en to target language and vice versa).

much better aligned vector spaces between English and these languages. Even though Tagalog had the smallest dataset with 36k pairs and that XLM-R was not pre-trained for this language, we achieve high accuracy scores of 86.2 and 84.0. We conclude that our strategy also works for low resource languages and can yield a significant improvement. The results for all languages in the Tatoeba test set can be found in the appendix.

5 Evaluation of Training Datasets

To evaluate the suitability of the different training sets, we trained bilingual XLM-R models for EN-DE and EN-AR on the described training datasets. English and German are fairly similar languages and have a large overlap in their alphabets, while English and Arabic are dissimilar languages with distinct alphabets. We evaluate the performance on the STS 2017 dataset.

The results for training on the full datasets are shown in Table 5. Table 6 shows the results for training only on the first k sentences of the TED2020 dataset.

First, we observe that the bilingual models are slightly better than the model trained for 10 languages (section 4.1): 2.2 points improvement for EN-DE and 1.2 points improvement for EN-AR. Conneau et al. (2019) calls this *curse of multilinguality*, where adding more languages to a model can degrade the performance as the capacity of the model remains the same.

For EN-DE we observe only minor differences between the datasets. It appears that the domain of the training data (news, subtitles, parliamentary debates, magazines) is of minor importance. Further, only little training data is necessary.

For the dissimilar languages English and Arabic, the results are less conclusive. Table 5 shows that more data does not necessarily lead to better results. With the Tatoeba dataset (only 27,000 parallel sentences), we achieve a score of 76.7, while with the UNPC dataset (over 8 Million sentences), we achieve only a score of 66.1. The domain of the parallel sentences is of higher importance. The results on the reduced TED2020 dataset (Table 6) show that the score improves slower for EN-AR than for EN-DE with more data.

Dataset	#DE	EN-DE	#AR	EN-AR
XLM-R mean	-	21.3	-	17.4

6 Target Language Training

In this section we evaluate whether it is better to transfer an English model to a certain target language or if training from-scratch on suitable datasets in the target language yields better results.

For this, we use the KorNLI and KorSTS datasets from Ham et al. (2020). They translated the English SNLI (Bowman et al., 2015), MultiNLI (Williams et al., 2018), and STSbenchmark (STSb) (Cer et al., 2017) datasets to Korean with an internal machine translation system. The dev and tests were post-edited by professional translators.

Ham et al. fine-tuned Korean RoBERTa and XLM-R on these datasets using the SBERT framework. We use the translated sentences they provide and tuned XLM-R using multilingual knowledge distillation. We use SBERT-nli-stsb as teacher model. Results are shown in Table 7.

Model	KO-KO
LASER	68.44
mUSE	76.32
Trained on KorNLI & KorSTS	
Korean RoBERTa-base	80.29
Korean RoBERTa-large	80.49
XLM-R	79.19
XLM-R-large	81.84
Multiling. Knowledge Distillation	
XLM-R ← SBERT-nli-stsb	81.47
XLM-R-large ← SBERT-large-nli-stsb	83.00

Table 7: Spearman rank correlation on Korean STS-benchmark test-set (Ham et al., 2020).

We observe a slight improvement of using multilingual knowledge distillation over training the models directly on the translated NLI and STS data. This is great news: Training on the Korean datasets yields a model only for Korean, while with multilingual knowledge distillation, we get a model for English and Korean with aligned vector spaces. Further, we do not necessarily have a performance drop if there is only training data for the sentence embedding method in English available.

7 Language Bias

Roy et al. (2020) introduces the concept of *language bias*: A model prefers one language or language pair over others. For example, a model would have a language bias if it maps sentences in the same language closer in vector space just because they are of the same language. Language bias can be an issue if the task involves a multilingual sentence pool: certain language pairs might get discriminated, potentially harming the overall performance for multilingual sentence pools.

Figure 2 shows the plot of the first two principle components for different multi-lingual sentence embeddings methods. In the plot, we encoded the English premise sentences from XNLI (Conneau et al., 2018) with their Russian translation. The plot shows for the LaBSE model a drastic separation between the two languages, indicating that the language significantly impacts the resulting embedding vector.

The experiments in Section 4 used so far mono-lingual sentence pools, i.e., all sentences in the source / target pool were of the same language. Hence, these benchmarks are not suited to measure a potential harmful effect from language bias. In order to measure a potential negative effect from language bias, we combine all sentence pairs from the multilingual STS dataset and compute similarity scores as described in Section 4.1. Note, in Section 4.1, the models had only to score e.g. EN-AR sentence pairs. Now, there are 10 language combinations in one joined set. A model without language bias would achieve on this joined set a performance similar to the average of the performances over the individual subsets. However, if a model has a language bias, sentence pairs from specific language combinations will be ranked higher than others, lowering the Spearman rank correlation for the joint set.

The results are depicted in Table 8. We observe that LaBSE has a difference of -1.29 and LASER has a difference of -0.92. Both scores are statistically significant with confidence $p < 0.001$. LASER and LaBSE both have a language bias which decrease the performance on multilingual pools compared to mono-lingual pools. In contrast, mUSE and the proposed multilingual knowledge distillation have a minor, statistically insignificant language bias. There, the performance for the joined set only decreases by -0.19 and -0.11 compared to the evaluation on the individual sets.

In summary, mUSE and the proposed multilingual knowledge distillation approach can be used on multilingual sentence pools without a negative performance impact from language bias, while LASER and LaBSE prefer certain language combinations over other, impacting the overall result.

8 Related Work

Sentence embeddings are a well studied area with dozens of proposed methods (Kiros et al., 2015; Conneau et al., 2017a; Cer et al., 2018; Yang et al., 2018). Most of the methods have in common that they were only trained on English. Multilingual representations have attracted significant attention in recent times. Most of it focuses on cross-lingual word embeddings (Ruder, 2017). A common approach is to train word embeddings for each language separately and to learn a linear transformation that maps them to a shared space based on a bilingual dictionary (Artetxe et al., 2018). This mapping can also be learned without parallel data (Conneau et al., 2017b; Lample et al., 2018).

A straightforward approach for creating cross-lingual sentence embeddings is to use a bag-of-words representation of cross-lingual word embeddings. However, Conneau et al. (2018) showed that this approach works poorly in practical cross-lingual transfer settings. LASER (Artetxe and

Model	Expected Score	Actual Score	Difference
LASER	69.5	68.6	-0.92
mUSE	81.7	81.6	-0.19
LaBSE	74.4	73.1	-1.29
XLM-R ← SBERT-paraphrases	84.0	83.9	-0.11

Table 8: Spearman rank correlation for the multilingual STS dataset. Expected score is the average over the performance on the individual sets (Table 1 & 2). Actual score is the correlation for one joined set of sentence pairs. Models without language bias would score on the joined set similar to the average over the individual sets. The difference shows the negative impact from the language bias.

Schwenk, 2019b) uses a sequence-to-sequence encoder-decoder architecture (Sutskever et al., 2014) based on LSTM networks. It trains on parallel corpora from neural machine translation. To create a fixed sized sentence representation, they apply max-pooling over the output of the encoder. LASER was trained for 93 languages on 16 NVIDIA V100 GPUs for about 5 days.

Multilingual Universal Sentence Encoder (mUSE)[10] (Chidambaram et al., 2019; Yang et al., 2019) uses a dual-encoder architecture. It was trained in a multi-task setup on SNLI (Bowman et al., 2015) and over 1 Billion crawled question-answer pairs from various communities. A translation ranking task was applied: Given a sentence in the source language and a set of sentences in the target languages, identify the correct translation pair. To work well, hard negative examples (similar, but incorrect translations) must be included in the ranking task. mUSE was trained for 16 languages with 30 million steps. LaBSE (Feng et al., 2020) is based on a BERT architecture and used masked language model and 6 Billion translation pairs for training. It was trained similar to mUSE with a translation ranking loss, however, without any other training data.

In this publication, we extended Sentence-BERT (SBERT) (Reimers and Gurevych, 2019). SBERT is based on transformer models like BERT (Devlin et al., 2018) and fine-tunes those using a siamese network structure. By using the pre-trained weights from BERT, suitable sentence embeddings methods can be trained efficiently. Multilingual BERT (mBERT) was trained on 104 languages using Wikipedia, while XLM-R (Conneau et al., 2019) was trained on 100 languages using CommonCrawl. mBERT and XLM-R were not trained on any parallel data, hence, their vector spaces are not aligned.

9 Conclusion

We presented a method to make monolingual sentence embeddings multilingual with aligned vector spaces between the languages. This was achieved by using *multilingual knowledge distillation*. We demonstrated that this approach successfully transfers properties from the source language vector space (in our case English) to various target languages. Models can be extended to multiple languages in the same training process.

This stepwise training approach has the advantage that an embedding model with desired properties, for example for clustering, can first be created for a high-resource language. Then, in an independent step, it can be extended to support further languages. This decoupling significantly simplifies the training procedure compared to previous approaches. Further, it minimizes the potential language bias of the resulting model.

We extensively tested the approach for various languages from different language families. We observe that LASER and LaBSE work well for retrieving exact translations, however, they work less well assessing the similarity of sentence pairs that are not exact translations. Further, we noticed that LASER and LaBSE show a language bias, preferring some language combinations over other.

Appendix

A Tatoeba Similarity Search

LASER (Artetxe and Schwenk, 2019b) introduces the Tatoeba test set: It consists of up to 1,000 English-aligned sentence pairs for various languages. Evaluation is done by finding for all sentences the most similar sentence in the other language using cosine similarity. Accuracy is computed for both directions (English to the other language and back). As the two scores are usually quite close, we report the average of the scores here.

For our multi-lingual knowledge distillation, we exclude all training data from Tatoeba. This is in contrast to LASER, which used Tatoeba also for training. As the overlap between the Tatoeba test and train set is enormous, this bears the risk that the scores for LASER are artificially high. For mUSE and LaBSE, it is unknown whether they used any parallel data crawled from the Tatoeba website.

Table 9 shows the results for the languages we had parallel training data. We achieve accuracy scores usually in the 90th. Note mUSE is only available for 16 languages, hence, we also tested multilingual knowledge distillation using DistilmBERT as student and mUSE as teacher. We report this as DistilmBERT ← mUSE in the table.

For the languages which we did not use any parallel data (Table), the scores show a much larger variance. But overall, the scores for languages without parallel data are in most cases low. This is expected, as the model did not learn how to align for these languages. Note, LaBSE and LASER had seen training data for most of the languages in Table .

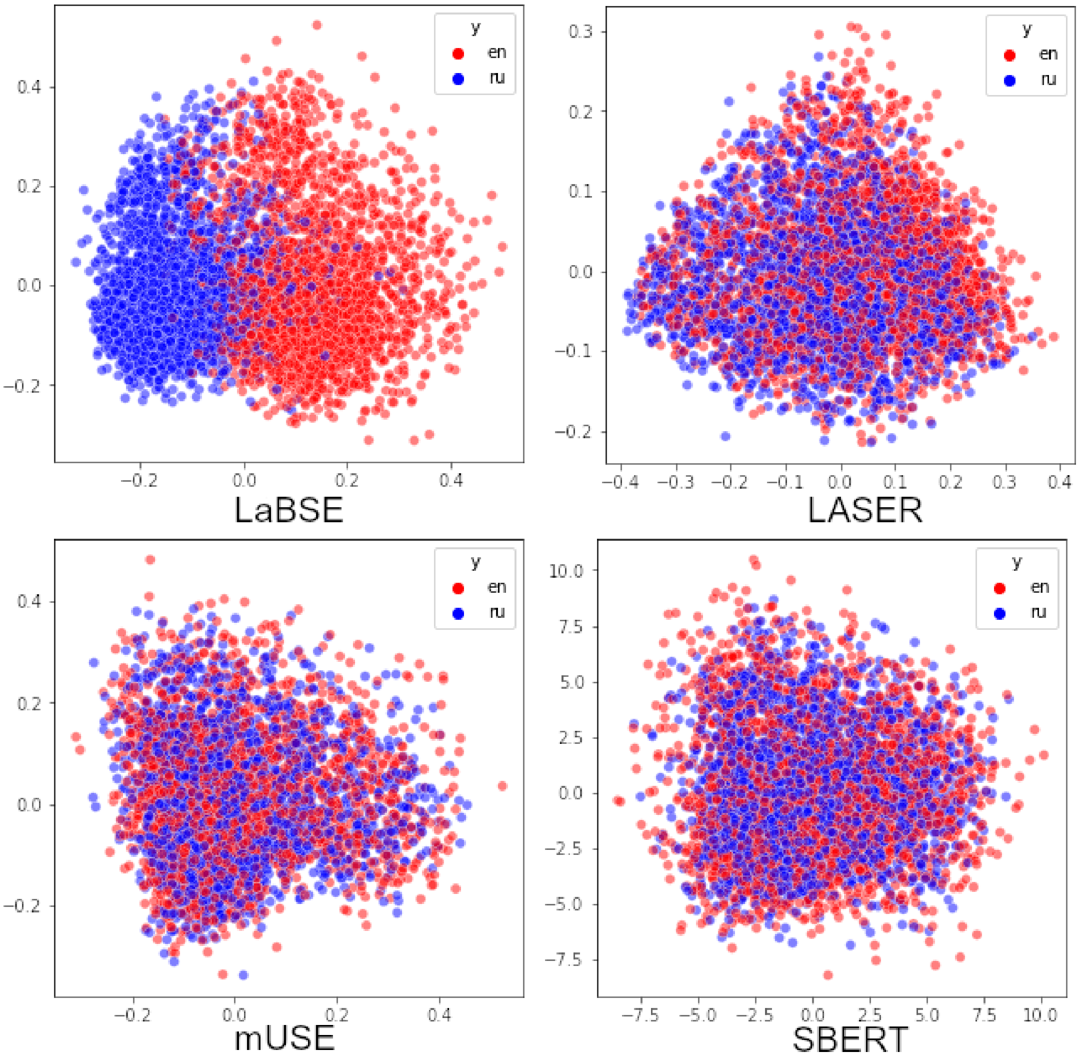

Figure 2: First two principle components for parallel sentences in English and Russian. For LaBSE, we observe a strong separation between the vector spaces, i.e., it is more biased for same language pairs. mUSE and the proposed multilingual knowledge distillation approach show nearly no language bias.

A Streaming Approach For Efficient Batched Beam Search

Kevin Yang, Violet Yao, John DeNero, Dan Klein

UC Berkeley

{yangk,violetyao,denero,klein}@berkeley.edu

Abstract

We propose an efficient batching strategy for variable-length decoding on GPU architectures. During decoding, when candidates terminate or are pruned according to heuristics, our streaming approach periodically "refills" the batch before proceeding with a selected subset of candidates. We apply our method to variable-width beam search on a state-of-the-art machine translation model. Our method decreases runtime by up to 71% compared to a fixed-width beam search baseline and 17% compared to a variable-width baseline, while matching baselines' BLEU. Finally, experiments show that our method can speed up decoding in other domains, such as semantic and syntactic parsing.

1 Introduction

While inference is often cheap compared to training in modern neural models, one may need to run inference frequently or continually. Such is the case for online machine translation (MT) services: as far back as 2016, Google Translate already translated 100 billion words daily (Turovsky, 2016). Large-scale inference is also required for methods such as iterative backtranslation and knowledge distillation to generate training data (Hoang et al., 2018; Kim and Rush, 2016). For such high-throughput applications, it is useful to decrease inference cost.

Meanwhile, we must preserve accuracy: beam search is slower than greedy decoding, but is nevertheless often preferred in MT. Not only is beam search usually more accurate than greedy search, but it also outputs a *diverse set* of decodings, enabling reranking approaches to further improve accuracy (Yee et al., 2019; Ng et al., 2019; Charniak and Johnson, 2005; Ge and Mooney, 2006).

However, it is challenging to optimize the performance of beam search for modern neural architectures. Unlike classical methods in sparse computation settings, modern neural methods typically operate in dense (batched) settings to leverage specialized hardware such as GPUs.

In this work, we propose a streaming method to optimize GPU-batched variable-output-length decoding. Our method does not use a fixed batch during inference; instead, it continually "refills" the batch after it finishes translating some fraction of the current batch. Our method then continues decoding on the remaining candidates in the batch, prioritizing those least expanded.

We apply our method to variable-width beam search. For variable-output-length decoding even in batched settings, variable-width beam search often modestly decreases accuracy in exchange for substantial speedups over fixed-width beam search (Freitag and Al-Onaizan, 2017; Wu et al., 2016). When decoding with Fairseq's state-of-the-art WMT'19 model (Ng et al., 2019), our method further improves over the speed of baseline variable-width beam search: up to 16.5% on a 32GB V100 GPU, without changing BLEU (Papineni et al., 2002). Our approach also improves decoding efficiency in lightweight models for semantic and syntactic parsing.[1] In principle, our method can be applied to any task which sequentially processes variable-length data.

2 Background: Beam Search

Given encoder $\mathcal{E}$ and decoder $\mathcal{D}$, our task is to convert inputs $\{x_1 \dots x_N\}$ into corresponding outputs $\{\bar{y}_1 \dots \bar{y}_N\}$, for data size N. For example, in machine translation, each x_i is a source sentence consisting of a sequence of tokens and each $\bar{y}_i$ is a translation. We assume $\mathcal{D}(e_i, y_i)$ receives $e_i = \mathcal{E}(x_i)$ and a partial y_i as input, constructing $\bar{y}_i$ one token at a time.

One method of constructing $\bar{y}_i$ for a given x_i is greedy search. Let $y_i^{l_t}$ be the in-construction *candidate* with length $l_t = t$ at timestep t. We initialize

November 16–20, 2020.

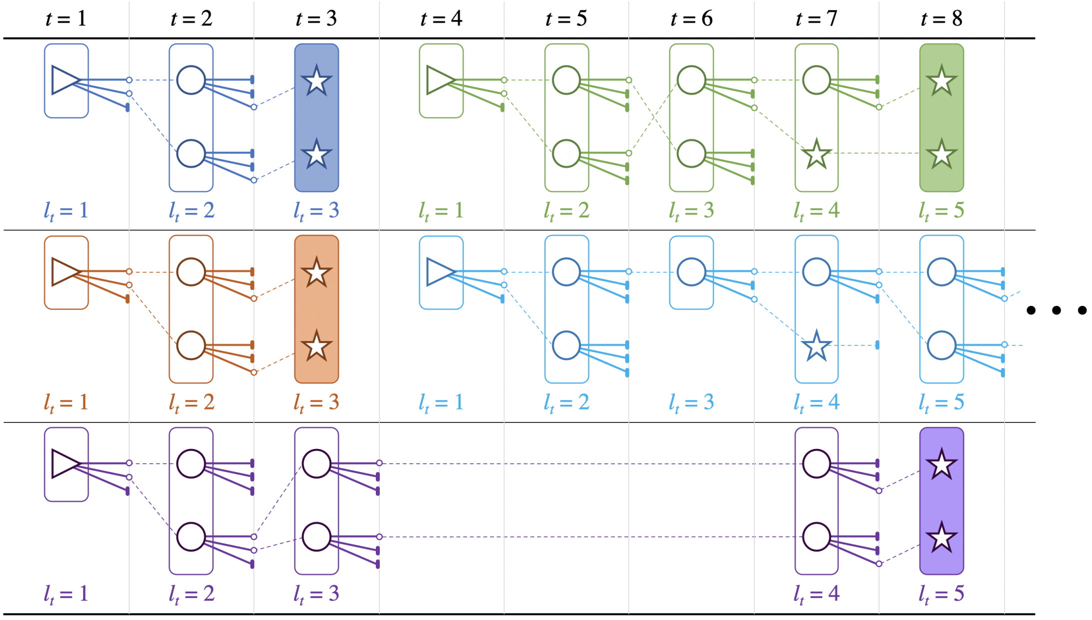

Figure 1: Illustration of our method Var-Stream for variable-width beam search with vocabulary size $|\mathcal{V}| = 3$, beam width $k = 2$, batch size $n = 3$, refill threshold $\epsilon = \frac{1}{3}$. Each color corresponds to the beam for a single input. The rounded rectangles at each timestep are beams $\mathcal{H}(B_i^{l_t})$, while the shapes inside are individual candidates. Shaded beams represent the end of the search. The right-facing triangles indicate the initial candidate containing just the start token w_{sos}, circles denote an active (non-terminated) candidate, and stars denote a finalized candidate. Candidates become finalized after following the third (bottom-most) branch in an expansion, corresponding to the end token w_{eos}; they then undergo only no-op expansions thereafter. The first two rows of beams depict normal operation of variable-width beam search, including heuristic pruning in the light blue beam at $t = 6$. The third row shows an important detail of our method: Var-Stream refills the batch after $t = 3$, when only ϵn beams remain, and the remaining purple beam halts computation until the two newly added beams reach the same l_t. (This detail matters in transformer architectures; see Appendix A.2.)

y_i^1 as the start token w_{sos}, and at each timestep t obtain $y_i^{l_t+1}$ by concatenating the maximum-probability token. We *finalize* $y_i^{l_t}$ as $\bar{y}_i$ once we append the end token, or at some maximum length.

Previous work has found that greedy search often underperforms beam search in accuracy, and gains from non-greedy decoding have also been observed in many classical models (Sutskever et al., 2014; Freitag and Al-Onaizan, 2017; Wilt et al., 2010). See the dark blue, green, and brown beams in Figure 1 for normal operation of fixed-width beam search using beam width $k = 2$. For each input x_i, fixed-width beam search tracks a length-l_t, width-k *beam* $B_i^{l_t}$ for each time t. $B_i^{l_t}$ contains k length-l_t candidates $y_{i1}^{l_t} \dots y_{ik}^{l_t}$ with maximum log-likelihood in order, denoted by the shapes inside the rounded rectangles (beams) in the figure. At each step, beam search considers all $k|\mathcal{V}|$ possible *candidate expansions* (one-token extensions of existing candidates), where $\mathcal{V}$ is the vocabulary. The top k expansions become the expanded beam $B_i^{l_t+1}$. Figure 1 shows these expansions at each timestep for $|\mathcal{V}| = 3$, with active non-terminated candidates (circles) becoming finalized (stars) after following the bottom-most branch, corresponding to the end token w_{eos}. In the end, beam search yields k finalized candidates $\bar{y}_{i1} \dots \bar{y}_{ik}$ compared to a single $\bar{y}_i$ in greedy search.

Variable-width beam search reduces the computational cost of the above *fixed-width* beam search by pruning the full beam $B_i^{l_t}$ using heuristics $\mathcal{H}$, for example at $t = 6$ for the light blue beam in the figure. The width of the resulting pruned beam $\mathcal{H}(B_i^{l_t})$ is no longer always exactly equal to k, and may vary over time.

3 Streaming Variable-Length Decoding

As an example, consider translating a batch of n German sentences into English via a traditionally-batched variable-width beam search (e.g., Freitag and Al-Onaizan (2017)) on a GPU. Henceforth we refer to this baseline as Var-Batch.

An inefficiency results from decoding being inherently variable in length: After t steps, we may have completed $m < n$ translations, but the last $n - m$ beams may take several more timesteps. For example, in Figure 1, our initial batch consists of the dark blue, brown, and purple beams. After the dark blue and brown beams terminate, we would still be stuck decoding the purple beam by itself.

The resulting GPU underutilization motivates our streaming approach VAR-STREAM applied to variable-width beam search (Figure 1). For batch size n, VAR-STREAM initially proceeds identically to VAR-BATCH. But when the number of remaining beams drops below ϵn for some constant $\epsilon \in (0, 1)$, VAR-STREAM encodes a new batch of inputs x to "refill" its batch to size n.[2] This occurs at $t = 4$ in Figure 1, where we refill the batch using the green and light blue beams.

Note the active beams are no longer of equal length $l_t = t$ for every beam after refilling. At each subsequent t, VAR-STREAM only expands beams $\mathcal{H}(B_i^{l_t})$ with minimal l_t; in particular, the purple beam in Figure 1 pauses computation at $t = 4$.[3] When decoding with state-of-the-art transformer architectures for MT, it is advantageous to expand only beams with minimal l_t at each step, because self-attention causes steps at higher l_t to be more expensive; see Appendix A.2. (For RNN-based architectures, it may be faster to expand all active beams at each step.)

We emphasize that VAR-STREAM is an implementation optimization, exactly matching the output of VAR-BATCH. Full details in Algorithm 1.

When the memory bottleneck is partially the decoding process itself rather than caching the input encodings $\mathcal{E}(x_i)$ or beams $\mathcal{H}(B_i^{l_t})$, VAR-STREAM can cache additional encodings and beams on GPU. At each t, VAR-STREAM then selects beams up to some limit on total beam width, filling GPU capacity even in the case of variable-width beams. This batching constraint addresses a second inefficiency in GPU utilization: the widths of the pruned beams $\mathcal{H}(B_i^{l_t})$ may vary over time. We exploit this in semantic (Sec. 4.2) and syntactic parsing (Sec. 4.3).

4 Experiments

We apply VAR-STREAM to variable-width beam search in machine translation, semantic parsing, and syntactic parsing. We use the absolute threshold and max candidates heuristics of Freitag and Al-Onaizan (2017) as $\mathcal{H}$, modifying only the heuristic hyperparameters for each domain based on a development set. The absolute threshold heuristic prunes candidates $y_{ij}^{l_t}$ whose log-probabilities fall short of the best candidate $y_{i1}^{l_t}$'s by some threshold δ, i.e. $\log P(y_{ij}^{l_t}) < \log P(y_{i1}^{l_t}) - \delta$. The max candidates heuristic prevents the search from selecting more than $M < k$ length-$l_t + 1$ candidates originating from the same length-l_t candidate at each step t.

Algorithm 1 VAR-STREAM

Input: inputs $X = \{x_1, \ldots x_N\}$, model $(\mathcal{E}, \mathcal{D})$, batch size n, refill threshold ϵ, beam width k, pruning heuristics $\mathcal{H}$

```
procedure DECODE($X, \mathcal{E}, \mathcal{D}, n, \epsilon, k, \mathcal{H}$)
    # initialize encodings, beams, final outputs
    $E, \mathcal{B}, Y = [\,], [\,], [\,]$
    # initialize index counter
    $c = 1$
    while $c \leq N$ or $|\mathcal{B}| > 0$ do
        if $c \leq N$ and $|\mathcal{B}| \leq \epsilon n$ then
            # refill batch by $m = n(1 - \epsilon)$
            $E = E + [\mathcal{E}(x_c) \ldots \mathcal{E}(x_{c+m-1})]$
            $\mathcal{B} = \mathcal{B} + [w_{sos}] \times m$
            $Y = Y + [\,] \times m$
            $c = c + m$
        Select $E_s \in E, \mathcal{B}_s \in \mathcal{B}$ with min $l_t$
        for $(e_i, \mathcal{H}(B_i^{l_t})) \in (E_s, \mathcal{B}_s)$ do
            for $y_{ij}^{l_t} \in \mathcal{H}(B_i^{l_t})$ do
                Compute expansion $\mathcal{D}(e_i, y_{ij}^{l_t})$
            Update $\mathcal{H}(B_i^{l_t})$ to $\mathcal{H}(B_i^{l_t+1})$
            Add finalized candidates to $Y[i]$
        Remove terminated beams from $E, \mathcal{B}$
    return $Y$
```

In each domain we compare four methods:

1. GREEDY, a greedy search,
2. FIXED, a fixed-width beam search,
3. VAR-BATCH, a batched variable-width beam search, and
4. VAR-STREAM, our streaming method.

We sort and bucket inputs by length for batching.

4.1 Machine Translation

We evaluate on the transformer architecture implemented in Fairseq (Ott et al., 2019), which scored highest on several tracks of WMT'19 (Barrault

---

[2] Our method is relatively insensitive to ϵ (Appendix A.3).

[3] As very long translations could get "stuck" in the batch, one can periodically finish computation on all remaining beams in the batch if latency is a concern in addition to throughput.

16GB	Var-Batch	39.04*	852.93 ± 9.11
	Var-Stream	39.04*	803.72 ± 15.94

Table 1: Top-1 BLEU and wall clock times for machine translation. Our method Var-Stream is substantially faster than Var-Batch (14-17% for $k = 50$ on 32GB, 19-27% for $k = 5$ on 32GB, 6% for $k = 50$ on 16GB) and Fixed (62-71% for $k = 50$, 8-10% for $k = 5$), while preserving high BLEU. *Our rules for finalizing candidates during decoding differ slightly from Fairseq, resulting in equal or higher BLEU for Var-Batch and Var-Stream compared to Fixed. Adapting our implementation to fixed-width beam search is slower but yields higher BLEU (Appendix A.1).[4]

et al., 2019). For our main experiments, we run German-English and Russian-English translation on newstest2018 using an ensemble of 5 models with $k = 50$, matching the setup of Ng et al. (2019) but without reranking. As smaller beam sizes are also common in practice, we evaluate with $k = 5$ as well. Our Greedy and Fixed baselines are Fairseq's implementation, while Var-Batch and Var-Stream are our own. For all methods, we evaluate 5 runs on a 32GB V100 GPU. For $k = 50$, we also run on a 16GB V100 GPU, noting that 32GB is likely more realistic in a production setting. We choose batch size to saturate the GPU, using $\epsilon = \frac{1}{6}$ for Var-Stream, with pruning heuristics $\delta = 1.5, M = 5$. Appendix A.3 details hyperparameter choices.

As shown in Table 1, on both GPU settings and on both languages, Greedy is fastest, but suffers heavily in BLEU. Our Var-Stream is the fastest beam-based search, and matches the BLEU of the beam search baselines. Compared to Var-Batch, Var-Stream is faster by 14-17% when using $k = 50$ on the 32GB GPU, and by 19-27% when $k = 5$. Var-Stream also remains 6% faster when using $k = 50$ on the 16GB GPU where overhead is higher. Var-Batch and Var-Stream match the BLEU of Fixed while being 2-3 times faster when using beam size 50, confirming the speedups from Var-Batch over Fixed in e.g., Freitag and Al-Onaizan (2017). Fixed is more competitive when $k = 5$ because the potential for heuristic beam pruning is much more limited; moreover, our implementations of Var-Stream and Var-Batch somewhat understate both speedups and BLEU cost compared to Fixed due to an implementation difference with Fairseq (Appendix A.1).[4] Thus Var-Batch becomes slower than Fixed when $k = 5$. Nevertheless, Var-Stream remains the fastest in this scenario by 8-10%.

4.2 Semantic Parsing

To explore our method's domain applicability, we experiment with semantic parsing using the seq2seq model of Dong and Lapata (2016). This lightweight model is no longer state of the art, but its decoding is representative of more recent architectures (Suhr et al., 2018; Yin and Neubig, 2018; Lin et al., 2019). We use the ATIS flight-booking dataset (Dahl et al., 1994), setting $n = k = \delta = 10, M = 3$. Due to the small dataset and model, our batching constraint is more theoretical: we constrain each method to expand at most

---

[4] Essentially, we allow finalized candidates to fall off the beam if we find enough other higher-likelihood candidates. See e.g., the star at $t = 7$ in the light blue beam in Figure 1. Fairseq does not allow this.

	Semantic Parsing (ATIS)				*Syntactic Parsing (Penn Treebank)*			
Method	**F1**	**Oracle**	**Time (s)**	**Exp. / Step**	**F1**	**Oracle**	**Time (s)**	**Exp. / Step**
GREEDY	86.4	86.4	1.4 ± 0.0	46.5	91.3	91.3	22.3 ± 0.2	86.7
FIXED	86.6	91.2	7.7 ± 0.1	48.0	91.2	94.0	224.2 ± 2.1	97.1
VAR-BATCH	86.6	90.2	8.2 ± 0.2	16.9	91.2	93.8	235.6 ± 1.8	48.2
VAR-STREAM	86.6	90.2	6.3 ± 0.1	72.1	91.2	93.8	220.5 ± 2.5	95.7

Table 2: Top-1 and oracle reranking F1, wall clock (avg. 5 runs), and average candidate expansions per timestep (i.e., total candidate expansions divided by total decoding timesteps) for semantic parsing on ATIS and syntactic parsing on the Penn Treebank (PTB). Theoretical maximum efficiency under our batching constraint is 100 expansions per step for both tasks. VAR-STREAM achieves substantially higher expansions per step than other methods on ATIS. On PTB, FIXED achieves near-perfect efficiency because all $\bar{y}_{ij}$ for a given x_i have the same length. But comparing variable-width beam searches, VAR-STREAM is much more efficient with batch capacity than VAR-BATCH.

$nk = 100$ candidates per timestep (i.e., total beam width), instead of simply saturating the GPU.[5]

As shown by the expansions per step in Table 2, VAR-STREAM uses the batch capacity of 100 most efficiently. Thus VAR-STREAM is faster than both VAR-BATCH and FIXED, despite overhead which is exacerbated in a small model. The speedup is larger on the JOBS and GEO datasets (Zettlemoyer and Collins, 2012) (Appendix A.4). While all methods achieve similar top-1 F1, oracle F1 (using an oracle to "rerank" all outputs $\bar{y}_{ij}$) highlights the benefit of producing a diverse set of translations.

4.3 Syntactic Parsing

We also experiment with the lightweight shift-reduce constituency parser of Cross and Huang (2016) on the Penn Treebank (Marcus et al., 1993). This task and model differ from our previous setups in that for a given input x_i, all valid parses $\bar{y}_{ij}$ have exactly the same length. When inputs are bucketed by length, this removes the variable-output-length inefficiency for traditional batching: we cannot get stuck finishing a small fraction of beams when the rest of the batch is done. Thus, this task isolates the effect of VAR-STREAM using batch capacity more efficiently in the case of variable-width beams. We use the same computational constraint as in semantic parsing, with $n = k = 10, \delta = 2.5, M = 3$.

As all $\bar{y}_{ij}$ have equal length for a given x_i, FIXED already achieves near-perfect efficiency in expansions per step (Table 2). Combined with the impact of overhead in this older (smaller) model, VAR-STREAM is not substantially faster than FIXED in this setting. However, when comparing variable-width beam searches where efficient batching is more difficult, we observe that VAR-STREAM doubles VAR-BATCH in expansions per step.

5 Discussion

In this work, we have proposed a streaming method for variable-length decoding to improve GPU utilization, resulting in cheaper inference. Applied to a state-of-the-art machine translation model, our method yields substantial speed improvements compared to traditionally-batched variable-width beam search. We also apply our method to both semantic and syntactic parsing, demonstrating our method's broader applicability to tasks that process variable-output-length data in a sequential manner.

A Appendices

A.1 Implementation Differences Compared to Fairseq

In our main machine translation experiments, the FIXED baseline is Fairseq's implementation. Running our own beam search implementation—the basis of VAR-BATCH and VAR-STREAM—with a fixed beam width differs from Fairseq's implementation as follows. In our implementation, henceforth FIXED-OURS, terminated candidates $y_{ij}^{l_{t_0}}$ with $i > 1$ are kept on the beam, added to our list of final outputs only if they become the top candidate $y_{i1}^{l_{t_1}}$ in the beam at a subsequent step t_1. Fairseq instead immediately adds $y_{ij}^{l_{t_0}}$ to the list of final outputs at time t_0. The difference is that $y_{ij}^{l_{t_0}}$ may be removed from the beam at time $t > t_0$ if we later find multiple terminated candidates originating from a higher-probability beam $y_{ij'}^{l_{t_0}}$ for $j' < j$, e.g. between $t = 7$ and $t = 8$ in the light blue beam in Figure 1.

FIXED-OURS is slower than Fairseq's implementation. However, while the two implementations achieve more similar BLEU on the development set, FIXED-OURS achieves higher BLEU on the test set (49.75 vs 49.57 on De-En and 39.19 vs 38.98 on Ru-En). See Table 3 for De-En experiment details.

For completeness, we also present results in Table 3 for FIXED-STREAM, our streaming implementation adapted to fixed-size beam search on newstest2018 on the 32GB Nvidia V100, with $k = 50$ as in the FIXED baseline. We keep the $\epsilon = \frac{1}{6}$ hyperparameter. FIXED-STREAM is significantly faster than FIXED-OURS, demonstrating that our streaming method can also speed up fixed-size beam search. However, FIXED-STREAM is slower than Fairseq's implementation, although it outperforms Fairseq. It is possible that our implementation is less optimized, but we do not formally claim this.

Method	BLEU	Wall Clock (s)
FIXED-FAIRSEQ	49.57	891.53 ± 0.77
FIXED-OURS	49.75	1280.59 ± 5.34
FIXED-STREAM	49.75	1004.18 ± 6.82

Table 3: De-En translation experiments test set (newstest2018) on 32GB Nvidia V100 using different implementations of fixed-size beam search. FIXED-FAIRSEQ is the FIXED baseline in the main paper, while FIXED-OURS is our implementation of fixed-size beam search. FIXED-STREAM is a streaming implementation with $\epsilon = \frac{1}{6}$; FIXED-OURS corresponds to $\epsilon = 0$. FIXED-STREAM improves over FIXED-OURS in wall clock, but is still slower than FIXED-FAIRSEQ, although it achieves higher BLEU.

A.2 Alternative Method Analysis

We briefly analyze an alternative streaming method to our proposed VAR-STREAM, which we label VAR-STR-FIFO. At each decoding timestep t, instead of selecting only the beams with minimal l_t as in VAR-STREAM, VAR-STR-FIFO selects beams up to its batch capacity starting with the beam of maximal l_t. In Figure 1, this corresponds to not pausing computation for the purple beam. This is intuitively appealing and has potential advantages: as shown in Table 5, unlike VAR-STREAM which uses slightly more timesteps than VAR-BATCH due to using a slightly smaller effective batch size, VAR-STR-FIFO significantly reduces the number of timesteps required for decoding in the De-En translation task. Yet VAR-STR-FIFO is significantly slower than both VAR-STREAM and VAR-BATCH. This is due to Fairseq's architecture, a transformer reliant on decoder self-attention, causing decoding timesteps with longer l_t to be more expensive (Figure 2). VAR-STR-FIFO suffers because it must pad all selected beams' lengths up to the maximum l_t among those selected.

The difference between VAR-STREAM and VAR-STR-FIFO demonstrates that selecting the correct beams to expand during decoding timesteps can be highly impactful on speed, illustrating a new axis of optimization made possible by streaming. While VAR-STREAM is superior for the transformers used in state-of-the-art machine translation, we hypothesize that VAR-STR-FIFO may be preferred in other applications, especially in RNN architectures which do not use self-attention.

Method	Wall Clock (s)	Timesteps
VAR-BATCH	308.15 ± 3.48	2007
VAR-STREAM	257.20 ± 0.54	2180
VAR-STR-FIFO	343.10 ± 0.41	1538

Table 4: Comparison of variable-size beam search methods on De-En translation of newstest2018 on 32GB Nvidia V100 GPU. All methods achieve equal BLEU and expand the same number of candidates. VAR-STR-FIFO uses the fewest timesteps but takes the most time due to the transformer architecture requiring more time per step at high values of l_t.

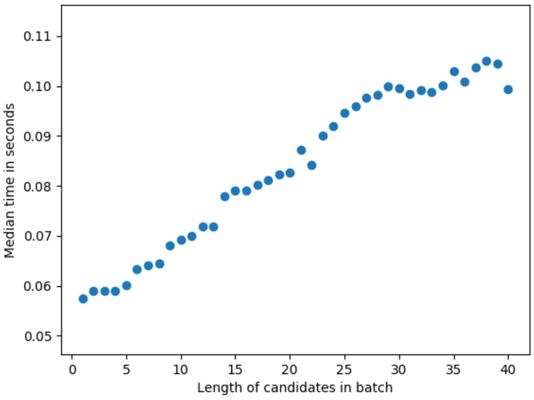

Figure 2: Median time for decoding steps at values of l_t up to 40, for a single run of De-En translation on the 32GB GPU with $k = 50$. The time taken increases roughly linearly with l_t due to self-attention in the transformer.

A.3 Experiment Details and Hyperparameters

We provide details on our setup. All code is written in Pytorch (Paszke et al., 2017). For hardware, for our 32GB and 16GB Nvidia V100 experiments, we use p3dn.24xlarge and p3.2xlarge instances respectively on AWS. Experiments are conducted serially with no other computation on the instance. Due to some variance between instances, all experiments within a single comparable group (e.g., all methods' runs for beam size 50 on a 32GB GPU) are conducted on the same instance.

Additionally, we specify an implementation detail: for the absolute threshold heuristic δ, we note that $y_{i1}^{l_t}$ may be a terminated candidate from a previous timestep.

For heuristic hyperparameters, in all domains we choose pruning heuristics to approximately match the performance of FIXED, based on the development set (newstest2017 for machine translation, and the ATIS and Penn Treebank development sets in semantic and syntactic parsing respectively). As usual, in heuristic selection, there is a tradeoff between time and performance, which we explore here in the machine translation domain.

We run FIXED and VAR-STREAM on the development set (newstest2017) for German-English translation using the 32GB Nvidia V100, using our main paper heuristics $\delta = 1.5, M = 5, \epsilon = \frac{1}{6}$. We additionally run versions where we individually tweak each heuristic, using $\delta = 0.5, \delta = 2.5, M = 3, M = 10, \epsilon = \frac{1}{12}, \epsilon = \frac{1}{4}$.

Both BLEU scores and computation time overall increase with δ and M (Table 5).

ϵ does not affect BLEU. Larger ϵ means we run fewer timesteps at high l_t, but our batch refills are smaller. At least in this machine translation setting, the effect of changing ϵ is typically a few seconds, indicating that our method is not overly sensitive to this hyperparameter choice as long as ϵ is small. (Note we re-adjusted batch sizes in multiples of 64 to saturate the GPU for each ablation.)

During initial hyperparameter selection, we ran $\epsilon = \frac{1}{6}, \frac{1}{3}$ and $\frac{1}{2}$. For M we tested $3, 5,$ and 10 and for δ we tested $1.5, 2.5, 5$ and 10 based on manual tuning with single runs. Note that BLEU and F1 scores do not change with multiple trials, as we do not retrain models. Meanwhile, runtimes generally have fairly small standard deviation (see all tables), so we did not heavily optimize. Overall, the speedups enabled by VAR-STREAM over baselines are relatively insensitive to heuristic hyperparameters.

Method	**Top 1 BLEU**	**Wall Clock (s)**	**Timesteps**	**Cand. Exp.**	**Exp. / Step**
FIXED	42.71	921.57 ± 2.95	6620	3967200	599
VAR-STREAM	42.71	259.78 ± 2.52	2261	651786	288
$\delta = 0.5$	42.49	104.28 ± 1.35	860	131108	152
$\delta = 2.5$	42.72	558.71 ± 5.49	4325	1788047	413
$M = 3$	42.7	248.45 ± 2.66	2070	625099	302
$M = 10$	42.71	268.62 ± 3.91	2543	655300	258
$\epsilon = \frac{1}{12}$	42.71	255.03 ± 0.49	2479	651786	263
$\epsilon = \frac{1}{4}$	42.71	264.73 ± 1.05	2352	651786	277

Table 5: Exploration of effect of different hyperparameter choices on VAR-STREAM performance on De-En development set (newstest2017). Top 1 BLEU, wall clock (average of 5 runs), total decoding timesteps, total candidate expansions, and average candidate expansions per step for several methods. All experiments on 32GB Nvidia V100. Larger values of δ and M result in a method closer to fixed-width beam search, which tends to increase BLEU while taking more time due to needing more candidate expansions. Efficiency in expansions per step generally increases as the method approaches fixed-width beam search, as variable-width beams are more difficult to pack efficiently. Nevertheless, for the purpose of wall-clock time, this effect is outweighed by the vastly larger number of expansions required by fixed-width beam search.

Method	**F1**	**Oracle**	**Time (s)**	**Timesteps**	**Cand. Exp.**	**Exp. / Step**
GREEDY	87.1	87.1	0.67 ± 0.02	136	2715	20.0
FIXED	87.1	90.0	2.36 ± 0.04	705	27781	39.4
VAR-BATCH	87.1	89.3	2.29 ± 0.02	585	5071	8.7
VAR-STREAM	87.1	89.3	1.47 ± 0.01	126	5071	40.2

Table 6: Semantic parsing experiments on JOBS dataset of job listings. Top-1 F1, oracle reranking F1, wall clock average of 5 runs, total decoding timesteps, total candidate expansions, and average expansions per timestep. Although VAR-STREAM is not much more efficient than FIXED in expansions per timestep, it requires many fewer total expansions and is thus faster. Meanwhile, VAR-STREAM is several times more efficient than VAR-BATCH. However, the variable beam searches suffer slightly in oracle F1 compared to FIXED, while still remaining above GREEDY.

A.4 Additional Semantic Parsing Experiments

In Tables 6 and 7, we present results from applying our method to the JOBS and GEO datasets. We use the same hyperparameters and heuristics as for ATIS, and operate under the same candidate-expansion constraint. VAR-STREAM is substantially faster than Fixed and VAR-BATCH under this setting.

Method	F1	Oracle	Time (s)	Timesteps	Cand. Exp.	Exp. / Step
GREEDY	82.5	82.5	0.96 ± 0.02	138	5492	39.8
FIXED	82.5	89.3	4.54 ± 0.09	1469	57550	39.2
VAR-BATCH	82.5	89.6	4.77 ± 0.05	1344	14154	10.5
VAR-STREAM	82.5	89.6	2.95 ± 0.04	248	14154	57.1

Table 7: Semantic parsing experiments on GEO dataset of geographical queries. VAR-STREAM is substantially more efficient than both FIXED and VAR-BATCH in expansions per timestep, and this is reflected in the wall clock time.

A.5 Dataset Details

A.5.1 Machine Translation

Evaluation datasets (newstest2018 and newstest2017) are available at `http://www.statmt.org/wmt19/translation-task.html`. newstest2018 contains 2998 and 3000 examples for De-En and Ru-En respectively, while newstest2017 contains 3004 and 3001.

A.5.2 Semantic Parsing

Datasets can be obtained by running the data scripts at `https://github.com/Alex-Fabbri/lang2logic-PyTorch`, which re-implements Dong and Lapata (2016) in PyTorch. We use Dong and Lapata (2016)'s training, development (for ATIS), and test sets. ATIS, JOBS, and GEO contain 5410, 640, and 880 examples respectively.

A.5.3 Syntactic Parsing

The Penn Treebank dataset and splits are available at `https://github.com/jhcross/span-parser`. The training, data, and test splits are the standard Penn Treebank splits (sections 2-21 for training, 22 for development, and 23 for test, containing 39832, 1700, and 2416 examples respectively).

Improving Multilingual Models with Language-Clustered Vocabularies

Abstract

State-of-the-art multilingual models depend on vocabularies that cover all of the languages the model will expect to see at inference time, but the standard methods for generating those vocabularies are not ideal for massively multilingual applications. In this work, we introduce a novel procedure for multilingual vocabulary generation that combines the separately trained vocabularies of several automatically derived language clusters, thus balancing the trade-off between cross-lingual subword sharing and language-specific vocabularies. Our experiments show improvements across languages on key multilingual benchmark tasks TyDi QA (+2.9 F1), XNLI (+2.1%), and WikiAnn NER (+2.8 F1) and factor of 8 reduction in out-of-vocabulary rate, all without increasing the size of the model or data.

1 Introduction

Multilingual models such as mBERT (Devlin et al., 2019), XLM (Lample and Conneau, 2019), and XLM-R (Conneau et al., 2020) have built on the advances of deep contextualized language modeling by pretraining on texts from many languages at once. One trait common to all of these models is the use of a single vocabulary containing subwords from all languages, used to segment the input text before transforming it into a sequence of embeddings. Conneau et al. (2020) showed that increasing the vocabulary size can produce quality gains, but unlike similar monolingual models, the vocabulary embedding matrix in each of these multilingual models constitutes a significant fraction of its total parameters; for example, 47% of XLM-R's parameters are in its embedding matrix. Therefore, scaling up a model's vocabulary size requires the construction of inductive biases that will guide the training procedure to effectively and efficiently learn these parameters.

The multilingual subword vocabularies used by the state-of-the-art models are generated by algorithms such as WordPiece (Schuster and Nakajima, 2012; Wu et al., 2016), SentencePiece (Kudo and Richardson, 2018),[1] or Byte Pair Encoding (BPE) (Sennrich et al., 2016). Given a desired vocabulary size, these algorithms select an inventory of subwords that compactly represents the training corpora, which means preferring subwords that occur frequently, and, by extension for multilingual models, occur frequently across languages.

Because these algorithms look at overall subword frequencies in the combined multilingual corpus, they may learn suboptimal decompositions for low-resource languages that happen to have character combinations that resemble subwords of high-resources languages.[2] Additionally, subwords in common scripts like Latin and Cyrillic have a higher chance of selection since their counts are combined across a large number of languages (Wu and Dredze, 2019).

By attempting to optimize for the best overall vocabulary across all languages without regard for the differences among those languages, the joint procedure over-emphasizes cross-lingual subword sharing—even across languages with little lexical overlap—which is at odds with the finding of K et al. (2020) that subword sharing is not the principal reason for the effectiveness of multilingual models. It also *under*-emphasizes the need for all languages—particularly low-resource languages or those written in scripts used by few languages—to contribute subwords that are most effective for their own representations.

*Work done as a member of the Google AI Residency Program.

[1] SentencePiece uses BPE or unigram language model.

[2] For example, the fact that *la* is a good subword in French and Spanish does not mean that the algorithm should split the prefix *la* away from words in all languages.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4536–4546,
November 16–20, 2020.

In this paper, we propose a novel approach to multilingual vocabulary generation that seeks to balance the trade-off between optimizing for cross-lingual subword sharing and the need for robust representation of individual languages. At a high level, we: 1) automatically group languages into clusters based on the distributional similarities of their individual subword vocabularies, 2) apply the SentencePiece algorithm separately to the data for each individual cluster, and finally 3) combine all cluster-vocabularies together to form a single unified multilingual model vocabulary.

We evaluate our approach on three distinct downstream tasks: TYDI QA, XNLI, and WikiAnn NER. Our experimental results show that our method improves model performance on all three tasks, and achieves a state-of-the-art result for TYDI QA and zero-shot cross-lingual NER. Crucially, our method improves performance without any changes to the model, and since it does not depend on the model architecture, it can be applied to any model that uses a vocabulary.

2 Clustered Vocabularies

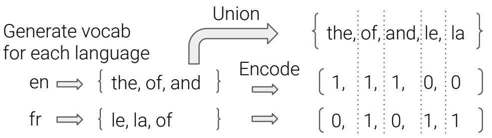

Figure 1: Encoding languages into binary vectors.

We begin by defining a vector representation for each language (Figure 1). For each language l in the set of languages L, we generate an l-specific vocabulary V^l by running the SentencePiece algorithm on l's corpus. Then we take the union of the resulting vocabulary to form the global vocabulary, $V^L = \bigcup_{l \in L} V^l$. Next, for each language, we form a binary vector $\mathbf{v}^l$ of dimension $\left|V^L\right|$, where each component of $\mathbf{v}^l$ corresponds to a subword in V^L, i.e., $\mathbf{v}^l_i = \mathbb{I}[V^L_i \in V^l]$ where $\mathbb{I}$ is an indicator function. In other words, $\mathbf{v}^l$ contains a 1 corresponding to each subword that is present in l's vocabulary, and two languages will have similar representations when their vocabularies have more subwords in common.

With each language encoded as a vector $\mathbf{v}^l$, we can apply standard clustering algorithms to assign each l to some c_j in the set of clusters C. For our experiments, we used k-means with cosine distance. Preliminary experiments (Table 1) indicated that using $k = 8$ would yield good results for our 104-language (the same set of languages used in mBERT) pretraining data so we fixed this value for all remaining experiments.

k	1	4	8	16	32	104
TYDI QA	55.6/69.4	56.9/70.5	**58.5/71.7**	57.3/70.9	57.0/70.2	55.5/69.3

Table 1: TYDI QA results for our k-means-based vocabulary generation approach on different values of k. $k = 1$ puts all languages in a single cluster, and is thus equivalent to the baseline JOINT approach; $k = 104$ generates a separate vocabulary for each language.

We then generate a vocabulary V^{c_j} for each cluster $c_j \in C$ by pooling all of the pretraining data for all languages $l \in c_j$ and running the SentencePiece algorithm. We set the target vocabulary size to be proportional to the size of the union of the individual vocabularies V^l of the languages belonging to the cluster i.e. $|V^{c_j}| \propto |\bigcup_{l \in c_j} V^l|$, ensuring that the proportion of the overall vocabulary allocated to a particular cluster is guided by two factors: it will increase if the cluster has more languages, and decrease if the cluster's languages have more vocabulary overlap. Finally, the multilingual model's overall vocabulary is the union of all of the cluster vocabularies: $V^C = \bigcup_{c_j \in C} V^{c_j}$.

Note that our method is a generalization of the conventional approach, which has $|C| = 1$.

3 Intrinsic Analysis

In this section, we directly examine the vocabularies produced by the standard recipe (JOINT) and our clustering-based method (CLUSTER) in order to assess the degree to which each approach is able to capture and balance the inductive biases introduced in §1: a multilingual vocabulary should encourage subword sharing across languages when appropriate, but each language should also have the freedom to contribute the subwords that are most effective for its own representation.

For all of our experiments, we generate vocabularies from the Wikipedia articles of 104 languages with 906M sentences. Each multilingual vocabulary is 488k subwords. The cluster assignments and sizes generated by CLUSTER are found in Table 2.

In order to quantify the extent of subword sharing between languages, we look at each language as a *distribution* over the vocabulary. In particular, we apply the multilingual vocabulary V's segmentation to each language l's monolingual corpus in order to count the frequency of each sub-

ja			0	1

Table 3: Wasserstein-1 distance (×1000).

word. The empirical distribution of a language l over the vocabulary V is defined by normalizing the frequencies of the monolingual corpus. Given these distributional representations of languages, we can use the Wasserstein-1 distance, W_1, between two languages to quantify the extent of subword sharing (Table 3). Unlike Joint for which W_1 is relatively small even for languages with distinct scripts (e.g., English and Urdu), Cluster manifests much larger values for empirically different languages (and hence in different clusters) while having even smaller values for languages in the same cluster (e.g., Japanese and Chinese). This suggests that the clustering based approach not only minimizes the subword sharing when languages are dissimilar but it also puts more emphasis on subword sharing when necessary.

We quantify the degree of language freedom granted by each approach by examining the fraction of the vocabulary's subwords that contain rare scripts (Table 4). Cluster has a higher percentage of Chinese, Japanese and Korean (grouped together as CJK) subwords because CJK languages are in the same cluster and by themselves, so CJK subwords can be selected independent of other languages. A similar pattern exists for Arabic script.

4 Experiments

In order to demonstrate the effectiveness of our approach across languages and downstream tasks, we evaluate our method on three distinct datasets:

	CJK	Arabic
Joint	2.8	3.4
Cluster	4.4	6.1

Table 4: Percentage of each vocabulary's subwords that contain CJK, or Arabic script characters.

- TyDi QA (Clark et al., 2020): question answering in 10 languages. Results in Table 5.
- XNLI (Conneau et al., 2018): natural language inference in 15 languages. Results in Table 6.
- WikiAnn NER (Pan et al., 2017): named entity recognition in 40 languages. Results in Table 7.

The principal goal of this work is to investigate the effect of improved *vocabulary composition* on multilingual models. We make a good-faith effort to control all other variables, e.g., hyperparameters, training/evaluation procedures. In particular, we keep the number of languages constant, since per-language model capacity is known to affect the performance of multilingual models as shown in Conneau et al. (2020). In addition, we keep the number of parameters constant[3], including the vocabulary size, since the performance of Transformer-based (Vaswani et al., 2017) models is strongly correlated with number of parameters (Lepikhin et al., 2020; Kaplan et al., 2020; Raffel et al., 2020; Conneau et al., 2020; Brown et al., 2020). With carefully controlled experiments, we are confident that any improvement in the results is solely attributable to vocabulary composition. In other words, our vocabularies improve models without increasing the model size, compute or data.

We pretrain using the masked language modeling (MLM) task on the raw text without applying any language-specific pre-processing.[4]

At a high level, the experimental results demonstrate that our Cluster approach to multilingual vocabulary generation improves over the standard Joint recipe, increasing the macro average performance across languages for all datasets and tasks. For TyDi QA, we see improvements on all languages. For XNLI, Cluster perform better or equally well in all languages except French. The results on individual languages are more mixed for NER, with Cluster providing large gains on low-resource or rare-script languages, and small losses on high-resource languages.

In the remainder of this section, we provide more

in-depth analyses of these results (§4.1), and show that our approach continues to perform well when used to train a large scale model (§4.2).

4.1 Analysis

We use the *minimum description length* principle (MDL) (Rissanen, 1989) to aid in our analysis. Consider an example where we want to encode data with a codebook. For example, each word in the data can be encoded by a unique sequence of bits, which is referred to as a codeword. The MDL principle favors the codebook with the minimal description length. Following Goldwater (2007), we define the description length (DL) as the length of combined codebook and encoded data; that is, the sum of the lengths of all codewords in our codebook plus the length of the encoded data.

We apply this to the setting of learning a subword vocabulary for neural network models. Our codebook is a mapping from a subword to a unique integer index of fixed length, typically 32 bits. Therefore, the description length is equivalent to the sum of the number of unique subwords, i.e. the vocabulary size, and the number of integers of the encoded or tokenized input data. Comparing the description length of two vocabularies is therefore equivalent to comparing the total number of subwords after the input corpus is tokenized by each vocabulary. Without loss of generality, we use the average number of tokens per sentence as an equivalent measure of the description length.

As shown in Table 8, Cluster does indeed reduce the DL of the training corpus, which correlates with the performance improvements we see on downstream tasks. With smaller DL, the input text is encoded with *longer* subwords, which we might expect to lead to a higher out-of-vocabulary (OOV) rate (Arivazhagan et al., 2019). However, Cluster has an 8 times smaller OOV rate than Joint (Table 8). We believe that this is related to the larger extent of language freedom as evidenced by the particularly large OOV rate reductions observed in rare-script languages. For example, the OOV rate is reduced by a factor of 26 (Korean), 18 (Japanese) and 17 (Chinese).

The longer DL of Joint means the average subword length is shorter. As a result, the model has learn to map from finer-grained input sequences to semantic meaning (Arivazhagan et al., 2019). As an extreme example, a character-based model would have to learn how to *reconstruct* each word, while a word-based model is exempt from this task. Though the difference in DL is smaller than this extreme case, the same logic applies and Joint must learn a more complex function than Cluster.

Finally, we note that this correlation between DL and downstream performance means we can use DL as a proxy metric to compare vocabularies, allowing for faster iteration over various vocabulary generation approaches without having to run the expensive model training.

Low-resource languages with common scripts. Languages like Swahili and Yoruba use Latin script but have small amounts of data and Cluster outperforms Joint for all three tasks on these languages, which we believe is attributable to better segmentation. In §1, we highlighted one example where over-segmentation can occur,[5] but we

---

[5] While Joint segments the common Swahili adverb *lazima* into *la* and *zima*, Cluster keeps it intact.

Model	**TYDI QA**	**XNLI**	**NER**
mBERT	52.7/64.4	65.4	62.2
XLM-R	-	**79.2**	65.4
Ours	**63.4/77.7**	77.0	**73.6**
Human	70.1/79.9	92.8	-

Table 9: Comparisons with a full-scale model using our approach. Scores are macro averages over languages. TYDI QA numbers are in (MINSPAN/SELECTP) format, and our results are on the test set via a submission to the official leaderboard. Baseline numbers for TYDI QA are from Clark et al. (2020) and the rest are from Hu et al..

can quantify this analysis more generally with DL: CLUSTER has 9.4% (Swahili) and 11.1% (Yoruba) shorter DL compared to JOINT, and this matches well with 7.5 and 8.0 higher NER F1, respectively.

Rare-script languages. For languages with rare scripts (e.g., CJK and Thai), CLUSTER strongly outperforms JOINT in all tasks. For NER, particularly large gains are achieved for Arabic-script languages in cluster c_2 (e.g., 28.9 F1 improvement in Urdu) and Indian languages in c_8. We hypothesize that the gain for this group of languages is due to the higher coverage of subwords in rare scripts, and consequently lower OOV rates (Table 4).

On clusters with languages in different scripts. Our vocabularies were trained from the Wikipedia articles, which frequently contain translations/transliterations. For example, the first sentence of both the Hindi- and Tamil-language versions of the article on "India" contain the exact English phrase "Republic of India". Since many of the same people/places will be topics in articles across Indic-script languages, it is not too surprising that the clustering algorithm groups some of these languages. We note that the NER performance on the Indic languages in cluster c_8 are especially strong (Table 7) possibly due to such shared representation of named entities.

A similar phenomenon can be seen with Korean, since Chinese characters are often appended in parentheses to a Korean word to disambiguate polysemy, which is particularly common for formal contents like Wikipedia. This is why Chinese, Japanese (having large lexical overlap with Chinese) and Korean are in the same cluster c_6. We note that these languages show especially strong improvement in all three tasks we considered as well as drastically large reduction in OOV rate.

Therefore, we see these behaviors as a *strength* of our data-driven approach, flexibly capturing the characteristics of the data which may not be obvious from a purely linguistic perspective.

4.2 Full-scale model

To evaluate the effectiveness of our method on a large scale model, we train a 24-layer Transformer model with CLUSTER and report the macro-averaged results in Table 9. We drastically outperform the baseline for TYDI QA with about 10.7 F1 absolute improvement on MINSPAN and 13.3 F1 on SELECTP, and NER with 8.2 F1 absolute improvement over XLM-R. There is a small loss on XNLI, though this may be due to training on less data, and only Wikipedia domain.

5 Conclusion

We describe a novel clustering-based multilingual vocabulary generation algorithm. We showed that this empirically motivated clustering-based method consistently outperforms the standard vocabulary generation recipe used by most multilingual pretrained language modeling work.

A Experiment details

A.1 Pretraining

We did not use any hyperparameter search for pretraining. We use LAMB optimizer (You et al., 2020) with batch size of 4096. You et al. (2020) also recommended learning rate of 0.0018, warm-up proportion of 2.5% of the total number of steps. We use linear warm-up and linear learning rate decay down to 0 in the last step. We use gradient clipping with a norm of 1.0.

For all the experiments except for the full-scale model, we trained using 64 Google Cloud TPUs. We pretrained models with two different sequence lengths: 128 and 512 with 500k and 125k steps, respectively. The model with sequence length of 512 runs at about 2.3 steps/second, which takes about 16 hours to finish; this model was used to run WikiAnn NER and TyDi QA. The model with sequence length of 128 runs at 9.8 steps/second and finishes in about 15 hours; this model was used to run XNLI. A step refers to one gradient update of the LAMB optimizer.

During pretraining, we sampled each language's data with the following strategy. First we compute the empirical distribution for each language

$$p^l = \frac{n^l}{\sum_{l' \in L} n^{l'}} \tag{1}$$

where n^l is the number of sentences in language l's corpus. Then we use the exponential smoothing value of 0.7 following (Devlin et al., 2019), i.e., we exponentiate p^l and renormalize to compute the sampling probabilities of each language.

We used whole-word masking during pretraining. However, since some languages do not typically use whitespace between words (e.g., Thai), we used the heuristic of SentencePiece meta symbol U+2581 to designate the beginning of the word. Therefore, a word is defined as the token span between two successive U+2581 symbols.

For the full-scale model, we pretrained with 256 Google Cloud TPUs for 1.5 million steps with a batch size of 4096 and learning rate of 0.0018, which took 8 days. We only trained one model, and used a sequence length of 512.

All experiments were run in TensorFlow.

A.2 SentencePiece configurations

We used the following configuration to train a SentencePiece model: unigram language model, character coverage of 0.9995, and 1M seed sentences.

A.3 Model architecture

Except for the full-scale model, all models were 12 layers of Transformers, with hidden size of 768 and 12 attention heads. For faster experimentation, we used an embedding size of 128, similar to Lan et al. (2020). The total number of parameters is 150M. The full-scale model has 24 Transformer layers, hidden size of 1024, and 16 attention heads. We used an embedding size of 512, totaling 550M parameters. We chose this number of parameters to mimic XLM-R.

A.4 Fine-tuning

We ran experiments with two seed values and chose the best model based on the average of the two runs. For fine-tuning, we used Adam optimizer (Kingma and Ba, 2015).

For WikiAnn NER, we used a learning rate of 4×10^{-5}, a batch size of 32, and 2 training epochs. We found that the performance is robust with respect to the set of hyperparameters, so we did not change this setting. The training was run with 4 TPUs which took about one hour to finish. The evaluation metric is span-level F1 score. Our evaluation code was tested against the `seqeval` library: https://github.com/chakki-works/seqeval, and produces the same scores.

For XNLI, we used a batch size of 32, performed grid search over the learning rate of $[1 \times 10^{-5},\ 2 \times 10^{-5},\ 3 \times 10^{-5}]$, and trained for 3 epochs. We chose the best model on the development set based on the macro-averaged accuracy and then used that model to report on the test set. The training was run with 8 TPUs which took about 2-3 hours to finish. The evaluation metric is classification accuracy.

For TyDi QA, we found that larger batch sizes improved the training stability, so we used a batch size of 512. With the larger batch size, longer epochs were helpful, so we used a grid search over the learning rate of $[3 \times 10^{-5},\ 4 \times 10^{-5},\ 5 \times 10^{-5}]$ and training epochs of $[7,\ 8,\ 9]$. We chose the best model based on the macro-averaged F1 score on 10 languages, excluding English following Clark et al. (2020). For the hyperparameters that are specific to TyDi QA, we used the same settings as the baseline model from (Clark et al., 2020): 45 maximum passages, 0.1 include unknown rates, sequence length of 512, and window stride of 128. The evaluation metric is F1 score, which we computed with the official evaluation script from https://github.com/google-research-

datasets/tydiqa.

B Datasets

For pretraining, we use 906M sentences of Wikipedia data covering 104 languages. The number of examples of the three datasets used for evaluation is summarized in Table 15. The XNLI data has a training set in English and development and test sets in 15 languages, which can be downloaded from https://cims.nyu.edu/ sbowman/multinli/.

The TYDI QA datasets are in 11 languages including English, which is excluded from the official evaluation. The link to download the dataset is https://github.com/google-research-datasets/tydiqa.

For Wikiann NER data, we follow XTREME (Hu et al.) and used the balanced train, development, test set splits of Rahimi et al. (2019), for 40 languages. The dataset can be downloaded from https://github.com/afshinrahimi/mmner.

We did not exclude any examples from the three datasets. For Wikiann NER, Greek, Thai, Japanese, Korean and Chinese data have incorrect IOB2 encoding, e.g., `I-PER` following `O`. We fixed those encoding with a simple rule such that a tag with `I` prefix starting after `O` is corrected to have `B` prefix.

We did not use any preprocessing for XNLI or TYDI QA.

C Performance on development set

The main body of the paper contains test set results for XNLI and WikiAnn NER. In this section, we report the development set results so that researchers can try to reproduce the results without consulting to the test set.

Table 10 shows the results for XNLI and the results for WikiAnn NER are summarized in Table 11. Both tables contain the best performing hyperparameters in the caption. Since the TYDI QA test set is private, we performed all experiments on the development set for TYDI QA except for the full-scale model for which we submitted to the official leaderboard.

C.1 Development set results for the full-scale model

For the full-scale model, Table 14 shows the development set results on WikiAnn NER, Table 13 for XNLI and, Table 12 for TYDI QA. We found that this large Transformer model requires different sets of hyperparameters to be effective. We used the LAMB optimizer to match the pretraining since it made the training more stable. For XNLI we did a grid search on over learning rates $[9 \times 10^{-5},\ 1 \times 10^{-4}]$, training epochs $[9,\ 10,\ 11]$, and a fixed batch size of 512. For TYDI QA we did a grid search over learning rates $[8 \times 10^{-5},\ 9 \times 10^{-5}]$ and training epochs $[13,\ 14,\ 15]$, and a fixed batch size of 512. For WikiAnn NER, we chose the learning rate from $[2 \times 10^{-5},\ 3 \times 10^{-5}]$, and used a fixed batch size of 32 and 2 training epochs.

C.2 WikiAnn NER test set results on all 40 languages

In this section, we expand the results in and Table 7 and Table 9, which only show subset of languages (or only average for the latter.

For these test set results, Table 16 expands on Table 7 and show results on all 40 languages considered in XTREME. Table 17 expands on Table 9 in a similar manner.

C.3 Language information

Table 18 lists all 104 languages considered in this paper and their script information.

Abstract

Learning what to share between tasks has become a topic of great importance, as strategic sharing of knowledge has been shown to improve downstream task performance. This is particularly important for multilingual applications, as most languages in the world are under-resourced. Here, we consider the setting of training models on multiple different languages at the same time, when little or no data is available for languages other than English. We show that this challenging setup can be approached using meta-learning: in addition to training a source language model, another model learns to select which training instances are the most beneficial to the first. We experiment using standard supervised, zero-shot cross-lingual, as well as few-shot cross-lingual settings for different natural language understanding tasks (natural language inference, question answering). Our extensive experimental setup demonstrates the consistent effectiveness of meta-learning for a total of 15 languages. We improve upon the state-of-the-art for zero-shot and few-shot NLI (on MultiNLI and XNLI) and QA (on the MLQA dataset). A comprehensive error analysis indicates that the correlation of typological features between languages can partly explain when parameter sharing learned via meta-learning is beneficial.

1 Introduction

There are more than 7,000 languages spoken in the world, over 90 of which have more than 10 million native speakers each (Eberhard et al., 2019). Despite this, very few languages have proper linguistic resources when it comes to natural language understanding tasks (Joshi et al., 2020). Although there is growing awareness in the field, as evidenced by the release of datasets such as XNLI (Conneau et al., 2018), most NLP research still only considers English (Bender, 2019). While one solution to this issue is to collect annotated data for all languages, this process is both too time-consuming and expensive to be feasible. Additionally, it is not trivial to train a model for a task in a particular language (e.g., English) and apply it directly to another language where only limited training data is available (i.e., low-resource languages). Therefore, it is essential to investigate strategies that allow one to use the large amount of training data available for English for the benefit of other languages.

Meta-learning has recently been shown to be beneficial for several machine learning tasks (Koch et al., 2015; Vinyals et al., 2016; Santoro et al., 2016; Finn et al., 2017; Ravi and Larochelle, 2017; Nichol et al., 2018). For NLP, recent work has also shown the benefits of this sharing between tasks and domains (Gu et al., 2018; Dou et al., 2019; Qian and Yu, 2019). Although cross-lingual transfer with meta-learning has been investigated for machine translation (Gu et al., 2018), this paper – to best of our knowledge – is the first attempt to study meta-learning for cross-lingual natural language understanding. Our contributions are as follows:

- We propose X-MAML[1], a cross-lingual meta-learning architecture, and study it for two natural language understanding tasks (Natural Language Inference and Question Answering);
- We test X-MAML on cross-domain, cross-lingual, standard supervised, few-shot as well as zero-shot learning, across a total of 15 languages;
- We observe consistent improvements over strong models including Multilingual BERT (Devlin et al., 2019) and XLM-RoBERTa (Conneau et al., 2020);

---

[1] Our code is available at `https://github.com/copenlu/X-MAML`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4547–4562,
November 16–20, 2020.

- We perform an extensive error analysis, which reveals that cross-lingual trends can partly be explained by typological commonalities between languages.

2 Meta-Learning

Meta-learning tries to tackle the problem of fast adaptation to a handful of new training data instances. It discovers the structure among multiple tasks such that learning new tasks can be done quickly. This is done by repeatedly simulating the learning process on low-resource tasks using many high-resource ones (Gu et al., 2018). There are several ways of performing meta-learning: (i) metric-based (Koch et al., 2015; Vinyals et al., 2016); (ii) model-based (Santoro et al., 2016); and (iii) optimisation-based (Finn et al., 2017; Ravi and Larochelle, 2017; Nichol et al., 2018). Metric-based methods aim to learn similarities between feature representations of instances from different training sets given a similarity metric. For model-based architectures, the focus has been on adapting models that learn fast (e.g., memory networks) for meta-learning (Santoro et al., 2016). In this work, we focus on optimisation-based methods due to their superiority in several tasks (e.g., computer vision (Finn et al., 2017)) over the above-mentioned meta-learning architectures. These optimisation-based methods are able to find good initialisation parameter values and adapt to new tasks quickly. To the best of our knowledge, we are the first to exploit the idea of meta-learning for transferring zero-shot knowledge in a cross-lingual setting for natural language understanding, in particular for the tasks of NLI and QA. Specifically, we exploit the usage of Model Agnostic Meta-Learning (MAML) which uses gradient descent and achieves a good generalisation for a variety of tasks (Finn et al., 2017). MAML is able to quickly adapt to new target tasks by using only a few instances at test time, assuming that these new target tasks are drawn from the same distribution.

Formally, MAML assumes that there is a distribution $p(\mathcal{T})$ of tasks $\{\mathcal{T}_1, \mathcal{T}_2, ..., \mathcal{T}_k\}$. The parameters θ of model $\texttt{M}$ for a particular task $\mathcal{T}_i$, sampled from the distribution $p(\mathcal{T})$, are updated to $\theta_i^{'}$. In particular, the parameters θ are updated using one or a few iterations of gradient descent steps on the training examples (i.e., D_i^{train}) of task $\mathcal{T}_i$. For example, for one gradient update,

$$\theta_i^{'} = \theta - \alpha \nabla_\theta \mathcal{L}_{\mathcal{T}_i}(\texttt{M}_\theta) \tag{1}$$

where α is the step size, the $\texttt{M}_\theta$ is the learned model from the neural network and $\mathcal{L}_{\mathcal{T}_i}$ is the loss on the specific task $\mathcal{T}_i$. The parameters of the model θ are trained to optimise the performance of $\texttt{M}_{\theta_i'}$ on the unseen test examples (i.e., D_i^{test}) across tasks $p(\mathcal{T})$. The meta-learning objective is:

$$\min_\theta \sum_{\mathcal{T}_i \sim p(\mathcal{T})} \mathcal{L}_{\mathcal{T}_i}(\texttt{M}_{\theta_i'}) = \sum_{\mathcal{T}_i \sim p(\mathcal{T})} \mathcal{L}_{\mathcal{T}_i}(\texttt{M}_{\theta - \alpha \nabla_\theta \mathcal{L}_{\mathcal{T}_i}(\texttt{M}_\theta)}) \tag{2}$$

The MAML algorithm aims to optimise the model parameters via a few number of gradient steps on a new task, which we refer to as the meta-update. The meta-update across all involved tasks is performed for the θ parameters of the model using stochastic gradient descent (SGD) as:

$$\theta \leftarrow \theta - \beta \nabla_\theta \sum_{\mathcal{T}_i \sim p(\mathcal{T})} \mathcal{L}_{\mathcal{T}_i}(\texttt{M}_{\theta_i'}) \tag{3}$$

where β is the meta-update step size.

3 Cross-Lingual Meta-Learning

The underlying idea of using MAML in NLP tasks (Gu et al., 2018; Dou et al., 2019; Qian and Yu, 2019) is to employ a set of high-resource auxiliary tasks/languages to find an optimal initialisation from which learning a target task/language can be done using only a small number of training instances. In a cross-lingual setting (i.e., XNLI, MLQA), where only an English dataset is available as a high-resource language, and a small number of instances are available for other languages, the training procedure for MAML requires some non-trivial changes. For this purpose, we introduce a cross-lingual meta-learning framework (X-MAML), which uses the following training steps:

1. Pre-training on a high-resource language $\texttt{h}$ (i.e., English): Given all training samples in a high-resource language $\texttt{h}$, we first train the model $\texttt{M}$ on $\texttt{h}$ to initialise the model parameters θ.
2. Meta-learning using low-resource languages: This step consists of choosing one or more auxiliary languages from the low-resource set. Using the development set of each auxiliary language, we construct a randomly sampled batch of tasks $\mathcal{T}_i$. Then, we update the model parameters using K data points of $\mathcal{T}_i$ (D_i^{train}) by one gradient descent step (see Eq. (1)). After this step, we can calculate the loss value using Q examples (D_i^{test}) in each task. It should be noted that

```
Algorithm 1: X-MAML
Input: high-resource language h, set of low-resource languages L,
Model M, step size $\alpha$ and learning rate $\beta$
Pre-train M on h and provide initial model parameters $\theta$
Select one or more languages from L as a set of auxiliary languages (A)
while not done do
    for $l \in A$ do
        Sample batch of tasks $\mathcal{T}_i$ using the development set of the auxiliary language $l$
        for each $\mathcal{T}_i$ do
            Sample $K$ data-points to form $D_i^{train} = \{(X^k, Y^k)\}_{k=1}^{K} \in \mathcal{T}_i$
            Sample $Q$ data-points to form $D_i^{test} = \{(X^q, Y^q)\}_{q=1}^{Q} \in \mathcal{T}_i$ for meta-update
            Compute $\nabla_\theta \mathcal{L}_{\mathcal{T}_i}(\mathtt{M}_\theta)$ on $D_i^{train}$
            Compute adapted parameters with gradient descent: $\theta' = \theta - \alpha \nabla_\theta \mathcal{L}_{\mathcal{T}_i}(\mathtt{M}_\theta)$
            Compute $\mathcal{L}_{\mathcal{T}_i}(\mathtt{M}_{\theta'})$ using $D_i^{test}$
    Update $\theta \leftarrow \theta - \beta \nabla_\theta \sum_i \mathcal{L}_{\mathcal{T}_i}(\mathtt{M}_{\theta'})$
Perform either (i) zero-shot or (ii) few-shot learning on $\{\mathtt{L} \setminus \mathtt{A}\}$ using meta-learned parameters $\theta$
```

the K data points used for training (D_i^{train}) are different from the Q data points used for testing (D_i^{test}). We sum up the loss values from all tasks to minimise the meta-objective function and to perform a meta-update using Eq. (3). This step is performed in multiple iterations.

3. Zero-shot or few-shot learning on the target languages: In the last step of X-MAML, we first initialise the model parameters with those learned during meta-learning. We then continue by evaluating the model on the test set of the target languages (i.e., zero-shot learning) or fine-tuning the model parameters with standard supervised learning using the development set of the target languages and evaluate on the test set (i.e., few-shot learning).

A more formal description of the proposed model X-MAML is given in Algorithm 1.

Natural Language Inference (NLI): NLI is the task of predicting whether a *hypothesis* sentence is true (entailment), false (contradiction), or undetermined (neutral) given a *premise* sentence. The Multi-Genre Natural Language Inference (MultiNLI) dataset has 433k sentence pairs annotated with textual entailment information (Williams et al., 2018). It covers a range of different genres of spoken and written text and thus supports cross-genre evaluation. The NLI premise sentences are provided in 10 different genres: *facetoface*, *telephone*, *verbatim*, *state*, *government*, *fiction*, *letters*, *nineeleven*, *travel* and *oup*. All of the genres appear in the test and development sets, but only five are included in the training set. To verify our learning routine more generally, we define $\mathcal{T}_i$ as an NLI task in each genre. We exploit MAML, in its original setting, to investigate whether meta-learning encourages the model to learn a good initialisation for all target genres, which can then be fine-tuned with limited supervision for each genre's development instances (2000 examples) to achieve a good performance on its test set.

The Cross-Lingual Natural Language Inference (XNLI) dataset (Conneau et al., 2018) consists of 5000 test and 2500 development hypothesis-premise pairs with their textual entailment labels for English. Translations of these pairs are provided in 14 languages: French (fr), Spanish (es), German (de), Greek (el), Bulgarian (bg), Russian (ru), Turkish (tr), Arabic (ar), Vietnamese (vi), Thai (th), Chinese (zh), Hindi (hi), Swahili (sw) and Urdu (ur). XNLI provides a multilingual benchmark to evaluate how to perform inference in low-resource languages, in which only training data for the high-resource language English is available from MultiNLI. This allows us to study the impact of meta-learning with one low-resource language to serve as an auxiliary language, and evaluate the resulting NLI model on the target languages provided in the XNLI test set.

Question Answering (QA): Given a context and a question, the task in QA is to identify the span in the context which answers the question. Lewis et al.

(2020) introduce a Multilingual Question Answering dataset (MLQA) that contains QA instances in 7 languages: English (en), Arabic (ar), German (de), Spanish (es), Hindi (hi), Vietnamese (vi) and Simplified Chinese (zh). It includes over 12k QA instances in English and 5k for every other language, with each QA instance being available in 4 languages (on average). This dataset has been used in many recent studies on cross-lingual transfer learning (e.g., Hu et al. (2020); Liang et al. (2020)). In our experiments, we investigate meta-learning for QA with one or two auxiliary languages.

4 Experiments

We want to investigate how meta-learning can be used for cross-lingual sharing. We implement X-MAML using the *higher* library[2]. We use the Adam optimiser (Kingma and Ba, 2014) with a batch size of 32 for both zero-shot and few-shot learning. We fix the step size α and learning rate β to $1e-4$ and $1e-5$, respectively. We experimented using $[10, 20, 30, 50, 100, 200, 300]$ meta-learning iterations in X-MAML. However, 100 iterations led to the best results in our experiments. The sample sizes K and Q in X-MAML are equal to 16 for each dataset. The results are reported for each experiment by averaging the performance over ten different runs. We experiment with different architectures in order to verify that our method generalises across them, further detailed below. We report results for *few-shot*, *zero-shot* cross-domain and cross-lingual learning.

NLI: We experiment with two different settings. (i) For MultiNLI, a cross-genre dataset, we employ the Enhanced Sequential Inference Model (ESIM) (Chen et al., 2016), which is commonly used for textual entailment problems. ESIM uses LSTMs with attention to create a rich representation, capturing the relationship between premise and hypothesis sentences. (ii) For XNLI, a cross-lingual dataset, we use the PyTorch version of BERT using Hugging Face's library (Devlin et al., 2019) as the underlying model $\mathtt{M}$. However, since our proposed meta-learning method is model-agnostic, it can easily be extended to any other architecture. Note that for Setting (i), we apply MAML, whereas for Setting (ii), we apply X-MAML on the original English BERT model (En-BERT) and on Multilingual BERT (Multi-BERT) models. As the first training step (i.e., pre-training on a high-resource language, see Step 1 in Section 3 for more information) in X-MAML for XNLI, we fine-tune En-BERT and Multi-BERT on the MultiNLI dataset (English) to obtain the initial model parameters θ for each experiment.

QA: For question answering, we use different base models $\mathtt{M}$ for X-MAML, namely XLM (Conneau and Lample, 2019) and XLM-RoBERTa (XLM-R) (Conneau et al., 2020), both state-of-the-art models. XLM uses a similar pre-training objective as Multi-BERT with a larger model, a larger shared vocabulary, and leverages both monolingual and parallel data. XLM-R is a RoBERTa version of XLM and is trained on a much larger multilingual corpus (i.e., Common Crawl), achieving state-of-the-art performance on most cross-lingual benchmarks (Hu et al., 2020). We employ the XLM-15 (Masked Language Model + Translation Language Model, 15 languages), XLM-R$_{base}$ and XLM-R$_{large}$ models released by the authors. The SQuAD v1.1 training data is used in the pre-training step of X-MAML (see Step 1 in Section 3). We use the cross-lingual development and test splits provided in the MLQA dataset for the meta-learning and evaluation steps, respectively.

Baselines: We create: (i) zero-shot baselines: directly evaluate the model on the test set of the target languages; (ii) few-shot baselines: fine-tune the model on the development set, then evaluate on the test set of the low-resource languages.

4.1 Few-Shot Cross-Domain NLI

We train ESIM on the MultiNLI training set to provide initial model parameters θ (see Step 1 in Section 3). We evaluate the pre-trained model on the English test set of XNLI (since the MultiNLI test set is not publicly available) as a baseline. Since MultiNLI is already split into genres, we use each genre as a task within MAML. We then include either the training set (5 genres) or the development set (10 genres) during meta-learning (similar to Step 2 in X-MAML).

In the last phase (similar to Step 3 in X-MAML), we first initialise the model parameters with those learned by MAML. We then continue to fine-tune the model using the development set of MultiNLI and report the accuracy on the English test set of XNLI. We proportionally select sub-samples $x = [1\%, 2\%, 3\%, 5\%, 10\%, 20\%, 50\%, 100\%]$ from the training data (with random sampling).

Figure 1: Differences in performance in terms of accuracy scores on the test set for zero-shot X-MAML on XNLI using the Multi-BERT model. Rows correspond to target and columns to auxiliary languages used in X-MAML. Numbers on the off-diagonal indicate performance differences between X-MAML and the baseline model in the same row. The coloring scheme indicates the differences in performance (e.g., blue for large improvement).

The results obtained by training on the corresponding proportions ($x\%$) of the MultiNLI dataset using ESIM (as the learner model `M`) are shown in Table 1. We observe that for both settings (i.e., MAML on the training (5 tasks) and on the development set (10 tasks)), the performance of all models (including baselines) improve as more instances become available. However, the effectiveness of MAML is larger when only limited training data is available (improving by 12% in accuracy when 2% of the data is available on the development set).

4.2 Zero- and Few-Shot Cross-Lingual NLI

Zero-Shot Learning: In this set of experiments, we employ the proposed framework (i.e., X-MAML) within a zero-shot setup, in which we do not fine-tune after the meta-learning step. We report the impact of meta-learning for each target language as a difference in accuracy with and without meta-learning on top of the baseline model (Multi-BERT) on the test set (Fig. 1). Each column corresponds to the performance of Multi-BERT after meta-learning with a single auxiliary language, and evaluation on the target language of the XNLI test set. Overall, we observe that our zero-shot approach with X-MAML outperforms the baseline model without MAML and results reported by Devlin et al. (2019). This way, we improve the state-of-the-art performance for zero-shot cross-lingual NLI (in several languages for up to $+3.6\%$ in accuracy, e.g., Hindi (hi) as target and Urdu (ur) as auxiliary language). For the exact accuracy scores, we refer to Table 5 in the Appendix. We hypothesise that the degree of typological commonalities among the languages has an effect (i.e., positive or negative) on the performance of X-MAML. It can be observed that the proposed learning approach provides positive impacts across most of the target languages. However, including Swahili (sw) as an auxiliary language in X-MAML is not beneficial for the performance on the other target languages. It is worth noting that we experimented by just training the model using an auxiliary language, instead of performing meta-learning (step 2). From this experiment, we observe that meta-learning has a strongly positive effect on predictive performance (see also Fig. 2 in the Appendix).

In Table 2, we include the original baseline performances reported in Devlin et al. (2019)[3] and Wu and Dredze (2019). We report the average and maximum performance by using one auxiliary language for each target language. We also report

Table 2: Accuracy results on the XNLI test set for zero- and few-shot X-MAML. Columns indicate the target languages. The models of Devlin et al. (2019) and Wu and Dredze (2019) are also Multi-BERT models. For our Multi-BERT baseline model for (i) zero-shot learning, we evaluate the pre-trained model on the test set of the target language; and for (ii) few-shot learning, we fine-tune the model on the development set and evaluate on the test set of the target language. The avg column indicates row-wise average accuracy. We also report the average (AVG) and maximum (MAX) performance by using one auxiliary language for each target language. (l_1, l_2) are the most beneficial auxiliary languages for X-MAML in improving the test accuracy of each target language X. In TRANSLATE-TEST (Devlin et al., 2019), the target language test data is translated to English and then the model is fine-tuned on English. In TRANSLATE-TRAIN (Wu and Dredze, 2019), the English training data is translated to the target language and the model is fine-tuned using the translated data.

the performance of X-MAML by also using Hindi (which is the most effective auxiliary language for the zero-shot setting, as shown in Fig. 1). We suspect that this is because of the typological similarities between Hindi (hi) and other languages. Furthermore, by using two auxiliary languages in X-MAML results to the largest benefit in our zero-shot experiments.

Few-Shot Learning: For few-shot learning, meta-learning in X-MAML (Step 3) is performed by fine-tuning on the development set (2.5k instances) of target languages, and then evaluating on the test set. Detailed ablation results are presented in the Appendix (Table 6 and Fig. 4). In Table 2, we compare X-MAML results with one or two auxiliary languages to the external and internal baselines. We also showcase the performance using specifically Swahili (sw), the overall most effective auxiliary language for meta-learning with Multi-BERT in the few-shot learning setting. In addition, we report results from Devlin et al. (2019) that use machine translation at test time (TRANSLATE-TEST) and results from Wu and Dredze (2019) that use machine translation at training time (TRANSLATE-TRAIN). Note that, using X-MAML, we are able to avoid the machine translation step (TRANSLATE-TEST) from the target language into English. The results also indicate that X-MAML boosts Multi-BERT performance on XNLI. It is worthwhile mentioning that Multi-BERT in the TRANSLATE-TRAIN setup outperforms few-shot X-MAML, however, we only use 2k development examples from the target languages, whereas in the aforementioned work, 433k translated sentences are used for fine-tuning.

4.3 Zero-Shot Cross-Lingual QA

We use a similar approach for cross-lingual QA on the MLQA dataset. Zero-shot results on MLQA are shown in Table 3. We compare our results to those reported in two benchmark papers, Hu et al. (2020) and Liang et al. (2020). We also report our own baselines for the task. The baselines are provided by training each base model on the SQuAD v1.1 train set (see Step 1 in Section 3) and evaluating on the test set of MLQA. All target languages benefit from meta-learning with at least one of the auxiliary languages. Using two auxiliary languages in X-MAML further improves results. Overall, zero-shot learning models with X-MAML outperform both internal and external baselines. The improvement is $+1.04\%$, $+0.89\%$ and $+1.47\%$ in average F_1 score compared to XLM-15, XLM-R_{base} and XLM-R_{large}, respectively.

We also evaluate on the less widely used cross-lingual QA dataset X-WikiRE (Abdou et al., 2019) for which we observe similar result trends, and 0.55% improvement in terms of average F_1 score on zero-shot QA. More details can be found in the Appendix (Section A.1).

5 Related Work

The main motivation for this work is the low availability of labelled training datasets for most of the world's languages. To alleviate this issue, a number of methods, including the so-called few-shot learning approaches have been proposed. Few-shot learning methods have initially been introduced within the area of image classification (Vinyals et al., 2016; Ravi and Larochelle, 2017; Finn et al., 2017), but have recently also been applied to NLP tasks such as relation extraction (Han et al., 2018), text classification (Yu et al., 2018; Rethmeier and Augenstein, 2020) and machine translation (Gu et al., 2018). Specifically, in NLP, these few-shot learning approaches include: (i) the transformation of the problem into a different task (e.g., relation extraction is transformed to question answering (Levy et al., 2017; Abdou et al., 2019)); or (ii) meta-learning (Andrychowicz et al., 2016; Finn et al., 2017).

Meta-Learning: Meta-learning or learning-to-learn has recently received a lot of attention from the NLP community. First-order MAML has been applied to the task of machine translation (Gu et al., 2018), where they propose to use meta-learning for improving the machine translation performance for low-resource languages by learning to adapt to target languages based on multilingual high-resource languages. However, in the proposed framework, they include 18 high-resource languages as auxiliary languages and five diverse low-resource languages as target languages. In our work, we assume access to only English as a high-resource language. For the task of dialogue generation, Qian and Yu (2019) address domain adaptation using meta-learning. Dou et al. (2019) explore MAML variants thereof for low-resource NLU tasks in the GLUE dataset (Wang et al., 2018). They consider different high-resource NLU tasks such as MultiNLI (Williams et al., 2018) and QNLI (Rajpurkar et al., 2016) as auxiliary tasks to learn meta-parameters using MAML. They then fine-tune the low-resource tasks using the adapted parameters from the meta-learning phase. All the above-mentioned works on meta-learning in NLP assume that there are multiple high-resource tasks or languages, which are then adapted to new target tasks or languages with a handful of training samples. However, in a cross-lingual NLI and QA setting, the available high-resource language is usually only English. Our work thus fills an important gap in the literature, as we only require a single source language.

Cross-Lingual NLU: Cross-lingual learning has a fairly short history in NLP, and has mainly been restricted to traditional NLP tasks, such as PoS tagging, morphological inflection and parsing. In contrast to these tasks, which have seen much cross-lingual attention (Plank et al., 2016; Bjerva, 2017; Kementchedjhieva et al., 2018; de Lhoneux et al., 2018), there has been relatively little work on cross-lingual NLU, partly due to lack of benchmark datasets. Existing work has mainly been focused on NLI (Agic and Schluter, 2018; Conneau et al., 2018; Zhao et al., 2020), and to a lesser degree on RE (Faruqui and Kumar, 2015; Verga et al., 2016) and QA (Abdou et al., 2019; Lewis et al., 2020). Previous research generally reports that cross-lingual learning is challenging and that it is hard to beat a machine translation baseline (e.g., Conneau et al. (2018)). Such a baseline is for instance suggested by Faruqui and Kumar (2015), where the text in the target language is automatically translated to English. We achieve competitive performance compared to a machine translation baseline (for XNLI), and propose a method that requires no training instances for the target task in the target language. Furthermore, our method is model agnostic, and can be used to extend any pre-existing model.

Table 3: F_1 scores (average over 10 runs) on the MLQA test set using zero-shot X-MAML. Columns indicate the target languages. The avg column indicates row-wise average F_1 score. We also report the most beneficial auxiliary language(s) for X-MAML in improving the test F_1 of each target language.

6 Discussion and Analysis

Cross-Lingual Transfer: Somewhat surprisingly, we find that cross-lingual transfer with meta-learning yields improved results even when languages strongly differ from one another. For instance, for zero-shot meta-learning on XNLI, we observe gains for almost all auxiliary languages, with the exception of Swahili (sw). This indicates that the meta-parameters learned with X-MAML are sufficiently language agnostic, as we otherwise would not expect to see any benefits in transferring from, e.g., Russian (ru) to Hindi (hi) (one of the strongest results in Fig. 1). This is dependent on having access to a pre-trained multilingual model such as BERT, however, using monolingual BERT (En-BERT) yields overwhelmingly positive gains in some target/auxiliary settings (see additional results in Fig. 3 in the Appendix). For few-shot learning, our findings are similar, as almost all combinations of auxiliary and target languages lead to improvements when using Multi-BERT (Fig. 4 in the Appendix). However, when we only have access to a handful of training instances as in few-shot learning, even the English BERT model mostly leads to improvements in this setting (see additional results in Fig. 5 in the Appendix).

Typological Correlations: In order to better explain our results for cross-lingual zero-shot and few-shot learning, we investigate typological features, and their overlap between target and auxiliary languages. We evaluate on the World Atlas of Language Structure (WALS, Dryer and Haspelmath (2013)), which is the largest openly available typological database. It comprises approximately 200 linguistic features with annotations for more than 2500 languages, which have been made by expert typologists through study of grammars and field work. We draw inspiration from previous work (Bjerva and Augenstein, 2018a,b; Bjerva et al., 2019a,b,c; Zhao et al., 2020) which attempts to predict typological features based on language representations learned under various NLP tasks. Similarly, we experiment with two conditions: (i) we attempt to predict typological features based on the mutual gain/loss in performance using X-MAML; (ii) we investigate whether sharing between two typologically similar languages is beneficial for performance using X-MAML. We train a simple logistic regression classifier per condition above, for each WALS feature. In the first condition (i), the task is to predict the exact WALS feature value of a language, given the change in accuracy in combination with other languages. In the second condition (ii), the task is to predict whether a main and auxiliary language have the same WALS feature value, given the change in accuracy when the two languages are used in X-MAML. We compare with two simple baselines, one based on always predicting the most frequent feature value in the training set, and one based on predicting feature values with respect to the distribution of feature values in the training set. We then investigate whether any features could be consistently predicted above baseline levels, given different test-training splits. We apply a simple paired t-test to compare our models predictions to the baselines. As we are running a large number of tests (one per WALS feature), we apply Bonferroni correction, changing our cut-off p-value from $p = 0.05$ to $p = 0.00025$.

We first investigate few-shot X-MAML, when using Multi-BERT, as reported in Table 6 (Appendix). We find that languages sharing the feature value for WALS feature *67A The Future Tense* are beneficial to each other. This feature encodes whether or not a language has an inflectional marking of future tense, and can be considered to be a morphosyntactic feature. We next look at zero-shot X-MAML with Multi-BERT, as reported in Table 5 (Appendix). For this case, we find that languages sharing a feature value for the WALS feature *25A Locus of Marking: Whole-language Typology* typically help each other. This feature describes whether the morphosyntactic marking in a language is on the syntactic heads or dependents of a phrase. For example en, de, ru, and zh are 'dependent-marking' in this feature. And if we look at the results in Fig. 1, they have the largest mutual gains from each other during the zero-shot X-MAML. In both cases, we thus find that languages with similar morphosyntactic properties can be beneficial to one another when using X-MAML.

7 Conclusion

In this work, we show that meta-learning can be used to effectively leverage training data from an auxiliary language for zero-shot and few-shot cross-lingual transfer. We evaluated this on two challenging NLU tasks (NLI and QA), and on a total of 15 languages. We are able to improve the performance of state-of-the-art baseline models for (i) zero-shot XNLI, and (ii) zero-shot QA on the MLQA dataset. Furthermore, we show in a typological analysis that languages which share certain morphosyntactic features tend to benefit from this type of transfer. Future studies will extend this work to other cross-lingual NLP tasks and more languages.

Acknowledgements

This research has received funding from the Swedish Research Council under grant agreement No 2019-04129, as well as the Research Foundation - Flanders (FWO). This work was also funded by UiO: Energy to support international mobility. We are grateful to the Nordic Language Processing Laboratory (NLPL) for providing access to its supercluster infrastructure.

A Appendices

A.1 X-MAML using X-WikiRE dataset

X-WikiRE: Levy et al. (2017) frame the Relation Extraction (RE) task as a QA problem using pre-defined natural language question templates. For example, a relation type such as `author` is transformed to at least one language question template (e.g., `who is the author of x?`, where `x` is an entity). Building on the work of Levy et al. (2017), a new dataset (X-WikiRE) is introduced for multilingual QA-based relation extraction in five languages (i.e., English, French, Spanish, Italian and German) by Abdou et al. (2019). Each instance in the dataset includes a question, a context, and an answer. The question is a transformation of a target relation and the context may contain the answer. If the answer is not present, it is marked as `NIL`. In this task, we evaluate the performance of our method on the `UnENT` setting of the X-WikiRE dataset, where the goal is to generalise to unseen entities. For the evaluation, we use F_1 scores (for questions with valid answers) similar to Kundu and Ng (2018).

QA experiments: We use the Nil-Aware Answer Extraction Framework (NAMANDA, Kundu and Ng (2018))[4] as the base model `M` in X-MAML for our QA experiments. NAMANDA encodes the question and context sequences to compute a similarity matrix. It creates evidence vectors through joint encoding of question and context and applies multi-factor self-attentive encoding. Finally, the evidence vectors are decomposed to output either the answer to the question or `NIL`. We set the parameters to the default values (as in the original work) for the training and evaluation phases. The NAMANDA model `M` is pre-trained on the full English training set (1M instances - see Step 1 in our training algorithm). The model `M` is further used by our meta-learning step to adapt the pre-trained QA model. We then evaluate how well the English model has been adapted by each of the auxiliary language through X-MAML via performing either few- or zero-shot learning. In few-shot X-MAML, the meta-learned `M` is fine-tuned on the development set (1k instances) of other languages (i.e., fr, es, it and de). For both few- and zero-shot learning, we evaluate on the 10k test set of each of the target languages. Following the work of Abdou et al. (2019), the Multi-BERT model is used to jointly encode text for different languages in the QA model.

Zero- and Few-Shot Cross-Lingual QA: We use a similar approach for cross-lingual QA on the X-WikiRE dataset. Table 4 shows the results of both zero- and few-shot X-MAML for the `UnENT` part (i.e., generalise to unseen entities) of the X-WikiRE dataset. We compare our results for the `UnENT` scenario on the X-WikiRE dataset to those reported in the original paper. All of the target languages benefit from at least one of the auxiliary languages by adapting the model using X-MAML, highlighting the benefits of this method. We were not able to directly reproduce the result for the zero-shot scenario of the original paper, thus we also report our own baseline for the task. We find that: (i) our zero-shot results with X-MAML improve on those without meta-learning (i.e., baselines); and (ii) we outperform Abdou et al. (2019) for the `UnENT` scenario of zero-shot cross-lingual QA. Furthermore, for the few-shot scenario, adapting the QA model using few-shot X-MAML with only 1k development data outperforms their cross-lingual transfer model where Abdou et al. (2019) use 10k in the fine-tuning phase.

Table 4: F_1 scores (average over 10 runs) for the test set of the `UnENT` part of the X-WikiRE dataset using zero- and few-shot X-MAML. Baseline for (i) zero-shot learning: we evaluate the pre-trained NAMANDA model on the test set of the target language indicated in each row; and for (ii) few-shot learning: we fine-tune the model on the development set and evaluate on the test set of the target language. We report results with few-shot X-MAML with only 1k instances from the development set.

Table 5: The performance in terms of average test accuracy for the zero-shot setting over 10 runs of X-MAML on the XNLI dataset using Multi-BERT (multilingual BERT), as base model. Each column corresponds to the performance of the Multi-BERT system after meta-learning with a single auxiliary language, and evaluation on the target language of the XNLI test set. The auxiliary language is not included during the evaluation phase. Results of the Multi-BERT model without X-MAML (baseline) are also reported.

Abstract

We present the Multilingual Amazon Reviews Corpus (MARC), a large-scale collection of Amazon reviews for multilingual text classification. The corpus contains reviews in English, Japanese, German, French, Spanish, and Chinese, which were collected between 2015 and 2019. Each record in the dataset contains the review text, the review title, the star rating, an anonymized reviewer ID, an anonymized product ID, and the coarse-grained product category (e.g., ‘books’, ‘appliances’, etc.) The corpus is balanced across the 5 possible star ratings, so each rating constitutes 20% of the reviews in each language. For each language, there are 200,000, 5,000, and 5,000 reviews in the training, development, and test sets, respectively. We report baseline results for supervised text classification and zero-shot cross-lingual transfer learning by fine-tuning a multilingual BERT model on reviews data. We propose the use of mean absolute error (MAE) instead of classification accuracy for this task, since MAE accounts for the ordinal nature of the ratings.

1 Introduction

Text classification is one of the fundamental tasks in natural language processing, and research in this area has been accelerated by the abundance of corpora across different domains (e.g., Twitter sentiment (Pak and Paroubek, 2010), movie ratings (Maas et al., 2011), textual entailment (Bowman et al., 2015), restaurant reviews (Yelp Inc., 2019), among many others).

Figure 1: A hypothetical review from our corpus.

The construction of *multilingual* classification systems which handle inputs from different languages has been studied extensively in previous work (e.g., Bel et al., 2003; De Melo and Siersdorfer, 2007). More recently, researchers have observed ‘zero-shot’ cross-lingual behavior (Lu et al., 2018; Artetxe and Schwenk, 2019) where classification performance in one language can be transferred to the same task in another, without target language supervision, as long as the encoder was pretrained on a machine translation task. In addition, contextual embeddings have shown unexpected cross-lingual behavior in classification, NER, and dependency parsing tasks (Wu and Dredze, 2019; Keung et al., 2019; Conneau et al., 2019).

As with all other areas in NLP, progress in multilingual research relies on the availability of high-quality data. However, large-scale multilingual text classification datasets are surprisingly rare, and existing multilingual datasets have some notable deficiencies.

The proprietary Reuters RCV1 (Lewis et al., 2004) and RCV2 (Reuters Ltd., 2005) corpora and its derivatives like MLDoc (Schwenk and Li, 2018) are relatively small; in RCV2, each language has ∼37,000 training examples on average, and the smallest language only has 1,794 examples. RCV1 and 2 are not easily accessible; a researcher who wishes to acquire the data would need to work with an organization that has obtained legal approval from Reuters Ltd.

The XNLI dataset (Conneau et al., 2018) was designed for evaluating zero-shot cross-lingual transfer and does not contain training data for non-

Table 1: Training corpus statistics. We provide 200,000 reviews per language.

English languages.

The Yelp corpus (Yelp Inc., 2019) contains reviews from international marketplaces, but the reviews from each marketplace can be written in multiple languages and the language identity is not provided. Furthermore, the Yelp corpus itself is refreshed from time to time, and previous versions are not made available for download, which affects the reproducibility of published results.

Several versions of the Amazon reviews corpus exist today. Neither the version from Ni et al. (2019) nor Amazon Inc. (2015) provide training, development, and test splits, and neither version focuses on the multilingual aspect of the reviews. Prettenhofer and Stein (2010) provide Amazon reviews in 4 languages (i.e., 2,000 training and test reviews, along with a variable number of unlabeled reviews), but the dataset is small by modern standards.

We address many of the above-mentioned limitations by releasing a subset of Amazon reviews specifically tailored for the task of multilingual text classification:

- We provide 200,000 reviews in the training set for each of the languages in the corpus.
- We apply language detection algorithms to ensure reviews are associated with the correct language with high probability.
- We distribute the corpus on AWS Open Datasets for easy access by any research group for non-commercial purposes.
- Unlike previous Amazon reviews datasets, we split the data into clearly defined training, development, and test sets.

The Multilingual Amazon Reviews Corpus (MARC) can be found at `https://registry.opendata.aws/amazon-reviews-ml/`. The dataset description, code snippets, and license agreement can be retrieved at `https://docs.opendata.aws/amazon-reviews-ml/readme.html`.

2 Data preparation

2.1 Inclusion Criteria

We gathered the reviews from the marketplaces in the US, Japan, Germany, France, Spain, and China for the English, Japanese, German, French, Spanish, and Chinese languages, respectively. We considered reviews that were submitted between November 1, 2015 and November 1, 2019. Only reviews with verified purchases were included.

We take no more than 20 reviews from the same product, and no more than 20 reviews from the same reviewer. Only products with at least 2 reviews were included in the dataset. Reviews must be at least 20 characters long.

2.2 Data Processing

The language of a review does not necessarily match the language of its marketplace (e.g., reviews from Amazon.de are primarily written in German, but could also be written in English, etc.). For this reason, we applied a language detection algorithm (Bojanowski et al., 2017) to determine the language of the review text. Only reviews written in the target language were retained. Based on a manual review of 200 randomly selected reviews per language, we observed 0, 0, 0, 0, 1, and 0 incorrectly classified reviews for English, Japanese, German, French, Spanish, and Chinese, respectively. At a score threshold of 0.8, the language filter removed 4.9%, 0.2%, 1.2%, 2.4%, 3.8%, and 5.3% of the English, Japanese, German, French, Spanish, and Chinese candidate reviews, respectively.

We also applied a vocabulary-based filter on the reviews. If a review contains a token that doesn't occur in at least 20 other reviews, then the review is excluded from the dataset. We used Jieba[1] for Chinese and KyTea[2] for Japanese word segmentation. The segmenters were only used during the filtering process, and the text provided in the dataset is not segmented or tokenized.

(d) Amount of source language training data versus same-language and zero-shot transfer performance (fine-grained, MAE×100). The training data comes from the English portion of the corpus only.

Table 2: mBERT classification mean absolute error (MAE×100). The 'fine-grained' classification task predicts the 5-star rating, whereas the 'binarized' task predicts whether the review is negative (i.e., 1-2 stars) or positive (i.e., 4-5 stars). Unless otherwise stated, we use the review body, review title, and product category as mBERT inputs.

We truncate all reviews at 2,000 characters. Newlines and tabs in the body of the review were removed.

Some Amazon reviews contain HTML markup. We used Lynx[3] to render the reviews as UTF-8 plain-text.

Product and reviewer IDs were anonymized by mapping each ID to a unique randomly generated integer.

We provide the product category labels for 30 common product types, and all other product categories are mapped to 'other'.

3 Corpus Characteristics

Amazon product ratings are given on a 5-star scale. To avoid any class imbalance issues in the dataset, we downsampled the reviews to ensure that each star rating constituted exactly 20% of the corpus. We provide 200,000, 5,000, and 5,000 reviews for the training, development, and test sets, respectively.

In Table 1, we compile some of the important statistics for the corpus. The number of unique products and reviewers is broadly similar across different languages.

In Figure 2, we show the distribution of product

---

[3] `https://lynx.invisible-island.net`

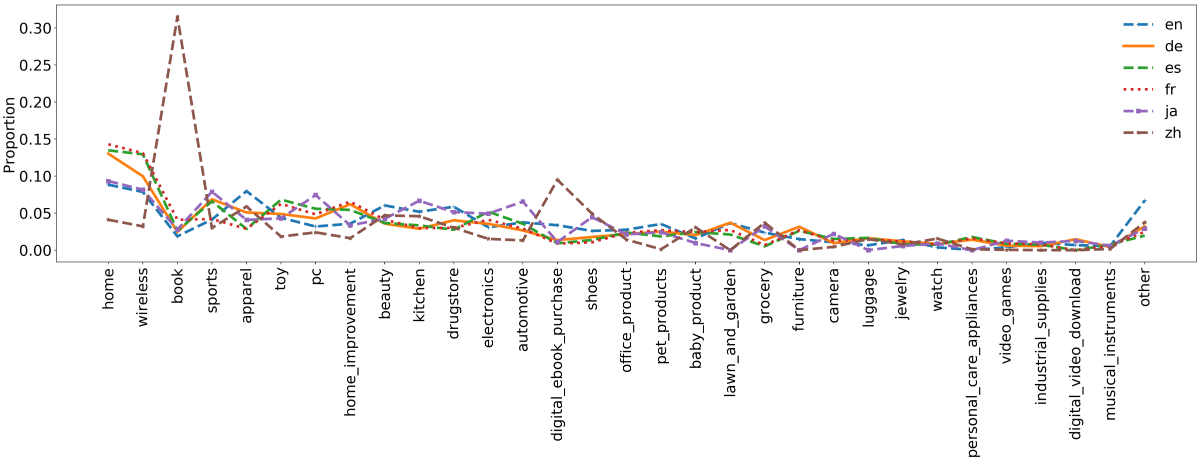

Figure 2: Distribution of product categories across the training data in different languages.

categories for each language. There is substantial variation in the distribution of product categories by language. Chinese reviews, most notably, are heavily skewed towards books.

4 Baseline Results

In Table 2, we provide baseline mean absolute error (MAE) results for supervised and zero-shot multilingual text classification with our corpus, where

$$MAE(y, \hat{y}) = \frac{\sum_{i=1}^{n} |y_i - \hat{y}_i|}{n}$$

and $y_i, \hat{y}_i \in \{1, 2, 3, 4, 5\}$ are the true star rating and the predicted rating for the i-th review respectively. All of our baseline models are initialized with the cased multilingual BERT (mBERT) base model (Devlin et al., 2019), which has 110M parameters.

Note that the star ratings for each review are *ordinal*, and a 2-star prediction for a 5-star review should be penalized more heavily than a 4-star prediction for a 5-star review. However, previous work on Amazon reviews classification (e.g., Yang et al., 2016) used the classification accuracy as the primary metric, which ignores the ordinal nature of the labels. We use MAE in our baselines as the primary metric instead. We also report the classification accuracy for completeness (Table 3), but we encourage the use of MAE in future work.

4.1 Experimental Setup

We predict the reviewer's rating using the text of the review (and possibly the product category) as the input. Following the procedure described in Devlin et al. (2019), we used the embedding of the CLS token for prediction. We fine-tuned the model for 15 epochs with the Adam optimizer using a constant learning rate of 8×10^{-7}. We used minibatches of 32 reviews. Each experiment required $\sim$10 hours to complete with a single GPU on an AWS p3.8xlarge instance with the MXNet GluonNLP framework. We truncated the review body at 180 wordpieces if it exceeded 180 wordpieces.

4.2 Supervised Text Classification

In Table 2a, we report our MAE on the fully supervised classification task, where the languages of the training and evaluation data are the same (i.e., train on French reviews and test on French reviews, etc.). We distinguish between the 'fine-grained' classification task, where we predict on the 5-star scale, and the 'binarized' classification task, where we predict whether the reviewer gave 1 to 2 stars or 4 to 5 stars. For the binarized task, we drop the 3-star reviews in the training and evaluation data.

We also distinguish between the case where the input is the body of the review alone and where the input is the review body combined with the review title and product category. In the latter case, we use mBERT for sentence pair classification, where the first 'sentence' is the review body and the second 'sentence' is the review title concatenated with the product category. The details for sentence pair classification can be found in Devlin et al. (2019).

4.3 Zero-shot Text Classification

In Tables 2b and 2c, we report zero-shot cross-lingual transfer MAE for fine-grained and binarized classification respectively, where we only fine-tune mBERT on data from one source language and test

	En	De	Es	Fr	Ja	Zh	Average
Fine-grained Classification							
Body only	56.5	58.3	56.9	55.5	53.9	51.4	54.4

50%	63.2	47.4	47.7	45.6	38.6	39.9	43.9
100%	63.3	48.1	48.0	45.4	39.0	39.7	44.0

(c) Amount of source language training data versus same-language and zero-shot transfer performance (fine-grained, accuracy). The training data comes from the English portion of the corpus only.

Table 3: mBERT classification accuracy. The 'fine-grained' classification task predicts the 5-star rating. Unless otherwise stated, we use the review body, review title, and product category as mBERT inputs.

the model on non-source languages. In our cross-lingual experiments, we used the review body, title, and product category as inputs.

Recent work by Conneau et al. (2019) recommended reporting zero-shot transfer results by using the target development sets for model checkpoint selection. In addition, Keung et al. (2020) showed that using the source language development set to select the checkpoint can lead to significant variation in zero-shot transfer performance and also recommended using the target development sets for checkpoint selection. Our results in Tables 2 and 3 follow their guidance, and we use the target development set to select the model checkpoint for each language.

In Table 2d, we vary the amount of English training data used in mBERT fine-tuning and examine the change in English test and non-English zero-shot MAE. Increasing the amount of English training data is generally helpful, although there are clearly diminishing returns.

5 Conclusion

We present a curated subset of Amazon reviews specifically designed to aid research in multilingual text classification. To the best of our knowledge, this is the largest public benchmark dataset for the training and evaluation of multilingual text classification models. With this work, we systematically address various gaps that we identified in existing multilingual corpora: we apply careful sampling, filtering, and text processing to the documents to minimize noise in the dataset, and we provide a large number of samples for training models in six languages with well-defined training, development, and test splits. We discuss the data preparation steps, analyze the distribution of the important characteristics of the corpus, and present baseline results for supervised and zero-shot cross-lingual text classification. With these contributions, we hope that this corpus will be an important resource to the research community.

Acknowledgments

We thank the anonymous reviewers for their insightful feedback. We also thank Peter Schmiedeskamp and Sharon Chiarella for their support in the preparation and release of this corpus. NAS acknowledges NSF support under grant 1813153.

Abstract

When humans read or listen, they make implicit commonsense inferences that frame their understanding of what happened and why. As a step toward AI systems that can build similar mental models, we introduce GLUCOSE, a large-scale dataset of implicit commonsense causal knowledge, encoded as causal minitheories about the world, each grounded in a narrative context. To construct GLUCOSE, we drew on cognitive psychology to identify ten dimensions of causal explanation, focusing on events, states, motivations, and emotions. Each GLUCOSE entry includes a story-specific causal statement paired with an inference rule generalized from the statement. This paper details two concrete contributions. First, we present our platform for effectively crowdsourcing GLUCOSE data at scale, which uses semi-structured templates to elicit causal explanations. Using this platform, we collected a total of ˜670K specific statements and general rules that capture implicit commonsense knowledge about everyday situations. Second, we show that existing knowledge resources and pretrained language models do not include or readily predict GLUCOSE's rich inferential content. However, when state-of-the-art neural models are trained on this knowledge, they can start to make commonsense inferences on unseen stories that match humans' mental models.

1 Introduction

Humans make countless implicit commonsense inferences about everyday situations. For example, consider the following short story from the ROCStories corpus (Mostafazadeh et al., 2016): *Gage was riding his bike. A car turned in front of him. Gage turned his bike sharply. He fell off of his bike. Gage skinned his knee.* When even young children read this story, they construct a coherent representation of what happened and why, combining information from the text with relevant background knowledge (Kintsch and Van Dijk, 1978). For example, they can construct the causal chain that explains how the car's unexpected turn ultimately led to Gage falling, describe how Gage's emotion and location changed throughout the story, and even hypothesize that he likely shouted for help after falling.

Though humans build such mental models with ease (Zwaan et al., 1995), AI systems for tasks such as reading comprehension and dialogue remain far from exhibiting similar commonsense reasoning capabilities. Two major bottlenecks have been acquiring commonsense knowledge and successfully incorporating it into state-of-the-art AI systems. To address the first bottleneck, we have built an effective platform to acquire causal commonsense knowledge at scale. To address the second, we show that pre-trained neural models can start to make similar inferences when trained on such rich curated data.

We introduce the GLUCOSE[1] (GeneraLized and COntextualized Story Explanations) dataset. Given a short story and a sentence X in the story, GLUCOSE captures ten dimensions of causal explanation related to X. These dimensions, inspired by human cognitive psychology, cover often-implicit causes and effects of X, including events, location, possession, and other attributes, the vast majority of which are not captured by existing resources

[1] Human brain functions such as thinking, memory, and learning are closely linked to the glucose levels and how efficiently the brain uses this fuel source (Mergenthaler et al., 2013). If there is not enough glucose in the brain, neurotransmitters are not produced and communication between neurons breaks down. We are calling this resource GLUCOSE, since we believe AI brains need this source of fuel to enable their basic thinking and fill in their reasoning gaps!

Dimension	**Semi-structured Specific Statement and Inference Rule**: antecedent *connective* consequent
1: Event that directly causes or enables X	$\underbrace{\text{A car}}_{\text{subject}}\ \underbrace{\text{turned}}_{\text{verb}}\ \underbrace{\text{in front of}}_{\text{preposition}}\ \underbrace{\text{him}}_{\text{object}}$ *Causes/Enables* $\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{turned}}_{\text{verb}}\ \underbrace{\text{his bike}}_{\text{object}}$
	$\underbrace{\text{Something}_A}_{\text{subject}}\ \underbrace{\text{turns}}_{\text{verb}}\ \underbrace{\text{in front of}}_{\text{preposition}}\ \underbrace{\text{Something}_B\text{ (that is Someone}_A\text{'s vehicle)}}_{\text{object}}$ *Causes/Enables* $\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{turns}}_{\text{verb}}\ \underbrace{\text{Something}_B}_{\text{object1}}\ \underbrace{\text{away from}}_{\text{preposition}}\ \underbrace{\text{Something}_A}_{\text{object2}}$
2: Emotion or basic human drive that motivates X	$\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{wants}}_{\text{verb}}\ \underbrace{\text{safety}}_{\text{object}}$ *Causes/Enables* $\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{turned}}_{\text{verb}}\ \underbrace{\text{his bike}}_{\text{object}}$
	$\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{wants}}_{\text{verb}}\ \underbrace{\text{safety}}_{\text{object}}$ *Causes/Enables* $\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{moves}}_{\text{verb}}\ \underbrace{\text{away from}}_{\text{preposition}}\ \underbrace{\text{Something}_A\text{ (that is dangerous)}}_{\text{object}}$
3: Location state that enables X	$\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{was}}_{\text{verb}}\ \underbrace{\text{close to}}_{\text{preposition}}\ \underbrace{\text{a car}}_{\text{object}}$ *Enables* $\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{turned}}_{\text{verb}}\ \underbrace{\text{his bike}}_{\text{object1}}\ \underbrace{\text{away from}}_{\text{preposition}}\ \underbrace{\text{the car}}_{\text{object2}}$
	$\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{is}}_{\text{verb}}\ \underbrace{\text{close to}}_{\text{preposition}}\ \underbrace{\text{Something}_A}_{\text{object}}$ *Enables* $\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{moves}}_{\text{verb}}\ \underbrace{\text{away from}}_{\text{preposition}}\ \underbrace{\text{Something}_A}_{\text{object}}$
4: Possession state that enables X	$\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{possesses}}_{\text{verb}}\ \underbrace{\text{a bike}}_{\text{object}}$ *Enables* $\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{turned}}_{\text{verb}}\ \underbrace{\text{his bike}}_{\text{object}}$
	$\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{possesses}}_{\text{verb}}\ \underbrace{\text{Something}_A}_{\text{object}}$ *Enables* $\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{moves}}_{\text{verb}}\ \underbrace{\text{Something}_A}_{\text{object}}$
5: Other attributes enabling X: N/A (the dimension is not applicable for this example)	
6: Event that X directly causes or enables	$\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{turned}}_{\text{verb}}\ \underbrace{\text{his bike}}_{\text{object}}$ *Causes/Enables* $\underbrace{\text{He}}_{\text{subject}}\ \underbrace{\text{fell off}}_{\text{verb}}\ \underbrace{\text{his bike}}_{\text{object}}$
	$\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{turns}}_{\text{verb}}\ \underbrace{\text{Something}_B\text{ (that is Someone}_A\text{'s vehicle)}}_{\text{object}}$ *Causes/Enables* $\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{falls off}}_{\text{verb}}\ \underbrace{\text{Something}_B}_{\text{object}}$
7: An emotion that is caused by X: N/A	
8: A change in location that X results in	$\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{turned}}_{\text{verb}}\ \underbrace{\text{his bike}}_{\text{object1}}\ \underbrace{\text{away from}}_{\text{preposition}}\ \underbrace{\text{the car}}_{\text{object2}}$ *Results in* $\underbrace{\text{Gage}}_{\text{subject}}\ \underbrace{\text{was}}_{\text{verb}}\ \underbrace{\text{further}}_{\text{object1}}\ \underbrace{\text{from}}_{\text{preposition}}\ \underbrace{\text{the car}}_{\text{object2}}$
	$\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{moves}}_{\text{verb}}\ \underbrace{\text{away from}}_{\text{preposition}}\ \underbrace{\text{Something}_A}_{\text{object}}$ *Results in* $\underbrace{\text{Someone}_A}_{\text{subject}}\ \underbrace{\text{is}}_{\text{verb}}\ \underbrace{\text{further from}}_{\text{preposition}}\ \underbrace{\text{Something}_A}_{\text{object}}$
9: A change of possession that X results in: N/A	
10: Other changes in property that X results in: N/A	

Table 1: Entries in the GLUCOSE dataset that explain the Gage story around the sentence X= *Gage turned his bike sharply*. White and gray rows show specific statements and general rules, respectively. The syntactic slots used for constructing each semi-structured entry are shown underneath it.

and models. Importantly, GLUCOSE encodes commonsense knowledge in the form of semi-structured inference rules[2] (mini-theories about the world), each grounded in a specific story. As the examples in Table 1 demonstrate, the specific statements exemplify how the general rules can be grounded in a particular context.

To facilitate acquisition at scale, we designed an effective multi-stage crowdsourcing platform and used it to acquire more than 670K GLUCOSE annotations in the context of children's stories. Our analysis shows that these explanations extend substantially beyond the scope of the existing knowledge resources.

Given the breadth of commonsense knowledge needed for real-world inference tasks, no static knowledge source is expected to provide sufficient coverage. GLUCOSE's key contribution is enabling models to dynamically produce general inference rules to explain novel scenarios. To systematically evaluate such models, we present an evaluation task where given a story S, a sentence X, and dimension d, a model predicts relevant specific and general rules as captured in GLUCOSE. We evaluate on the task using a curated test set, based on novel stories not used for any training purposes. We show a strong correlation between human and automatic evaluation metrics, which makes systematic and reliable evaluation of models feasible. We show that pre-trained neural models perform poorly on the task; however, when fine-tuned on GLUCOSE data, they are able to generate commonsense explanations that rival humans'.

---

[2] We will use "inference rule" and "explanation" interchangeably: the "explanations" we are interested in are inference rules that explain a given sentence's causes and effects.

This finding supports our hypothesis that a promising recipe for giving machines commonsense is to use quality-monitored crowdsourced commonsense knowledge for training neural models that have pre-existing lexical and conceptual knowledge.

2 Related Work

Recently, there has been a renewed interest in commonsense reasoning (Talmor et al., 2019; Tandon et al., 2019; Rashkin et al., 2018a; Zellers et al., 2018), further fostered by the increasing need for explainable AI systems (Yang et al., 2018).

One well-known type of commonsense knowledge is script knowledge, defined by Schank and Abelson (1977) as structured knowledge about stereotypical event sequences and their participants. However, manual encoding of such knowledge is notoriously unscalable and brittle. A more recent line of work is unsupervised learning of "narrative schemas" (Chambers and Jurafsky, 2008, 2009; Balasubramanian et al., 2013; Sha et al., 2016), where common event sequences are automatically induced from large corpora. While promising, this approach has not produced high-quality knowledge usable for downstream tasks at scale (Mostafazadeh et al., 2016). Furthermore, since commonsense knowledge is often implicit, such corpus-based methods are unlikely to induce implicit commonsense inferences (Gordon and Van Durme, 2013). In contrast, our data collection framework has enabled us to acquire high-quality and robust commonsense knowledge, including often unstated rules such as "Someone$_A$ gives Someone$_B$ Something$_A$ *Results in* Someone$_B$ possesses Something$_A$" or "Someone$_A$ is at Somewhere$_A$ *Enables* Someone$_A$ puts Something$_A$ at Somewhere$_A$".

The most fruitful efforts to date for acquiring commonsense knowledge have been crowdsourced knowledge resources. ConceptNet (Speer et al., 2017), a partially-crowdsourced resource, is a relational knowledge graph that connects short natural-language phrases via semantic edges. Most ConceptNet knowledge is taxonomic, consisting of factoids like "apple *is a* fruit", however, it also includes some causal relations, e.g., "kill *is motivated by* revenge." Despite its broad coverage, ConceptNet has been found to be noisy (Zhou et al., 2019). Its knowledge also lacks context, hampering accurate application at inference time, e.g., "kill *requires* eat breakfast" is hard to make sense of without more context.

A more directly relevant resource is ATOMIC (Sap et al., 2019), which consists of 877K textual descriptions of if-then knowledge. Each entry describes a likely cause/effect of one of 24K+ events. ATOMIC entries are organized into nine categories such as xIntent (PersonX's intention) and xEffect (effect on PersonX). For instance, "PersonX makes PersonY's coffee xEffect PersonX gets thanked". ATOMIC is a great step forward in acquiring high-quality inferential knowledge. However, it has two main shortcomings. First, ATOMIC is non-contextual and conflates knowledge about an event that may have occurred under different scenarios, which hinders interpreting and applying the knowledge in context. For example, the event "PersonX arrives the next day" has xIntents "to go on vacation" and "to attend a reunion," and xEffects "get time to relax" and "meet some friends." Although each xIntent should be associated with only one of the xEffects, such dependencies are not encoded in ATOMIC. As a result, ATOMIC cannot be used to determine which xEffect is more likely given an xIntent. GLUCOSE addresses this by grounding each piece of inferential knowledge to a particular story context consistent across dimensions.

Second, events and relations in ATOMIC are person centric; agentless events are not covered, and each relation is either about PersonX or PersonY. As a result, ATOMIC cannot describe events involving common entity types such as places, things, or groups of people, nor can it encode causes and effects other than to PersonX and their peers. In GLUCOSE, sentence X can describe any event/state, and GLUCOSE general rules can refer to indexed variables such as "Someone$_A$" or "Somewhere$_C$." Beyond these major shortcomings, ATOMIC also does not cover many commonsense knowledge types in GLUCOSE, including change of attributes such as location, which will be further discussed in Section 4.3.

3 The Knowledge Model of GLUCOSE

GLUCOSE has a unique take on explaining story events. As illustrated in Table 1, each story is explained through ten causal dimensions. The semi-structured explanation for each dimension includes both a specific statement and a general rule.

3.1 Causal Dimensions of Explanation

One of our main contributions is the identification of ten causal dimensions of explanation in the context of narratives, for which we can reliably collect high quality data from lay crowd workers. Cognitive psychology research on human comprehension of narratives (Kintsch and Van Dijk, 1978; Zwaan and Radvansky, 1998; Grazzani et al., 2018) suggests that humans primarily focus on events, their timeline, locations of entities throughout the story, causes and motivations of events, and emotional trajectory of characters.

Based on this research, GLUCOSE dimensions are designed to focus on causal reasoning around events and states, eliciting event causal chains, character motivations, emotions, naive psychology, and change of attributes such as location and possessions to core story entities. For an event or state X stated in a sentence, we categorize the dimensions of causality into events and states happening *before* X and those occurring *after* X. Each category includes five dimensions, as shown in Table 1. The precise definition and scope of these ten dimensions are the result of multiple pilot studies with crowd workers to identify intuitive and distinguishable causal dimensions, so that the overlap among dimensions is minimized and the agreement among workers is maximized.

3.2 Semi-structured Inference Rules

To uncover what constitutes a good explanation, we ran several pilot studies exploring how people define, generate, and present explanations about short stories. We concluded that in order to achieve some consensus among explanations and to facilitate further processing and evaluation, the explanations should not be entirely free-form. Instead, we represent them as semi-structured inference rules whose expressivity lies between free text and logical forms. Each rule takes the form "antecedent *connective* consequent," where the antecedent and consequent are composed by filling in syntactic slots for subject, verb, object(s), and preposition(s). For some dimensions, slot-filling involves choosing from a predefined list, e.g., dimension 2, which states a motivating emotion or basic human drive, limits its verb choices to *feel, want*, and *like*. Details regarding the slots can be found in Appendix A.

To eliminate the need for pronoun resolution when applying our general rules, variables are indexed, such as "Someone$_A$" and "Something$_A$ and Something$_B$", to refer to the same entities on both sides of the rule. Each variable can be further elaborated using an *attribute phrase* in the form of a relative clause, e.g., "Somewhere$_C$ (that is Someone$_A$'s location)." Our studies indicate that this format gives the explainers sufficient expressivity to convey their reasoning, yet constrains the resulting explanations enough to identify commonalities between them. Note that the semi-structured rules are deterministically converted to natural language form by simply concatenating all the filled slots. Table 1 shows examples of semi-structured GLUCOSE explanations.

3.3 Generalized and Contextualized

Each GLUCOSE explanation is stated both as a specific statement (grounded in a given context) and a corresponding general rule (applicable to other contexts). Research in cognitive psychology suggests that humans typically choose which of an event's many causes to cite based on its relevance to the context (Miller, 2019). Hence, grounding explanations in context is crucial for acquiring accurate explanations. Furthermore, it has been shown that human explanations take situation-specific information and link it to pre-existing knowledge about the world; people explain by appealing to broader theories that enable generalization (Lombrozo, 2006). Also, there is evidence that explanations and generalizations help scaffold cognitive development in humans (Busch et al., 2018), which can potentially play a role in the learning capabilities of AI systems as well. By explicitly stating general rules as mini-theories of how the world works, GLUCOSE seeks to enable better generalization and causal reasoning in future AI systems.

4 The GLUCOSE Dataset

4.1 Data Acquisition Platform

To enable developing models that can build mental models of narratives, we aimed to crowdsource a large, quality-monitored dataset. Beyond the scalability benefits, using crowd workers (as opposed to a small set of expert annotators) ensures diversity of thought, thus broadening coverage of a commonsense knowledge resource.

The annotation task is complex: it requires annotators to understand different causal dimensions in a variety of contexts and to come up with generalized theories beyond the story context. For strict quality control, we designed a three-stage knowledge acquisition pipeline for crowdsourcing the GLUCOSE dataset on the Amazon Mechanical Turk (Mturk) Platform. The workers first go through a qualification test[3] where they must score at least 90% on 10 multiple-choice questions on select GLUCOSE dimensions. Next, qualified workers can work on the main GLUCOSE data collection task: given a story S and a story sentence X, they are asked to fill in (allowing for non-applicable) all ten GLUCOSE dimensions, getting step-by-step guidance from the GLUCOSE data acquisition UI.[4] To ensure data consistency, the same workers answer all dimensions for an S, X pair. Finally, the submissions are reviewed by an expert who rates each worker on a scale from 0 to 3, and provides feedback on how to improve. Our final UIs are the result of more than six rounds of pilot studies, iteratively improving the interaction elements, functionality, dimension definitions, instructions, and examples.[5] See Appendix B for more details on our crowdsourcing pipeline.[6]

4.2 Dataset Composition and Statistics

Our source of stories for the GLUCOSE dataset is ROCStories (Mostafazadeh et al., 2016). ROCStories consists of crowdsourced five-sentence everyday stories rich in causal and temporal relations, making them ideal for acquiring commonsense knowledge. We focus on children's stories due to their simpler language and concepts. We computed an estimated target age[7] for each story and sampled from the 5–8 age group. To ensure diverse viewpoints and hypotheses, each S, X pair was assigned to three workers. Data collection statistics are shown in Table 2 and Figure 1.

# total annotations	~670K
# total pair of rules	~335K
# total unique stories S	4,881
# workers participated	371
Avg # of submissions by a worker	130.7
Max # of submissions by a worker	3,757
Avg minutes of work time / submission	8.78
Avg payment / submission	$1.60
Avg # of dimensions filled in / submission	4.5

Table 2: Statistics about the GLUCOSE dataset.

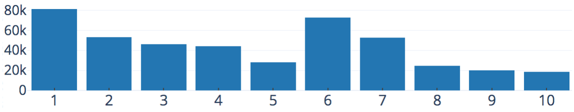

Figure 1: Number of rules collected for each dimension. Dimensions 1 and 6 have the most representation, while dimensions 9 and 10 are most often marked as not applicable.

As Figure 1 shows, the causal dimensions (1 and 6) have the most representation (18.1% and 16.4%, respectively). As our examples in Table 1 show, specific statements for these dimensions sometimes define a causal connection over paraphrases of story sentences[8], rather than introduce novel non-story content in either the antecedent or the consequent. To estimate how prevalent this phenomenon is, we manually evaluated 100 random samples of specific rules for each of dimensions 1 and 6. We found that for 66% and 63% of the samples, for dimensions 1 and 6 respectively, at least one of the annotators contributed statements that contained inferences with non-story content. The new content includes events that are likely to follow from the story as well as world knowledge about story entities.

4.3 Comparison to Other Resources

To assess the novelty of GLUCOSE knowledge, we compared its coverage against that of the two most relevant commonsense resources: ConceptNet and ATOMIC.[9] We performed a best-effort mapping from GLUCOSE dimensions to relations in ConceptNet and ATOMIC. For example, GLUCOSE dimensions 1 and 6 are mapped to ConceptNet's *Causes*, *HasSubevent*, *HasPrerequisite*, and to ATOMIC's *xEffect* and *oEffect*. For all mappings see Appendix A.

Since all three resources contain mostly natural-language entries, it is not possible to automatically quantify their precise overlap, so we adopted a

---

[3] GLUCOSE qualification UI: https://bit.ly/34Pej0N

[4] GLUCOSE main knowledge acquisition UI: https://bit.ly/2R8XcTt

[5] Our pilot studies helped narrow our dimensions from 18 down to 10 which workers could reliably distinguish. Notably, we collapsed Enable and Cause on which workers had significant disagreement.

[6] Additional information about the pipeline and data quality management can be found at https://tinyurl.com/y2pn5cgl

[7] Target age of individual stories was judged by age-of-acquisition and readability tests: Flesch-Kincaid Grade Level, the Coleman-Liau Index, and the Dale-Chall formula (Kuperman et al., 2012). It is important to note that this method depends on vocabulary and does not ensure that all content is appropriate for children in this age group.

[8] It is important to note that, even if the antecedent and consequent are both in the story, making the causal link between them explicit is considered to have fulfilled the purpose of providing common sense knowledge.

[9] Note that (Rashkin et al., 2018a) and (Rashkin et al., 2018b) are in essence a subset of ATOMIC, and hence, have even lower coverage compared with GLUCOSE.

Dimension	1	2	5	6	7	10
ConceptNet	1.2%	0.3%	0%	1.9%	0%	0%
ATOMIC	7.8%	1.2%	2.9%	5.3%	1.8%	4.9%

Table 3: Ceiling overlap between GLUCOSE and other resources. Omitted dimensions had no overlap.

lenient evaluation scheme. For each GLUCOSE general rule[10] A *relation* B, we queried each target resource for tuples $R'(A', B')$, where R' is the resource's mapped equivalent of *relation*, and A' and B' consist of just the main verbs in A and B. Using fuzzy matching on A' and B', we retrieved a large number of hits for the query, then filtered to those with $>$50% lexical overlap with the GLUCOSE rule.

The results, shown in Table 3, represent a ceiling in overlap with other resources. The results indicate that GLUCOSE captures extensive commonsense knowledge unavailable in existing resources. Note that GLUCOSE's knowledge model is a superset of ATOMIC's. GLUCOSE is designed to encompass all nine categories of inferential commonsense knowledge that ATOMIC covers, which are captured across different GLUCOSE dimensions. Note that there are definitely some individual pieces of knowledge that have been acquired in ATOMIC which do not exist in GLUCOSE, since some ATOMIC events may not have appeared in the GLUCOSE stories.

5 Empirical Evaluation Task

We set up a standalone evaluation task for evaluating models that predict GLUCOSE explanations: given a story S, a story sentence X, and a dimension d, provide an explanation in both specific and general forms.

Test Set Curation For a test set on commonsense reasoning to offer accurate and reliable evaluation, it should contain unambiguous examples with clear gold answers. This led to a curation process that identifies examples on which humans have high agreement, as follows: we sampled S, X pairs annotated by any three workers with the highest quality rating. A dimension d for S, X was allowed into the test set if 1) d was annotated by all three workers, and 2) the three specific statements had a round-robin average sentence-level BLEU (Lin and Och, 2004) score[11] above 0.75. Finally, two in-house annotators manually removed cases with typographical or core content errors, resulting in a test set of 500 story/sentence pairs, each with 1-5 dimensions answered.

Human and Automatic Evaluation Human evaluation is crucial for any language generation task. We crowdsourced our human evaluation on MTurk, using a dedicated UI,[12] asking three of our top-rated crowd workers from the main GLUCOSE crowdsourcing job to rate the predictions. We set up the following evaluation process to ensure calibrated judgments: the judge first reads a story with a highlighted sentence X, then reads a question about X corresponding to a GLUCOSE dimension. Next, they are shown a shuffled list of candidate answers, each produced by a different system. Finally, the judge rates each candidate answer on a four-point Likert scale: "completely incorrect," "almost incorrect," "almost correct," and "completely correct." To compare system performance, the ratings are mapped to numerical scores of 0–3, which are then averaged.

Automatic evaluation for tasks involving language generation has been a major bottleneck for research (Liu et al., 2016; Hashimoto et al., 2019). BLEU's ease of replicability has made it a popular automated metric, but its correlation with human judgement has proven weak on various tasks (Novikova et al., 2017; Gatt and Krahmer, 2018). For automatic evaluation, we use SacreBLEU (Post, 2018) with equal weights up to 4-grams at corpus-level on the three-reference test set. Using pairwise correlation analysis, we found strong correlation between human and BLEU scores on our test set, with correlation coefficients Spearman = 0.891, Pearson = 0.855, and Kendall's τ = 0.705, all with p-value < 0.001. The high correlation is due to various design choices, including 1) semi-structured inference rules in GLUCOSE are designed to be evaluable, where the structure constrains the variability of the rules, and 2) we minimized the noise in our human evaluation by designing a UI that could collect calibrated ratings from human judges educated about the task. The strong correlation suggests that BLEU is a viable metric for reporting future results on the GLUCOSE test set.

---

[10] We evaluated GLUCOSE's specific statements against ConceptNet, with nearly identical results to those in Table 3.

[11] We averaged the BLEU scores obtained, in round-robin fashion, by taking one rule as candidate and the other two as references. We used BLEU with equal weights up to 4-grams.

[12] GLUCOSE evaluation UI: https://bit.ly/2rJWFwy

6 Models

We developed several models for tackling the prediction task described in Section 5. The train and development sets for each model consisted of the initial 440K total annotations[13] (in the context of 3,360 stories) in the GLUCOSE dataset, minus the entries that share the context story with the test instances.

Due to their superior performance in sequence prediction, all our neural models use transformer blocks (Vaswani et al., 2017), which use multi-headed attention and fully connected layers to encode sequences. For decoding, all models use top-k random sampling (Fan et al., 2018). Details on all the models we experimented with can be found in Appendix C.

6.1 Pretrained Language Model (PT-LM)

PT-LM tests what GLUCOSE-like knowledge is captured by the pretrained 774M-parameter GPT-2 (Radford et al., 2019) language model. We elicit commonsense explanations from GPT-2 by prompting it with the story followed by sentence X and a dimension-specific trigger word like "because", and allowing the model to complete the sentence. For best results, we implemented "constrained decoding" by conditioning the GPT-2 model on the input S, X as context, then generating the next token for a dimension d as follows: if dimension d's template specifies a set of allowable words at the current position—e.g., locative prepositions for dimensions 3 and 8—sample from the options based on their likelihood as conditioned on the preceding tokens. Otherwise, allow sampling freely from the entire vocabulary. See Appendix C for a list of all templates used.

6.2 Models Trained on GLUCOSE

6.2.1 Language Models

We finetuned separate language models for specific and general rules. Each model monolithically covers all ten GLUCOSE dimensions: it generates rules given a dimension indicator as input.[14] Rules are sampled from the learned distribution $p(s) = \prod_{i=1}^{n} p(s_i \mid s_1, \ldots, s_{i-1})$, where s is the concatenation of input and output sequences. For all models in this section, we finetuned the PT-LM model described above.

One-sided Generation (1S-LM) One side of a GLUCOSE rule—the antecedent or the consequent, depending on the dimension—is always a paraphrase and/or a generalization of sentence X. In the one-sided model, we use X as is for this side of the specific statement; the model generates only the *target* side. Each training example is a text sequence *S#X#d#answer#EOS*, where d is the dimension number and *answer* is the target side. At test time, the model generates answer characters until it produces an EOS token.

Full Rule Generation (Full-LM) Full-LM learns to produce the complete rule, including the connective and the paraphrase of X. Instead of just the target side of the rule, the training examples have the full rule as the *answer* portion of the sequence. This allows the model to produce more human-like rules, including paraphrasing and/or generalizing X appropriately.

6.2.2 Encoder-Decoder Model (Enc-Dec)

Our most complex model is an encoder-decoder transformer model that jointly predicts the specific and general rules. It maximizes $p(y \mid x) = \prod_{i=1}^{n} p(y_i \mid x; y_1, \ldots, y_{i-1})$, where x is the input and y is the answer. We obtained the best results by formulating the input as *#d:* $S^*[X]$, where d is the dimension and $S^*[X]$ is the story S with sentence X surrounded by asterisks. We chose to finetune the state-of-the-art T5 model (with 770M-parameters, to be comparable to the size of the LM model), using the same hyperparameters as in (Raffel et al., 2020).

7 Results and Discussion

Table 4 shows the results from the models described in Section 6, evaluated as per Section 5. It shows that Enc-Dec uniformly outperforms all other models, confirming that full visibility into context[15] helps an architecture better learn the intricacies of GLUCOSE rules.

In fact, Enc-Dec performs competitively with humans in many dimensions. The strength of this model's performance in predicting both specific

---

[13] Table 2 shows the statistics of the final dataset, whereas all training for the models in the paper were conducted before the crowdsourcing of the dataset was finished.

[14] We experimented with training separate models for each dimension, which yielded much worse results.

[15] A clear drawback of language models is that the model's representation of the ith item depends only on items preceding i, and not the full input context. We show that better predictions can be made given full visibility into the entire input sequence.

	2.5	2.6	2.4	2.6	2.4	2.6	2.6	2.6	2.6*	2.7	N/A									

Table 4: Evaluation results for GLUCOSE models. Human evaluation scores are out of 3; BLEU scores are out of 100. Gray and regular rows show results on general and specific rules, respectively. Human model's performance was computed by showing judges a randomly selected answer from the three gold references. We performed paired sample t-tests on the human evaluation scores for each dimension for Full-LM against Enc-Dec, and then again for Enc-Dec against Human. The vast majority of differences are statistically significant at $p < 0.05$, with the exceptions noted in asterisk. Note that the dimensions where performance differences are not statistically significant strongly correlate with those with the least amount of data, as shown in Figure 1.

Model	**Dim 3: A location state that *Enables* X**	**Dim 6: An event that X *Causes/Enables***
Full-LM	Karen is at home *Enables* Karen made a pan of lasagna and brought it to the party	Karen made lasagna *Causes/Enables* Karen ate lasagna
	Someone$_A$ is in Somewhere$_A$ *Enables* Someone$_A$ makes Something$_A$ (that is edible)	Someone$_A$ cooks Something$_A$ (that is food) *Causes/Enables* Some People$_A$ to be turned away because of Something$_A$ (that is food)
Enc-Dec	Karen is in the kitchen *Enables* Karen makes a pan of lasagna	Karen makes a pan of lasagna *Causes/Enables* Karen eats it for a week
	Someone$_A$ is in a kitchen *Enables* Someone$_A$ cooks Something$_A$	Someone$_A$ makes Something$_A$ (that is food) *Causes/Enables* Someone$_A$ eats Something$_A$
Human	Karen is in the kitchen *Enables* Karen made a pan of lasagna	Karen made a pan of lasagna *Causes/Enables* She brought it to a party
	Someone$_A$ is in a kitchen *Enables* Someone$_A$ prepares Something$_A$ (that is a dish)	Someone$_A$ prepares Something$_A$ (that is a dish) *Causes/Enables* Someone$_A$ takes Something$_A$ to Something$_B$ (that is an event)

Table 5: Example model generations for the input story: *Karen made a pan of lasagna. She brought it to the party. Nobody wanted to eat lasagna. Karen ate it for a week. She became tired of lasagna.* (Sentence X is underlined.) Note that all test stories are unseen in the train or validation set.

and general rules is a testament to the high quality of the GLUCOSE training data. Its worst performance is on general rules for dimensions 5 and 10, which have the lowest number of training points and are the most diverse in content.

Other models perform as expected. PT-LM's poor performance shows that finetuning on our dataset significantly improves the commonsense inference capabilities of LMs. 1S-LM, which only predicts half of an inference rule, outperforms Full-LM in predicting specific statements, but lacks the ability to generalize them. We also tested various other baselines, including an ATOMIC-trained transformer model (Bosselut et al., 2019), retrieval of K-nearest-neighbors, and non-contextual variants of the presented models, all of which significantly underperformed the results in Table 4, and are presented in Appendix C.

Our results also show that our best models perform noticeably better on specific statements than on general rules. This is because generating a specific statement involves paraphrasing a story sentence and predicting an antecedent/consequent, while a general rule requires further generalizing the paraphrase and the antecedent/consequent appropriately such that the rule remains a generally valid statement about the world.

Although rule generalization can sometimes be as simple as replacing a named entity (e.g., *Gage*) with a typed variable (*Someone*$_A$), more often more complex transformations are needed, such as generalizing the action and producing type constraints on variables in the form of attribute phrases. For example, take into account the Enc-Dec results in Table

5. For dimension 3, the generalization of the story sentence, *Karen makes a pan of lasagna*, included generalizing *Karen* to $Someone_A$ and *makes a pan of lasagna* to *cooks* $Something_A$. Note that sentence generalizations are dimension-specific: For dimension 6, the generalization of same sentence retains the verb *make* but adds a type constraint to the object, $Something_A$ *(that is a food)*, which is required for making the rule generally valid. Table 1 shows another complex transformation example where *turning his bike* is generalized into *moves away from Something (that is dangerous)*, that takes into account story context.

Overall, our evaluation results show that the state-of-the-art pre-trained models finetuned on the GLUCOSE dataset are well capable of dynamically producing GLUCOSE-like inference rules on the fly, which is the ultimate usecase of the GLUCOSE dataset. It is important to note that there is still a consistent performance gap between the best-performing model and human's on generating specific statements and general rules, which indicates that there is still a large headroom for improvement on designing better models for generalizable commonsense reasoning.

Note that in our current evaluation setup, we have made the simplifying assumption of evaluating each dimension for each sentence individually, without consideration for consistency across dimensions or across sentences. Joint prediction of all the dimensions and sentences across the story is a considerably more challenging task that can potentially yield more accurate predictions for a downstream task. We encourage the future work to focus on building models that perform joint predictions, which can be readily evaluated using our test-set. It is important to note that static test sets are inherently narrow and prone to hidden curation biases (Sharma et al., 2018; Belinkov et al., 2019). We believe that the ultimate evaluation for models that show GLUCOSE-like commonsense reasoning capabilities should be on naturally-occurring arbitrary stories and through our presented human evaluation process. As future work, we are planning to show the value of incorporating GLUCOSE-trained models in other downstream NLP tasks such as reading comprehension and dialog.

8 Conclusions

We introduced GLUCOSE, a large-scale dataset of implicit commonsense knowledge, encoded as explanatory mini-theories grounded in a narrative context. The theories are categorized into ten causal dimensions, inspired by cognitive psychology.

We presented our multi-stage pipeline for acquiring semi-structured causal explanations at scale from lay workers, resulting in ˜670K annotations in the context of everyday children's stories. We demonstrated the utility of GLUCOSE data in two ways. First, our analysis showed that GLUCOSE rules capture knowledge not available in existing resources or pre-trained models. Second, in order to evaluate how well AI models can predict GLUCOSE knowledge on novel inputs, the ultimate value of such a dataset, we defined a standalone evaluation task for predicting specific and general inference rules given a story/sentence pair and a dimension. We curated a doubly-vetted test set, developed a platform to facilitate human judgment of system outputs, and validated BLEU as a strong automated evaluation metric. We show that training on GLUCOSE data improves model performances significantly on unseen stories.

Our results validate our hypothesis that a promising approach for imbuing machines with commonsense is to use carefully-crafted data, as in GLUCOSE, to train neural architectures that have a wide range of lexical and conceptual knowledge encoded, as in models pretrained on large corpora. Together with this paper, we release our dataset[16] and models[17], which we hope will enable the AI research community to explore effective approaches to incorporate commonsense reasoning capabilities into various downstream tasks.

Acknowledgments

We would like to thank the hundreds of amazing crowdworkers whose dedication made this work possible. We thank David Ferrucci for his valuable insights and support throughout the GLUCOSE project. We thank Andy Beck for the discussions around the GLUCOSE knowledge model and Jesse Dunietz for his discussions on the paper. We are grateful for the invaluable comments of the anonymous reviewers, Niranjan Balasubramanian, and Owen Rambow on this paper.

Appendix A: The Knowledge Model for Collecting GLUCOSE data

Semi-structured Inference Rules

The knowledge represented in GLUCOSE is captured in the form of semi-structured inference rules that are accompanied by a specific statement that grounds the rule in the context of a specific story. Each specific statement and its corresponding general rule use the common template of *antecedent connective consequent*. The antecedent and consequent are each composed by filling in a few syntactic slots, namely, subject, verb, object(s), and preposition(s). In order to further shape the semantics of the acquired knowledge, some of these slots have a pre-defined list of options to choose from.

Table 6 lists the pre-defined options for filling in the syntactic slots per GLUCOSE dimension[18]. Some of the slots allow adding a custom entry to the list of options, hence soft constraints, and some do not, hence hard constraints. Note that beyond the options listed in this table, the general rule slots across all the dimensions have pre-defined options for subject and object slots such as $Someone_A$ or $Some\ People_C$.

Comparison to Other Resources

To assess the value of the GLUCOSE dataset, we compared its coverage against the two most relevant commonsense knowledge resources: ConceptNet and ATOMIC. Table 7 shows our best-effort mapping among knowledge dimensions of GLUCOSE and relations in ConceptNet and ATOMIC.

Appendix B: Data Collection Pipeline

To ensure obtaining our desired quality, we designed a three-stage knowledge acquisition pipeline for crowdsourcing the GLUCOSE dataset on the Amazon Mechanical Turk (Mturk): The qualification test, the main task, and the expert review. In this Section we provide more detail about each stage and its designated UI design.

Qualification Test The qualification test contained questions testing workers' understanding in three areas: Identifying correct use of the UI slots for composing their answers (Figure 2), recognizing the right level of generalization (Figure 3), and identifying causes and effects with proper temporal understanding of the stories (Figure 4). Understanding generalization is the most difficult, and the most important, aspect of our task. Assessing the prospective workers' understanding of generalization was done through curating questions demonstrating under-generalization or over-generalization. The full Qualification UI, along with all the detailed instructions that were visible to the workers, is accessible here https://bit.ly/34Pej0N.

Main Task The qualified workers were able to access large batches of data with no limit. The main task starts with a page like the one shown in the Figure 5. The user loops through each of the 10 dimensions of GLUCOSE data collection, in order, presented as questions. Note that the user could answer the question by simply marking the dimension as not applicable and skipping it. If they choose to answer, as shown in Figure 6, they will be presented with the structured rule slots to input their answers. The full Main GLUCOSE UI, along with all the detailed instructions that were visible to the workers, is accessible here https://bit.ly/2R8XcTt.

Expert Review For work contributed through the main UI, data quality was controlled through daily monitoring of a percentage of incoming submissions and statistics on average dimensions filled out. For managing this process, we built a specialized UI for reviewing the incoming structured data. The percentage of answers reviewed by an in-house expert were used to update worker ratings. Workers enter the task with a score of "1", then advance to "2" as they become more proficient, getting a bonus increase. The top rating is "3". Select workers with a "3" rating were also moved into "top rated" batches that paid more per HIT and included higher bonuses and incentives. If work quality dropped, workers' ratings were adjusted accordingly. If their work was at a risk of degrading the quality of the dataset, they were disqualified from the task.[19]

Appendix C: Details on the Models

ATOMIC-trained Model

This model is a transformer language model, specifically GPT-1 architecture, fine-tuned on ATOMIC resource. The language model is fine-tuned to generate triplet sequences such as 'PersonX goes to

---

[18] A sample of the semi-structured rules in GLUCOSE can be found through https://bit.ly/2LFuwOt.

Please answer the following questions to get qualified for the "Explain a Story" HIT.

Story:

Enzo and Zoe were running a race. Enzo fell. He hurt his knee. Zoe looked back. Enzo was her friend. She ran to Enzo. She helped him up.

Let's call the highlighted sentence *X* = She ran to Enzo.

Query:

Consider the likely emotions and basic human drives of the participants in X. Does any of these states of mind/feelings motivate the participant to do X?

Below is a partial answer to the above query:

Step 1: We have composed the following Specific Statement.

The specific statement in natural language is:
"Zoe felt worried" Motivates "Zoe ran to Enzo"

Which of the following is the correct use of the slots for expressing the above Specific Statement?

○

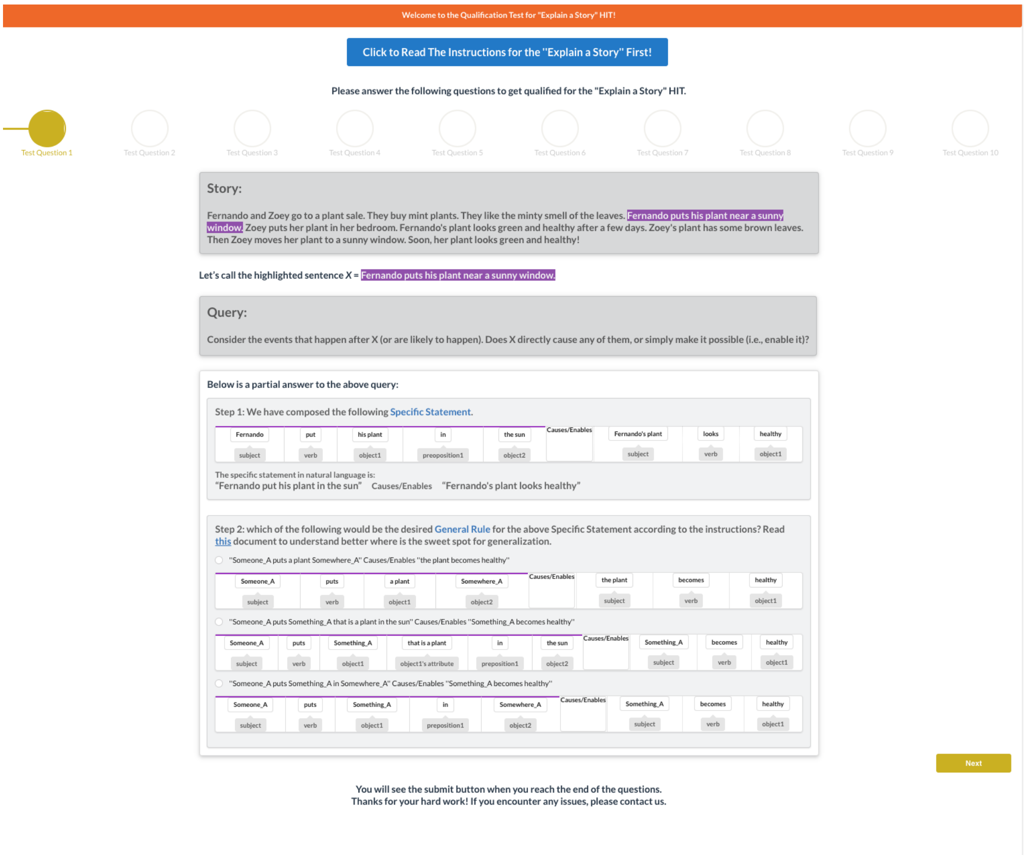
Zoe	felt	worried	Motivates	Zoe	ran	to	Enzo
subject	verb	object1		subject	verb	preposition1	object1

○

Zoe	felt worried	Motivates	Zoe	ran to Enzo
subject	verb		subject	verb

You will see the submit button when you reach the end of the questions.
Thanks for your hard work! If you encounter any issues, please contact us.

Figure 2: Example qualification question about the correct use of the slots.



Please answer the following questions to get qualified for the "Explain a Story" HIT.

Story:

Fernando and Zoey go to a plant sale. They buy mint plants. They like the minty smell of the leaves. Fernando puts his plant near a sunny window. Zoey puts her plant in her bedroom. Fernando's plant looks green and healthy after a few days. Zoey's plant has some brown leaves. Then Zoey moves her plant to a sunny window. Soon, her plant looks green and healthy!

Let's call the highlighted sentence *X* = Fernando puts his plant near a sunny window.

Query:

Consider the events that happen after X (or are likely to happen). Does X directly cause any of them, or simply make it possible (i.e., enable it)?

Below is a partial answer to the above query:

Step 1: We have composed the following Specific Statement.

Fernando	put	his plant	in	the sun	Causes/Enables	Fernando's plant	looks	healthy
subject	verb	object1	preoposition1	object2		subject	verb	object1

The specific statement in natural language is:
"Fernando put his plant in the sun" Causes/Enables "Fernando's plant looks healthy"

Step 2: which of the following would be the desired General Rule for the above Specific Statement according to the instructions? Read this document to understand better where is the sweet spot for generalization.

○ "Someone_A puts a plant Somewhere_A" Causes/Enables "the plant becomes healthy"

Someone_A	puts	a plant	Somewhere_A	Causes/Enables	the plant	becomes	healthy
subject	verb	object1	object2		subject	verb	object1

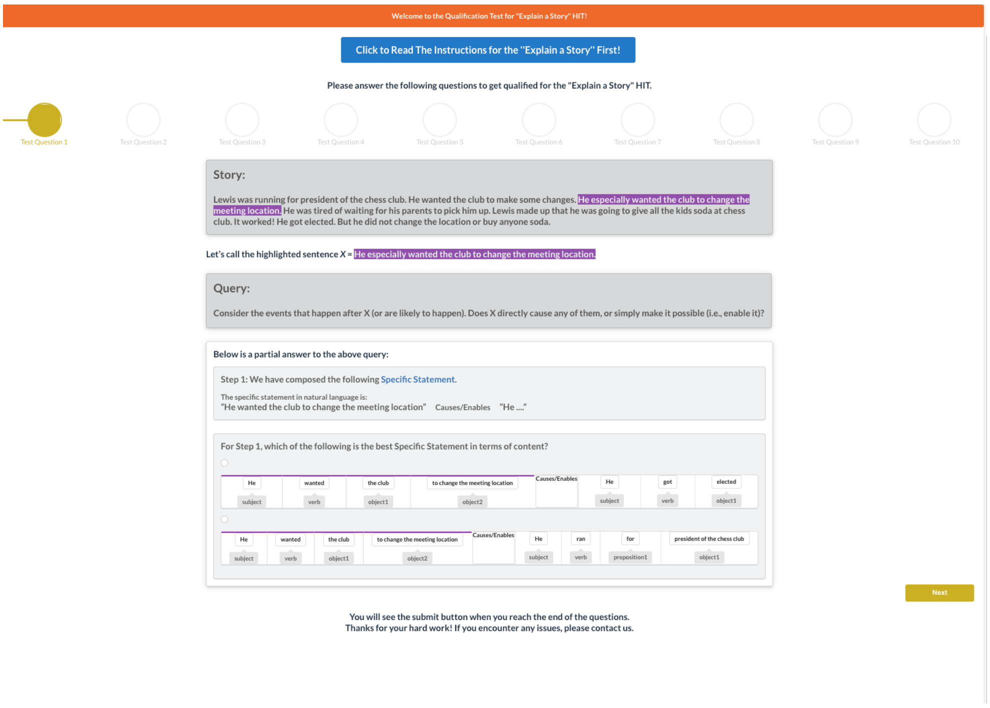
Figure 3: Example qualification question about the correct level of generalization.



Please answer the following questions to get qualified for the "Explain a Story" HIT.

Story:

Lewis was running for president of the chess club. He wanted the club to make some changes. He especially wanted the club to change the meeting location. He was tired of waiting for his parents to pick him up. Lewis made up that he was going to give all the kids soda at chess club. It worked! He got elected. But he did not change the location or buy anyone soda.

Let's call the highlighted sentence *X* = He especially wanted the club to change the meeting location.

Query:

Consider the events that happen after X (or are likely to happen). Does X directly cause any of them, or simply make it possible (i.e., enable it)?

Below is a partial answer to the above query:

Step 1: We have composed the following Specific Statement.

The specific statement in natural language is:
"He wanted the club to change the meeting location" Causes/Enables "He ...."

For Step 1, which of the following is the best Specific Statement in terms of content?

○

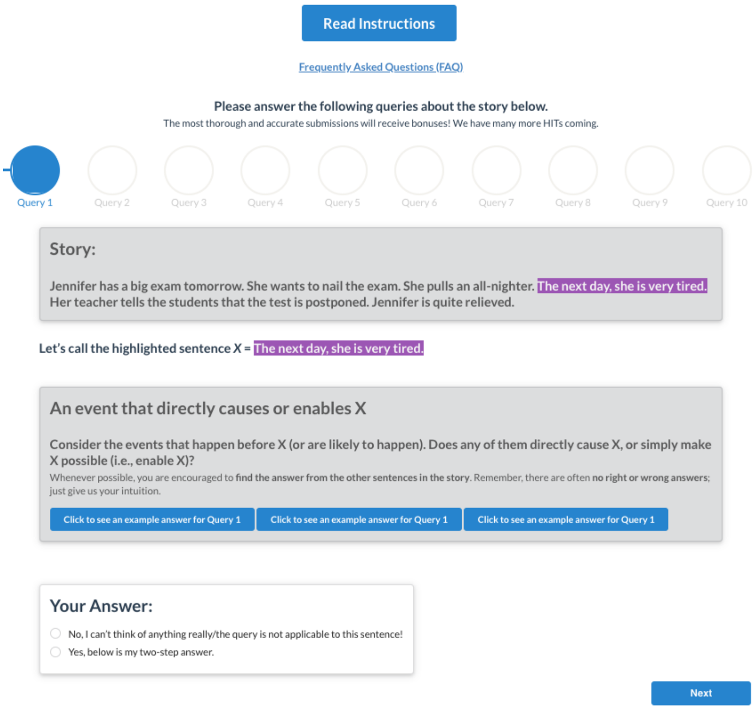
He	wanted	the club	to change the meeting location	Causes/Enables	He	got	elected
subject	verb	object1	object2		subject	verb	object1

○

He	wanted	the club	to change the meeting location	Causes/Enables	He	ran	for	president of the chess club
subject	verb	object1	object2		subject	verb	preposition1	object1

You will see the submit button when you reach the end of the questions.
Thanks for your hard work! If you encounter any issues, please contact us.

Figure 4: Example qualification question about understanding causal relations between events.



Please answer the following queries about the story below.
The most thorough and accurate submissions will receive bonuses! We have many more HITs coming.

Story:

Jennifer has a big exam tomorrow. She wants to nail the exam. She pulls an all-nighter. The next day, she is very tired. Her teacher tells the students that the test is postponed. Jennifer is quite relieved.

Let's call the highlighted sentence X = The next day, she is very tired.

An event that directly causes or enables X

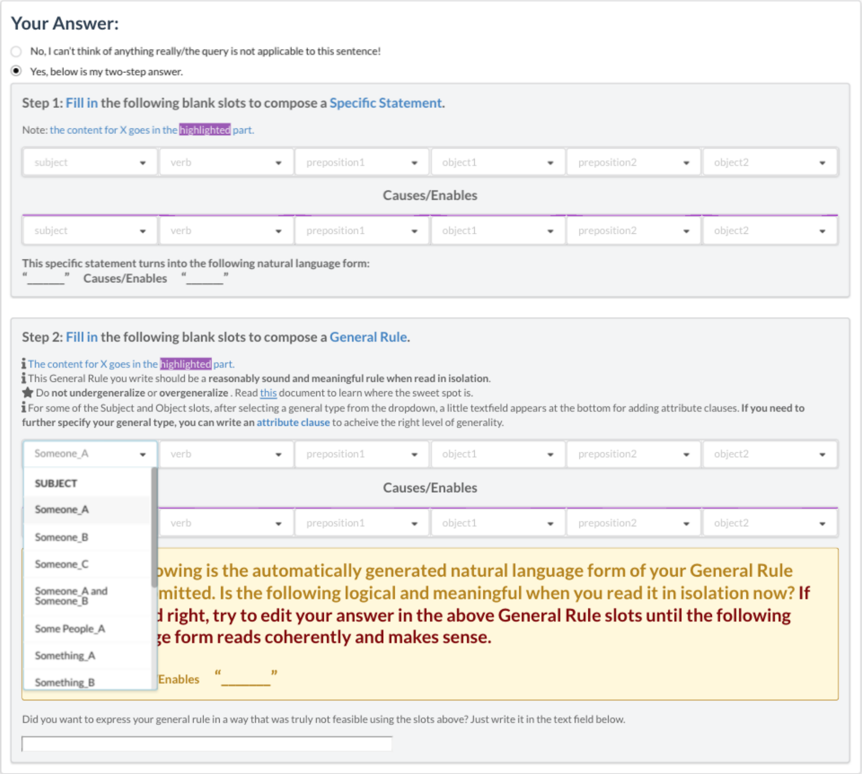
Consider the events that happen before X (or are likely to happen). Does any of them directly cause X, or simply make X possible (i.e., enable X)?

Whenever possible, you are encouraged to **find the answer from the other sentences in the story**. Remember, there are often **no right or wrong answers**; just give us your intuition.

Your Answer:

○ No, I can't think of anything really/the query is not applicable to this sentence!
○ Yes, below is my two-step answer.

Figure 5: The preview page of the Main UI for GLUCOSE data collection, which can be accessed via https://bit.ly/2R8XcTt.



Your Answer:

○ No, I can't think of anything really/the query is not applicable to this sentence!

● Yes, below is my two-step answer.

Step 1: Fill in the following blank slots to compose a Specific Statement.

Note: the content for X goes in the highlighted part.

This specific statement turns into the following natural language form:
"______" Causes/Enables "______"

Step 2: Fill in the following blank slots to compose a General Rule.

The content for X goes in the highlighted part.
This General Rule you write should be a **reasonably sound and meaningful rule when read in isolation**.
Do **not undergeneralize** or **overgeneralize** . Read this document to learn where the sweet spot is.
For some of the Subject and Object slots, after selecting a general type from the dropdown, a little textfield appears at the bottom for adding attribute clauses. **If you need to further specify your general type, you can write an attribute clause** to acheive the right level of generality.

owing is the automatically generated natural language form of your General Rule
mitted. Is the following logical and meaningful when you read it in isolation now? **If**
d right, try to edit your answer in the above General Rule slots until the following
ge form reads coherently and makes sense.

Enables "______"

Did you want to express your general rule in a way that was truly not feasible using the slots above? Just write it in the text field below.

Figure 6: The answer-entry part of the main UI. When "Yes" is selected for "Your Answer" on the main UI for GLUCOSE data collection, the workers can input answers to the dimension in question.

the mall <xIntent >to buy clothes'. We use the same exact model trained for (Bosselut et al., 2019). This model is only applicable to General Rule prediction. The results from this model were significantly worse than the PT-LM model, which is the worst-performing model presented in the main paper. This was expected, given the little overlap that exists between the ATOMIC dataset and the GLUCOSE knowledge, as presented in the main paper under "Comparison to Other Resources" Section.

K-Nearest Neighbor (KNN)

For a given test pair S, X, the KNN baseline retrieves the K most similar training instances and returns one as the prediction. It uses BERT (Devlin et al., 2019) sentence embeddings to compute cosine similarity between a candidate and each retrieved training instance. We tuned three parameters on the development set: K, min_sim, and max_sim. If a candidate has a similarity score above max_sim, it is emitted as the prediction. Otherwise, candidates scoring below min_sim are dropped, and the centroid among the remaining pool is emitted. We evaluate KNN only for general rules, since it is not meaningful to retrieve specific statements from the training set. The results from this model were significantly worse than the PT-LM model, which is the worst-performing model presented in the main paper. The performance of the KNN model highlights the importance of generalizing beyond the training data.

Pretrained Language Model (PT-LM)

We experimented with prompting the pretrained language models, specifically GPT-2, as is, for predicting GLUCOSE dimensions. Table 8 shows the list of particular templates used for decoding. We used 774M-parameter GPT-2 model, with top-K random sampling for decoding, with K = 15. The decoding for this model was done on CPU.

1S-LM and Full-LM

This model uses the exact model as with PT-LM. These models were finetuned on 8 NVIDIA Tesla V100 GPUs for 10K steps.

Enc-Dec Model

We finetuned the 770M-parameter pre-trained T5 model using the exact same hyperparameters as in (Raffel et al., 2020). We have used top-K random

sampling for decoding, with K = 15. We did the training and decoding for this model on Google TPU v3-8. We trained this model for 500k steps after pre-training, which took about 72 hours.

We also experimented with non-contextual version of all the models presented in the main paper. For non-contextual models, the story S is simply removed from the input. The non-contextual models all underperformed their contextual counterparts. This further validates the importance of using context in making commonsense inferences.

Abstract

We combine character-level and contextual language model representations to improve performance on Discourse Representation Structure parsing. Character representations can easily be added in a sequence-to-sequence model in either one encoder or as a fully separate encoder, with improvements that are robust to different language models, languages and data sets. For English, these improvements are larger than adding individual sources of linguistic information or adding non-contextual embeddings. A new method of analysis based on semantic tags demonstrates that the character-level representations improve performance across a subset of selected semantic phenomena.

1 Introduction

Character-level models have obtained impressive performance on a number of NLP tasks, ranging from the classic POS-tagging (Santos and Zadrozny, 2014) to complex tasks such as Discourse Representation Structure (DRS) parsing (van Noord et al., 2018b). However, this was before the large pretrained language models (Peters et al., 2018; Devlin et al., 2019) took over the field, with the consequence that for most NLP tasks, state-of-the-art performance is now obtained by fine-tuning on one of these models (e.g., Conneau et al., 2020).

Does this mean that, despite a long tradition of being used in language-related tasks (see Section 2.1), character-level representations are no longer useful? We try to answer this question by looking at semantic parsing, specifically DRS parsing (Abzianidze et al., 2017; van Noord et al., 2018a). We aim to answer the following research questions:

1. Do pretrained language models (LMs) outperform character-level models for DRS parsing?
2. Can character and LM representations be combined to improve performance, and if so, what is the best method of combining them?
3. How do these improvements compare to adding linguistic features?
4. Are the improvements robust across different pretrained language models, languages, and data sets?
5. On what type of sentences do character-level representations specifically help?

Why semantic parsing? Semantic parsing is the task of automatically mapping natural language utterances to interpretable meaning representations. The produced meaning representations can then potentially be used to improve downstream NLP applications (e.g., Issa et al., 2018; Song et al., 2019; Mihaylov and Frank, 2019), though the introduction of large pretrained language models has shown that explicit formal meaning representations might not be a necessary component to achieve high accuracy. However, it is now known that these models lack reasoning capabilities, often simply exploiting statistical artifacts in the data sets, instead of actually *understanding* language (Niven and Kao, 2019; McCoy et al., 2019). Moreover, Ettinger (2020) found that the popular BERT model (Devlin et al., 2019) completely failed to acquire a general understanding of negation. Related, Bender and Koller (2020) contend that meaning cannot be learned from form alone, and argue for approaches that focus on grounding the language (communication) in the real world. We believe formal meaning representations therefore have an important role to play in future semantic applications, as semantic parsers produce an explicit model of a real-world interpretation.

Why Discourse Representation Structures? DRS parsing is a task that combines logical, pragmatic and lexical components of semantics in a

single meaning representation. The task is complex and comprises other NLP tasks, such as semantic role labeling, word sense disambiguation, co-reference resolution and named entity tagging. Also, DRSs show explicit scope for certain operators, which allows for a more principled and linguistically motivated treatment of negation, modals and quantification, as has been advocated in formal semantics. Moreover, DRSs can be translated to formal logic, which allows for automatic forms of inference by third parties. Lastly, annotated DRSs are available in four languages (Abzianidze et al., 2017, see Section 3.3), allowing us to evaluate our models on multiple languages.

2 Background

2.1 Character-level models

The power of character-level representations has long been known in the field. In earlier work, they were successfully used in a range of tasks, including text-to-speech (Sejnowski and Rosenberg, 1987), parallel text alignment (Church, 1993), grapheme to phoneme conversion (Kaplan and Kay, 1994), language identification (Dunning, 1994), topical similarity prediction (Cavnar, 1994), named entity recognition (Klein et al., 2003), authorship attribution (Peng et al., 2003) and statistical machine translation (Vilar et al., 2007).

More recently, they also proved useful as input representations for neural networks, starting with success in general language modelling (Sutskever et al., 2011; Kim et al., 2016; Bojanowski et al., 2017), but also for a range of other tasks, including tokenization (Evang et al., 2013), POS-tagging (Santos and Zadrozny, 2014; Plank et al., 2016), dependency parsing (Ballesteros et al., 2015; Vania et al., 2018) and neural machine translation (Chung et al., 2016; Costa-jussà and Fonollosa, 2016; Luong and Manning, 2016; Cherry et al., 2018).

In semantic parsing, if character-level representations are employed, they are commonly used in combination with non-contextual word-level representations (Lewis et al., 2016; Ballesteros and Al-Onaizan, 2017; Groschwitz et al., 2018; Cai and Lam, 2019). There are a few recent studies that did use character-level representations in combination with BERT (Zhang et al., 2019a,b; Cai and Lam, 2020), though only Zhang et al. (2019a) provided an ablation score without the characters. Moreover, it is not clear if this small improvement was significant. van Noord and Bos (2017) and van Noord et al. (2018b), on the other hand, used solely character-level representations in an end-to-end fashion, using a bi-LSTM sequence-to-sequence model, which outperformed word-based models that employed non-contextual embeddings.

2.2 Discourse Representation Structures

DRSs are formal meaning representations introduced by Discourse Representation Theory (Kamp and Reyle, 1993) with the aim to capture the meaning of texts (Figure 1). Many variants of DRS have been proposed throughout the years. We adopt Venhuizen et al. (2018)'s version of DRT, which is close to Kamp's original ideas, but has a neo-Davidsonian view of event semantics and explicitly represents presuppositions.

Corpora The Groningen Meaning Bank (GMB, Basile et al., 2012; Bos et al., 2017) was the first attempt of annotating open domain English texts with DRSs. The released documents are partially corrected, but there are no gold standard sets available for evaluation. A similar corpus is the Parallel Meaning Bank (PMB, Abzianidze et al., 2017), which builds upon the GMB in a number of ways. It contains (parallel) texts in four languages: English, German, Italian and Dutch, with more fine-grained and language-neutral DRSs. Semantic tags are used during annotation (Bjerva et al., 2016; Abzianidze and Bos, 2017), and all non-logical DRS symbols are grounded in either WordNet (Fellbaum, 1998) or VerbNet (Bonial et al., 2011). Moreover, its releases contain gold standard DRSs. For these reasons, we take the PMB as our corpus of choice to evaluate our DRS parsers.

DRS parsing Early approaches to DRS parsing employed rule-based systems for small English texts (Johnson and Klein, 1986; Wada and Asher, 1986; Bos, 2001). The first open domain DRS parser is Boxer (Bos, 2008, 2015), which is a combination of rule-based and statistical models. Le and Zuidema (2012) used a probabilistic parsing model that used dependency structures to parse GMB data as graphs. More recently, Liu et al. (2018) proposed a neural model that produces (tree-structured) DRSs in three steps by first learning the general (box) structure of a DRS, after which specific conditions and referents are filled in. In follow-up work (Liu et al., 2019a) they extend this work by adding an improved attention mechanism and constraining the decoder to ensure well-formed output. This model achieved impressive performance on both sentence-level and document-level DRS parsing on GMB data. Fu et al. (2020) in turn improve on this work by employing a Graph Attention Network during both encoding and decoding.

The introduction of gold standard DRSs in the PMB enabled a principled comparison of approaches. In our previous work (van Noord et al., 2018b), we showed that sequence-to-sequence models can successfully learn to produce DRSs, with characters as the preferred representation. In follow-up work, we improved on these scores by adding linguistic features (van Noord et al., 2019). The first shared task on DRS parsing (Abzianidze et al., 2019) sparked more interested in the topic, with a system based on stack-LSTMs (Evang, 2019) and a neural graph-based system (Fancellu et al., 2019). The best system (Liu et al., 2019b) used a similar approach as van Noord et al. (2018b), but swapped the bi-LSTM encoder for a Transformer. We will compare our approach to these models in Section 4.

3 Method

3.1 Neural Architecture

As our baseline system, we start from a fairly standard sequence-to-sequence model with attention (Bahdanau et al., 2015), implemented in AllenNLP (Gardner et al., 2017).[1] We improve on this model in a number of ways, mainly based on Nematus (Sennrich et al., 2017): (i) we initialize the decoder hidden state with the mean of all encoder states, (ii) we add an extra linear layer between this mean encoder state and the initial decoder state and (iii) we add an extra linear layer after each decoder state.

Specifically, given a source sequence $(s_1, \ldots, s_l)$ of length l, and a target sequence $(t_1, \ldots, t_k)$ of length k, let $\mathbf{e}_i$ be the embedding of source symbol i, let $\mathbf{h}_i$ be the encoder hidden state at source position i and let $\mathbf{d}_j$ be the decoder state at target position j. A single forward encoder state is obtained as follows: $\overrightarrow{\mathbf{h}}_i = \text{LSTM}(\overrightarrow{\mathbf{h}}_{i-1}, \mathbf{e}_i)$. The final state is obtained by concatenating the forward and backward hidden states, $\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]$. The decoder is initialized with the average over all encoder states: $\mathbf{c}_{\text{tok}} = \left(\sum_{i=1}^{l} \mathbf{h}_i\right) / \, l$ and $\mathbf{d}_0 = \tanh\left(\mathbf{W}_{\text{init}}\, \mathbf{c}_{\text{tok}}\right)$.

Characters in one encoder We will experiment with adding character-level information in either one or two encoders. For one encoder, we use char-CNN (Kim et al., 2016), which runs a Convolutional Neural Network (LeCun et al., 1990) over the characters for each token. It applies convolution layers for certain *widths*, which in essence select n-grams of characters. For each width, it does this a predefined number of times, referred to as the number of *filters*. The filter vectors form a matrix, which is then pooled to a vector by taking the max value of each initial filter vector. A detailed schematic overview of this procedure is shown in Appendix A. However, we usually do not look at only a single width, but at a range of widths, e.g., $[1, 2, 3, 4, 5]$. In that case, we simply concatenate the resulting vectors to obtain our final char-CNN embedding: $\mathbf{e}_{\text{char}_i} = [\mathbf{e}_{w1}; \mathbf{e}_{w2}; \mathbf{e}_{w3}; \mathbf{e}_{w4}; \mathbf{e}_{w5}]$. Each width-filter combination has independent learnable parameters. Finally, the char-CNN embedding is concatenated to the token-level representation, which is fed to the encoder: $\mathbf{e}_i = [\mathbf{e}_{\text{tok}_i}; \mathbf{e}_{\text{char}_i}]$.

Characters in two encoders In the two-encoder setup, we run separate (but structurally identical) bi-LSTM encoders over the tokens and characters, and concatenate the resulting context vector before we feed it to the decoder:

$$\mathbf{d}_0 = \tanh\left(\mathbf{W}_{\text{init}}\, [\mathbf{c}_{\text{tok}}; \mathbf{c}_{\text{char}}]\right)$$

In the decoder, we replace the LSTM with a doubly-attentive LSTM, based on the doubly-

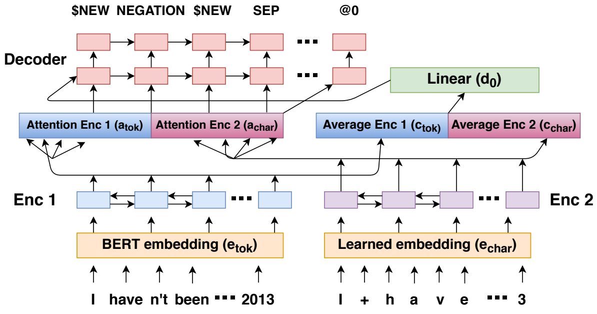

Figure 2: Schematic overview of our neural architecture when using two encoders (BERT and characters).

attentive GRU (Calixto et al., 2017). We apply soft-dual attention (Junczys-Dowmunt and Grundkiewicz, 2017) to be able to attend over both encoders in the decoder (also see Figure 2):

$$
\begin{aligned}
\mathbf{d}'_j &= \mathrm{LSTM}_1\left(\mathbf{d}_{j-1}, \mathbf{e}_{t_{j-1}}\right) \\
\mathbf{a}_j &= \left[\mathrm{ATT}\left(\mathbf{C}_{\text{tok}}, \mathbf{d}'_j\right); \mathrm{ATT}\left(\mathbf{C}_{\text{char}}, \mathbf{d}'_j\right)\right] \\
\mathbf{d}_j &= \mathrm{LSTM}_2\left(\mathbf{d}'_j, \mathbf{a}_j\right)
\end{aligned}
$$

Here, $\mathbf{e}_{t_{j-1}}$ is the embedding of the previously decoded symbol t, C the set of encoder hidden states for either the tokens or characters, ATT the attention function (dot-product) and $\mathbf{d}_j$ the final decoder hidden state at step j. This model can easily be extended to more than two encoders, which we will experiment with in Section 4.

This type of multi-source model is commonly used to represent different languages, e.g., in machine translation (Zoph and Knight, 2016; Firat et al., 2016) and semantic parsing (Susanto and Lu, 2017; Duong et al., 2017), though it has also been successfully applied in multi-modal translation (Libovický and Helcl, 2017), multi-framework semantic parsing (Stanovsky and Dagan, 2018) and adding linguistic information (Currey and Heafield, 2018; van Noord et al., 2019). To the best of our knowledge, we are the first to represent the characters as a source of extra information in a multi-source sequence-to-sequence model.

Transformer We also experiment with the Transformer model (Vaswani et al., 2017), using the stacked self attention model as implemented in AllenNLP. A possible advantage of this model is that it might handle longer sentences and documents better. However, it might be harder to tune (Popel and Bojar, 2018)[2] and its improved performance has mainly been shown for large data sets, as opposed to the generally smaller semantic parsing data sets (Section 3.3). Indeed, we cannot outperform the LSTM architecture (see Section 4), even when tuning more extensively. We therefore do not experiment with adding character-level representations to this architecture, though the char-CNN can be added similarly as for the LSTM model.

Hyper-parameters To make a fair comparison, we conduct an independent hyper-parameter search on the development set for all nine input text representations (see Section 3.2) across the two neural architectures, starting from the settings of van Noord et al. (2019). We found that the best settings were very close for all systems, with the only notable difference that the learning rate of the Transformer models is considerably smaller than for the bi-LSTM models (0.0002 vs 0.001).[3]

For the char-CNN model, we use 100 filters, an embedding size of 75 and n-gram filter sizes of $[1, 2, 3]$ for English and $[1, 2, 3, 4, 5]$ for German, Italian and Dutch. For experiments where we add characters or linguistic features, the only extra search we do is the size of the hidden vector of the RNN encoder ($300 - 600$), since this vector now has to contain more information, and could potentially benefit from a larger size. Note that (possible) improved performance is not simply due to larger model capacity, since during tuning of the baseline models a larger RNN hidden size did not result in better performance.

3.2 Representations

We will experiment with five well-known pre-trained language models: ELMO (Peters et al., 2018), BERT base/large (Devlin et al., 2019) and ROBERTA base/large (Liu et al., 2019c).[4] The performance of these five large LMs is contrasted with results of a character-level model and three word-based models. The word-based models either learn the embeddings from scratch or use non-contextual GLOVE (Pennington et al., 2014) or FASTTEXT (Grave et al., 2018) embeddings. Pre- and postprocessing of the DRSs is done using the method described in van Noord et al. (2018b).[5] The DRSs are linearized, after which the variables are rewritten to a relative representation. The character-level model

---

[2] Also see: `https://twitter.com/srush_nlp/status/1245825437240102913`

[3] See Appendix B for specific hyperparameter settings.

[4] We are aware that there exist several other large pre-trained language models (e.g., Yang et al., 2019; Raffel et al., 2020; Clark et al., 2020), but we believe that the models we used have had the largest impact on the field.

has character representations for the DRS concepts and constants, but not for variables, roles and operators. For all word-level models, the DRS concepts are initialized with GLOVE embeddings, while the other target tokens are learned from scratch.

BERT specifics For the BERT models, we obtained the best performance by only keeping the vector of the first WordPiece per original token (e.g., only keep `play` out of `play ##ing`). For ROBERTA, it was best to use the WordPiece tokenization as is. Since linguistic features are added on token level, we duplicate the semantic tags for multi-piece tokens of ROBERTA in Table 5. Interestingly, we found that for both BERT and ROBERTA, it was best to keep the pretrained weights frozen. This was not a small difference: models using fine-tuning always obtained low scores (45 to 60).

3.3 Data and Evaluation

We use PMB releases 2.2.0 and 3.0.0[6] in our experiments (Table 1). The latter is a larger and more diverse extension of 2.2.0, which will be used for most of our experiments. We use 2.2.0 to compare to previous work and to verify that our results are robust across datasets. The PMB releases contain DRSs for four languages (English, German, Italian and Dutch) for three levels of annotation: gold (fully manually checked), silver (partially manually corrected) and bronze (no manual corrections). To make a fair comparison to previous work, we only employ the gold and silver data, by pretraining on gold + silver data and subsequently fine-tuning on only the gold data. If there is no gold train data available, we train on silver + bronze and fine-tune on silver. Unless otherwise indicated, our results are on the English development set of release 3.0.0.

Table 2: Example representation for each source of linguistic information (PMB document p00/d1489).

Linguistic features We want to contrast our method of character-level information to adding sources of linguistic information. Based on van Noord et al. (2019), we employ these five sources: part-of-speech tags (POS), dependency parses (DEP), lemmas (LEM), CCG supertags (CCG) and semantic tags (SEM). For the first three sources, we use Stanford CoreNLP (Manning et al., 2014) to parse the documents in our dataset. The CCG supertags are obtained by using easyCCG (Lewis and Steedman, 2014). For semantic tagging, we train our own trigram-based tagger using TnT (Brants, 2000).[7] Table 2 shows a tagged example sentence for all five sources of information. Moreover, we also include non-contextual GLOVE and FASTTEXT embeddings as an extra source of information.

We add these sources of linguistic information in the same way as we add the character-level information, in either one or two encoders (see Section 3.1). In two encoders, we can use the exact same architecture. For one encoder, we (obviously) do not use the char-CNN, but learn a separate embedding for the tags (of size 200), that is then concatenated to the token-level representation, i.e., $\mathbf{e}_i = [\mathbf{e}_{\mathrm{tok}_i}; \mathbf{e}_{\mathrm{ling}_i}]$. If we use two encoders with a LM, characters *and* linguistic information (e.g., Table 4), the characters are added separately in the second encoder, while the LM and linguistic information representations are added in the first encoder.

Evaluation We compare the produced DRSs to the gold standard using Counter (van Noord et al., 2018a), which calculates micro precision, recall and F1-score based on the number of matching clauses.[8] We use Referee (van Noord et al., 2018b) to ensure that the produced DRSs are syntactically and semantically well-formed (i.e., no free variables, no loops in subordinate relations) and form a connected graph. DRSs that are ill-formed get

---

[6] `https://pmb.let.rug.nl/data.php`

[7] This tagger is also used in the PMB pipeline, see Abzianidze and Bos (2017). It outperformed an ngram-based CRF-tagger (Lafferty et al., 2001) we also tried, obtaining an accuracy of 94.4% on the dev set.

[8] `https://github.com/RikVN/DRS_parsing/`

an F1-score of 0.0. All shown scores are averaged F1-scores over five training runs of the system, in which the same five random seeds are used.[9] For significance testing we use approximate randomization (Noreen, 1989), with $\alpha = 0.05$ and $R = 1000$.

We also introduce and release **DRS-JURY**. This program provides a detailed overview of the performance of a DRS parser, but can also compare experiments, possibly over multiple runs. Features include significance testing, semantic tag analysis (Section 5.1), sentence length plotting (Section 5.2), new detailed Counter scores (Appendix D), and analysing (relative) best/worst produced DRSs (Appendix E). We hope this is a step in the direction of a more principled way of evaluating DRS parsers.

4 Results

LMs vs char-level models DRS parsing is no exception to the general trend in NLP: it is indeed the case that the pretrained language models outperform the char-only model (Table 3). Interestingly, the Transformer model has worse performance for all representations.[10] Surprisingly, we find that BERT-BASE is the best model, though the differences are small.[11] We use this model in further experiments (referred to as BERT).

Adding characters to BERT We can see the impact of adding characters to BERT (first row of results in Table 4). For both methods, it results in a clear and significant improvement over the BERT-only baseline, 87.6 versus 88.1.

Adding linguistic features to BERT However, another common method of improving performance is adding linguistic features to the token-level representations. We try a range of linguistic features (described in Section 3.3), that are added in either one or two encoders. We see in the first two columns of results of Table 4 that even though linguistic information sources indeed do improve performance (up to 0.4 absolute), there is no single source that can beat adding just the character-level representations (88.1).

	bi-LSTM	**Transformer**

Table 4: Results for adding characters, linguistic information and a combination of the two to the bi-LSTM BERT-BASE model on 3.0.0 English dev.

Combining characters and linguistic features An obvious follow-up question is whether we still see improvements for character-level models when also adding linguistic information. In a single encoder, adding characters (third column of results in Table 4) is beneficial for 6 out of 7 linguistic sources (i.e., compared to the first column of results). The scores are, however, not higher than simply adding characters on their own, suggesting that linguistic features are not always beneficial if character-level features are also included. For two encoders, the pattern is less clear, but we do find our highest score thus far when we combine characters and semantic tags (88.4).[12] Using three encoders did not yield clear improvements over two encoders. Therefore, we do not experiment with using more than three encoders.

Robustness to different LMs We want to verify that the character improvements are robust to using different language models (Table 5). We see that adding characters results in improvement for all the LMs under consideration, even for ELMO, which already incorporates characters in creating the initial embeddings. Moreover, combining characters and

Table 6: Comparison of our four main models to previous work for PMB 2.2.0 and 3.0.0 (English only).

semantic tags also results in an improvement over just using characters for all the LMs considered.

Robustness across languages We train systems for German, Italian and Dutch for four models: char-only, BERT-ONLY, BERT + char in 1 encoder, and BERT + char in two encoders.[13] The BERT model we use is `bert-multilingual-uncased`. The results for both PMB releases are shown in Figure 3. For all languages, adding characters leads to a clear improvement for both one and two encoders, though for Dutch the improvement is smaller than for German and Italian. Interestingly, the two-encoder setup seems to be preferable for these smaller, non-English data sets. For 2.2.0, we outperform the system of Fancellu et al. (2019) for German and Italian and obtain competitive scores for Dutch.

Comparison to previous work To check whether the improvements hold on unseen data, we run our best models on the test set and compare the scores to previous work (Table 6).[14] We see that adding the character-level information has similar (significant) improvements for dev and test on both data sets. The addition of semantic tags might be questionable: for 2.2.0, both the BERT + char models outperform this model, while for 3.0.0 the 0.1 improvement over BERT + char in one encoder is not significant. Despite this, we reach state-of-the-art performance on both data sets, significantly outperforming the previous best scores by van Noord et al. (2019) and Liu et al. (2019b). We also compare to the semantic parser Boxer, which needs input for 6 different PMB layers (Abzianidze et al., 2017). *Amateur Boxer* is trained with internal PMB taggers, while *Pro Boxer* uses the output of a neural multi-task learning system based on BERT (van der Goot et al., 2020). Even though this is an unfair comparison to our system, since the rule-based components of Boxer are (partly) optimized on the dev and test sets, our best model still improves slightly over *Pro Boxer* (significantly on test).

---

[13] We do not train a model that uses semantic tags as features, since there is not enough gold semantic tag data available to train a good tagger for any of these languages.

[14] For the detailed Counter scores see Appendix D.

5 Analysis

5.1 Semantic tag analysis

We are also interested in finding out *why* the character-level representations help improve performance. As a start, we investigate on what type of sentences and semantic phenomena the character representations are the most beneficial. We introduce a novel method of analysis: selecting subsets of sentences based on the occurrence of certain semantic tags. In the PMB release, each token is also annotated with a semantic tag, which indicates the semantic properties of the token in the given context (Abzianidze and Bos, 2017). This allows us to easily select all sentences that contain certain (semantic) phenomena and evaluate the performance of the different models on those sentences.[15]

The selected phenomena and corresponding F-scores for our four best models (see Table 6) are shown in Table 7.[16] Our best model (+ch+sem) has the best performance on six of the seven phenomena selected, even though the differences are small. The character-level representations seem to help across the board; the +char models improve on the baseline (BERT) in almost all instances.

For *Numerals* and *Named Entities* we expected the characters to help specifically, since (i) BERT representations might not be as optimal for all individual numerals (Wallace et al., 2019), and (ii) the character representations might attend more to capital letters, which often indicate the presence of a named entity. Indeed, the character representations clearly help for *Numerals*, but less so for *Named Entities*. Of course, this analysis only scratched the surface as to why the character-level representations improve performance. We leave a more detailed investigation to future work.

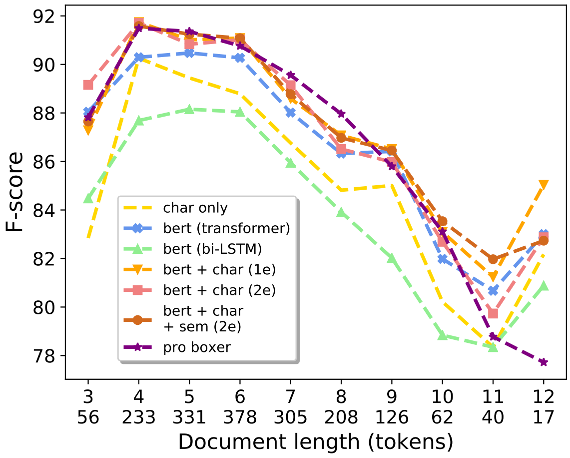

Figure 4: F-scores over document length (tokens) on the combined English dev and test set of 3.0.0. X-axis shows document length (top) and the number of documents for that length (bottom).

5.2 Sentence length analysis

We are also interested in finding out which model performs well on longer documents. When the Transformer model was introduced, one of the advantages was less decrease in performance for longer sentences (Vaswani et al., 2017). Also, since Boxer is partly rule-based and not trained in an end-to-end fashion, it might be able to handle longer sentences better. Figure 4 shows the performance over sentence length for seven of our trained systems. We see a similar trend for all models: a decrease in performance for longer sentences. We also create a regression model that predicts F-score, with as predictors parser and document length in tokens, similar to van Noord et al. (2018b). We do not find a significant interaction of any model with sentence length, i.e., none of the models decreases significantly less or more than any other model.

To get some idea how well our models would do on longer (possibly multi-sentence) documents, we create a new evaluation set. We select all silver documents with 15 or more and less than 51 tokens that have at least the semtagging or CCG layer marked as gold standard. This resulted in a

---

[15] Note that this method of analysis can easily be used for other NLP tasks as well, the only requirement being that a semantic tagger has to be used to get the semantic tags.

[16] See Appendix C for the list of semtags per category.

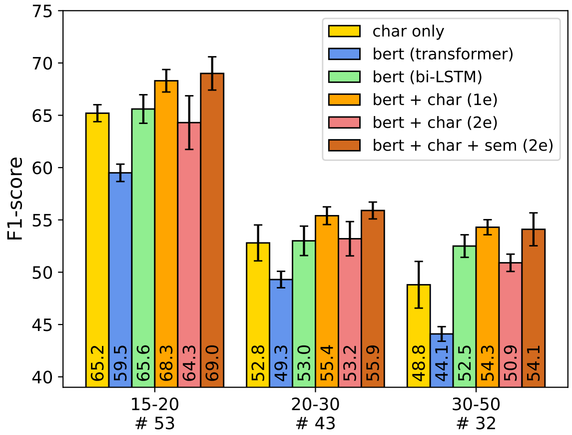

Figure 5: F-scores over document length (tokens) on the silver standard evaluation set of longer documents. X-axis shows the sentence length bins (top) and the number of documents for that length (bottom).

set of 128 DRSs, which should contain the higher quality silver documents. We retrain our models with those sentences removed and plot the performance over sentence length in Figure 5. We see that performance still decreases for longer sentences, though not as much after 30 tokens per document. The Transformer model does not seem to catch up with the bi-LSTM models, even for longer documents. The addition of characters is still beneficial for longer documents, though only in one encoder.

5.3 Discussion

We found that adding character-level representations generally improved performance, though we did not find a clear preference for either the one-encoder or two-encoder model. We believe that, given the better performance of the two-encoder model on the fairly short documents of the non-English languages (see Figure 3), this model is likely the most useful in semantic parsing tasks with single sentences, such as SQL parsing (Zelle and Mooney, 1996; Iyer et al., 2017; Finegan-Dollak et al., 2018), while the one encoder char-CNN model has more potential for tasks with longer sentences/documents, such as AMR (Banarescu et al., 2013), UCCA (Abend and Rappoport, 2013) and GMB-based DRS parsing (Bos et al., 2017; Liu et al., 2018, 2019a). The latter model also has more potential to be applicable for other (semantic parsing) systems as it can be applied to all systems that form token-level representations from a document. In this sense, we hope that our findings here are also applicable for other, more structured, encoder-decoder models developed for semantic parsing (e.g., Yin and Neubig, 2017; Krishnamurthy et al., 2017; Dong and Lapata, 2018; Liu et al., 2019a).

An unexpected finding is that the BERT models outperformed the larger ROBERTA models. In addition, it was even preferable to use BERT only as initial token embedder, instead of fine-tuning using the full model. Perhaps this is an indication that certain NLP tasks cannot be solved by simply training ever larger language models. Moreover, the Transformer model did not improve performance for any of the input representations, while being harder to tune as well. We are a bit hesitant with drawing strong conclusions here, though, since we only experimented with a vanilla Transformer, while recent extensions (e.g., Dehghani et al., 2019; Guo et al., 2019; Press et al., 2020) might be more promising for smaller data sets.

6 Conclusion

We performed a range of experiments on Discourse Representation Structure Parsing using neural sequence-to-sequence models, in which we vary the neural representation of the input documents. We show that, not surprisingly, using pretrained contextual language models is better than simply using characters as input (**RQ1**). However, characters can still be used to improve performance, in both a single encoder and two encoders (**RQ2**). The improvements are larger than using individual sources of linguistic information, and performance still improves in combination with these sources (**RQ3**). The improvements are also robust across different languages models, languages and data sets (**RQ4**) and improve performance across a range of semantic phenomena (**RQ5**). These methods should be applicable to other semantic parsing and perhaps other natural language analysis tasks.

Acknowledgements

This work was funded by the NWO-VICI grant "Lost in Translation—Found in Meaning" (288-89-003). The Tesla K40 GPU used in this work was kindly donated to us by the NVIDIA Corporation. A Char-CNN

Figure 6 shows a schematic overview of using the char-CNN (Kim et al., 2016) to encode the word *have* with a width of 2. A width of 2 selects the bigrams *ha*, *av* and *ve*, returning a scalar for each bigram operation, which in turn form a vector $\mathbf{f}_1$ for filter 1. We then take the max value of this vector to obtain the first value of our width 2 (w_2) char-CNN embedding $\mathbf{e}_{\mathrm{w}2_1}$. The final vector $\mathbf{e}_{w2}$ is thus of length n.

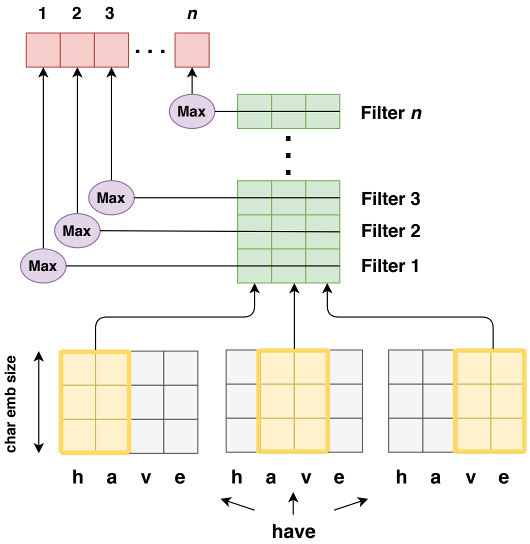

Figure 6: Overview of the char-CNN encoder, encoding the word *have* with bigrams (width = 2) for *n* filters.

B Experimental settings

Tuning Table 8 gives an overview of the hyperparameters we used and/or experimented with in the tuning stage. This table only gives an overview of the settings for the BERT-BASE model, though the settings for the other representations (described in 3.2) are usually very similar. We performed manual tuning, selecting the settings with the highest F1-score. The number of tuning runs was between 10 and 40 for each representation type and model combination (see Table 3). Output, evaluation (containing F1-scores, standard deviation and confidence interval) and configuration files for our four best models (see Table 6) are available here: `https://github.com/RikVN/Neural_DRS/`.

Data filtering We filtered ill-formed DRSs from the PMB data sets, which only occurs for silver and bronze data ($<$ 0.1% of DRSs). For the bi-LSTM models, the filtering of source and target tokens (see Table 8) only filters out three very large documents from training. This was done for efficiency and memory purposes, it did not make a difference in terms of F1-score. However, for the Transformer model this improved F1-score by around 0.5.

Training time and model size A single run of the baseline BERT model takes about 5 hours to train on a single NVIDIA V100 GPU, with around 17 million trainable parameters. Adding character-level representations in one encoder (using the char-CNN) uses around 55 million trainable parameters, with a runtime of around 6 hours. Using a two encoder setup increases this to around 8 hours, but with only 34 million trainable parameters.

New evaluation set When training models that are evaluated on the silver-standard evaluation set of longer documents, we do not perform fine-tuning on the gold standard data. Also, we run Counter with the `--default-sense` setting (not punishing models that get the word sense wrong), since the word senses of the evaluation set are not gold standard. This has a similar increase of around 1.0 for all models.

Parameter	LSTM	Transf.	Range
Hidden RNN size	300	NA	200 - 600
Decoder RNN size	300	NA	300
Num heads	NA	6	2, 4, 6, 10
hidden_dim	NA	300	300 - 600
ff_hidden_dim	NA	900	300 - 1200
dropout: layer	NA	0.1	0.1, 0.2
residual	NA	0.2	0.1, 0.2
attention	NA	0.1	0.1, 0.2

Table 8: An overview of the hyperparameters used for the LSTM and Transformer architecture, that use the BERT-BASE representations. Parameters not specified are left at their default value.

C Semantic tag selection

Modality	`NOT` `NEC` `POS`
Logical	`ALT` `XCL` `DIS` `AND` `IMP` `BUT`
Pronouns	`PRO` `HAS` `REF` `EMP`
Attributes	`QUC` `QUV` `COL` `IST` `SST`
	`PRI` `DEG` `INT` `REL` `SCO`
Comparatives	`EQU` `APX` `MOR` `LES`
	`TOP` `BOT` `ORD`
Named entities	`PER` `GPE` `GPO` `GEO` `ORG` `ART`
	`HAP` `UOM` `CTC` `LIT` `NTH`
Numerals	`QUC` `MOY` `SCO` `ORD` `DAT`
	`DOM` `YOC` `DEC` `CLO`

Table 9: Semantic tags that were used to select sentences that contain a certain phenomenon. The example sentence in Table 2 is included in the categories *Modality*, *Pronouns*, *Named Entities* and *Numerals* .

D Detailed scores

Table 10 shows the detailed F-scores for the English dev and test sets of release 2.2.0 and 3.0.0. *Infreq. sense* is the F-score on all concept clauses that were not the most frequent sense for that word in the training set (e.g., `be.v.01`, `like.v.03`). *Perfect sense* is the F-score when we ignore word senses during matching, i.e., `be.v.01` can match with `be.v.02`. The last 9 rows are not in the original detailed Counter scores, but are produced by **DRS-JURY**. Character-level representations help to produce fewer ill-formed and more perfect DRSs, especially on 3.0.0.

E Sentence analysis

Table 11 shows the sentences for which our best model (on 3.0.0 English dev) produced the lowest quality DRSs, with a possible explanation. In Table 12, we show the sentences for which our best model has the best performance (relative to the BERT-ONLY baseline model). It is harder to give an explanation in this case, though we indicate which clauses were (in)correctly predicted by the models.

Abstract

Knowledge of a disease includes information of various aspects of the disease, such as signs and symptoms, diagnosis and treatment. This disease knowledge is critical for many health-related and biomedical tasks, including consumer health question answering, medical language inference and disease name recognition. While pre-trained language models like BERT have shown success in capturing syntactic, semantic, and world knowledge from text, we find they can be further complemented by specific information like knowledge of symptoms, diagnoses, treatments, and other disease aspects. Hence, we integrate BERT with disease knowledge for improving these important tasks. Specifically, we propose a new disease knowledge infusion training procedure and evaluate it on a suite of BERT models including BERT, BioBERT, SciBERT, ClinicalBERT, BlueBERT, and ALBERT. Experiments over the three tasks show that these models can be enhanced in nearly all cases, demonstrating the viability of disease knowledge infusion. For example, accuracy of BioBERT on consumer health question answering is improved from 68.29% to 72.09%, while new SOTA results are observed in two datasets. We make our data and code freely available.

1 Introduction

Human disease is "a disorder of structure or function in a human that produces specific signs or symptoms" (Oxford-English-Dictionary, 2020). Disease is one of the fundamental biological entities in biomedical research and consequently it is frequently searched for in the scientific literature (Islamaj Dogan et al., 2009) and on the internet (Brownstein et al., 2009).

Table 1: Disease knowledge of *COVID-19* is presented from three aspects: symptoms, diagnosis and treatment (based on Wikipedia).

Disease	Aspect	Information
COVID-19	symptoms	Fever is the most common symptom, but highly variable in severity and presentation, with some older...
COVID-19	diagnosis	The standard method of testing is real-time reverse transcription polymerase chain reaction (rRT-PCR)...
COVID-19	treatment	People are managed with supportive care, which may include fluid therapy, oxygen support, and supporting...

Knowledge of a disease includes information about various aspects of the disease, like the signs and symptoms, diagnosis, and treatment (Saleem et al., 2012; Urnes et al., 2008; Du Jeong et al., 2017). As an example, Table 1 highlights several aspects for COVID-19. Specialized disease knowledge is critical for many health-related and biomedical natural language processing (NLP) tasks, including:

- *Consumer health question answering* (Abacha et al., 2019) - the goal is to rank candidate passages for answering questions like "What is the diagnosis of *COVID-19*?" as shown in Figure 1a;
- *Medical language inference* (Romanov and Shivade, 2018) - the goal is to predict if a given hypothesis (description of a patient) can be inferred from a given premise (another description of the patient);
- *Disease name recognition* (Doğan et al., 2014) - the goal is to detect disease concepts in text.

For these tasks, it is critical for NLP models to capture disease knowledge, that is the semantic relations between a disease-descriptive text and its corresponding aspect and disease:

- As shown in Figure 1a, if models can semantically relate "...real-time reverse transcrip-

November 16–20, 2020.

tion polymerase chain reaction..." (disease-descriptive text) to the diagnosis (aspect) of *COVID-19* (disease), it is easier for them to pick up the most relevant answer among the candidates.

- Likewise, as shown in Figure 1b, if models know that the premise is the symptoms (aspect) of *Aphasia* (disease) in the hypothesis, they can easily predict that it is entailment not contradiction.

- Another example is shown in Figure 1c, if models can semantically relate "CTG expansion' to the cause (aspect) of *Myotonic dystrophy* (disease), it is easier for them to detect this disease.

In a nutshell, NLP models require the disease knowledge for these disease-related tasks.

Recently, a new style of knowledge learning and leveraging has shaken NLP field with dramatic successes, enabled by BERT (Devlin et al., 2019) and its variants (Yang et al., 2019; Liu et al., 2019b; Raffel et al., 2019; Lan et al., 2020). These models capture language and world knowledge (Qiu et al., 2020; Rogers et al., 2020) in their parameters via self-supervised pre-training over large-scale unannotated data and then leverage these knowledge in further fine-tuning over downstream tasks. Moreover, many biomedical BERT models such as BioBERT (Lee et al., 2020) are proposed, which are pre-trained over biomedical corpora via a masked language model (MLM) that predicts randomly masked tokens given their context. This MLM strategy is designed to capture the semantic relations between random masked tokens and their context, but not the disease knowledge. Because the corresponding disease and aspect *might not be randomly masked or might not be mentioned at all* in the disease-descriptive text, the semantic relations between them cannot be effectively captured via MLM. Therefore, a new training strategy is required to capture this disease knowledge.

In this paper, we propose a new *disease knowledge infusion* training procedure to explicitly augment BERT-like models with the disease knowledge. The core idea is to train BERT to infer the corresponding disease and aspect from a disease-descriptive text, enabled by weakly-supervised signals from Wikipedia. Given a passage extracted from a section (normally describes an aspect) of a disease's Wikipedia article, BERT is trained to infer the title of the corresponding section (aspect name) and the title of the corresponding article (disease name). For example, in Table 1, given "...testing is real-time reverse transcription polymerase chain reaction (rRT-PCR)...", BERT is trained to infer that this passage is from the section "diagnosis" of the article "COVID-19". Moreover, because some passages do not mention the disease and aspect, we construct auxiliary sentences that contain the disease and aspect, such as "What is the diagnosis of COVID-19?" and insert this sentence at the beginning of the corresponding passage. After that, we mask the disease and aspect in the auxiliary sentence and then let BERT-like models infer them given the passage. In this way, BERT learns how to semantically relate a disease-descriptive text with its corresponding aspect and disease.

Question: ...keen to learn **how to get COVID-19 diagnosed**, many thanks

Answer 1: ... real-time reverse transcription polymerase chain reaction...
Answer 2: ... diagnosis of vipoma requires demonstration of diarrhea...
Answer 3: ...affected by this disorder are not able to make lipoproteins...

Label: Answer 1 is the most relevant
Disease Knowledge: Answer 1 is the diagnosis of COVID-19

(a) Consumer Health Question Answering

Premise: She was **not able to speak, but appeared to comprehend well**

Hypothesis: Patient had **aphasia**

Label: entailment
Disease Knowledge: Premise describes the symptoms of aphasia

(b) Medical Language Inference

Text: **Myotonic dystrophy** (DM) is **caused by a CTG expansion** in the 3 untranslated region of the DM gene.

Label: Myotonic dystrophy
Disease Knowledge: the text contains the cause of Myotonic dystrophy

(c) Disease Name Recognition

Figure 1: Examples of tasks that can benefit from disease knowledge.

To evaluate the quality of disease knowledge infusion, we conduct experiments on a suite of BERT models – including BERT, BlueBERT, ClinicalBERT, SciBERT, BioBERT, and ALBERT – over consumer health question (CHQ) answering, medical language inference, and disease name recognition. We find that (1) these models can be enhanced in nearly all cases. For example, accuracy of BioBERT on CHQ answering is improved from 68.29% to 72.09%; and (2) our method is superior to MLM for infusing the disease knowledge. Moreover, new SOTA results are observed in two datasets. These results demonstrate the potential of disease knowledge infusion into pre-trained language models like BERT.

2 Related Work

Knowledge-Enriched BERT: Incorporating external knowledge into BERT has been shown to be effective. Such external knowledge includes world (factual) knowledge for tasks such as entity typing and relation classification (Zhang et al., 2019; Peters et al., 2019; Liu et al., 2019a; Xiong et al., 2019), sentiment knowledge for sentiment analysis (Tian et al., 2020; Yin et al., 2020), word sense knowledge for word sense disambiguation (Levine et al., 2019), commonsense knowledge for commonsense reasoning (Klein and Nabi, 2020) and sarcasm generation (Chakrabarty et al., 2020), legal knowledge for legal element extraction (Zhong et al., 2020), numerical skills for numerical reasoning (Geva et al., 2020), and coding knowledge for code generation (Xu et al., 2020).

Biomedical BERT: BERT can also be enriched with biomedical knowledge via pre-training over biomedical corpora like PubMed, as in BioBERT (Lee et al., 2020), SciBERT (Beltagy et al., 2019), ClinicalBERT (Alsentzer et al., 2019) and BlueBERT (Peng et al., 2019). These biomedical BERT models report new SOTA performance on several biomedical tasks. Disease knowledge, of course, is a subset of biomedical knowledge. However, there are two key differences between these biomedical BERT models and our work: (1) Many biomedical BERT models are pre-trained via BERT's default MLM that predicts 15% randomly masked tokens. In contrast, we propose a new training task: disease knowledge infusion, which infers the disease and aspect from the corresponding disease-descriptive text; (2) Biomedical BERT models capture the general syntactic and semantic knowledge of biomedical language, while our work is specifically designed for capturing the semantic relations between a disease-descriptive text and its corresponding aspect and disease. Experiments reported in Section 4 show that our proposed method can improve the performance of each of these biomedical BERT models, demonstrating the importance of disease knowledge infusion.

Biomedical Knowledge Integration Methods with UMLS: Previous non-BERT methods connect data of downstream tasks with knowledge bases like UMLS (Sharma et al., 2019; Romanov and Shivade, 2018). For example, they map medical concepts and semantic relationships in the data to UMLS. After that, these concepts and relationships are encoded into embeddings and incorporated into models (Sharma et al., 2019). The advantage is that they can explicitly incorporate knowledge into models. However, these methods have been outperformed by biomedical BERT models such as BioBERT in most cases.

Table 2: Eight aspects of knowledge of a disease that are considered in this work.

Aspect Name	Definition
Information	The general information of a disease.
Causes	The causes of a disease.
Symptoms	The signs and symptoms of a disease.
Diagnosis	How to test and diagnose a disease.
Treatment	How to treat and manage a disease.
Prevention	How to prevent a disease.
Pathophysiology	The physiological processes of a disease.
Transmission	The means by which a disease spread.

3 Proposed Method: Disease Knowledge Infusion Training

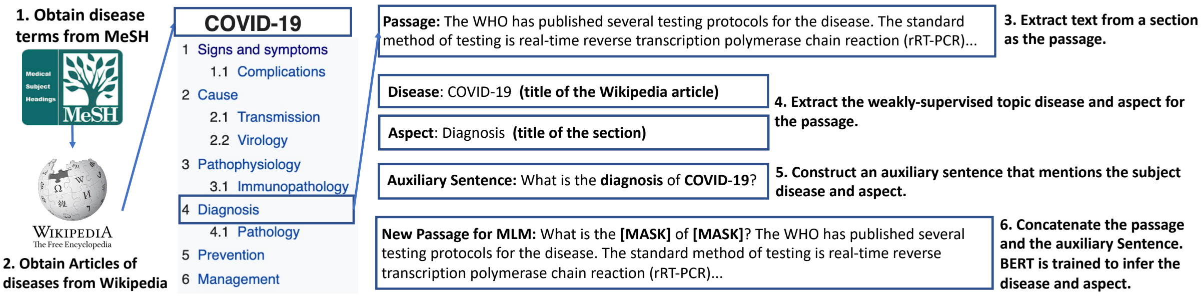
In this section, we propose a new training task: Disease Knowledge Infusion Training. Our goal is to integrate BERT-like pre-trained language models with disease knowledge to achieve better performance on a variety of medical domain tasks including answering health questions, medical language inference, and disease name recognition. Our approach is guided by three questions: Which diseases and aspects should we focus on? How do we infuse disease knowledge into BERT-like models? What is the objective function of this training task?

3.1 Targeting Diseases and Aspects

First, we seek a disease vocabulary that provides disease terms. Several resources include Medical Subject Headings (MeSH) (Lipscomb, 2000), the National Cancer Institute thesaurus (De Coronado et al., 2004), SNOMED CT (Donnelly, 2006), and Unified Medical Language System (UMLS) (Bodenreider, 2004). Each has a different scope and design purpose, and it is an open question into which is most appropriate here. As a first step, we select MeSH, which is a comprehensive controlled vocabulary proposed by the National Library of Medicine (NLM) to index journal articles and books in the life sciences, composed of 16 branches like anatomy, organisms, and diseases. We collect all unique disease terms from the Disease (MeSH tree number C01-C26) and Mental Disorder branch (MeSH tree number F01), resulting in 5,853 total disease terms.

---

https://meshb.nlm.nih.gov/treeView



Passage: The WHO has published several testing protocols for the disease. The standard method of testing is real-time reverse transcription polymerase chain reaction (rRT-PCR)...

3. Extract text from a section as the passage.

Disease: COVID-19 **(title of the Wikipedia article)**

Aspect: Diagnosis **(title of the section)**

4. Extract the weakly-supervised topic disease and aspect for the passage.

Auxiliary Sentence: What is the **diagnosis** of **COVID-19**?

5. Construct an auxiliary sentence that mentions the subject disease and aspect.

New Passage for MLM: What is the **[MASK]** of **[MASK]**? The WHO has published several testing protocols for the disease. The standard method of testing is real-time reverse transcription polymerase chain reaction (rRT-PCR)...

6. Concatenate the passage and the auxiliary Sentence. BERT is trained to infer the disease and aspect.

Figure 2: Disease Knowledge Infusion Training: An example with COVID-19.

Knowledge of a disease involves information about various aspects of the disease (Saleem et al., 2012; Urnes et al., 2008; Du Jeong et al., 2017). For each aspect, we focus on text alone (excluding images or other media). Following Abacha and Demner-Fushman (2019), we consider eight disease aspects as shown in Table 2.

3.2 Weakly Supervised Knowledge Infusion from Wikipedia

Given the target set of diseases and aspects, the next challenge is how to infuse knowledge of the aspects of these diseases into BERT-like models. We propose to train BERT to infer the corresponding disease and aspect from a disease-descriptive text. By minimizing the loss between the predicted disease and aspect and the original disease and aspect, the model should memorize the semantic relations between the disease-descriptive text and its corresponding disease and aspect.

A straightforward approach is to mask and predict the disease and aspect in the disease-descriptive text. However, this strategy faces two problems: (1) Given a passage extracted from disease-related papers, clinical notes, or biomedical websites, the ground-truth of its topic (i.e., disease and aspect) is difficult to identify. Medical expert annotation is time-consuming and expensive; while automatic annotation can suffer from large errors. For example, we need to recognize disease names in the passage, which is yet another challenging and still open problem in biomedical text mining (Doğan et al., 2014); (2) Diseases and aspects mentioned in a passage are not necessarily the topic words. Multiple disease names or aspect names might appear, making it difficult to determine which is the correct topic. For example, in Table 1, the symptoms of *COVID-19* also mentions *fever* , while the correct topic is *COVID-19*.

Weakly-Supervised Knowledge Source: Instead of annotating an arbitrary disease-related passage, we exploit the structure of Wikipedia as a weakly-supervised signal. In many cases, each disease's Wikipedia article consists of several sections where each introduces an aspect of the disease (like diagnosis). For example, step 2 in Figure 2 shows several aspects on the Wikipedia page for *COVID-19*. By extracting the passage from each section, the title of the section (e.g., diagnosis) is the topic aspect of the passage and the title of the article is the topic disease (e.g., COVID-19). Specifically, we search Wikipedia to obtain the articles for the 5,853 target disease terms from MeSH and apply regular expressions to extract the text of the sections corresponding to the appropriate aspects. In total, we collect a disease knowledge resource consisting of 14,617 passages. In fact, there are other online resources with the similar structure. As a first step, we start with Wikipedia.

Auxiliary Sentences for Disease and Aspect Prediction: The second problem is that the extracted passages do not necessarily mention the corresponding disease and the aspect. For example, in Table 1, the disease name "COVID-19" does not appear in the information of its symptoms. In the disease knowledge resource, we find that only 51.4% of passages mention both the corresponding diseases and aspects. Hence, we cannot simply mask-and-predict the disease and aspect because the passage does not mention them at all.

A remedy for this problem is an auxiliary sentence that contains the corresponding disease and aspect for each passage. We use a template of question style: "What is the [*Aspect*] of [*Disease*]?" to automatically generate auxiliary sentences as shown in step 5 in Figure 2. Some examples are

---

Fever is included in the disease branch of MeSH.

Note that each disease article does not necessarily have all eight target aspects.

`https://medlineplus.gov/skincancer.html` shown in Table 3. The advantage of this question style template is that the cloze statement of the auxiliary sentences for all aspects (except for the “information” aspect) are the same (What is the [MASK] of [MASK]?). Hence, the auxiliary sentences provide no clues (i.e., bias) for predicting the corresponding aspect.

Table 3: Examples of auxiliary sentences

Aspect Name	Auxiliary Sentence
Diagnosis	What is the diagnosis of COVID-19?
Treatment	What is the treatment of COVID-19?
Prevention	What is the prevention of COVID-19?
Transmission	What is the transmission of COVID-19?
Cloze Statement	What is the [MASK] of [MASK]?

After that, we replace the corresponding disease and aspect with the special token [MASK] in the auxiliary sentences. Then, we insert the auxiliary sentence at the beginning of its corresponding passage to form a new passage with a question-and-answer style as shown in Figure 2, where BERT is trained to predict the original tokens of the masked disease and aspect.

3.3 Training Objective and Details

Finally, we show the objective function of disease infusion training. Since most disease names are out of BERT vocabulary, the WordPiece tokenizer (Wu et al., 2016) will split these terms into sub-word tokens that exist in the vocabulary. For example, “COVID-19" will be split into 4 tokens: “co", “vid", “-" and “19". Formally, let $X = (x_1, ..., x_T)$ denote a sequence of T tokens that are split from a disease name where x_t is the t-th token. The original cross-entropy loss is to get the conditional probability of a masked token as close as possible to the 1-hot vector of the token:

$$\mathcal{L}_{disease} = -\sum_{t=1}^{T} log\ p(x_t|passage) \tag{1}$$

where $p(x_t|context)$ is a conditional probability over x_t given the corresponding passage, which can be defined as:

$$p(x_t|passage) = \frac{exp(z_t)}{\sum_{z \in \mathcal{V}} exp(z)} \tag{2}$$

where $\mathcal{V}$ is the vocabulary and z_t is the unnormalized log probability of x_t. Let $\mathbf{y}_t$ denote the embedding of token x_t from the output layer of BERT. We can estimate z_t via:

$$z_t = \mathbf{w} \cdot \mathbf{y}_t \quad b \tag{3}$$

where the weight $\mathbf{w}$ and bias b are learnable vectors.

Note that the vocabulary size of BERT is around 30,000 which means masked language modeling task is a 30,000 multi-class problem. The logits (like z_t) after the normalization of softmax (Equation 2) will be pretty small (the expectation of mean should be around 1/30,000=3.3*e-5), which might cause some obstacles for the learning. Therefore, we also maximize the raw logits (like z_t) before softmax normalization which might keep more useful information. Empirically, we add the reciprocal of the logits to the cross-entropy loss:

$$\mathcal{L}_{disease} = -\sum_{t=1}^{T} logp(x_t|passage) \quad \frac{\beta}{\sum_{t=1}^{T} z_t} \tag{4}$$

where β balances the two parts of the loss. The final objective function is combined with the loss of the disease and aspect: $\mathcal{L} = \mathcal{L}_{disease} \quad \mathcal{L}_{aspect}$ where $\mathcal{L}_{aspect} = -log\ p(a|passage)$ and a is the token of the aspect name. By minimizing this loss function, BERT can update its parameters to store the disease knowledge.

4 Experiments

In this section, we examine disease knowledge infusion into six BERT variants over three disease-related tasks: health question answering, medical language inference, and disease name recognition.

Reproducibility: *The code and data in this paper is released.* A model is firstly initialized with the pre-trained parameters from BERT or its variants and then is further trained by disease knowledge infusion to capture the disease knowledge. We use a widely used Pytorch implementation of BERT and Adam as the optimizer. We empirically set learning rate as 1e-5, batch size as 16 and β as 10. Because MeSH (5,853 disease terms) is chosen as the disease vocabulary in our experiments, as a smaller vocabulary compared with others like UMLS (540,000 disease terms), we obtain a relatively small dataset of 14,617 passages. Hence, the training of disease knowledge infusion is as fast as fine-tuning BERT over downstream datasets, which takes 2-4 epochs to enhance BERT for a better performance on downstream tasks, which will be discussed in Section 4.5. The training is performed on one single NVIDIA V100 GPU and

---

`https://github.com/heyunh2015/diseaseBERT`

`https://github.com/huggingface/transformers` it takes about 10 minutes to complete one training epoch using BERT-base architecture. The reproducibility for fine-tuning over downstream tasks will be detailed in Section 4.2.

4.1 BERT and its Biomedical Variants

We consider six BERT models: two pre-trained over general language corpora (BERT and ALBERT) and four pre-trained over biomedical corpora (Clinical BERT, BioBERT, BlueBERT and SciBERT).

BERT (Devlin et al., 2019) is a multi-layer bidirectional Transformer encoder. Since the following biomedical versions of BERT are often based on the BERT-base architecture (12 layers and 768 hidden embedding size with 108M parameters), we choose BERT-base here for fair comparison.

ALBERT (Lan et al., 2020) compresses the architecture of BERT by factorized embedding parameterization and cross-layer parameter sharing. Via this compression, ALBERT can have a substantially higher capacity than BERT, with stronger performance on many tasks. We choose the maximum version ALBERT-xxlarge (12 layers and 4096 hidden embedding size with 235M parameters).

BioBERT (Lee et al., 2020) is the first BERT pre-trained on biomedical corpora. It is initialized with BERT's pre-trained parameters (108M) and then further trained over PubMed abstracts (4.5B words) and PubMed Central full-text articles (13.5B words). We choose the best version BioBERT v1.1.

ClinicalBERT (Alsentzer et al., 2019) is a BERT model initialized from BioBERT v1.0 (Lee et al., 2020) and further pre-trained over approximately 2 million notes in the MIMIC-III v1.4 database of patient notes (Johnson et al., 2016). We adopt the best performing version of ClinicalBERT (108M parameters) based on discharge summaries of clinical notes: Bio-Discharge Summary BERT.

BlueBERT (Peng et al., 2019) is firstly initialized from BERT (108M parameters) and further pre-trained over a biomedical corpus of PubMed abstracts and clinical notes (Johnson et al., 2016).

SciBERT (Beltagy et al., 2019) is a BERT-base (108M parameters) model pre-trained on a random sample of the full text of 1.14M papers from Semantic Scholar (Ammar et al., 2018), with 18% of papers from the computer science domain and 82% from the biomedical domain.

Table 4: Summary of Tasks and Datasets.

Datasets	Train	Dev	Test

4.2 Tasks

We test disease knowledge infusion over three biomedical NLP tasks. The dataset statistics are in Table 4. For fine-tuning of BERT and its variants, the batch size is selected from [16, 32] and learning rate is selected from [1e-5, 2e-5, 3e-5, 4e-5, 5e-5].

Task 1: Consumer Health Question Answering. The objective of this task is to rank candidate answers for consumer health questions.

Datasets. We consider two datasets: MEDIQA-2019 (Ben Abacha et al., 2019) and TRECQA-2017 (Abacha et al., 2017). MEDIQA-2019 is based on questions submitted to the consumer health QA system CHiQA . TRECQA-2017 is based on questions submitted to the National Library of Medicine. Medical experts manually re-ranked the original retrieved answers and provide *Reference Score* (1 to 11) and *Reference Rank* (4: Excellent, 3: Correct but Incomplete, 2: Related, 1: Incorrect).

Fine-tuning. MEDIQA-2019 and TRECQA-2017 are used as the fine-tuning dataset for each other. MEDIQA-2019 also contains a validation set for tuning hyper-parameters for both datasets. Following Xu et al. (2019), the task is cast as a regression problem where the target score is: $score = Reference\ Score - \frac{Reference\ Rank-1}{m}$ where m is the number of candidate answers. Each question-answer pair is packed as a single sequence as the input for BERT. A single linear layer is on top of the output embedding of the special token [CLS] to generate the predicted score. MSE is adopted as the loss and we use Adam as the optimizer. All hyper-parameters are tuned on the validation set in terms of accuracy, where we set the batch size as 16 and learning rate as 1e-5.

SOTA*	78.00	**93.67**	81.91	77.23	54.57	57.54	84.00	**87.15**	**89.71**

* SOTA, state-of-the-art as of May 2020, to the best of our knowledge.
* " + disease" means that we train BERT via disease knowledge infusion training before fine-tuning.

SOTA. The state-of-the-art (SOTA) performance on MEDIQA-2019 is achieved by Xu et al. (2019), which is an ensemble method. Because TRECQA-2017 is fine-tuned on MEDIQA-2019, which is different from the original settings (Abacha et al., 2017) (BERT had not been proposed at that time), we use the best result of SciBERT among the BERT models as SOTA for TRECQA-2017.

Task 2: Medical Language Inference. The goal of this task is to predict whether a given hypothesis can be inferred from a given premise.

Datasets. MEDNLI (Romanov and Shivade, 2018) is a natural language inference dataset for the clinical domain. For each premise (a description of a patient) selected from clinical notes (MIMIC-III), clinicians generate three hypotheses: entailment (alternate true description of the patient), contradiction (false description of the patient), and neutral (alternate description that might be true).

Fine-tuning. Following Peng et al. (2019), we pack the premise and hypothesis together into a single sentence. A linear layer is on top of the output embedding of [CLS] to generate logits. Cross-entropy loss function is adopted, and we use Adam as the optimizer. All hyper-parameters are tuned on the validation set in terms of accuracy, where we set the batch size as 32 and learning rate as 1e-5.

SOTA. To the best of our knowledge, the state-of-the-art on MEDNLI is achieved by BlueBERT, reported in Peng et al. (2019).

Task 3: Disease Name Recognition. This task is to detect disease names from free text.

Datasets. BC5CDR (Wei et al., 2016) and NCBI (Doğan et al., 2014) are collections of PubMed titles and abstracts. Medical experts annotate diseases mentioned in the collection. Since BC5CDR includes both chemicals and diseases, we focus on diseases in this dataset.

Fine-tuning. Following Peng et al. (2019), we cast this task as a token-level tagging (classification) problem, where each token is classified into three classes: B (beginning of a disease), I (inside of a disease) or O (out of a disease). Cross-entropy is adopted as the loss function and we use Adam as the optimizer. All hyper-parameters are tuned on the validation set in terms of F1, where we set the batch size as 32 and learning rate as 5e-5.

SOTA. The best performance is achieved by BioBERT v1.1, reported in Lee et al. (2020) .

4.3 Results

The experimental results are presented in Table 5. We show each original model and its disease

https://github.com/ncbi-nlp/BLUE_Benchmark

https://www.ncbi.nlm.nih.gov/CBBresearch/Dogan/

Although SciBERT reports a better result in NCBI, it uses a conditional random field on top of BERT, which is more complicated than the linear layer normally used in fine-tuning for BERT models including BioBERT.

knowledge infused variant (e.g,. *BERT* and *BERT + disease*). We have two main findings:

Effectiveness of Disease Infusion. First, by infusing disease knowledge via our new training regimen, we see a significant improvement in nearly all cases. For example, *ALBERT + disease* achieves 80.10% in terms of accuracy which is superior to 75.09% by ALBERT alone on TRECQA-2017. Standing on the shoulders of ALBERT, disease knowledge infusion leads to state-of-the-art results on MEDIQA-2019 and MEDNLI, to the best of our knowledge. Although BERT and ALBERT are pre-trained on all of Wikipedia, including the articles of diseases, they might not pay enough attention to the disease part since Wikipedia is so large. Hence, disease knowledge infusion that leverages the Wikipedia structure to capture the disease knowledge is a complement for BERT and ALBERT. Moreover, it is encouraging to see the improvements of disease knowledge infusion in biomedical BERT models, even though these variants are already pre-trained over large-scale biomedical corpora like PubMed with access to comprehensive disease information. This improvement demonstrates that the disease knowledge captured by our method – that is, the semantic relations between a disease-descriptive text and its corresponding aspect and disease – is different from the general linguistic knowledge in the biomedical domain captured by the randomly masked tokens prediction strategy of these biomedical BERT models. To sum up, the results show that the proposed disease knowledge infusion method can effectively complement BERT and its biomedical variants and hence improve the performance on health question answering, medical language inference, and disease name recognition.

Effectiveness of Biomedical BERT Models. We also observe that BERT models pre-trained on biomedical corpora outperform the same BERT architecture that is pre-trained on general language corpora. For example, BioBERT achieves 68.29% in terms of accuracy on MEDIQA-2019 while BERT only obtains 64.95%. This demonstrates that with the same model architecture, pre-training on biomedical corpora can capture more biomedical language knowledge that improves BERT for downstream biomedical tasks.

Table 6: Ablation Study on MEDIQA-2019

Variants	Accuracy	MRR	Precision
Default	79.49	90.00	84.02
- Auxiliary Sentence	78.23	90.89	78.10
- Aspect Prediction	78.41	89.06	80.00
- Disease Prediction	72.90	85.72	79.44
15% Randomly Masked Tokens	77.06	87.33	85.18

In addition, we find that a high-capacity model like ALBERT can achieve similar performance as biomedical BERT models on TRECQA-2017, BC5CDR and NCBI, and even better performance on MEDIQA-2019 and MEDNLI. This observation might motivate new biomedical pre-trained models based on larger models like ALBERT-xxlarge.

4.4 Ablation Study

We present the results of an ablation study on MEDIQA-2019 in Table 6. Similar results are observed on other datasets but omitted here due to the space limitation. We first remove "Auxiliary Sentence". That is, we remove the auxiliary question: "What is the [*Aspect*] of [*Disease*]?" and let BERT to predict the corresponding disease and aspect in the original passage if they appear. We observe worse results in terms of accuracy and precision, which shows that the auxiliary sentence is an effective remedy for the problem that some passages do not mention their disease and aspects. We also remove aspect prediction or disease prediction in the auxiliary sentence; both lead to worse results but removing disease prediction leads to a much lower performance. This shows that it is more important for BERT to infer the disease than the aspect from the passage. We also pre-train BERT on the same corpus (the disease-related passages) as our method. Following Devlin et al. (2019), we randomly mask 15% tokens in each sentence and let BERT to predict them. As shown in "15% Randomly Masked Tokens", we observe that our proposed disease infusion training task outperforms the default masked language model in BERT. This shows that our approach that leverages the structure of Wikipedia article to enhance the disease knowledge infusion works better than simply adding more data to the training process. Specifically, via leveraging the Wikipedia structure, we could effectively mask key words like aspect names and disease names that are related to disease knowledge and hence more effective than randomly masking strategy over the simply added data.

Note that our results for the biomedical BERT models in Table 5 are slightly different from the results reported in the original papers that normally only provide a search range for hyper-parameters and not the specific optimal ones.

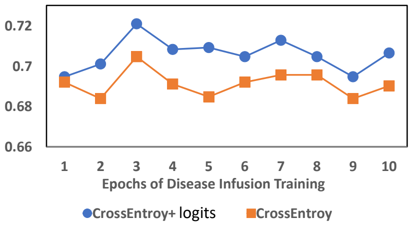

Figure 3: Learning curve of disease infusion knowledge. The y-axis is the accuracy of BERT models over MEDIQA-2019.

4.5 Learning Curve

In this section, we present the learning curve of our proposed disease infusion training task. The x-axis denotes the training epochs and the y-axis denotes the performance of BERT models that are augmented with disease infusion training at that epoch. We take BioBERT and MEDIQA-2019 as examples; similar results are obtained in other models over other tasks. The results in terms of accuracy are presented in Figure 3, where we observe that (1) disease knowledge infusion takes only three epochs to achieve the optimal performance on BioBERT over the CHQ answering task. (2) cross-entropy loss used by disease knowledge infusion can be enhanced by adding the term of maximizing the raw logits (Equation 4).

5 Conclusions

In this paper, we propose a new disease infusion training procedure to augment BERT-like pre-trained language models with disease knowledge. We conduct this training procedure on a suite of BERT models and evaluate them over disease-related tasks. Experimental results show that these models can be enhanced by this disease infusion method in nearly all cases.

Unsupervised Commonsense Question Answering with Self-Talk

Abstract

Natural language understanding involves reading between the lines with implicit background knowledge. Current systems either rely on pre-trained language models as the sole implicit source of world knowledge, or resort to external knowledge bases (KBs) to incorporate additional relevant knowledge. We propose an unsupervised framework based on *self-talk* as a novel alternative to multiple-choice commonsense tasks. Inspired by inquiry-based discovery learning (Bruner, 1961), our approach inquires language models with a number of information seeking questions such as *"what is the definition of ..."* to discover additional background knowledge. Empirical results demonstrate that the self-talk procedure substantially improves the performance of zero-shot language model baselines on four out of six commonsense benchmarks, and competes with models that obtain knowledge from external KBs. While our approach improves performance on several benchmarks, the self-talk induced knowledge even when leading to correct answers is not always seen as helpful by human judges, raising interesting questions about the inner-workings of pre-trained language models for commonsense reasoning.

1 Introduction

Human level natural language understanding involves reading between the lines and relying on implicit background knowledge. Consider the sentence: *Alice let Bob stand in front of her at the concert*. Using physical and social commonsense – (i) Bob and Alice want to see the stage, and (ii) If Bob is taller, they would block Alice's view – one can infer that Alice is taller than Bob. Such examples are ubiquitous across natural language understanding (NLU) tasks such as reading comprehension (Hirschman et al., 1999) and recognizing textual entailment (Dagan et al., 2013), and even more so in tasks dedicated to commonsense reasoning such as the Winograd schema challenge (Levesque et al., 2012). Most current NLU models rely on pre-trained language models (LMs; e.g. Radford et al., 2019; Devlin et al., 2019; Raffel et al., 2020). The standard practice is to fine-tune a pre-trained LM in a supervised manner on task-specific data. Alternatively, LM score is used to rank answer choices in a zero-shot setup (Wang et al., 2019; Bosselut and Choi, 2019). In both setups, pre-trained LMs yield improved performance upon prior methods, greatly due to the world knowledge that such LMs capture, having been trained on massive texts (Petroni et al., 2019; Davison et al., 2019).

Despite the performance boost, LMs as knowledge providers suffer from various shortcomings: (i) *insufficient coverage*: due to reporting bias, many trivial facts might not be captured by LMs because they are rarely written about (Gordon and Van Durme, 2013). (ii) *insufficient precision*: the distributional training objective increases the probability of non-facts that are semantically similar to true facts, as in negation ("birds cannot fly"; Kassner and Schütze, 2020). LMs excel in predicting the semantic category of a missing word, but might predict the wrong instance in that category (e.g., depending on the phrasing, BERT sometimes predicts *red* as the color of a dove). Finally, (iii) *limited reasoning capabilities*: it is unclear that LMs are capable of performing multiple reasoning steps involving implicit knowledge.

To increase the coverage of high-precision world knowledge and facilitate multi-hop reasoning by making intermediate reasoning steps explicit, prior work incorporated KBs (e.g. ConceptNet; Speer and Havasi, 2012) and knowledge-informed models into LM-based models (Xia et al., 2019; Bosselut and Choi, 2019; Chen et al., 2019).

In this paper, we study pre-trained LMs as an alternative to external KBs in providing knowledge

Because Brett found an internship while in college but Ian was unable to, **Brett** found a job less quickly after graduation. The definition of "job" is to be employed by someone.

Because Brett found an internship while in college but Ian was unable to, **Ian** found a job less quickly after graduation. The definition of "job" is to be employed by someone.

Figure 1: Model illustration for WinoGrande. Each answer choice (Brett, Ian) is assigned to the concatenation of the context and a clarification. The score for each choice is the best LM score across clarifications (2 in this case).

to commonsense question answering tasks. We propose an unsupervised model that uses an LM as the answer scorer, and a (possibly different) LM as a knowledge source. We formulate the process of obtaining relevant knowledge as a *self-talk*, inquiry-based discovery learning (Bruner, 1961), with the following steps: 1) seeking out knowledge by generating natural-language "clarification questions" conditioned on a given context, 2) generating their corresponding answers ("clarifications"), and 3) incorporating the clarifications as additional context.

Our model does not rely on external knowledge or additional supervision. Yet, we show that on 4 out of 6 tasks it substantially improves upon a zero-shot baseline that relies on LM score alone and performs on par, and sometimes better than, models that use external knowledge sources.

Integrating external knowledge warrants discerning relevant and helpful facts for solving a particular instance. LMs further require identifying that a clarification is factually-correct. We show that even among the clarifications that helped the prediction, humans perceived many as unhelpful or even incorrect, demonstrating that LM-based models often solve problems correctly for seemingly incorrect reasons. Our results call for future research on robust and correct knowledge integration to LM-based question answering systems.

2 Tasks

We focused on the multiple-choice question answering tasks detailed below. Each instance consists of an optional context, an optional question, and several answer choices.

COPA: Choice of Plausible Alternatives (Gordon et al., 2012): Asking about either a plausible cause or a plausible result, among two alternatives, of a certain event expressed in a simple sentence.

CommonSenseQA: commonsense Question Answering (Talmor et al., 2019): General questions about concepts from ConceptNet. To increase the challenge, the distractors are related to the target concept either by a relationship in ConceptNet or as suggested by crowdsourcing workers.

MC-TACO: Multiple Choice Temporal commonsense (Zhou et al., 2019): Questions about temporal aspects of events such as ordering, duration, frequency, and typical time. The distractors were selected in an adversarial way using BERT.[1]

Social IQa: Social Interaction Question Answering (Sap et al., 2019b): Questions regarding social interactions, based on the ATOMIC dataset (Sap et al., 2019a). Contexts describe social interactions and questions refer to one of a few aspects (e.g. the subject's motivation, following actions, etc.). The answers were crowdsourced.

PIQA: Physical Interaction Question Answering (Bisk et al., 2020): Questions regarding physical commonsense knowledge. Contexts are goals derived from an instruction website, typically involving less prototypical uses of everyday objects (e.g., using a bottle to separate eggs). The answers were crowdsourced, and an adversarial filtering algorithm was used to remove annotation artifacts.[2]

WinoGrande (Sakaguchi et al., 2020): A large-scale version of WSC that exhibits less bias thanks to adversarial filtering and use of placeholders instead of pronouns. As opposed to WSC that was curated by experts, WinoGrande was crowdsourced with a carefully designed approach that produces diverse examples which are trivial for humans.

3 Models

A given instance consists of an optional context c, an optional question q, and answer choices: $a_{i=1}^{k}$. We first describe the baseline model, which makes

---

[1] To make this task compatible with the other tasks, we only kept a single correct answer per instance, making our results not comparable to previously reported results.

[2] Word associations and dataset-specific features that are not informative for the task are identified by a strong baseline and removed (Gururangan et al., 2018; Zellers et al., 2018).

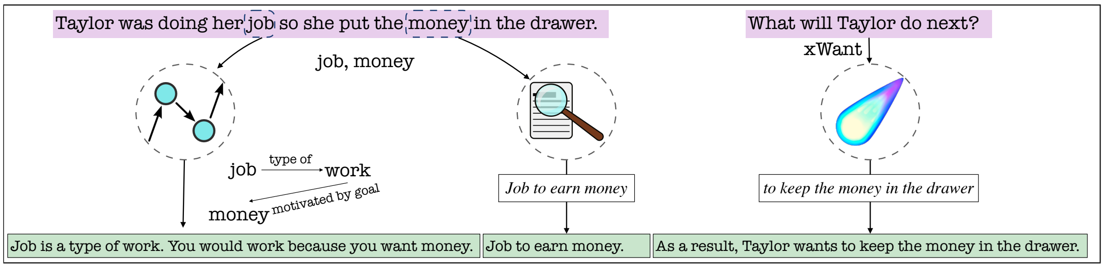

Figure 2: Generating a single clarification using ConceptNet, Google Ngrams, and COMeT (Social IQa instance).

the prediction based on the instance alone (§3.1). We then describe a knowledge-informed model that relies on external resources (§3.2). Finally, we discuss our self-talk model, which uses a pre-trained LMs to produce clarifications (§3.3).

3.1 LM-only Baseline

We use a pre-trained language model $\mathbb{LM}_s$ to score the plausibility of different text fragments. We experiment with the various LMs provided by the transformers package (Wolf et al., 2019): GPT (Radford et al., 2018), GPT2 (Radford et al., 2019, all sizes), a distilled GPT2 (Sanh et al., 2019), and XLNet (Yang et al., 2019, both sizes).

We assign each of the answer choices a_i into the combination of the context and the question, and obtain $\text{opt}_i = \text{combine}(c, q, a_i)$. The combine function is computed differently for each task. For example, in COPA, where the question might be either about the cause or the effect of the context, we create the following texts for cause: “[context]. *As a result*, [choice]” and for effect: “[context]. *The cause for it was that* [choice]”.

We denote the score of each answer choice as $\text{score}(a_i) = \text{CE}(\text{opt}_i)$, where CE is cross-entropy loss defined as:
$\text{CE}(t_1...t_n) = -\frac{1}{n}\sum_{i=1}^{n} \log_2 p_{\mathbb{LM}_s}(t_i \mid t_1...t_{i-1})$.
We predict the a_i with the lowest score as the correct answer, which is the most likely option according to $\mathbb{LM}_s$: $y = \text{argmin}_i\, \text{score}(a_i)$.

3.2 Baseline Model with External Knowledge

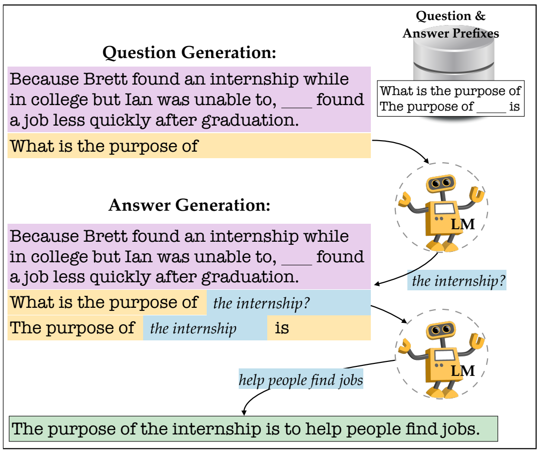
In the setup illustrated in Figure 1, each instance consists of an additional clarification list: $CL = \{cl_1, ..., cl_m\}$. Those are text fragments containing potentially relevant knowledge for solving the instance. For example, the clarification “*The purpose of the internship is to help people find jobs*” might help answering the question “*which of Brett and Ian found a job less quickly after graduation?*”. We don’t expect all the clarifications to be relevant and helpful for answering the main question. Instead, the model relies on the single clarification that increases its belief of a certain answer choice. Thus, the score of each answer choice is selected as the score of the text containing the clarification that most supports it, i.e., whose combination with it yields the minimal loss: $\text{score}(a_i) = \min_{cl \in CL} \text{CE}(opt_i + cl)$.
Again we predict $y = \text{argmin}_i\, \text{score}(a_i)$.

We extract clarifications from the following sources, exemplified in Figure 2.

ConceptNet. Similarly to previous work, we extract relation paths between words from the context and the question, and words from the answer choices. Since we incorporate the knowledge into the model as text, we convert each ConceptNet relation to a natural language template as in Davison et al. (2019). We limit the path length to 2 edges in order to maintain high precision.

Corpus. For pairs of words from the context and question and from the answer choices, we extract their joint occurrences (with minimum frequency of 100) in Google N-grams (Brants and Franz, 2006). This yields text fragments of up to 5 words rather than well-formed sentences, with the potential of describing the relationship between the two words (Shwartz and Dagan, 2018).

COMeT. COMeT (Bosselut et al., 2019) is a knowledge base construction model trained on the ATOMIC resource (Sap et al., 2019a) which consists of everyday situations along with multiple commonsense dimensions such as their causes, effects, pre- and post-conditions, etc. We generate all the dimensions unless we can generate specific relations that are more likely to help. Specifically, in Social IQa, we heuristically try to understand which type of relation in COMeT the question asks for. In COPA, we use the pre-condition relations for cause questions (`xIntent`, `xNeed`) and the post-condition relations for effect questions (`xEffect`,



Because Brett found an internship while in college but Ian was unable to, ___ found a job less quickly after graduation.
What is the purpose of

Because Brett found an internship while in college but Ian was unable to, ___ found a job less quickly after graduation.
What is the purpose of *the internship?*
The purpose of *the internship* is

The purpose of the internship is to help people find jobs.

Figure 3: Generating a clarification with LM: 1) Generate a question, conditioned on the context (pink) and question prefix (yellow). 2) Generate an answer, conditioned on the context, generated question and a corresponding answer prefix. The clarification is a concatenation of the answer prefix and generated text (green).

`xReact`, `xWant`, `oEffect`, `oReact`, `oWant`). When possible, we replace `personX` with the syntactic subject of the context or the question.

3.3 Self-talk Model

Our proposed model makes the prediction identically to Figure 1, but extracts the clarifications from pre-trained LMs. We treat the knowledge extraction from LMs as a process of self-asking clarification questions about the context and "discovering" their answers. Figure 3 exemplifies this process for WinoGrande with a generator language model $\mathbb{LM}_g$. For the sake of simplicity, the illustration depicts the process of generating a single pair of clarification question and answer.

We start by generating multiple clarification questions conditioned on the context, by 1) concatenating one of several question prefixes, which we curated for each task (e.g. "What is the purpose of", see Table 6 in the appendix); and 2) generating 5 questions for each prefix using Nucleus sampling with $p = 0.2$, i.e., sampling from the top 20% tokens (Holtzman et al., 2019).[3] We limit the question length to up to 6 additional tokens.

For each well-formed question that we obtained at the previous step, e.g. "*What is the purpose of the internship*?", we generate multiple answers using a similar method. Each question prefix corresponds to an answer prefix. We use the concatenation of the context, generated clarification question, and answer prefix as the prompt for generating an answer (clarification). We limit the answer length to 10 generated tokens, and use Nucleus sampling with $p = 0.5$. We generate 10 answers for each clarification question and keep all the well-formed clarifications. Note that the clarification questions themselves are only means to generate the clarifications, and they are not used by our model.[4]

Since we did not train the clarification generator to ask sensical, relevant, and helpful questions, nor did we train the answer generator to generate coherent and factually correct answers, we can assume that some of the generated clarifications do not provide useful information to the model.

4 Results

Table 2 displays the performance of the best model in each category according to the development accuracy. We report the performance of the following models: majority baseline, LM baseline (Baseline), LM-based model with external knowledge (Ext. Knowledge), Self-talk, supervised models from prior work when applicable (Pre. Sup), and human performance. Our zero-shot models are highlighted in purple. As expected, the overall performance is worse for the zero-shot models compared to the state-of-the-art supervised models, but they perform substantially better than the majority baselines on most tasks, with the exception of WinoGrande where they only slightly outperform it. Among the LM-based models, self-talk performs on par or within a few points from the external knowledge model.

Best Knowledge Source. Among the knowledge informed models, COMeT achieves the best performance across tasks. This likely happens because COMeT can dynamically generate predictions for any context, while the other two knowledge sources are static and lack coverage.

Table 1 shows the relative improvement in accuracy points compared to the zero-shot baseline,

---

[3] $p = 0.2$ is significantly lower than the standard value of $p = 0.9$ in the literature. We optimized for factual correctness, and our preliminary experiments have shown that lower p values produce texts that are more faithful to the LM training corpus, at the price of being more bland.

[4] In some datasets, an instance consists of a question. In this case, we can use the instance question as a "clarification" question and generate additional clarification questions similar to it. For example, the Social IQa context "*Austin fought for Quinn's life, but they eventually died on the operating table.*", the LM answers the question "*Why did Austin do this?*" directly with: "*Austin did this because they wanted to keep him alive*" (the correct answer is "*Because Austin wanted to save Quinn*").

Table 2: Best setup for each model type, according to development accuracy (excluding unpublished leaderboard submissions). Test accuracy is reported when labels are available or leaderboard submission was possible. *COMeT-CGA (Bosselut and Choi, 2019) is a zero-shot model performing probabilistic inference over generated inferences from a COMeT model trained on GPT2. ** (Lin et al., 2020).

for each knowledge source averaged across LMs for each dataset. Interestingly, the relative improvement is fairly uniform across knowledge sources, but it varies substantially across tasks. While some tasks benefit from any added knowledge, others benefit from none.

We also experimented with combining the clarifications from all the knowledge sources, which didn't prove beneficial except for MC-TACO (where it added +7.9 points to the dev accuracy, bringing it to 66.7). We assume that some resources added noise, making the whole smaller than the sum of its parts.

5 Analysis

While the performance on the end task serves as an extrinsic evaluation for the quality of the generated clarifications, we are also interested in evaluating it intrinsically. From preliminary experiments we know that there is a high ratio of noisy clarifications. We thus focus on and analyze two types of clarifications: useful (§5.1) and harmful (§5.2).[5]

5.1 Useful Clarifications

We define a clarification as *useful* if (a) it is the clarification with the best LM score in its instance (i.e., the clarification used in practice); and (b) the instance was incorrectly predicted by the zero-shot baseline but correctly predicted by the self-talk model. We sampled up to 50 useful clarifications for each combination of task and knowledge source, using the best performing LM (See Table 3 in the appendix for examples). We showed crowdsourcing workers an instance along with a clarification question and its answer, and asked them: 1) whether the question is grammatical, not entirely grammatical but understandable, or completely not understandable; and if the answer was anything but "completely not understandable", 2) whether the question is relevant, i.e. on topic with the instance. We asked the same questions about the answer, in addition to: 3) whether the answer is factually correct or likely true; and 4) whether the answer adds helpful information to solve the instance.

The annotation task was carried out in Amazon Mechanical Turk. To ensure the quality of annotations, we required that the workers be located in the US, UK, or Canada, and have a 99% approval rate for at least 5,000 prior tasks. We aggregated annotation from 3 workers using majority vote. The annotations yielded moderate levels of agreement, with

Figure 4: Ratio of clarifications considered as **relevant** (top), **factually correct** (middle), and **helpful** (bottom), among the useful and grammatical or understandable clarifications for each task and knowledge source. Answers in Social IQa were evaluated for helpfulness when the clarification question was different from the main question.

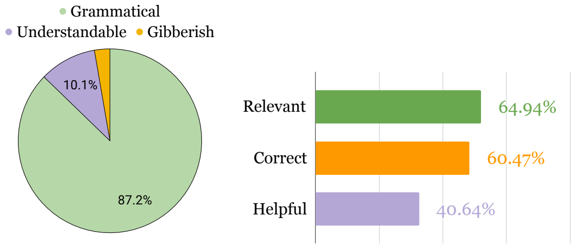

Figure 5: Human evaluation of the clarifications, aggregated across tasks and knowledge sources. **Left:** ratio of grammatical, not entirely grammatical but understandable, and completely not understandable clarifications. **Right:** percent of grammatical/understandable clarifications considered relevant, correct, and helpful.

Fleiss' Kappa $\kappa = 0.43$ (Landis and Koch, 1977). Among the different categories of annotations we measured pairwise accuracy, which ranged from 60.41% (the answer is factually correct) to 92.26% (the question is completely not understandable).

For the sake of brevity, we focus on the analysis of the answers to the clarification questions. The left part of Figure 5 shows that across tasks and resources, most clarifications are grammatical or at least understandable. Among the clarifications considered grammatical or understandable, the right part of the figure shows the percentage of clarifications considered relevant, correct, and helpful. Most clarifications were considered relevant to the context and factually correct, but only 40% on average were considered helpful. Considering that these are all clarifications that indeed helped the model, this is an interesting though not completely unexpected finding: the model utilizes knowledge that humans wouldn't consider as helpful.[6]

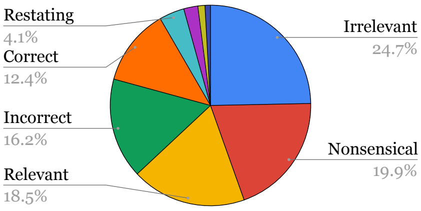

Figure 6: Types of errors caused by the harmful clarifications across all tasks and knowledge sources.

Breaking down by knowledge source, Figure 4 shows the ratio of clarifications considered by humans as **relevant** (top), **factually correct** (middle), and **helpful** (bottom), for each task and knowledge source. XLNet performs worse on all measures. ConceptNet's clarifications are often judged as irrelevant likely because they are limited to a very specific type of clarification (the relationship between a pair of terms). It's not too surprising that clarifications generated by LMs were sometimes judged as factually incorrect. We also note that COMeT generated factually correct clarifications for Social IQa (which is based on ATOMIC, on which COMeT was trained), and ConceptNet generated factually correct clarifications for CommonSenseQA (which is based on ConceptNet).

Table 3 demonstrates the types of knowledge in useful and relevant clarifications, showing that pre-trained LMs do particularly well in definitions.

---

[6] Seemingly unhelpful clarifications may yet increase the LM score by adding relevant lexical cues. A manual examination of a sample of answers judged as relevant but unhelpful revealed that 53.33% were answers for unhelpful questions, 20% were correct but unhelpful, 16.67% were factually incorrect, 10% were helpful to some extent (containing knowledge deemed too trivial by the annotators), and 10% had corresponding unanswerable instances.

Task	Source	Instance	Clarification
		Preconditions	
CSQA	ConceptNet	**Q:** Working on the elaborate task was taxing, it require extreme what? **Choices**: holding, concentration, energy, job, energy	**Q:** What is the relationship between ‘working’ and ‘concentration’? **A:** In order for working to happen, concentration needs to happen.
	COMeT	**Q:** When you travel you should what in case of unexpected costs? **Choices**: go somewhere, energy, spend frivolously, fly in airplane, have money	**Q:** What do they want as a result? **A:** As a result, they want to make sure they have enough money.
MC-TACO	GPT2-XL	**C:** [...] Mark Bailey didn’t dream of becoming a judge. **Q:** How many years did it take for Mark to become a judge? **Choices**: 63 years, [...], 7 months, 180, 7 weeks, 7 years, [...], 7 hours	**Q:** What happened first? **A:** The first thing that happened was he went to law school and became an attorney.
Social IQa	GPT2-M	**C:** Carson was at a friends house and decided to play video games. **Q:** What does Carson need to do before this? **Choices:** know about their friends house, of though about playing video games, of thought about their friend	**Q:** What does Carson need to do before this? **A:** Before doing that, Carson first had to get his mother’s permission before playing the game.
		Social Commonsense	
Wino Grande	COMeT	**C:** Neil looked all over the neighborhood for their missing dog until Samuel called and __ got their dog back. **Choices**: Neil, Samuel	**Q:** What does Neil feel as a result? **A:** As a result, Neil feels happy to have the dog back.
		Definitions and Lexical Knowledge	
PIQA	COMeT	**Q:** how to sanitize a toothbrush **Choices**: [...] antibacterial mouthwash into a small toilet bowl [...] soak your toothbrush [...] [...] antibacterial mouthwash into a small cup [...] soak your toothbrush [...]	**Q:** What does you want as a result? **A:** As a result, you wants to get rid of germs.
Wino Grande	GPT2-L	**C:** During the summer, I like visiting the zoo more than the aquarium because the __ is inside. **Choices**: zoo, aquarium	**Q:** What is the definition of ’zoo’? **A:** The definition of a ’zoo’ is an area where people can see animals in captivity.
Social IQa	ConceptNet	**C:** Jan had been on vacation in Hawaii for a week. Last night, she finally returned home. **Q:** What will Jan want to do next? **Choices**: return to her family, Return to work, Leave for another vacation.	**Q:** What is the relationship between ‘vacation’ and ‘work’? **A:** Vacation is the opposite of work.
		Functions	
CSQA	DistilGPT2	**Q:** What do professors primarily do? **Choices**: master physics, state facts, wear wrinkled tweed jackets, school students, teach courses	**Q:** What is the main function of a professor’s teaching career,? **A:** The main function of a professor’s teaching career, is to teach students how they can improve their knowledge.

Table 3: Example of relevant useful clarifications and the type of knowledge they provide.

5.2 Harmful Clarifications

Symmetrically, we also study the *harmful* clarifications. A clarification is harmful if (a) it is the clarification with the best LM score in its instance; and (b) the instance was correctly predicted by the zero-shot baseline but incorrectly predicted by the self-talk model. We sampled up to 25 harmful clarifications from the predictions of the best setup (LM and knowledge source) for each task, and manually categorized the errors into the following types.

1. **Irrelevant**: the clarification was off topic.
2. **Nonsensical or ungrammatical**: the clarification was not a complete sentence, or had other grammar or meaning issues.
3. **Relevant**: the clarification contributed relevant knowledge but it wasn’t enough for predicting the correct answer.
4. **Factually Incorrect**: the clarification made a factually incorrect statement, often in support of one of the distractors.
5. **Correct**: the clarification yielded an alternative correct answer for the main instance.
6. **Restating the instance**: the clarification repeated the context or the main question.
7. **Wrong sense**: the clarification interpreted a word from the instance in the wrong sense.
8. **Dataset error**: the instance is incorrect or lacks information required for answering it correctly.

Figure 6 shows the percent of each error type across all the tasks and knowledge sources. The majority of clarifications are irrelevant, ungrammatical or nonsensical, or relevant but not helpful for making the correct prediction. We judged a non-negligible 12.4% of the clarifications as providing alternative correct answers, phrased differently from the gold answer. Table 4 provides an instance for each error type.[7]

6 Related Work

6.1 External Knowledge in Neural Models

Approaches for incorporating external knowledge into a neural model consist of several components: (1) the task addressed; (2) neural model; (3) knowledge sources; and (4) incorporation method. Most models target tasks that require commonsense knowledge, such as the story cloze test (Mostafazadeh et al., 2016) and machine comprehension tasks (Kočiskỳ et al., 2018; Ostermann

---

[7] See Figures 8 and 9 in the appendix for a breakdown of error types by task and knowledge source.

Task	**Know. Source**	**Instance**	**Clarification**
Irrelevant			
PIQA	GPT2-XL	**Q:** how do you sit a baby in a restaurant? **Choices**: place them in a booster seat., place them on the table.	**Q:** What is the definition of “a good time”? **A:** The definition of “a good time” is not the same as what constitutes an acceptable meal.
Nonsensical or ungrammatical			
Social IQa	XLNet	**C:** Cameron went out of their way to help a friend who was in need of help. **Q:** How would Cameron feel after helping? **Choices**: Cameron then frustrated., Cameron then happy., Cameron then annoyed.	**Q:** How would Cameron feel after helping? **A:** Cameron felt they were doing, but then he realized that.
Relevant			
WinoGrande	GPT2-XL	The children were not vaccinated, which was fine with Betty but annoyed Mary. ___ believed they made kids autistic. **Choices**: Betty, Mary	**Q:** What does it mean to be “autistic”?” **A:** Be “autistic” means to have problems in social interaction and communication skills.
Factually Incorrect			
WinoGrande	COMeT	Derrick really liked working in Human Resources and William wanted to work at the same company, and ___ subsequently offered a position. **Choices**: Derrick, William	**Q:** What will Derrick want as a result? **A:** As a result, Derrick wants to go to work with them
Correct			
CSQA	Google Ngrams	**Q:** What do people usually feel when falling in love? **Choices**: getting married, pain, happiness, getting married, suffering	**Q:** - **A:** Suffering from unrequited love.
Restating the instance			
CSQA	COMeT	**Q:** Billy set aside a block of time for having fun after work. Why might he do this? **Choices**: happiness, stress relief, pleasure, ocean, may laugh	**Q:** What will Billy want as a result? **A:** As a result, they want to do something fun.
Wrong Sense			
MC-TACO	ConceptNet	**C:** [...] Islam thrived as a strong, male-dominated religion of individuality [...] preaching brotherhood [...]. **Q:** What happened after Islam became popular in the region? **Choices**: they drank liquor, it died off, it expanded even further, they drank alcohol, it died out, it died down	**Q:** What is the relationship between brotherhood and alcohol? **A:** You are likely to find brotherhood in a fraternity house. You are likely to find alcohol in a fraternity house.

Table 4: An example for each of the error types among the harmful clarifications.

et al., 2018; Clark et al., 2018; Talmor et al., 2019). The neural component has recently shifted from biLSTM to transformer-based representations, specifically pre-trained LMs (Devlin et al., 2019; Liu et al., 2019).

With respect to the knowledge source, the vast majority of papers rely on ConceptNet to extract relation paths between concepts and entities identified in the input (Speer and Havasi, 2012, see an example in Figure 2). Additional resources include WordNet (Lin et al., 2017; Wang and Jiang, 2019), retrieval or statistics mind from corpora (Lin et al., 2017; Mitra et al., 2019; Joshi et al., 2020), knowledge base embeddings (Chen et al., 2019; Xiong et al., 2019), hand-crafted rules (Lin et al., 2017; Tandon et al., 2018), and tools such as sentiment analyzers (Chen et al., 2019) and knowledge-informed LMs (Bosselut and Choi, 2019).

The external knowledge is typically incorporated into the neural model by learning a vector representation of the symbolic knowledge (e.g. subgraphs from ConceptNet), and attending to it via attention mechanism when representing the inputs (Bauer et al., 2018; Paul and Frank, 2019; Lin et al., 2019). Alternative approaches include using the knowledge to score answer candidates and prune implausible ones (Lin et al., 2017; Tandon et al., 2018), and training in a multi-task setup via auxiliary tasks pertaining to knowledge (Xia et al., 2019).

To the best of our knowledge, our method is the first to generate knowledge from pre-trained language models and incorporate it as external knowledge into a question answering model. Concurrently, Latcinnik and Berant (2020) used one language model to generate hypotheses and another language model as an answer scorer for CommonSenseQA.

6.2 Extracting Knowledge from LMs

Pre-trained LMs such as GPT2 (Radford et al., 2019) and BERT (Devlin et al., 2019) capture various types of world knowledge. Petroni et al. (2019) showed that such LMs can be used in a KB completion task over ConceptNet and Wikidata (Vrandečić and Krötzsch, 2014) by converting KB relations into natural language templates and querying the LM for the missing part in the triplet (concept$_1$, relation, concept$_2$). For instance, querying BERT for suitable substitutes to the mask in “Dante was born in [MASK]” assigns the highest probability to Rome. Davison et al. (2019) similarly showed that BERT assigns higher scores to natural language fragments of true rather than fictitious ConceptNet triplets, and semi-automated the template creation by using GPT2 to score hand-crafted templates.

While both works have shown somewhat promising results, other work showed that knowledge extracted from LMs is expectantly not always accurate. Specifically, Kassner and Schütze (2020) showed that negated facts are also considered likely by the LM, while Logan et al. (2019) pointed out that LMs may over-generalize and produce incorrect facts such as “Barack Obama’s wife is Hillary”.

6.3 Generating Questions and Explanations

There are numerous research directions investigating automatic question generation (Vanderwende, 2008). Motivations vary from data augmentation to QA tasks (Du et al., 2017; Dhingra et al., 2018; Du and Cardie, 2018; Sachan and Xing, 2018; Fabbri et al., 2020) through conversational machine reading (Saeidi et al., 2018; Pan et al., 2019), simplifying questions to make them more easily answerable (Buck et al., 2018; Talmor and Berant, 2018; Perez et al., 2020), to using questions as means for other purposes such as sentence representation and summarization (Guo et al., 2018; Potash and Suleman, 2019).

In particular, our work is pertinent to previous work in producing clarification questions and explanations. Rao and Daumé III (2019) worked on questions from forums (e.g. Stack Exchange). They proposed a model that generates clarification questions and corresponding answers for a given question, using the question’s comments (clarification questions and answers) as supervision. Question-answer pairs were scored based on how much relevant information they add to the context.

Shen et al. (2019) developed an active learning framework for image captioning that learns to detect uncertainty about generated words and ask natural language questions to reduce its uncertainty. A visual question answering (VQA) model provides an answer which is then used to change the caption. The framework is trained with reinforcement learning, but the gold standard captions are used during a warmup steps and the VQA model is supervised.

Klein and Nabi (2019) proposed a joint question generation and question answering framework. They fine-tuned GPT2 on a question answering dataset to generate a question and an answer span for a given passage, and trained BERT to answer the generated question given the passage. Finally, Rajani et al. (2019) proposed a model for CommonSenseQA that generates explanations for its predictions. They collected human explanations and used them to fine-tune LMs to automatically generate explanations. These explanations were then added as additional inputs. The shortcoming of this approach is that it requires collecting specific human explanations for each new dataset.

7 Discussion and Conclusion

We presented an unsupervised framework for multiple choice commonsense tasks that generates and integrates background knowledge from pre-trained LMs. On most tasks, it performs substantially better than the baseline and similarly to a model that had access to external knowledge resources.

We have listed several shortcomings of using pre-trained LMs as knowledge providers: (i) *insufficient coverage*, (ii) *insufficient precision*, and (iii) *limited reasoning capabilities*. Despite their insufficient precision compared to a KB like ConceptNet, we showed that clarifications generated by LMs resulted in similar or superior empirical gains. Among the clarifications used in practice by the answer scorer, about 60% of those that yielded a correct prediction and 12% of those that yielded an incorrect prediction were judged by humans as factually correct.

By design, our model makes a single additional reasoning step explicit, aiming to facilitate reasoning about implicit inferences. A preliminary experiment in which we incorporated clarification pairs to facilitate two hops got mixed results. An interesting future direction is to generate each clarification in response to the previous ones, in a dialogue setup (Saeidi et al., 2018). Another challenge is the “needle in a haystack” problem of the clarifications, and one way to address it is to develop a model that is capable of “introspection”, specifically knowing what it doesn’t know. A more structured knowledge generation might also make the combination of various knowledge sources more successful.

Filling in knowledge gaps and making implicit intermediate reasoning steps explicit is imperative going forward. We hope that our framework will facilitate future research in this area. Our code and data will be made available upon publication. Our code and data is available at github.com/vered1986/self_talk.

A Question and Answer Prefixes

We came up with question and answer prefixes by experimenting with a few generic prefixes and observing what generally yields accurate answers. For example, we observed that LMs are not very good at causal and temporal relationships but are pretty good at definitions. For the datasets whose instances include questions (e.g. Social IQa) we also used the corresponding question prefixes.

Table 6 presents the question and answer prefixes used for each task. "_" in the answer prefix is replaced with the generated question (excluding the question mark), e.g. "What is the definition of a cat?" yields the answer prefix: "The definition of a cat is". The Social IQa templates correspond to COMeT dimensions. X is replaced with the syntactic subject of the sentence.

B Best Language Model

Table 5 shows the average development accuracy of the LMs across the different knowledge sources. In general there is a preference to GPT-2, and in particular to the larger models, except for COPA in which the distilled version works best. A possible explanation might be that the language model distillation reduces the likelihood of rare words (Tang and Lin, 2018), which works well for the simple sentences in COPA. The XLNet models perform poorly, perhaps due to their smaller training corpus (16GB vs 40GB in GPT-2, both using web text).

	GPT	Distil-GPT2	GPT2	GPT2-M	GPT2-L	GPT2-XL	XLNet	XLNet-L
COPA	58.64	63.73	59.73	61.82	60.64	57.91	51.91	49.45
CSQA	27.57	25.45	25.64	27.74	31.75	31.22	21.47	20.79
MC-TACO	47.72	48.75	50.06	52.99	56.61	58.05	34.18	37.03
Social IQa	41.62	40.39	41.80	43.39	44.39	45.50	33.12	33.65
PIQA	57.91	59.63	61.95	65.57	67.89	69.59	49.24	48.80
WinoGrande	52.18	50.94	51.16	50.18	52.85	54.04	49.07	48.74

Table 5: Average self-talk accuracy for each LM answer scorer, averaged across knowledge sources.

	COMET	ConceptNet	Distil-GPT2	GPT2	GPT2-M	GPT2-XL	GPT2-L	GPT	XLNet	XLNet-L
WinoGrande	94.00	93.70	92.00	83.60	93.70	96.00	88.90	85.70	81.80	83.30
Social IQa	96.00	90.00	94.00	92.00	94.00	94.00	94.00	94.00	50.00	62.00
MC-TACO	94.00	62.50	84.30	89.40	94.00	96.00	98.00	87.40	78.20	100.00
PIQA	98.00	78.00	70.00	84.00	88.00	74.00	84.00	55.00	50.00	66.60
CSQA	94.00	96.50	88.90	89.70	90.00	98.00	96.00	100.00	-	81.40

Figure 7: Ratio of clarifications considered by humans as **grammatical or understandable** among the useful clarifications for each task and knowledge source.

Dataset	Question Prefix	Answer Prefix
COPA & CSQA	What is the definition of	The definition of _ is
	What is the main purpose of	The purpose of _ is to
	What is the main function of a	The main function of a _ is
	What are the properties of a	The properties of a _ are that
	What is a	_ is
	What happened as a result of	As a result of _,
	What might have caused	The cause of _ was

C Analysis

C.1 Useful Clarifications

Figure 7 shows, for each task and knowledge source, the ratio of useful clarifications that were considered by humans as either grammatical or at least understandable. The majority of the helpful clarifications are considered as grammatical. The XLNet models are slightly worse in terms of grammaticality. For example, the clarification question "*What are the properties of a you sharpen a pencil, ?*" and the answer "*The properties of a you sharpen a pencil, are that it will not break or be dulled*" generated for the PIQA instance "sharpen a pencil" by XLNet-base. Despite its grammar errors, the answer was still useful for a LM to determine the correct answer.

C.2 Harmful Clarifications

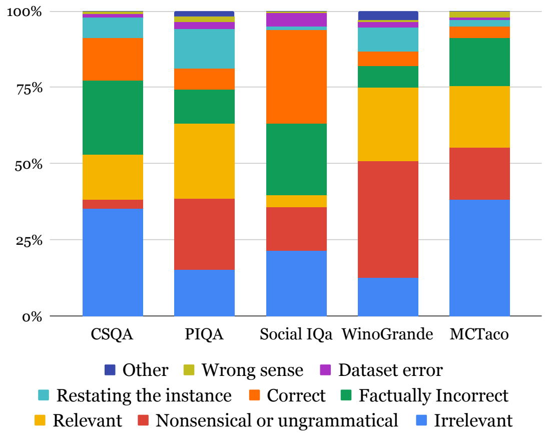

Figure 8: Types of errors caused by the harmful clarifications, for each task, across all knowledge sources.

Figure 8 breaks down by task the type of errors found in the harmful clarifications. In Social IQa and CommonSenseQA, many alternative correct answers are generated, but this doesn't happen in WinoGrande, that by design only allows for one correct answer. Clarifications in MC-TACO are more than average irrelevant. In the future, it would be interesting to investigate whether this is due to inherent lack of temporal commonsense in LMs or due to misguided attempts to extract it.

Figure 9 similarly breaks down the errors by

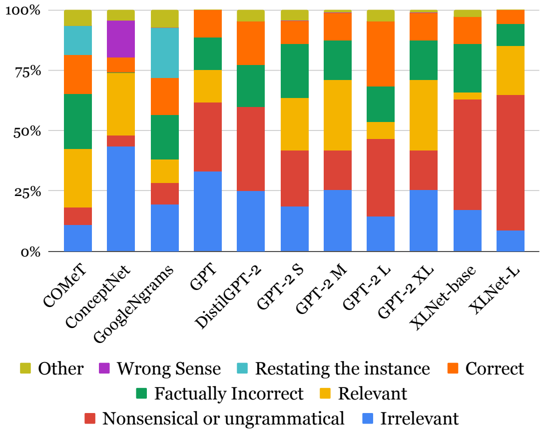

Figure 9: Types of errors caused by the harmful clarifications, for each knowledge source, across all tasks.

knowledge source. All knowledge sources except for ConceptNet make incorrect statements, but LMs also tend to make nonsensical statements, especially XLNet. ConceptNet tends to generate irrelevant clarifications (about the relationship between two unimportant terms). Being a static resource, is was also insensitive to the word senses. Google Ngrams, the only other static knowledge source, didn't suffer from this issue. This is likely because a polysemous term x related to y in one of its senses wouldn't typically co-occur with y in its non-related senses (Shwartz and Dagan, 2016).

Reasoning about Goals, Steps, and Temporal Ordering with WikiHow

Qing Lyu[*] **Li Zhang**[*] **Chris Callison-Burch**
University of Pennsylvania
{lyuqing,zharry,ccb}@seas.upenn.edu

Abstract

We propose a suite of reasoning tasks on two types of relations between procedural events: GOAL-STEP relations ("learn poses" is a step in the larger goal of "doing yoga") and STEP-STEP TEMPORAL relations ("buy a yoga mat" typically precedes "learn poses"). We introduce a dataset targeting these two relations based on wikiHow, a website of instructional how-to articles. Our human-validated test set serves as a reliable benchmark for commonsense inference, with a gap of about 10% to 20% between the performance of state-of-the-art transformer models and human performance. Our automatically-generated training set allows models to effectively transfer to out-of-domain tasks requiring knowledge of procedural events, with greatly improved performances on SWAG, Snips, and Story Cloze Test in zero- and few-shot settings.

1 Introduction

If you ask Alexa or Siri where to "buy a yoga mat," it should ideally infer that your goal is probably to "do yoga" and therefore suggest information on subsequent steps like "learn some poses." This requires the system to reason about the GOAL-STEP relation and the STEP-STEP TEMPORAL relation among events in a procedure. Though event relation reasoning is a popular task, existing datasets mostly focus on temporal relations (Pustejovsky et al., 2003; Ning et al., 2018), causal relations (Hashimoto et al., 2014; Caselli and Vossen, 2017), spatiotemporal containment and coreference relations (Glavaš et al., 2014; Liu et al., 2014). Less attention has been paid to relations among procedural events, the understanding of which is critical to task-oriented intelligent systems. The knowledge of procedural events is also crucial to learning scripts (Feigenbaum et al., 1981), which describe sequences of stereotypical human activities.

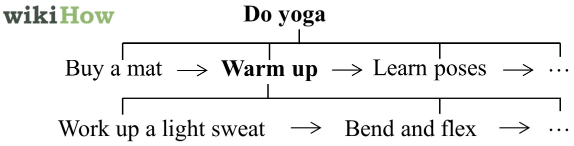

Figure 1: Goals and steps (slightly paraphrased) from wikiHow articles "How to Do Yoga" and "How to Warm Up". The lines denote GOAL-STEP relations; the arrows denote STEP-STEP TEMPORAL relations.

To bridge this gap, we propose a dataset for *goal-step inference* targeting these two event relations. We collect data from wikiHow[1], a website consisting of more than 110,000 professionally-edited how-to articles spanning a surprisingly wide range of domains. Each wikiHow article describes a commonplace human activity, organized as a goal and a sequence of steps (Figure 1). Our dataset includes 3 tasks: inferring steps given a goal, the goal given a step, and the ordering between two steps given a goal. For each task, we automatically generate 100,000 to 800,000 examples as the training set, using a negative sampling strategy based on semantic similarity; we also provide a human-validated test set with 1,000 to 3,000 examples.[2]

Our test set serves as a reliable benchmark for commonsense inference, with a performance gap of 10% to 20% between human and state-of-the-art transformer models trained in-domain. Moreover, when pre-trained on our tasks, a model can transfer knowledge of procedural event relations to other NLU tasks, with a zero-shot improvement over the baselines by 24% for a commonsense reasoning benchmark (Zellers et al., 2018), 13% for a story cloze test (Mostafazadeh et al., 2016) and 64% for an intent detection task (Coucke et al., 2018).

---

2 WikiHow Corpus

We construct a new corpus by crawling the latest wikiHow website. Our corpus has 112,505 how-to articles after deduplication in an easy-to-process JSON format (statistics by category are shown in Appendix B). Each article contains: main bodies of texts (titles, methods/parts, headers, descriptions), related articles, references, Q&A, tips and warnings. To facilitate multi-modal research, we also include links to images and videos aligned with texts.

3 Goal-Step Inference Tasks

We propose 3 goal-step inference tasks derived from the corpus. In each article, we define **Goal** as the title without "How to", and **Step** as the header of each paragraph (example shown in Figure 1).

3.1 Step Inference Task

We first introduce the *Step Inference* task, targeting GOAL-STEP relations between events. We formulate this as a 4-choose-1 multiple choice format evaluated using accuracy.

In this task, a system is given a prompt goal and 4 candidate steps and needs to choose the step that helps achieve the goal. For example, given the goal "Prevent Coronavirus" and the candidate steps:

A. wash your hands	B. wash your cat
C. clap your hands	D. eat your protein

the correct step would be A.

Obtaining the prompt and the positive candidate is straightforward, as we sample them iteratively from each how-to article. However, it is challenging to sample negative candidates (Chao et al., 2018; Zellers et al., 2019a) which should have high semantic relatedness with the positive candidate (or the question becomes trivial) while being incorrect answers. We first map each step in wikiHow to a vector representation by taking the average of the BERT embeddings (Devlin et al., 2019) of the verbs. Given the positive step, we then choose 3 steps under different wikiHow categories with the highest cosine similarity to it as the negative candidates (see Appendix C for other strategies). The nearest-neighbors are computed using FAISS (Johnson et al., 2017).

It has recently become clear that the latest NLP models can exploit statistical artifacts from a dataset (Poliak et al., 2018; Si et al., 2019; Zellers et al., 2019b). To prevent the model from learning the negative sampling strategy and relying on just the candidates, we randomly reassign one of the candidates as positive, and the others as negative. Then, we replace the prompt goal with the goal attached to the new positive candidate. This strategy ensures that any model performs no better than chance when given access to only the candidates and not the prompt.

For each step in wikiHow, we create an example by using it as the positive candidate, followed by the negative sampling and label reassignment processes as described above. Then, we apply a collection of hand-crafted filters to remove low-quality examples (Appendix D).

3.2 Goal Inference Task

Next, we introduce the *Goal Inference* task, formulated in a similar way as Step Inference.

In this task, a system is given a prompt step and 4 candidate goals and needs to choose the correct goal which the step helps achieve. For example, given the step "choose a color of lipstick" and the candidate goals:

A. Get Pink Lips	B. Read One's Lips
C. Lip Sync	D. Draw Lips

the correct goal would be A.

For each goal in wikiHow, we create the set of 4 candidates by using it as the positive candidate, followed by the negative sampling, label reassignment, and filtering processes as in Step Inference. For each positive candidate goal, we use each of its steps to create an example.

3.3 Step Ordering Task

Finally, we introduce the *Step Ordering* task, targeting STEP-STEP TEMPORAL relations between events. This task is in a 2-choose-1 multiple choice format evaluated using accuracy.

In this task, given a prompt goal and 2 steps, a system needs to determine which step temporally precedes the other. For example, given the goal "Clean Silver" and the steps:

A. dry the silver B. handwash the silver

the correct answer would be B precedes A.

Unfortunately, not all steps in every wikiHow article follow an underlying order. We observe that there are 2 types of wikiHow articles. One is *unordered*, where the steps are parallel alternatives, such as ways to "Stay Healthy" ("develop an exercise routine", "get enough sleep", "eat a healthy diet", etc.). The other is *ordered*, such as recipes for cooking or manuals for fixing appliances, where most steps should be taken sequentially.

We ask 3 annotators to label 1,000 wikiHow articles as ordered or not as a coarse-grained approximation for whether their steps are ordered. We finetune a pre-trained RoBERTa model using 5-fold cross-validation, finding an average precision of 88%. We then ask a 4th annotator to label another 40 articles as the held-out test set, where the finetuned model achieves 100% precision. Finally, we only consider articles that the model predicts as ordered (around 40%) for the Step Ordering task.

For each goal in wikiHow, we create a set of examples by using it as the prompt and sampling every pair of its adjacent steps as candidates. Then, we randomly shuffle the candidates, so each appears first with 50% chance.

3.4 Test Set Construction and Validation

There exists some noise in our automatically generated examples, because some of them do not have a single correct answer. Errors can be introduced when a sampled negative candidate is in fact correct. For example, in the Goal Inference task, consider an example where the give step is "practice swings", the expected positive candidate step is "Play Golf", and a candidate negative example is "Play Drums". "Play Drums" is sampled due to its high embedding similarity with "Play Golf" and is also a reasonable goal for "practice swings (of the drumsticks)". This is an ambiguous example and should be excluded from the test set. Therefore, we ask crowd workers to validate a subset of the examples.

We perform crowdsourcing on Amazon Mechanical Turk, requiring Master Qualification and a lifetime HIT approval rate over 90%.[3]

For each of Step Inference and Goal Inference, we randomly sample 4,800 examples as input, and for each example we ask 3 crowd workers to choose the most likely candidate. Every HIT includes 15 examples with a pay of $0.83, estimated to be completed in 5 minutes, equivalent to an hourly rate of $9.96.

For Step Ordering, we randomly sample 9,300 examples, and for each example we ask 3 crowd workers to order the events (with a "neutral" option). Every HIT includes 30 examples with a pay of $0.83, estimated to be completed in 5 minutes, equivalent to an hourly rate of $9.96.

In the test set, we only keep examples where all 3 workers agree with the gold label as our benchmark. We remove all examples from the automatically generated ones whose prompt or candidates appear in the test set, and use the remaining data as the training set.

	Step Infer.	Goal Infer.	Step Ordering
Train size	374,278	185,231	836,128
Test size	2,250	1,703	3,100
BERT	.874	.798	.819
XLNet	.867	.783	.826
RoBERTa	.882	.820	.835
GPT-2	.836	.686	.801
Human	.965	.980	.975

Table 1: The accuracy of state-of-the-art models on the test sets after being finetuned on our training sets.

4 In-Domain Evaluation

We finetune pretrained BERT (Devlin et al., 2019), XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019) and GPT-2 (Radford et al., 2019) models on the training set and report accuracy on the test set. Modeling details including hyperparameter settings are shown in Appendix A. To benchmark human performance, two authors each annotate 100 random examples from the test set and report the average accuracy. The results are shown in Table 1, indicating a performance gap of 10% to 20% between human and models trained on all available in-domain data.

4.1 Open-Ended Examples

In addition to quantitatively evaluating models on our multiple-choice tasks, we perform qualitative evaluation on some open-ended examples from wikiHow unseen during training, using RoBERTa.[4]

For Step Inference, we rank 100 steps with high embedding similarity for their likelihood of helping achieve a given goal. For example, for the goal "Eat in Islam", the top 3 ranked steps are "understand what type of meats are permissible" (correct), "start by adding mild spices to your food," and "gather supplies and ingredients." Similarly for Goal Inference, we rank 100 goals against some steps. For example, for the steps "spend the holiday with your beloved, eat KFC, check out the light displays," the top 3 ranked goals are "Celebrate a Japanese

---

[3] HIT designs and related details are in Appendix E, F.

[4] Modeling details and more examples are in Appendix G.

Christmas" (correct)[5], "Celebrate a Czech Christmas," and "Celebrate a British Christmas." These examples show that the model trained on our data can retrieve texts based on GOAL-STEP relations, beyond simply semantic relevance.

For Step Ordering, the model can perfectly order some articles with as much as 10 steps. For example, given the goal "Clean a Trumpet," the first 5 predicted, ordered steps are "gather your materials," "disassemble your trumpet," "fill up a bathtub," "place a towel down in the tub," and "set your trumpet parts down to soak." This shows that the model trained on our data can order certain long sequences of events based on STEP-STEP TEMPORAL relations.

5 Out-of-Domain Transfer Learning

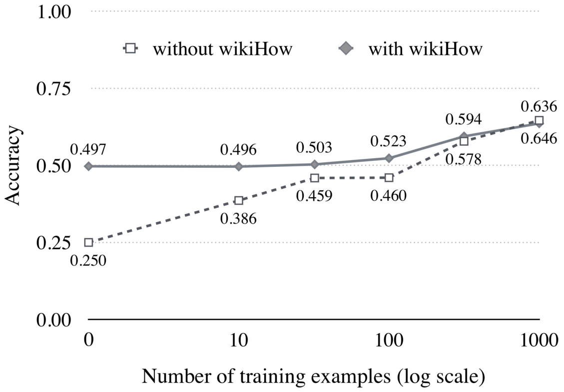
To show that our tasks can serve as an effective transfer learning resource especially in zero- or few-shot settings, we consider 3 tasks in different domains, using a subset of their training data to simulate a low-resource scenario. Therefore, we are not comparing to the state-of-the-art performances involving the entire in-domain training sets.

For each target task, we finetune a vanilla RoBERTa model and one pretrained on our task on increasingly larger portions of the target training set, and observe accuracy on the validation set, as the test set labels are not publicly available.

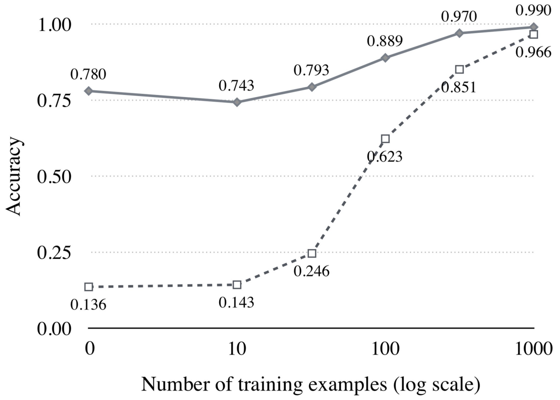
SWAG (Zellers et al., 2018) is a *commonsense inference* dataset in the video caption domain. Given a context, a system chooses one event most likely to happen from four candidates. For transfer learning, we use up to 1,000 examples for training and the standard validation set. We use the model trained on our Step Inference task to transfer to this task.

Snips (Coucke et al., 2018) is an *intent detection* dataset in the dialogue system and spoken query domain, where a system classifies an utterance into one of 7 intents. For transfer learning, we use up to 1,000 examples for training and the standard validation set. We use the model trained on our Goal Inference task to transfer to this task. To enable zero-shot transfer, we convert each example in our training data to a 7-choose-1 format by adding 3 empty strings as additional negative candidates.

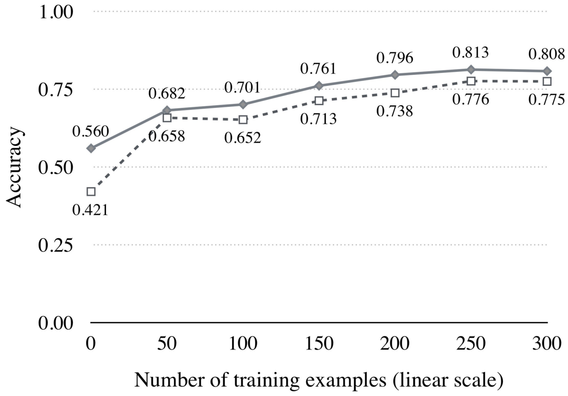
Story Cloze Test (Mostafazadeh et al., 2016) is a *story understanding* dataset in the fiction domain, where a system chooses an ending to a 4-sentence-story from 2 candidates. We use up to 314 examples for training and 1,571 examples for validation, from the 2016 and 2018 data releases after removing duplicates. We use the model trained on our Step Ordering task to transfer to this task. To mimic the "next sentence prediction" format, we convert each example in our task to a "next step prediction" question with 4 prompt steps and 2 candidate steps, exactly one of which happens after the prompt.



(a) SWAG



(b) Snips



(c) Story Cloze Test

Figure 2: Accuracy of RoBERTa on SWAG, Snips and Story Cloze Test with different training set sizes, with and without being previously fine-tuned on our tasks.

Figure 2 shows the learning curves of the downstream tasks with an increasing number of their training samples, demonstrating a clear advantage

---

[5] KFC and light displays are Japanese Christmas traditions (Kimura and Belk, 2005).

of using our training data in low-resource settings. For SWAG, the model trained on our data has a zero-shot performance 24% over chance, outperforming the vanilla model when up to 1,000 training examples are given. For Snips, the model trained on our data boasts an impressive 78% zero-shot performance, approaching perfect accuracy rapidly after some in-domain training. For the Story Cloze Test which has the largest domain-mismatch with our data, the model still benefits from the knowledge learned from it consistently, given any portion of in-domain training data up to the full size in our experiment. These results show that the model learns real-world procedural knowledge from our wikiHow-based tasks, which can be readily applied to various domains and writing styles.

6 Related Work

Script Learning A field of research related to our work is script learning, proposed by Feigenbaum et al. (1981). Scripts encode the knowledge of stereotypical event sequences, such as going to a restaurant or visiting a doctor. A branch of research has focused on distilling *narrative* scripts from newswire and literature (Chambers and Jurafsky, 2008; Jans et al., 2012; Pichotta and Mooney, 2014), while another, which is more similar to our work, focuses on *procedural* scripts that are core to task-oriented intelligent systems. A few large-scale crowdsourced corpora of the latter kind are OMICS (Gupta et al., 2004), SMILE (Regneri et al., 2010), the Li et al. (2012) corpus and DeScript (Wanzare et al., 2016). As wikiHow articles consist of chains of human activities, we believe wikiHow may be a useful resource for script learning as well. Specifically, while most previous research either mined noisy scripts from raw texts or crowdsourced them, wikiHow's particular text structure can provide a huge number of clean scripts for free. We will explore it in our future work.

WikiHow as a Resource WikiHow has been used in several past NLP efforts, including knowledge-base construction (Pareti et al., 2014; Chu et al., 2017), text generation (Nguyen et al., 2017), household activity prediction (Zhou et al., 2019), and summarization (Koupaee and Wang, 2018). HellaSwag (Zellers et al., 2019b), a recent commonsense reasoning dataset, presents a sentence completion task derived from wikiHow texts. However, it is likely that artifacts exist in the dataset, since BERT achieves 41% accuracy in the candidate-only setting and RoBERTa achieves 83% zero-shot performance.[6] Apart from HellaSwag, Park and Motahari Nezhad (2018) addressed classification tasks involving similar event relations to the ones we consider. Nevertheless, few existing research efforts attempted to prove the potential of wikiHow as a transfer resource on out-of-domain tasks. In comparison, our contributions are two-fold, in that we propose both a human-validated benchmark and an effective learning resource using wikiHow.

7 Summary

We propose 3 goal-step inference tasks using wikiHow to complement research of event relation reasoning. Our test sets serve as a reliable benchmark for commonsense inference, and more importantly, our dataset is an effective transfer learning resource, improving transformer models' performance on various tasks in zero- or few-shot settings. This implies a strong potential for pre-training models to better generalize in low-data scenarios.

A Modeling Details

All our models are implemented using the HuggingFace Transformer service[7].

We tune our model hyperparameters using cross-validation on our benchmarks. We do so on the validation sets of the out-of-domain datasets. As 4 different models each with different hyperparameters are involved, we do not list them here. Instead, the hyperparameter values and pretrained models are available in our Github repository. We save the model every 1,000 training steps, and choose the model with the highest validation performance to be evaluated on the test set.

We run our experiments on an NVIDIA GeForce RTX 2080 Ti GPU, with half-precision floating point format (FP16) with O1 optimization.

B Category Distribution of WikiHow Articles

WikiHow has articles from a broad range of domains, with 19 top-level categories: Arts and Entertainment, Cars & Other Vehicles, Computers and Electronics, Education and Communications, Family Life, Finance and Business, Food and Entertaining, Health, Hobbies and Crafts, Holidays and Traditions, Home and Garden, Personal Care and Style, Pets and Animals, Philosophy and Religion, Relationships, Sports and Fitness, Travel, Work World, and Youth. We plot the distribution of the top eight categories in Figure 3.

C Negative Sampling Strategies

In our preliminary experiments, we tried several negative sampling strategies before arriving at the one described in § 3.1 of the paper.

Random Strategy: Each negative example is a

---

[7] `https://github.com/huggingface/transformers`

randomly sampled step or goal from another article. With high probability, it is indeed incorrect with regard to the current prompt: the sampled step cannot be used to accomplish the current goal, or the sampled goal cannot be accomplished by the current steps. Empirically, data sampled with this approach makes the tasks too easy for both models and human accuracy, as the negative examples are too irrelevant. As an example for Step Inference, given the goal “Play Guitar” and the positive step “practice basic scales”, the negative candidates are “buy a used car”, “gather the ingredient“, and “wind down with meditation”.

Other Keyword-KNN Strategies: Instead of taking the embedding of the verbs in each goal or step phrase, we consider nouns, concrete part-of-speeches and all words. Empirically, data sampled with this approach includes many ambiguous questions, as many negative candidates have identical meaning to the positive candidate. As an example considering all words for Step Inference, given the goal “Play Guitar” and the positive step “practice basic scales”, the negative candidates are “play basic scales”, “learn the scales“, and “learn basic chords”.

Masked Language Model Strategy: We also experiment with using Masked Language Modeling (MLM), BERT’s pre-training task, to generate (instead of sampling) negative candidates from the positive one. Given the positive candidate, we iteratively mask out a random token and ask BERT to predict the most likely token different than the original one. For example, after several such iterations, a step like “read your local phone book” could become “find your local history book”, “read your favorite story book”, or “call my own phone number”, which would be the three negative candidates. The idea is to use BERT as an adversary for subsequent models, by generating negative candidates that have high MLM likelihood and therefore make the examples challenging. Empirically, however, it turns out that such an adversary is imperfect and can be easily conquered by models; moreover, the iterative prediction process is too time-consuming to scale.

D Quality Control Filters

As described in § 3.1 and § 3.2, we apply a collection of hand-crafted filters to the automatically generated examples to remove low-quality ones. The details of each filter are as follows:

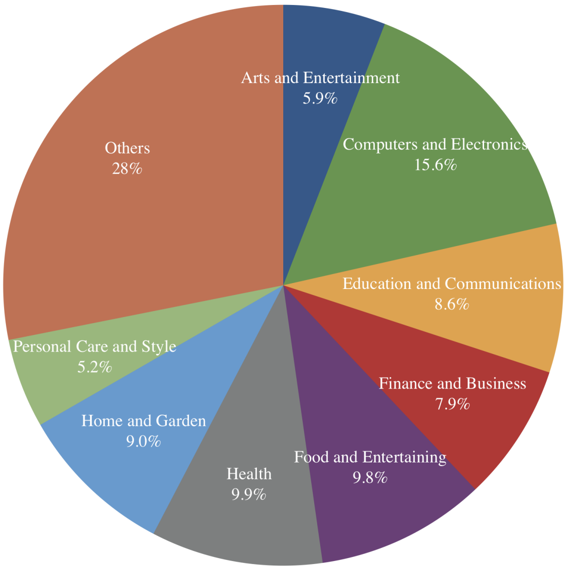

Figure 3: Category distribution of wikiHow articles.

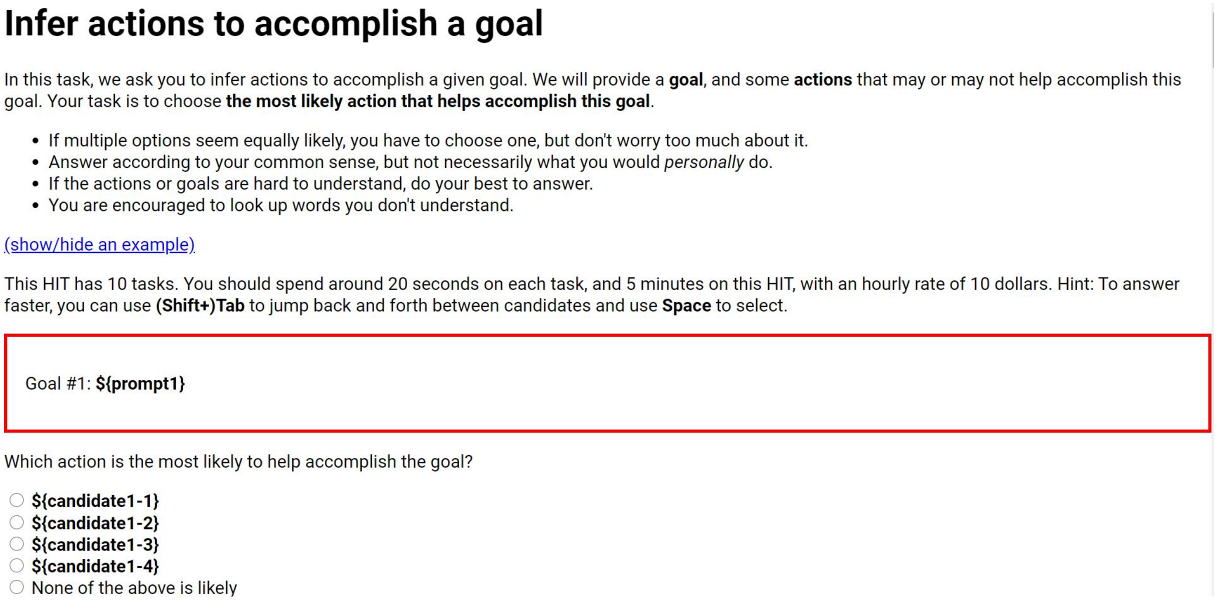
Category filter: We remove examples involving articles under certain wikiHow categories. The categories we leave out are either too obscure (e.g. Astrology Relationships) or require expert domain knowledge to reason about (e.g. Car Engine Repairs), with the hope that the remaining categories contain more what we would call “common sense” knowledge that an average human has.

Lexical-Overlap filter: We remove examples where there is a lexical overlap between the prompt and each candidate. We exclude stopwords and lemmatize each word using spaCy before computing the overlap.

TF-IDF filter: We remove examples with overly uninformative prompts or candidates. We exploit TF-IDF as a proxy for how indicative a certain step is of the article it comes from. The motivation is that in Step Inference, for example, given a prompt step, the task is to choose its corresponding goal; then a prompt step like “gather your materials” is almost not informative at all for humans/models to tell which goal it serves, as a large number of articles may include a step like this. Thus, we treat each wikiHow article as a document and calculate the TF-IDF of each token, and only retain steps that have at least one token whose TF-IDF value surpasses a certain threshold.

Length filter: We remove examples with overly short prompts or candidates. The motivation is similar to that of the TF-IDF filter, i.e. too short goals/steps may not be informative enough to make a clean example. For example, steps like “Fin-



Infer actions to accomplish a goal

In this task, we ask you to infer actions to accomplish a given goal. We will provide a **goal**, and some **actions** that may or may not help accomplish this goal. Your task is to choose **the most likely action that helps accomplish this goal**.

- If multiple options seem equally likely, you have to choose one, but don't worry too much about it.
- Answer according to your common sense, but not necessarily what you would *personally* do.
- If the actions or goals are hard to understand, do your best to answer.
- You are encouraged to look up words you don't understand.

(show/hide an example)

This HIT has 10 tasks. You should spend around 20 seconds on each task, and 5 minutes on this HIT, with an hourly rate of 10 dollars. Hint: To answer faster, you can use **(Shift+)Tab** to jump back and forth between candidates and use **Space** to select.

Goal #1: **${prompt1}**

Which action is the most likely to help accomplish the goal?

○ **${candidate1-1}**
○ **${candidate1-2}**
○ **${candidate1-3}**
○ **${candidate1-4}**
○ None of the above is likely

Figure 4: Screenshot of the HIT design for the Step Inference task.

ished!" or "Serve!" are hard to tell apart if one of them is the positive candidate while the other is negative. To reduce such kind of noise in the automatically generated examples, we filter out steps/goals that are shorter than a specific threshold.

Similarity filter: We use similarity-based filters to remove examples where some negative candidate is also likely to be a plausible answer. The similarity scores are calculated using cosine similarity between BERT embeddings described in § 3.1. In Step Inference, we set an upper threshold on the similarity between any negative step and any step from the prompt goal, with the motivation that negative steps should not serve the prompt goal. For Goal Inference, likewise, we ensure that the similarity between the prompt step and all steps from any negative goal is lower than a threshold, thus trying to minimize the cases where the prompt step also helps achieve negative goals.

E Crowdsourcing Details

Some noise exists in our automatically generated examples, because some of them do not have a single correct answer. This can happen when a sampled negative candidate is in fact correct. For example, in the Goal Inference task, consider an example where the give step is "practice swings", the expected positive candidate step is "Play Golf", and a candidate negative example is "Play Drums". "Play Drums" is sampled due to its high embedding similarity with "Play Golf" and is also a reasonable goal for "practice swings (of the drumsticks)". This is an ambiguous example and should be excluded from the test set, which is supposed to be a benchmark for models. Hence, we ask crowd workers to validate a subset of the examples. An example is shown in Figure 4.

We perform crowdsourcing on Amazon Mechanical Turk, requiring Master Qualification and a lifetime HIT approval rate over 90% for the crowd workers.

For each of Step Inference and Goal Inference, we randomly sample 4,800 examples as input, and for each example we ask 3 crowd workers from Amazon Mechanical Turk to choose the most likely candidate. Every HIT includes 15 examples with a pay of $0.83, estimated to be completed in 5 minutes, equivalent to an hourly rate of $9.96.

For Step Ordering, we randomly sample 9,300 examples, and for each example we ask 3 crowd workers to order the events. Every HIT includes 30 examples with a pay of $0.83, estimated to be completed in 5 minutes, equivalent to an hourly rate of $9.96.

In the test set, we retain only examples where all 3 crowd workers agree on the correct answer. See Table 2 for the distribution of annotators' agreement with the gold labels and the final yield rate (i.e. proportion of examples with all 3 workers answering correctly).

# Wokers selecting expected positive	Step Infer.	Goal Infer.	Step Ordering
0	307	534	1,014
1	556	813	1,854
2	1,031	1,122	2,732
3	2,250	1,703	3,100
Yield rate	.543	.408	.356

Table 2: The distribution of agreement with the gold labels and the yield rate for each task.

	Step Infer.	Goal Infer.	Step Ordering
Train size	404,057	239,239	841,317
Test size	1,031	1,122	2,732
BERT	.731	.563	.681
XLNet	.750	.623	.680
RoBERTa	.789	.623	.692
Crowd workers	.67	.67	.67

Table 3: The accuracy of state-of-the-art models on the sub-benchmarks, finetuned on the training sets.

F Harder and Noisier Benchmarks

As described in § 3.4, only examples where all 3 crowd workers choose the correct label are kept in the benchmarks to ensure high quality. We also release the *sub-benchmarks* including examples where 2 out of 3 workers choose the correct label. Naturally, these sets include both examples that require more attention to answer correctly and those that are inherently ambiguous, which we cannot distinguish at present. The performance of some state-of-the-art transformer models are shown in Table 3.

G More Open-Ended Examples

In addition to the examples in § 4.1, we provide more open-ended examples for each task here.

G.1 Step Inference

For these open ended examples, our Step Inference model is trained in a 100-choose-1 format with 99 negative samples, instead of 4-choose-1, given 3 steps instead of 1. During evaluation, we use the softmax value in the final layer as the probability for each candidate. We rank the probabilities and report the top 3. Here are some more examples:
Input goal: Choose a Role Model
Predicted steps: learn about their successes and failures (correct), show interest in their lives, ask about their life

Input goal: End a Letter of Apology
Predicted steps: use a signature that conveys your emotions (correct), try to personalize the letter as much as possible, focus on the facts of the situation

G.2 Goal Inference

For Goal Inference, we follow the same procedure as above. Here are some more examples:
Input steps: buy or rent a good hammer drill, drill a pilot hole, insert a high quality masonry drill bit
Predicted goals: Drill Into Concrete (correct), Drill Holes Through Glass, Dig a Hole

Input steps: cultivate a memorable persona, keep an equal balance between your vlogging and your work life. review your channel
Predicted goals: Become a YouTube Guru (correct), Become a Film Buff, Become a Videographer

G.3 Step Ordering

For Step Ordering, the model can perfectly order the steps in many wikiHow articles unseen during training. To perfectly order an article, the model needs to correctly order all possible pairs of steps in an article. Here are 2 example articles with 10 steps:
Change Your Name of a Minor in Colorado: (1) make sure the child is eligible for a name change, (2) choose the right court, (3) download and review your forms, (4) get a fingerprint-based criminal background check, (5) complete the necessary forms, (6) get consent from the non-custodial parent, (7) file your petition with the appropriate court, (8) serve the non-custodial parent, (9) publish the proposed name change, (10) attend the hearing on your petition.

Draw a Simple Teddy Bear: (1) draw a circle for the teddy bear's head and an oblong for its body, (2) add two curved lines on each side of the oblong for the bear's arms, (3) draw two small circles below the oblong for the bear's feet, (4) add the ears using two small circles on each side of the head, (5) draw details of the face, (6) add details on the bear's pads using three small circles and a bean shape below it, (7) draw a shirt for the bear, (8) make the bear look furry by using small strokes in drawing its body, (9) erase unnecessary lines, (10) color the drawing.

Structural Supervision Improves Few-Shot Learning and Syntactic Generalization in Neural Language Models

Abstract

Humans can learn structural properties about a word from minimal experience, and deploy their learned syntactic representations uniformly in different grammatical contexts. We assess the ability of modern neural language models to reproduce this behavior in English and evaluate the effect of structural supervision on learning outcomes. First, we assess few-shot learning capabilities by developing controlled experiments that probe models' syntactic nominal number and verbal argument structure generalizations for tokens seen as few as two times during training. Second, we assess invariance properties of learned representation: the ability of a model to transfer syntactic generalizations from a base context (*e.g.*, a simple declarative active-voice sentence) to a transformed context (*e.g.*, an interrogative sentence). We test four models trained on the same dataset: an *n*-gram baseline, an LSTM, and two LSTM-variants trained with explicit structural supervision (Dyer et al., 2016; Charniak et al., 2016). We find that in most cases, the neural models are able to induce the proper syntactic generalizations after minimal exposure, often from just two examples during training, and that the two structurally supervised models generalize more accurately than the LSTM model. All neural models are able to leverage information learned in base contexts to drive expectations in transformed contexts, indicating that they have learned some invariance properties of syntax.

1 Introduction

Recurrent Neural Network language models (Elman, 1990; Hochreiter and Schmidhuber, 1997) have been shown to learn many aspects of natural language syntax including a number of long-distance dependencies and representations of incremental syntactic state (Marvin and Linzen, 2018; Wilcox et al., 2018; Futrell et al., 2018). However, previous studies have not investigated the relationship between a token's frequency in the training corpus and syntactic properties models learn about it. In this work, we assess neural models' ability to make robust syntactic generalizations about a token's nominal number or verbal argument structure based on minimal exposure with the token during training. Because of the Zipfian distribution of words in a corpus, the vast majority of word types will be seen only a handful of times during training (Zipf, 1949). Therefore, the few-shot learning capabilities of neural LMs are critical to their robustness as an NLP system and as a cognitive model.

However, human learning goes beyond simply learning syntactic properties in particular constructions. People apply the same properties across different constructions, meaning that their representations of the syntactic features of a word are in some sense *invariant* to the grammatical context of that word. For example, speakers and listeners are sensitive to a verb's argument structure relationships and can easily recognize that a verb which cannot take a direct object in active, declarative sentences cannot be passivized (as in the ungrammatical sentence *"The ship was arrived."*) The relationship between an active sentence and a passive sentence has been termed a *transformation* in the linguistic literature (Chomsky, 1957). Many semantic-syntactic rules that govern word co-occurrence in one form, such as a verb's argument structure relationships, hold uniformly across transformations. It remains an open question whether models learn grammatical rules invariant to their surface realization, a property we call *syntactic invariance*.

We combine assessment of few-shot learning and syntactic invariance for two grammatical features of English: whether a noun is singular or

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4640–4652,
November 16–20, 2020.

plural (nominal number) and whether a verb is transitive or intransitive (verbal argument structure). We assess whether a model is able to make different predictions based on number or argument structure in a simple active voice *base context*. We then assess whether models are able to make similar distinctions in a *transformed context*—passive voice for verbs and polar questions for nouns. In the *transformed contexts*, we test models with tokens that occur only in the *base context* during training. (As a control, we also test verbal passive voice with tokens that occur in the passive voice in the training data to establish that models have learned the proper syntactic rules for this context.) For models to succeed in the transformed contexts they must represent syntactic features in a way that is invariant to the specific realization of those features in terms of word co-occurrences in different constructions. For each grammatical feature, we introduce a suite of novel targeted test sentences, similar to those presented in Marvin and Linzen (2018).

We find that all neural models tested are able to induce the proper syntactic generalizations in the *base* and *transformed* contexts after just two or three exposures, whereas a baseline *n*-gram model fails to learn the relevant generalizations. For all constructions tested our two neural models enhanced with explicit structural supervision outperform the purely sequence model. Assessing invariance properties, we find that neural models demonstrate proper behavior in transformed contexts, even for tokens seen only in base contexts during training. This behavior indicates that models are able to deploy generalizations learned in one syntactic context into different syntactic environments, a key component of human linguistic capabilities that has been so far untested in the neural setting.

1.1 Related Work

Bayesian models of word learning have shown successes in acquiring proper syntactic generalizations from minimal exposure (Tenenbaum and Xu, 2000; Wang et al., 2017), however it is not clear how well neural network models would exhibit these rapid generalizations. Comparing between neural network architectures, recent work has shown that models enhanced with explicit structural supervision during training produce more human-like syntactic generalizations (Kuncoro et al., 2017, 2018; Wilcox et al., 2019), but it remains untested whether such supervision helps learn properties of tokens that occur rarely during training.

Previous studies have found that Artificial Neural Networks (ANNs) are capable of learning some argument structure paradigms and make correct predictions across multiple frames (Kann et al., 2018), however these capabilities remain untested for incremental language models. Much has been written about the ability of ANNs to learn number agreement (Linzen et al., 2016; Gulordava et al., 2018; Giulianelli et al., 2018), including their ability to maintain the dependency across different types of intervening material (Marvin and Linzen, 2018) and with coordinated noun phrases (An et al., 2019). Hu et al. (2020) find that model architecture, rather than training data size, may contribute most to performance on number agreement and related tasks. Focusing on RNN models, Lakretz et al. (2019) find evidence that number agreement is tracked by specific "number" units that work in concert with units that carry more general syntactic information like tree depth. Jumelet et al. (2019) argue that when learning dependencies RNNs acquire a default form (which they postulate to be singular and masculine), and predicting a non-default form requires explicit contrary evidence. Our results support their hypothesis. Models are more accurate with singular nouns and transitive verbs seen only a few times in training, behavior that indicates these forms are expected when evidence is sparse.

2 General Methods

2.1 Psycholinguistic Assessment Paradigm

In order to assess the learning outcomes of neural LMs, we adopt the Psycholinguistic Assessment Paradigm (Linzen et al., 2016; Futrell et al., 2018). In this paradigm models are exposed to sentences that reveal the syntactic generalizations learned during training. For example, Linzen et al. (2016) used as input sentences with the prefix *The keys to the cabinet*... and inspected the relative probabilities of the continuations *is* and *are*. If the model has learned the grammatical rule that the head of a subject noun phrase governs plural agreement, then P(*are*) should be greater than P(*is*).

In order to assess the few-shot learning capabilities of the models tested, we sample words from eight "exposure buckets" based on the number of times the word appears in the training corpus, with the majority of buckets for words seen less than 10

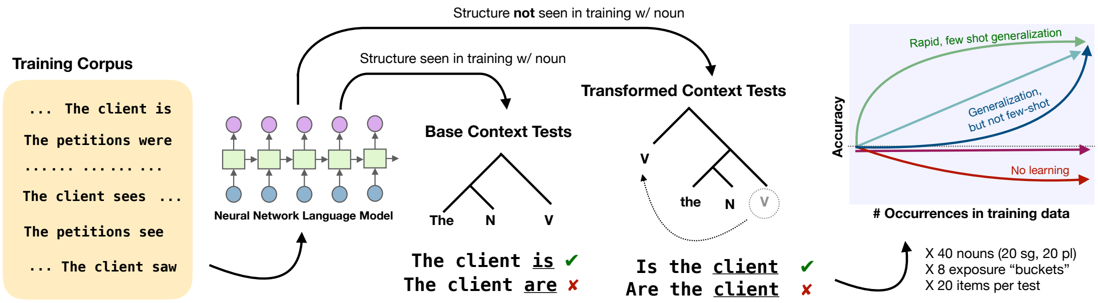

Figure 1: Experimental pipeline, given for Nominal Number tests without any modification.

times during training.[1] For each test, we sample 40 words balanced across syntactic categories. For each word, we generate 20 test sentences—each with a grammatical and ungrammatical condition—and measure the proportion of sentences in which the model shows higher probability in the grammatical condition in a particular critical region. In total, each test contains 12,800 sentences.

For each experiment, we report two metrics: First, we report the number of exposure buckets for which the models' accuracy is significantly above chance, which is 50% in all cases. Second, in order to assess the impact of structural supervision we report the results of a logistic regression model trained to predict accuracy with fixed effects of model class and exposure and random by-sentence intercepts.[2] A significant positive effect of model class means that the architecture contributes to more robust learning across all exposure buckets tested.

2.2 Models Tested

All models are trained on sections 2-21 of the Wall Street Journal portion of the Penn Treebank (PTB) (Marcus et al., 1993), which contains $\sim$1,000,000 tokens of newswire text. While this dataset is relatively small compared to the ones on which neural models were trained in Linzen et al. (2016) and Gulordava et al. (2018), it was imperative that we collect accurate metadata for all tokens in the training data and PTB is one of the largest datasets expertly hand annotated with both syntactic structure and part-of-speech information. Argument structure statistics were obtained from a Universal Dependency representation of the dataset, converted from its original phrase structure parse via the Stanford Parser (Schuster and Manning, 2016). Additional argument structure information was collected from the Celex2 dataset (Baayen et al., 1995).

***n*-Gram Baseline** We used a 5-gram baseline with modified Kneser-Ney smoothing trained using SRILM (Stolcke, 2002).

Recurrent Neural Network LMs model a sentence in a purely sequential basis, without explicitly representing the latent syntactic structure. We use the LSTM architecture (Hochreiter and Schmidhuber, 1997) and, following Futrell et al. (2018) derive the word surprisal from the LSTM language model by directly computing the negative log value of the predicted conditional probability from the softmax layer. This and subsequent neural models were trained with embedding size 256, dropout 0.3 following the hyper-parameters in Van Schijndel and Linzen (2018).

Recurrent Neural Network Grammars (RNNGs) (Dyer et al., 2016) jointly model a sentence as well as its syntactic parse. The model explicitly represents parse trees and composes partially built phrase structures, an approach that may result in better performance on tree-structurally local but linearly distal relationships (see (Dyer et al., 2016)). Models are supervised with Penn-Treebank style parses during training; we assess whether this explicit syntactic supervision translates into better few-shot learning and syntactic invariance outcomes. We use the same hyperparameters used by Dyer et al. (2016).

ActionLSTM Model: We ablate the composition function of an RNNG, producing a model that predicts the **action sequence** of a parse tree as well as the upcoming word. In this sense, it is an incrementalized version of the Parsing-as-Language-

---

[1] Our exposure buckets were: 2, 3, 4, 5, 6-10, 11-20, 21-30, 50-100, and we use the end of the range to label the buckets in figures. Thus, if a token is in exposure bucket "4" it occurred four times in the training corpus; if it is in exposure bucket "20," it occurred between 11 and 20 times in the training corpus.

[2] The R code used to run the model was `glm(accuracy` $\sim$ `model + exposure-bucket + (1|sentence-id))`

Modeling configuration presented in Charniak et al. (2016). We refer to this model as the "ActionLSTM" model in the following sections.[3]

3 Nominal Number

In English, the matrix verb of a tensed clause must agree in number with the head of the subject Noun Phrase. Neural LMs are capable of learning this relationship based on a pure language modeling objective in multiple languages and across a variety of intervening material (Gulordava et al., 2018; Marvin and Linzen, 2018). Previous work assessing neural learning of subject-verb number agreement has not directly compared the learning outcome to the amount of experience models receive during training.

3.1 Base Contexts: Active Voice

In order to assess the few-shot learning capabilities of neural models in base contexts, we randomly select 20 plural and 20 singular nouns in each exposure bucket and generated test items for each following (1). (In (1) and following examples, ungrammatical sentence variants are marked with a *, which is for presentational purposes only and not included in test items. Underlined portions of the sentences indicate critical regions, whose joint probability was used to calculate accuracy scores.) To test whether models' representations are impervious to modification, we also generate a set of test items with prepositional phrases (PPs) and object relative clauses (ORCs) modifying the head verb, following (2) and (3). In this and all following experiments, sentences are generated using templates and—other than the target token—contain tokens that occur at least 50 times in the training data. As described in 2.1, strength of nominal number feature learning was evaluated by calculating model accuracy, or the proportion of times the models preferred the grammatical variant.

(1) **Base No Modifier** (singular example)
  a. The president is...
  b. *The president are...

(2) **Base w/ PP Modifier** (plural example)
  a. *The petitions near the old investment is...
  b. The petitions near the old investment are...

(3) **Base w/ ORC Modifier** (singular example)
  a. The client that the lawyers like is...
  b. *The client that the lawyers like are...

The results for this experiment can be seen in Figure 2, in the left panels. This is the same presentational paradigm we will use for all results in this paper: the y-axis is the model's accuracy, pooled across performance on singular and plural nouns, and the x-axis is the model's exposure for each token—the number of times it occurs during training. The scale of the x-axis is log-transformed. Points represent mean accuracy for each exposure bucket and error bars are 95% binomial confidence intervals. Lines show logistic regression fits from the raw data, with standard errors.

In the *Base Simple* experiment, the n-gram shows moderate few-shot learning, above chance in 5/8 exposure buckets. All neural models show robust few-shot learning and are above chance in all exposure buckets. We find a significant effect of structural supervision, with both the ActionLSTM and RNNG outperforming the LSTM model ($p < 0.05$ and $p < 0.001$ respectively). The experiments with modifiers prove more difficult: In the *Base PP* experiment, we find no few-shot generalization for the n-gram model, weak few-shot generalization for the LSTM (1/8 buckets), moderate generalization for the RNNG (4/8 buckets) and strong generalization for the ActionLSTM (7/8 buckets). In the *Base RC* experiments we find a similar pattern: No generalization for the n-gram (0/8 buckets), weak generalization for the LSTM (2/8 buckets), but stronger generalization for the two structurally supervised models (6/8 and 7/8 buckets for the RNNG and ActionLSTM respectively). For these two experiments, we find an effect of structural supervision on accuracy, with both the ActionLSTM and RNNG out-performing the LSTM ($p < 0.001$ except for the RNNG RC-Modifier where $p < 0.05$). Our results are generally in line with those presented in Marvin and Linzen (2018), who find performance in the 50-60% accuracy range for number agreement across PP and RC modifiers. Some studies, such as Lakretz et al. (2019) find higher performance performance on a similar task; we attribute these differences to the relative size of the training data.

Overall, these results indicate that all models are capable of making grammatical generalizations based on minimal exposure with a token, and capa-

---

[3] As RNNG and ActionLSTM jointly model terminal words and syntactic parses, we use word-synchronous beam search (Stern et al., 2017) to compute surprisal values incrementally. ActionLSTM was able to achieve a parsing F1 score of 92.81 on the PTB, which is in the same range as the original architecture on the same test set, as reported in Kuncoro et al. (2017).

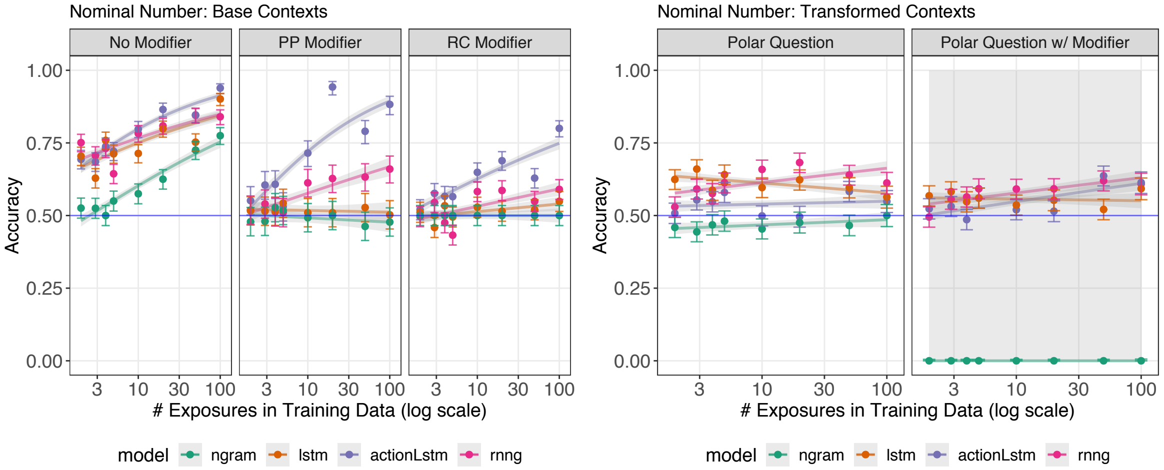

Figure 2: Results from the novel word learning experiments for Base Contexts (left) and Transformed Contexts (right). Results are averaged across singular and plural nouns. Points represent by-exposure bucket means, with 95% binomial confidence intervals. Smooth lines are results of logistic regression model fits on the raw data.

ble of leveraging increased exposure to make more accurate number agreement predictions. (For statistical analysis of the effects of exposure on accuracy across all of our experiments, see Appendix A.) Although the graphs in Figure 2 are pooled across noun category, models demonstrate much higher accuracy for *singular* nouns, especially if they occur only a few times in training. Improvement from increased exposure comes as models get better at accurately predicting number agreement for plural nouns. These findings are in line with the singular bias reported in Marvin and Linzen (2018) and support the hypothesis from Jumelet et al. (2019) that models have learned a "default" prediction, in this case *singular*. For results and analysis from all of our experiments broken down by grammatical category, see Appendix B.

3.2 Transformed Contexts & Syntactic Invariance

Because subjects precede verbs in English, most evidence available to a neural model for a noun's number follows the noun linearly. However, in English *polar question* formation, the matrix verb is moved to the front of the sentence inverting the base noun-verb order, as in (4). If models have learned nominal number feature that is invariant to linear order, verbs that set off polar questions should set up expectations for nominal subjects that match in number. In order to assess whether models were robust to such transformations, we created test items following the template in (4) and (5), which includes an additional four word modification. Half of the sentences were in present tense, half in past tense. We measure the model's accuracy at the noun directly and pool accuracy scores across singular and plural nouns.

(4) **Polar Question** (singular example)
  a. Is the president...
  b. *Are the president...

(5) **Polar Question w/ Modifier** (plural example)
  a. *Is the very big and important hearings...
  b. Are the very big and important hearings...

Although polar questions are relatively rare in the WSJ section of the Penn Treebank—the ratio of active to inverted polar sentences is ∼1000:1—some nouns do occur in both base for and inverted form. Because our aim here is to assess models' generalization to novel syntactic frames, we filtered every noun from our previous set that occurred in both frames, a total of 15 nouns. The results presented here therefore address whether the models have learned a representation of number that is invariant to linear order. Successful learning, in this case, means that models have learned that nouns which set up expectations for singular verbal inflections should also be more likely in contexts where singular nouns are expected, and likewise for plurals.

The results for this experiment can be seen in Figure 2 in the right-hand panel. In the *Transformed Simple* experiment we find no generalization for the *n*-gram model, which was not above chance in any exposure bucket, moderate generalization for the ActionLSTM (above chance in 5/8 buckets) and strong generalization for the LSTM and RNNG model (8/8 buckets and 7/8 buckets respectively). Results are similar for the *Transformed Modifier* experiment. In this case the *n*-gram model is at 0% accuracy for all buckets; this is because it assigns equal probability to the critical region in each condition, which we count as a "failure." The ActionLSTM displays moderate generalization (4/8 buckets) and the RNNG and LSTM stronger generalization (7/8 and 8/8 buckets respectively). In these experiments, the ActionLSTM under-performs compared to the LSTM in the *No Modifier* experiment ($p < 0.001$), but the RNNG outperforms it in the *Transformed Modifier* experiment ($p < 0.05$). These results indicate that all the neural models are able to leverage information gained in the base contexts to drive expectations in the inverted context, however note that the accuracy scores are lower here than in the base contexts, with no model breaking the 70% accuracy threshold. This may be due to the relatively few number of polar questions in the corpus.

4 Verbal Argument Structure

In this section, we assess the ability of neural models to represent verbal argument structure, which we simplify to whether a verb is transitive or intransitive. If it is transitive, then it requires a theme, which must be realized as a direct object in the active voice. If it is intransitive then it requires an empty theme position and cannot have an object in the active voice. Verbal argument structure is a hard task, insofar as both intransitivity and transitivity can only be inferred through *indirect negative evidence*. We assess neural models' sensitivity for indirect negative evidence by investigating how much experience models need with a particular verb before they make robust predictions about whether an object should follow that token at test time.

4.1 Base Contexts: Active Voice

In order to assess the generalizations models have learned about verbal argument structure, we selected 20 transitive verbs and 20 intransitive verbs. Verb transitivity was assessed using the hand-coded Celex2 Corpus, and double-checked using a Universal Dependencies representation of the original PTB Phrase Structure trees; verbs marked "transitive" in Celex were dropped if they occurred without arguments in 3rd person past tense active voice less than 90% of the time and verbs marked "intransitive" in Celex were dropped if they took arguments in 3rd person past tense more than 10% of the time.

We generated sentences for each verb in an *infinitival* construction, following (6) (which gives a transitive example) and in *past tense* following (7) (which gives an intransitive example). Infinitival tense sentences were generated because most verbs are ambiguous between their past tense and past participle forms, which can occur without a direct object, even for transitive verbs (e.g. *The patient was cured*). Model accuracy was assessed by comparing the surprisal of the `adverb + period` region at the end of each sentence (e.g. "today ." in the examples below) and accuracy scores are pooled across verb type. For transitive verbs, this region should be more surprising if an object is absent; for intransitive verbs this region should be more surprising if it is present.

(6) **Active, Infinitival Tense** (transitive example)
  a. The doctor can cure the patient today.
  b. *The doctor can cure today.

(7) **Active, Past Tense** (intransitive example)
  a. *The doctor slept the patient today.
  b. The doctor slept today.

The results for this experiment can be seen in Figure 3 on the left, with the *infinitival* experiment on the far left and the *past tense* experiment in the middle. For the *Active Infinitival* results we find no generalization for the *n*-gram model, but strong generalization for the three neural models: The LSTM is significantly above chance in 6/8 exposure buckets, the ActionLSTM in 8/8 and the RNNG in 7/8. For the *Active Past* experiment we find no few-shot learning for the *n*-gram model (it is above chance in 0/8 buckets), moderate few-shot learning for the LSTM model (5/8 buckets) but strong few-shot learning for the two supervised models (8/8 buckets for both). We find a significant effect of structural supervision, whereby the ActionLSTM and RNNG outperform the LSTM in both experiments ($p < 0.001$). These results indicate that not only that all neural models have learned the basic facts of argument structure, but that they are willing to generalize about the likelihood of an upcoming object after just two exposures during training.

Interestingly, the LSTM model shows a decrease in accuracy in our Past Tense test as words grow more frequent in the training data. We hypothesized that this is because high-frequency tokens ending in "-ed" are more likely to be used in pas-

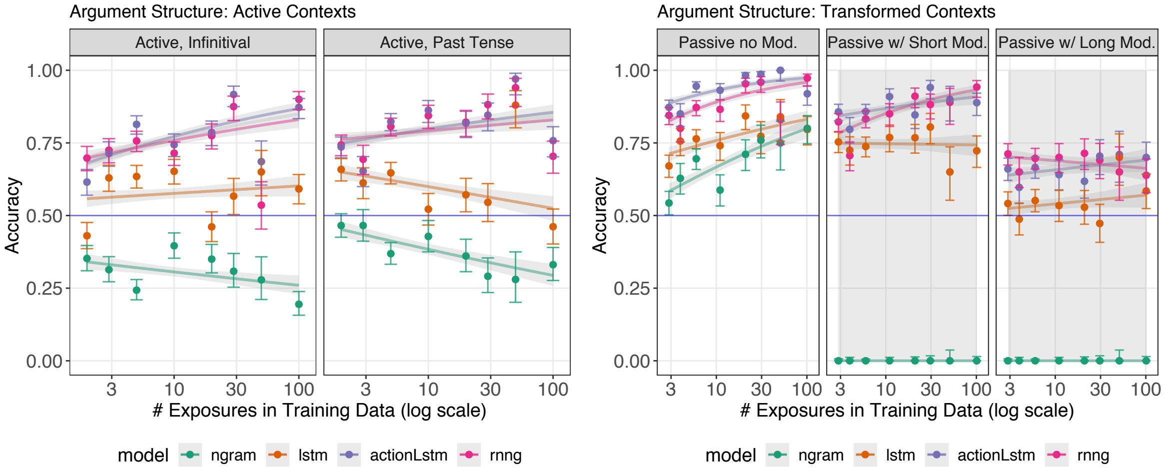

Figure 3: Results from the few shot learning experiments for active contexts (left) and transformed, passive, contexts (right). Points represent mean accuracy for each exposure and error bars are 95% binomial confidence intervals. Lines show logistic regression fits from the raw data, with standard errors.

sive voice, where they occur without a direct object. Models that lack POS disambiguation, would erroneously come to expect these tokens to occur without an object, even when they are being used in active voice, which explains why we do not see the trend for infinitival tests, nor for the supervised models which predict POS tags. We confirmed our hypothesis with two follow-up statistical tests: We found a positive correlation between a token's frequency and the percentage of time it is used in passive voice in the training data ($cor = 0.39; p < 0.001$). And we ran a statistical model looking at the effect of passive usage on accuracy, finding a positive effect for the two supervised models and a negative effect for the LSTM ($p < 0.001$ in all cases).[4]

4.2 Transformed Context: Passive Voice

When verbs are realized in different syntactic frames, or *syntactic transformations*, their argument structure properties are preserved. For example, because passive voice promotes the semantic *theme*—which plays the syntactic role of object in active voice—to the subject position, it is impossible for a truly intransitive verb to be realized in passive voice, as in the ungrammatical (8-c).

In order to assess whether models have learned the rules governing the passive transformation, we designed tests with the same verbs as in Section 4.1). Verbs were dropped if they had different forms for 3rd person past-tense and passive participle, such as the verb *give* (*gave*, *given*). We generated items following three tests sketched in (8), (9) and (10). Model accuracy was assessed by comparing the surprisal of the `verb + adverb + period` following a prefix that contains a passive "was" versus a prefix that does not, and accuracy scores are pooled across transitive and intransitive verbs. If models are learning the proper grammatical generalizations, then intransitive verbs should be unexpected in passive voice, and the verb should be more surprising when it follows the passivizing "was". Conversely, transitive verbs should be more likely in passive voice than in active voice without a direct object, which is ruled out by the `adverb + period` portion of our continuation, and therefore should be more likely when the passivizing "was" is absent. Because we use verbs that do appear in passive voice during training this section does not test models' invariance properties, but rather their few-shot learning capabilities for this grammatical context. After these control experiments, we turn to invariance tests in Section 4.3.

(8) **Passive Voice: No Modifier**
Example with Transitive verb
a. The doctor was cured yesterday .
b. *The doctor cured yesterday .
Example with Intransitive Verb
c. *The doctor was arrived yesterday .
d. The doctor arrived yesterday.

(9) **Passive Voice: Short Modifier**
a. The dog was quickly and fully cured today.
b. *The dog quickly and fully cured today.

---

[4] The statistical model used was `glm(accuracy ∼ percent_VBN + (1|sentence_id)`, where the predictor `percent_VBN` indicates the proportion of total occurrences the token is tagged as a passive participle.

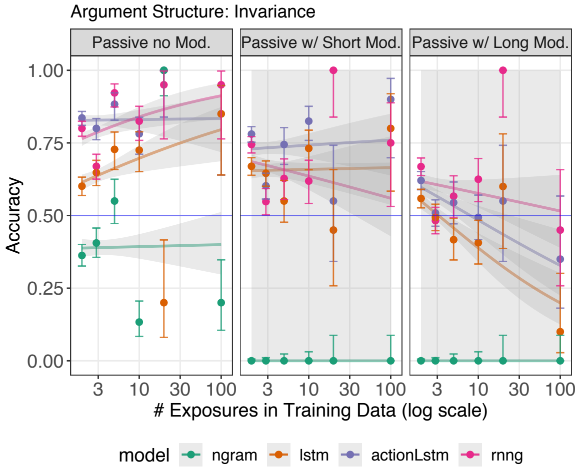

Figure 4: Invariance to transformation for argument structure. Error bars are 95% confidence intervals.

(10)**Passive Voice: Long Modifier**

a. The dog was quickly, suddenly, and entirely cured yesterday.

b. *The dog quickly, suddenly, and entirely cured yesterday.

The results for this experiment can be seen in Figure 3, in the right panel. For the *Passive No-Modifier* test, all models are significantly above chance for all exposure buckets tested. For the *Short Modifier* test, we find no few-shot learning for the *n*-gram model (above chance in 0/8 buckets), but strong few-shot learning for all neural models tested (8/8 buckets). For the *Long Modifier* experiment the *n*-gram shows no few-shot learning (0/8 buckets) and the LSTM shows moderate few-shot generalization (4/8 buckets), but the RNNG and ActionLSTM are still robust (8/8 buckets for both). Across all three experiments, we find that the structurally supervised neural models perform better than the LSTM ($p < 0.001$).

For these experiments, models were more accurate with transitive verbs, especially for ones that occur infrequently during training. This transitive bias was also present in the *base context* tests for the ActionLSTM and RNNG, indicating that transitvity may be the default assumption, and models expect verbs to be able to occur in passive frames unless they have a large amount of indirect negative evidence to the contrary.

4.3 Syntactic Invariance

In this section, we run the same *passive* experiments described in Section 4.2, however we use verbs that occur only in the *active* voice during training. In order for models to achieve higher than 50% accuracy, they must learn the co-variation between direct objects in the active voice and passive nominal subjects in the passive voice, even for verbs which they have only seen in the active voice. That is, they must learn a grammatical rule that is invariant to syntactic transformation and verb type.

We sampled all the verbs that occurred with the `VBD` but not the `VBN` (past participle) part-of-speech in our training data and generated 20 sentences for each verb. This came to 56 verbs in total, with no transitive verbs in the 50 or 100 exposure buckets. The results from this experiment can be seen in Figure 4. For the *No-Modifier* experiment, the *n*-gram model shows little few-shot learning, above chance in only 1/8 exposure buckets. However, the neural models show moderate few-shot learning, with accuracy scores above chance in 5/8 buckets (LSTM), 6/8 (ActionLSTM) and 6/8 (RNNG). For the *Short Modifier* experiment we find no few-shot learning for the *n*-gram models, but moderate few-shot learning for all neural models tested (LSTM: 4/8 bucekts; ActionLSTM: 5/8 and RNNG: 6/8). Models fare worse in the *Long Modifier* experiment with week few-shot learning for the LSTM and ActionLSTM (1/8 buckets each) and moderate few-shot learning for RNNG model (4/8 buckets each). The *n*-gram is below chance in all buckets. Turning to the effects of structural supervision: We find that the RNNG and the ActionLSTM generally outperform the LSTM ($p < 0.001$ for all three, except RNNG/*Short Modifier* which is not significant). Because there were so few verbs in our training data that occurred only in active verbal frames, error estimates are larger for this experiment and the results are somewhat less consistent. Despite this, it is clear that in the *No Modifier* and *Short Modifier* tests, all the neural models show moderate accuracy outcomes, indicating that their learned representations are at least somewhat invariant to syntactic information.

5 Discussion

In this paper, we have tested the few-shot learning capabilities of neural language models, as well as whether these models can learn grammatical representations that are invariant to syntactic transformation. First, we addressed neural models' ability to learn **nominal number**, introducing a novel testing paradigm that leveraged *polar questions* to assess subject/verb number agreement learning in syntactically transformed settings. Second, we

Table 1: Left columns: Few shot learning outcomes with the results from our tests of syntactic invariance in the bottom quadrant. Colors correspond to the proportion of exposure buckets for which each model achieved accuracy scores significantly above chance, colored by tertiles. Right columns indicate whether the two structurally supervised models outperform the LSTM for each test, where *s indicate the significance level from our statistical tests and !s indicate significantly worse performance than the LSTM.

turned to neural models' ability to represent verbal **argument structure**, developing two novel suites of tests that assessed preference for *themes*—either realized as direct objects or passive subjects—in both active contexts and passive contexts. In each experiment we assessed the effect of syntactic supervision on learning outcomes by comparing two supervised models to one purely sequence model.

A summary of our results can be seen in Table 1, with few-shot learning outcomes in colored cells on the left, and the effect of structural supervision on the right. The results from experiments that assess syntactic invariance are on the bottom, below the line break. This table makes it clear that all neural models are capable of making syntactic generalizations about a token from minimal exposure during training. Although model accuracy is reduced for tests that assess syntactic invariance, all neural models show at least a moderate ability to generalize across syntactic transformations. Furthermore, Table 1 shows that syntactic invariance is enhanced in structurally supervised models. Interestingly, both ActionLSTM and RNNG have access to syntactic information, but the comparison in Table 1 indicates that RNNG can leverage that information more effectively to produce syntactic invariance. Therefore we suggest that RNNG's improved performance does not come from the mere *presence* of syntactic information in the training and test data, but rather from the fact that it uses syntactic information to structure its computation in a non-sequential way.

Because these experiments require careful and robust syntactic analysis of the training data, we evaluated models trained on a relatively small, human-annotated corpus. While the small training data poses some limitations when interpreting the results, it makes them more relevant to low-resource NLP applications and suggests that using structurally supervised models can lead to better generalization in a sparse data environment. While sub-word tokenization schemes such as Byte-Pair Encoding (Sennrich et al., 2015) have helped reduce the number of individual lexical items that need to learned, they do not completely eliminate the long tail of sub-word units. Thus, robust few-shot generalization is still an important problem in these environments. It may be that larger amounts of training data support even better few-shot learning and syntactic invariance outcomes. Scaling these carefully-controlled methods to the larger data setting will be an important next step. However, even with the relatively small models tested here, the results support a growing body of evidence that incremental statistical models of language are able to induce many key features of human linguistic competence.

A Effect of Exposure on Model Accuracy

In this section we report the result for statistical tests assessing the effect of a token's frequency in training on model accuracy for that token. We derive significance from a general linear model with # of exposures as a sole predictor, with random by-item intercepts (`glm(accuracy ∼ #_occurrences + (1|item_number))`)

Nominal Number For the base context, in the no modifier condition we find a positive effect of increased exposure for all models ($p < 0.001$). For the *PP modifier* test we find an effect of exposure for the ActionLSTM and the RNNG ($p < 0.001$), and a negative, but insignificant effect for the n-gram and the LSTM. For the *RC Modifier* experiment we find an effect of increased exposure for all three neural models ($p < 0.001$ for the RNNG and ActionLSTM; $p < 0.05$ for the LSTM), but no effect for the n-gram. For the inverted contexts: in the *no modifier* tests we find no effect of increased exposure, except for the LSTM, where the effect is negative ($p < 0.01$). For the *modifier* tests, we find a significant effect for the ActionLSTM and the RNNG ($p < 0.001$).

Argument Structure For the base context (active voice): In the infinitival tests, we find a significant effect of exposure on accuracy for the ActionLSTM and the RNNG ($p < 0.001$) and a negative effect for the n-gram model ($p < 0.001$). In the past-tense, we find no significant effect for the RNNG or the ActionLSTM, and a negative effect for the n-gram and LSTM models ($p < 0.001$). In the transformed contexts (passive voice), for the *no-modifier* tests we find a significant effect of exposure for all models ($p < 0.001$ for all except ActionLSTM where $p < 0.05$). For the *short-modifier* tests we find an effect for the ActionLSTM ($p < 0.05$) and the RNNG ($p < 0.001$). And in the *long-modifier* test we find a marginally significant effect for the three neural models ($p \sim 0.05$ for all).

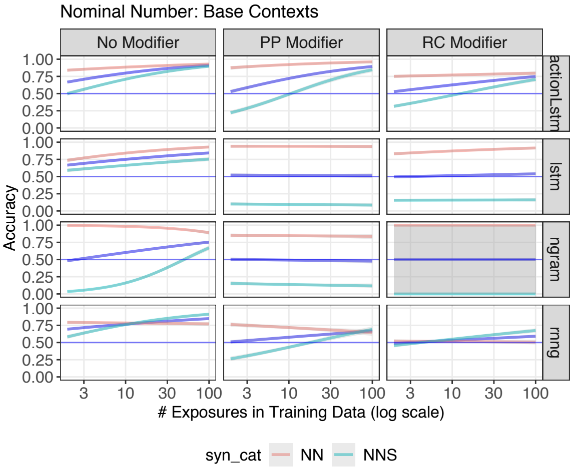

Figure 5: Number: Base Contexts

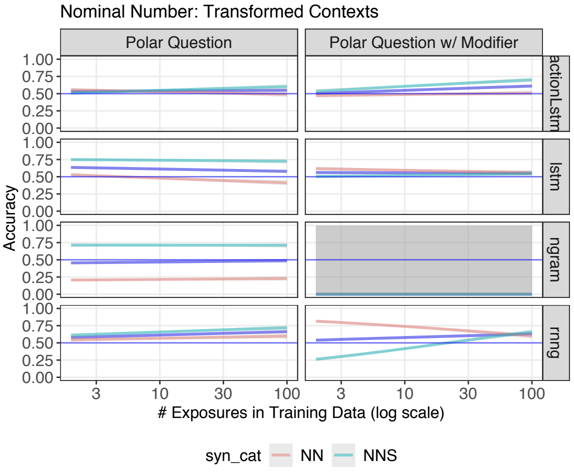

Figure 6: Number: Transformed Contexts

B Learning Outcomes by Grammatical Condition

In this section, for each test reported in the paper, we break down model performance by grammatical category, either singular vs plural nouns (for nominal number tests) or transitive vs. intransitive verbs (for our argument structure tests). Charts follow the same presentational paradigm: y-axis shows accuracy and x-axis the number of times each word appears during training, on a log-10 scale. Smooth lines are results of logistic regression model fits on the raw data, with shaded regions indicating standard error. Dark blue lines show model performance averaged between the two conditions (these are the same fits that appear in charts in the main body of the paper).

The data presented here are consistent with the hypothesis from (Jumelet et al., 2019). When models receive scant evidence of a token's syntactic properties in training, they assume that it belongs to a "base" category, which is *singular* for nouns and *transitive* for verbs. Thus, models are more accurate for singular nouns and transitive verbs seen rarely in training. As the model receives more evidence that a token is not in the base category, its predictions flip. Hence, gains in overall-accuracy tend to come from models learning the proper agreement for non-base tokens (plural nouns and intransitive verbs). Generally, these effects are stronger for nominal number learning, and stronger for structurally supervised models than for the LSTM, which is consistent with the findings presented in the main body of the text.

B.1 Number: Base Contexts

The nominal number breakdown for base contexts can be seen in Figure 5, with accuracy scores for singular nouns (`NN`) in red and plural nouns `NNS`) in teal. Over all, models tended to show higher accuracy scores for singular nouns, which indicates the presence of a singular bias. Interestingly, the ActionLSTM and the RNNG are capable of overcoming the singular bias when presented with sufficient data, however the LSTM remains equally biased for tokens seen 2 and 100 times in training.

B.2 Number: Transformed Contexts

The nominal number breakdown for transformed can be seen in Figure 6. The empirical picture is more complicated here, however if anything models show higher performance for plural nouns. This behavior suggests that *is* sets up weaker expectations for singular nouns than *are* does for plural nouns. Such a pattern is consistent with the hypothesis that models learn the singular as a base form, in which case it would set up weaker expectations for singular nouns. These results compliment those from An et al. (2019) (section 6), who also test in inverted settings and find that models tend not to be surprised at coordinated NPs following a singular

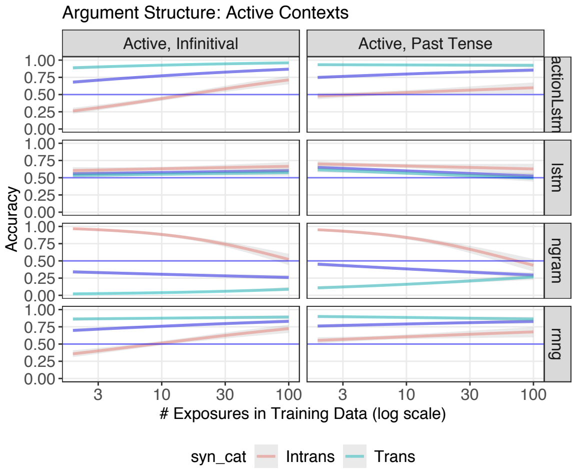

Figure 7: Number: Arg Struct: Base Contexts

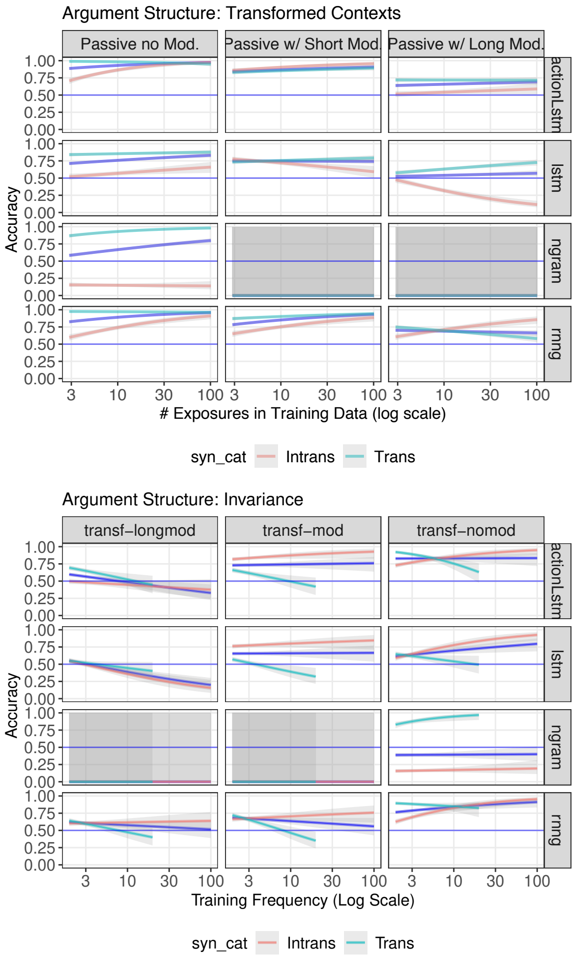

Figure 8: Argument Structure: Transformed Contexts (top) and Invariance (bottom)

verb, as in the ungrammatical sentence **What is the pig and the cat eating?*

B.3 Argument Structure: Base Contexts

The breakdown for argument structure learning base contexts can be seen in Figure 7, with accuracy scores for *intransitive* verbs in red and *transitive* verbs in teal. Here, we see a strong transitive bias for the two structurally supervised models, with no obvious bias for the LSTM and an intransitive bias for the *n*-gram.

B.4 Argument Structure: Transformed Contexts and Invariance

The breakdown for argument structure learning in the transformed contexts can be seen in Figure 8 with transformation tests on the top and invariance tests on the bottom. In this case, where performance is different between the two conditions models display higher accuracy scores for transitive verbs.

Investigating representations of verb bias in neural language models

Abstract

Languages typically provide more than one grammatical construction to express certain types of messages. A speaker's choice of construction is known to depend on multiple factors, including the choice of main verb – a phenomenon known as *verb bias*. Here we introduce DAIS, a large benchmark dataset containing 50K human judgments for 5K distinct sentence pairs in the English dative alternation. This dataset includes 200 unique verbs and systematically varies the definiteness and length of arguments. We use this dataset, as well as an existing corpus of naturally occurring data, to evaluate how well recent neural language models capture human preferences. Results show that larger models perform better than smaller models, and transformer architectures (e.g. GPT-2) tend to out-perform recurrent architectures (e.g. LSTMs) even under comparable parameter and training settings. Additional analyses of internal feature representations suggest that transformers may better integrate specific lexical information with grammatical constructions.

1 Introduction

When we use language, we are often faced with a choice between several possible ways of expressing the same message. For example, in English, to express an event of intended or actual transfer between two animate entities, one option is the *double-object* (DO) construction, in which two noun phrases follow the verb. Alternatively, the same content can be expressed using the *prepositional dative* (PO) construction.

(1) a. Ava gave him something. *DO*
b. Ava gave something to him. *PO*

Speakers' preferences for one or the other construction depend on multiple factors, including the length and definiteness of the arguments (Oehrle, 1976; Arnold et al., 2000; Wasow, 2002; Bresnan, 2007). One particularly subtle factor is the lexical *verb bias*. While some verbs readily occur in either construction, others have strong preferences for one over the other (Levin, 1993):

(2) a. ?Ava said him something. *DO*
b. Ava said something to him. *PO*

Decades of work in linguistics and psychology has investigated how humans learn these distinctions (Gropen et al., 1989; Perfors et al., 2010; Barak et al., 2014; Goldberg, 2019). Yet, as deep neural networks have achieved state-of-the-art performance across many tasks in natural language processing, little is known about the extent to which they have acquired similarly fine-grained preferences. Although neural language models robustly capture certain types of grammatical constraints, e.g., subject-verb agreement and long distance dependencies (Linzen and Baroni, 2021; Manning et al., 2020), they continue to struggle with other aspects of syntax, including argument structure (e.g. Warstadt et al., 2019). Verb biases provide a particularly interesting testbed. Successfully predicting these psycholinguistic phenomena requires the integration of specific lexical information with representations of higher-level grammatical structures, with implications for understanding differential performance between models on other tasks.

In the current work, we take an analytic and comparative approach. First, we introduce the *DAIS* (*D*ative *A*lternation and *I*nformation *S*tructure) dataset, containing 50K human preference judgments for 5K sentence pairs, using 200 unique verbs. These empirical judgments indicate that verb bias preferences are highly gradient in practice (Ryskin et al., 2017; Ambridge et al., 2018), rather than belonging to binary "alternating" and "non-alternating" classes, as commonly assumed. Second, we evaluate the predictions of a variety of neural models, including both recurrent architectures and transformers, and analyze their internal

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4653–4663,
November 16–20, 2020.

states to understand what drives differences in performance. Finally, we evaluate our models on natural production data from the Switchboard corpus, finding that transformers achieve similar classification accuracy as prior work using hand-annotated features ($\sim 93\%$; Bresnan et al., 2007).

2 Related Work

Several recent studies have investigated how neural language models represent the dative alternation. Kann et al. (2018) constructed a corpus of verbs in common alternations, including the dative, and showed that a degree of information about acceptability is decodable directly from embeddings of the verb. However, acceptability was not based on empirical data and verb bias was treated as a binary variable, preventing an analysis of gradient effects. Kelly et al. (2020) found that DO constructions are separable from non-DO constructions in high-dimensional sentence embeddings (including BERT), but did not investigate verb bias. Futrell and Levy (2019) confirmed that recurrent neural networks (RNNs) show human-like sensitivity to several other important aspects of gradience in dative alternations, including the length and definiteness of arguments. However, they included only 16 verbs, all considered "alternating." Additionally, in these studies, a limited range of neural models were considered, leaving it unclear exactly how predictions may depend on architectural choices, model size, and training regime.

3 The DAIS dataset

The DAIS dataset contains 50,136 human preference judgments for 5,000 sentence pairs, constructed as follows. First, to obtain a large and heterogeneous set of verbs, we collected the 100 most frequent verbs influentially classified by Levin (1993) as alternating (i.e. acceptably appearing in both PO and DO constructions), as well as the 100 most frequent verbs classified as "non-alternating" (appearing only in the PO construction). This set contains most of the verbs examined in prior corpus-based analyses (see Sec. 5). For each verb, we generated DO and PO sentences across 5 different conditions, manipulating the length and definiteness of the recipient argument (see ex. 3).

(3) a. Ava gave *him* a book.
b. Ava gave *the man* a book.
c. Ava gave *a man* a book.
d. Ava gave *the man from work* a book.
e. Ava gave *a man from work* a book.

Finally, to obtain a range of distinct items in each condition, we created 5 plausible theme arguments for each verb, including 2 definite and 3 indefinite, for a total of 5,000 alternation pairs.

We collected judgments from 1011 participants on Amazon Mechanical Turk. Each participant was shown 50 dative alternation pairs (DO vs. PO) using unique verbs, balanced across the possible recipient and theme conditions. On each trial, participants used a continuous slider to indicate the strength of their preference for the DO or the PO, with the midpoint used to indicate they were "about the same" (see Appendix A for details)[1].

4 Results

4.1 Characterizing human judgments

We begin by characterizing benchmark patterns of human judgments in our dataset. First, we examine the degree of gradience in DO preference across verbs. Traditionally, verbs have been grouped into binary "classes": alternating verbs which appear freely in both constructions, and non-alternating verbs which are only acceptable in one (Levin, 1993). While verbs in the "alternating" class were indeed rated more acceptable on average in the DO than "non-alternating" verbs ($b = -15.0, t = -46.5, p < 0.001$), there was

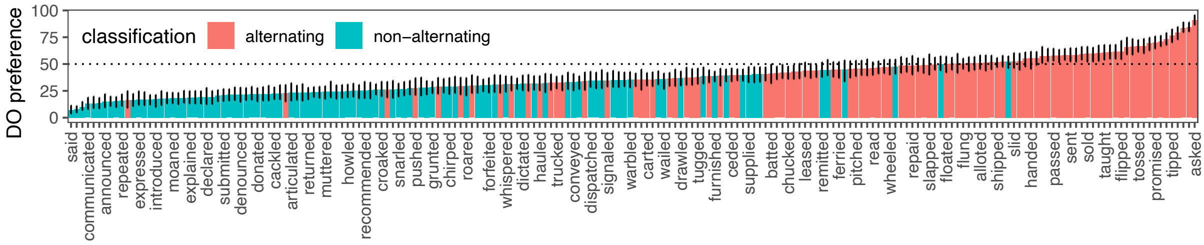

Figure 1: Human judgments across 200 verbs, pronoun recipients only. Classification from Levin (1993).

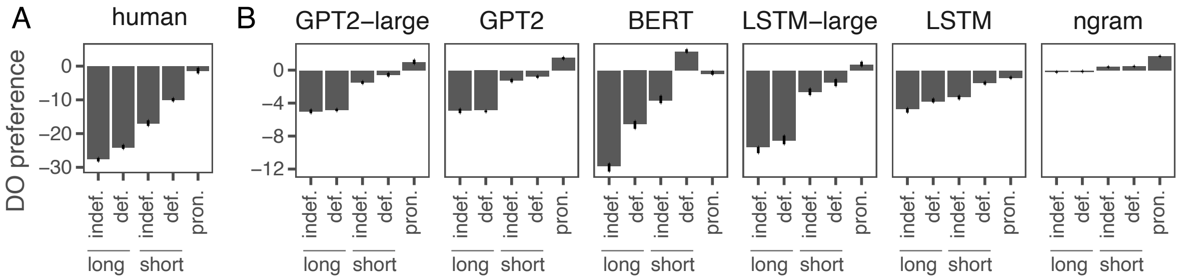

Figure 2: Average (A) human and (B) model DO preferences for "alternating" verbs, as recipient argument varies in length and definiteness. For "non-alternating" verbs and effects of theme definiteness and, see Fig. S1 in Appendix.

substantial overlap between the two classes, confirming the need to verify introspective classifications with human judgments. Moreover, we found that verbs fell along a continuous spectrum of acceptability in the DO (Lau et al., 2017; Gibson and Fedorenko, 2013, see Fig. 1; individual responses are shown in Supplemental Fig. S2). To measure the stability of this ranking across participants, we repeatedly split the dataset in half, measured the mean judgment for each verb across recipient conditions, and took the Spearman correlation between the two halves. Across 100 splits, we found an average correlation of $r = 0.95$, which also serves as a noise ceiling for our model comparison.[2]

Second, we examine human sensitivity to the length and definiteness of the arguments (Fig. 2A). Consistent with previous findings (Wasow, 2002; Futrell and Levy, 2019), participants more strongly preferred the double-object construction when the recipient was shorter ($b = 16.3, t = 21.1, p < 0.001$) and definite ($b = 3.9, t = 14.4, p < 0.001$), and when the theme was indefinite ($b = 2.2, t = 11.0, p < 0.001$; see Appendix B for more details). These effects were roughly additive: although longer recipient arguments rarely occur in the DO construction, we nonetheless found a preference for long definite arguments compared to long indefinites. Similar effects were found when limiting analysis to only "non-alternating" verbs (see Fig. S1 in Appendix). Indeed, "non-alternating" verbs with short, pronoun recipients were judged to be more acceptable in the double-object construction than "alternating" verbs with long, indefinite recipients, highlighting the interplay between verb biases and information structure.

Table 1: Details of each model we consider.

4.2 Comparing model predictions

Next, we evaluated the performance of several pre-trained neural language models (see Table 1) against the fine-grained human judgments in DAIS. We included two recurrent architectures of different sizes: the 2-layer LSTM model from Gulordava et al. (2018), which has been used for a variety of previous syntactic evaluations, as well as the larger 1B-parameter "BIG LSTM+CNN" (Jozefowicz et al., 2016). We also included several transformer architectures, including BERT (Devlin et al., 2018), and two sizes of GPT-2 (Radford et al., 2019). These choices allow us to explore both effects of architecture as well as size and training regime. As a baseline, we included a 5-gram model and interpolated using the methods described in Heafield et al. (2013).

For the LSTM and GPT2 architectures, we calculated sentence probabilities by taking the sum of the surprisal of each word, conditioning on all of the preceding words. For BERT, which uses bidirectional context, we used the surprisal of each word conditioned on the full context (Wang and Cho, 2019). We then measured the models' relative preference for the DO construction by taking the likelihood ratio of the two sentences.

We began by examining how each model cap-

---

[2] One concern is that gradience is an artifact of using a continuous slider (Armstrong et al., 1983; Yang, 2008). Recent work (e.g. Lau et al., 2017) has addressed this concern by examining the histograms of ratings on different measures, finding higher similarity to gradient control tasks than binary control tasks. Still, it is important to note that gradient judgments are compatible with categorical grammars due to multiple binary factors or individual differences (Schütze, 2011).

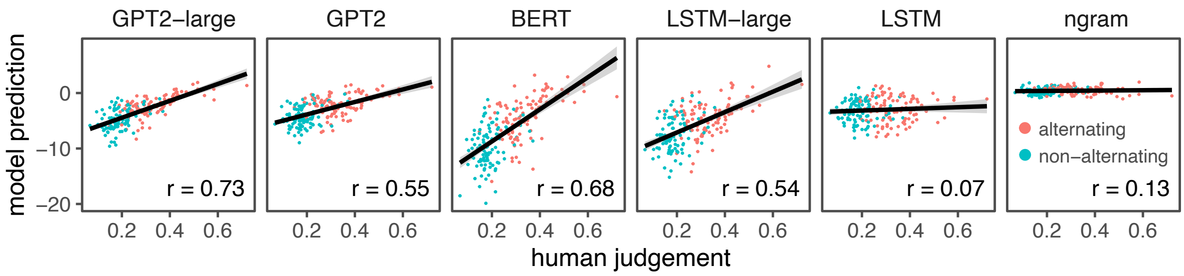

Figure 3: Spearman correlation between human judgment and model prediction, across 200 verbs. Judgments were averaged across themes and recipients, hence the lower overall preferences for the double-object.

tures the full spectrum of human verb biases (Fig. 3). To do this, we measured the Spearman correlation between human judgments and model predictions across the 200 verbs, averaging over recipients and themes. We found that the transformer architectures are particularly sensitive to human-like verb biases, with the larger GPT2 model having the highest correlation ($r = 0.73$). The larger LSTM model had an even greater number of parameters but accounted for significantly less variance, suggesting that simply increasing model size may not be sufficient to learn verb-specific preferences (van Schijndel et al., 2019).

Next, we examined the extent to which each model qualitatively accounts for human sensitivity to argument length and definiteness (Fig. 2B), averaging across verbs. For all models except the n-gram model, we found significant effects of recipient length, recipient definiteness, and theme definiteness (see Table S5 in Appendices for details). Overall, however, the LSTM models were more sensitive to the effect of definiteness, showing the same additive effects as human speakers. Additionally, all models except BERT reflected the fact that ratings on the DO are highest when the recipient is labeled by a (definite) pronoun.

4.3 Probing internal representations

Having established key differences in the predictive accuracy of different models, we now investigate the internal representation of this knowledge. We hypothesized that sensitivity to verb bias requires the ability to integrate the verb's lexical embedding with the higher-level structure of the sentence. Thus, successful models should contain information about acceptability early in the sentence.

To focus on verb bias, we began with the subset of 1000 sentences with pronoun recipients. For the 4 auto-regressive models (two different sizes of LSTMs and GPT-2), we then extracted the hidden state after each word. To analyze how acceptability was represented throughout the sentence, we fit regularized linear regressions using the hidden state features as input and human judgments as output (see Appendix C for more details). We then compared these predictions at three key points in the sentence: after the verb, after the first argument, and after the second argument.

Upon seeing the verb, human preferences for the DO were already decodable from the GPT2 models' features with higher precision than from the LSTMs' (see Fig. 4), reflecting richer lexical representations. At the same time, predictive accuracy increased for all models after the first argument, reflecting additional cues from the word sequence. For example, the model may represent that a pronoun recipient appearing after a PO-biased verb is likely to be less acceptable (e.g. **Alice said him...*). Finally, we observed that all of the models lost information about construction preference near the end of the sentence.

How does the representation of verb bias change as a function of depth in the best-fitting GPT2-large architecture? Recent analyses have found that the ability to decode syntactic information peaks near the middle layers of transformers (Tenney et al., 2019; Hewitt and Manning, 2019). In the previous analysis, we took the single layer that maximized explained variance; here, we repeat this analysis across all layers (Fig. 5). Immediately after observing the verb, decodability of DO preferences is

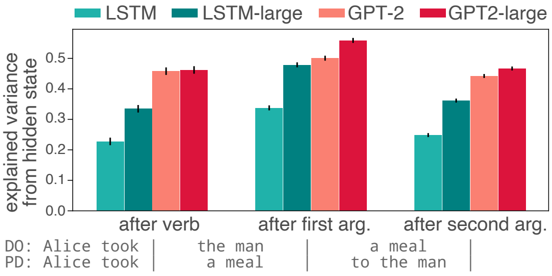

Figure 4: Variance predicted by hidden states throughout the sentence. Error bars show cross-validated SEM.

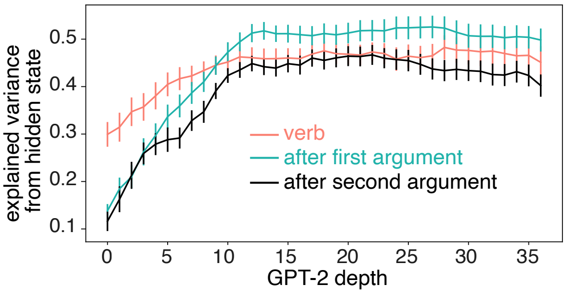

Figure 5: Decodability at each layer of GPT2-large.

already high in the earliest layers, suggesting that this information is directly available from the verb's lexical embedding. Later in the sentence, however, DO preferences are no longer decodable at lower layers; instead, it has shifted to intermediate layers, suggesting increasing reliance on context and higher-order structure.

5 Analysis on natural corpus

While there are many advantages of human judgment datasets like DAIS — including the ability to include a wider range of infrequently observed verbs and to control for potential confounds — there are also distinct advantages of corpus data. We thus conducted a further evaluation using DO and PO utterances extracted from the Switchboard corpus by Bresnan et al. (2007). Instead of testing how well each model was able to predict continuous judgments, we now ask how well each model is able to categorically predict whether the DO vs. PO was naturally produced by a corpus speaker.

For each DO or PO utterance in the corpus, we used the extracted verb, theme, and recipient to generate the alternating sentence, pairing the attested example with its hypothetical alternation. Subjects were chosen from a list of names, as in the DAIS dataset. After removing incoherent sentences, we obtained 2,206 pairs of sentences in total.

For each model, we calculated the likelihood ratio of the PO vs. DO construction for all corpus examples. Following Bresnan et al. (2007), we then constructed a classifier to predict which construction was actually produced by fitting a decision threshold for likelihood ratios. The accuracy achieved by each model is shown in Table 2, reproducing roughly the same ranking that we observed for the DAIS dataset. Critically, the GPT2 models achieved comparable accuracy to the 92% previously reported by Bresnan et al. (2007) using a logistic regression on 14 hand-annotated binary features (e.g. animacy, accessibility, definiteness).

GPT2 (large)	GPT2	BERT	LSTM (large)	LSTM	Ngram
93.51	93.47	91.29	88.21	81.13	80.05

Table 2: Classification accuracy on Switchboard

An important difference between Switchboard datives and the DAIS dataset is the set of verbs represented. Switchboard only contains 37 distinct verbs compared to our 200, and is heavily skewed by frequency ('give' accounts for 42% of examples). Additionally, while we intentionally included 100 verbs traditionally considered "non-alternating," the 37 verbs in Switchboard are skewed toward "alternating." Of the 27 of these appearing in (Levin, 1993), all were classified as "alternating," and all but one of the 37 appeared in the double-object construction at least once in the dataset. These features may help account for why Switchboard was unable to distinguish between our GPT2 models: it may be an easier task than DAIS.

6 Conclusions

In natural languages, speakers routinely select one alternative over others to express their intended message. These choices are sensitive to many interacting factors, including the choice of the main verb and the length and definiteness of arguments. Our new dataset, DAIS, not only offers a higher-resolution window into the richness of human preferences, it also provides a newly powerful benchmark for evaluating and understanding the corresponding sensitivity of language models. We found that transformer architectures corresponded especially well with human verb bias judgments.

Further work is needed to more precisely determine the source of the architectural differences we observed. One possibility is that the transformer's self-attention mechanism and layer-wise organization improves its ability to represent lexically-specific structures. However, it is also possible that differences are attributable to training data. Another line of future research is to compare the incremental predictions of neural models to finer-grained eye-tracking evidence during sentence processing of double-object sentences (e.g. Filik et al., 2004). As neural language models become more complex, subtler phenomena like verb bias may yield new insights into how lexical and grammatical representations are jointly learned and successfully integrated for language understanding.

Appendix A: Data collection details

There are many possible ways of empirically eliciting acceptability judgements (Marty et al., 2019; Podesva and Sharma, 2014; Langsford et al., 2018). We chose to present pairs of sentences together with a continuous slider to maximize our power to detect gradient preferences. We generated a sentence pair for each verb-theme item by randomly selecting a subject from a list of 8 names (e.g. Juan, Alice), and selecting recipients from a short list corresponding to the given condition (e.g. "him," "her," or "them" for the pronoun condition; "the man," "the woman," "the team" for the short definite condition, etc.) See Table S1 for examples. We implemented our study using jsPsych (De Leeuw, 2015) and paid participants a $1.00 base pay in addition to an additional $1.00 completion bonus.

To ensure data quality, we excluded participants who failed an initial comprehension quiz or either of two attention checks where one of the sentences in the pair was randomly scrambled:

(4) a. The man ate a slice of cake.
b. The man cake of slice ate a.

We also excluded individual trials with response times of < 3 seconds, and all trials from participants who responded this quickly for more than a quarter of their responses, since it was not possible to read the sentences in that time. Due to these exclusions, as well as generic participant dropout on Mechanical Turk, not all sentences received the same number of judgements, but we ensured that at least 5 judgements were collected for each sentence pair.

Appendix B: Regression specifications

To evaluate the binary effect of alternating vs. non-alternating verbs in Section 4.1, we constructed a mixed-effects model predicting human preferences including a dummy-coded fixed effect for the "alternating" vs. "non-alternating" classification from

Levin (1993). We also included random intercepts and slopes for each human participant.

To evaluate the effect of information structure in Section 4.1, our mixed-effects model included fixed effects for recipient length, recipient definiteness, and theme definiteness. We included random intercepts and effects of recipient length and definiteness for each participant and verb to control for clustered variance at these levels. See Fig. S1 for the full pattern of results, split by "alternating" and "non-alternating" verbs. Complete regression results are shown in Tables S3 and S4.

Appendix C: Analysis details

For each of three sentence positions of interest investigated in section 5 (after verb, after first argument, and after second argument), we fit a linear regression predicting human judgements from the hidden states. Because of the high dimensionality of these states, we used ridge regression to prevent overfitting[3]. The ridge regression regularization hyper parameter was optimized for each regression model through a log-scale grid search ($\alpha \in [10^0, 10^7]$) on a held-out validation set. As our evaluation metric, we computed R^2, or variance explained. Results were averaged across 10 runs of cross-validation, using random 80/20 splits (see Table S2 for best-performing hyperparameter configurations).

Because the predicted judgements were relative preferences between the two sentences, we concatenated the hidden states of the two sentences together as input. For the 2-layer LSTMs, we used the final hidden state. For the deeper GPT-2 architectures, which are known to represent different information at different layers, we did not know *a priori* which layer would be most appropriate. We thus conducted the regression analysis separately for each layer, and reported the highest performance that was achievable by the model across all layers. In other words, we computed the cross-validated mean performance for each layer and selected the best. This approach has also been used in other recent work (Schrimpf et al., 2020).

Abstract

When speakers describe an image, they tend to look at objects before mentioning them. In this paper, we investigate such sequential cross-modal alignment by modelling the image description generation process computationally. We take as our starting point a state-of-the-art image captioning system and develop several model variants that exploit information from human gaze patterns recorded during language production. In particular, we propose the first approach to image description generation where visual processing is modelled *sequentially*. Our experiments and analyses confirm that better descriptions can be obtained by exploiting gaze-driven attention and shed light on human cognitive processes by comparing different ways of aligning the gaze modality with language production. We find that processing gaze data sequentially leads to descriptions that are better aligned to those produced by speakers, more diverse, and more natural—particularly when gaze is encoded with a dedicated recurrent component.

1 Introduction

Describing an image requires the coordination of different modalities. There is a long tradition of cognitive studies showing that the interplay between language and vision is complex. On the one hand, eye movements are influenced by the task at hand, such as locating objects or verbally describing an image (Buswell, 1935; Yarbus, 1967). On the other hand, visual information processing plays a role in guiding linguistic production (e.g., Griffin, 2004; Gleitman et al., 2007). Such cross-modal coordination unfolds sequentially in the specific task of image description (Coco and Keller, 2012)—i.e., objects tend to be looked at before being mentioned. Yet, the temporal alignment between the two modalities is not straightforward (Griffin and Bock, 2000; Vaidyanathan et al., 2015)

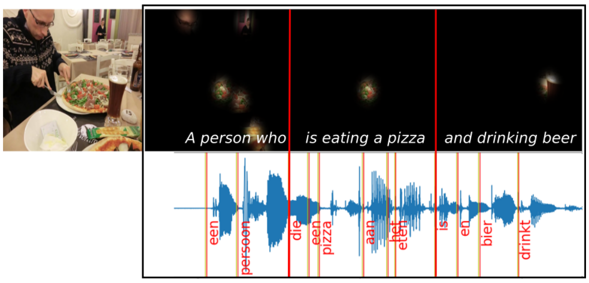

Figure 1: In our approach, an image captioning model is fed with a *sequence* of masked images encoding the gaze fixations of a *single* human speaker during language production. This diagram is a toy illustration.

In this paper, we follow up on these findings and investigate cross-modal alignment in image description by modelling the description generation process computationally. We take a state-of-the-art system for automatic image captioning (Anderson et al., 2018) and develop several model variants that exploit information derived from eye-tracking data. To train these models, we use a relatively small dataset of image descriptions in Dutch (DIDEC; van Miltenburg et al., 2018) that includes information on gaze patterns collected during language production. We hypothesise that a system that encodes gaze data as a proxy for human visual attention will lead to better, more human-like descriptions. In particular, we propose that training such a system with eye-movements sequentially aligned with utterances (see Figure 1) will produce descriptions that reflect the complex coordination across modalities observed in cognitive studies.

We develop a novel metric that measures the level of semantic and sequential alignment between descriptions and use it in two ways. First, we analyse cross-modal coordination in the DIDEC data, finding that the product of content and sequentiality better captures cross-modal correlations than content alone. Second, we test whether our

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4664–4677,
November 16–20, 2020. ©2020 Association for Computational Linguistics

models generate captions that capture sequential alignment. Our experiments show that exploiting gaze-driven attention helps enhance image caption generation, and that processing gaze patterns sequentially results in descriptions that are better aligned with those produced by speakers, as well as being more diverse—both in terms of variability per image and overall vocabulary—particularly when gaze is encoded with a dedicated recurrent component that can better capture the complexity of the temporal alignment across modalities. Our data and code are publicly available at `https://github.com/dmg-illc/didec-seq-gen`.

Overall, this work presents the first computational model of image description generation where both visual and linguistic processing are modelled sequentially, and lends further support to cognitive theories of sequential cross-modal coordination.

2 Related Work

Image captioning Various models have been proposed to tackle the challenging task of generating a caption for a visual scene (Bernardi et al., 2016). Contemporary approaches make use of deep neural networks and encoder-decoder architectures (Sutskever et al., 2014). In the influential model by Vinyals et al. (2015), a Convolutional Neural Network (CNN) is used to encode the input image into a feature representation, which is then decoded by a Long Short-Term Memory network (LSTM; Hochreiter and Schmidhuber, 1997) that acts as a generative language model. In recent years, there have been many proposals to enhance this basic architecture. For instance, via extracting features from a lower layer of a CNN, Xu et al. (2015) obtain representations for multiple regions of an image over which attention can be applied by the LSTM decoder. The 'Bottom-up and Top-down Attention' model by Anderson et al. (2018) further refines this idea by extracting multiple image features with the help of Faster R-CNN (Ren et al., 2015), which results in the ability to focus on regions of different sizes better aligned with the objects in the image. Other models based on unsupervised methods (e.g., Feng et al., 2019) and Generative Adversarial Networks (Chen et al., 2019) have also been proposed recently.

We take as our starting point the model by Anderson et al. (2018) for two main reasons: first, it is among the best-performing architectures on standard image captioning benchmarks; second, its underlying idea (i.e., bottom-up and top-down attention) is explicitly inspired by human visual attention mechanisms (Buschman and Miller, 2007), which makes it suitable for investigating the impact of adding human gaze information.

Eye tracking In computer vision, human eye movements collected with eye-tracking methods have been exploited to model what is salient in an image or video for object detection (Papadopoulos et al., 2014), image classification (Karessli et al., 2017), image segmentation (Staudte et al., 2014), region labelling (Vaidyanathan et al., 2015, 2018), and action detection (Vasudevan et al., 2018). More relevant for the present study, gaze has also been used in automatic description generation tasks, such as video frame captioning (Yu et al., 2017) and image captioning (Sugano and Bulling, 2016; Chen and Zhao, 2018; He et al., 2019). In all these approaches, gaze data from different participants is *aggregated* into a *static* saliency map to represent an abstract notion of saliency. This aggregated gaze data is used as supervision to train models that predict generic visual saliency.

In contrast, in our approach, we model the production process of a *single* speaker by directly inputting information about where that speaker looks at during description production, and compare this to the aggregation approach. In addition, we exploit the *sequential* nature of gaze patterns, i.e., the so-called scanpath, and contrast this with the use of static saliency maps. Gaze scanpaths have been used in NLP for diverse purposes: For example, to aid part-of-speech tagging (Barrett et al., 2016) and chunking (Klerke and Plank, 2019); to act as a regulariser in sequence classification tasks (Barrett et al., 2018); as well as for automatic word acquisition (Qu and Chai, 2008) and reference resolution (Kennington et al., 2015). To our knowledge, the present study is the first attempt to investigate sequential gaze information for the specific task of image description generation.

3 Data

We utilise the Dutch Image Description and Eye-Tracking Corpus (DIDEC; van Miltenburg et al., 2018). In particular, we use the data collected as part of the description-view task in DIDEC, where participants utter a spoken description in Dutch for each image they look at. The gaze of the participants is recorded with an SMI RED 250 eye-tracking device while they describe an image. Overall, DIDEC consists of 4604 descriptions in Dutch (15 descriptions per image on average) for 307 MS COCO images (Lin et al., 2014). For each description, the audio, textual transcription, and the corresponding eye-tracking data are provided.

3.1 Preprocessing

We tokenise the raw captions, lowercase them, and exclude punctuation marks and information tokens indicating, e.g., repetitions (<rep>). We then use CMUSphinx[1] to obtain the time intervals of each word given an audio file and its transcription. See Appendix A for more details.

Gaze data in DIDEC is classified into gaze events such as fixations, saccades or blinks. We discard saccades and blinks (since there is no visual input during these events) and use only fixations that fall within the actual image. We treat consecutive occurrences of such fixations as belonging to the same fixation window.

3.2 Saliency maps

Using the extracted fixation windows, we create two types of saliency maps, *aggregated* and *sequential*, which indicate the prominence of certain image regions as signalled by human gaze.

Aggregated saliency maps *(per image)* The aggregated saliency map of an image is computed as the combination of all participants' gazes and represents what is generally prominent given the image description task. To create it, we first compute the saliency map of each participant who looked at the given image. Following Coco and Keller (2015), for each fixation window of the participant, we create a Gaussian mask centered at the window's centroid with a standard deviation of 1° of visual angle. Given the data collection setup of DIDEC, this standard deviation corresponds to 44 pixels. We sum up the masks weighted by relative fixation durations and normalise the resulting mask to have values in the range $[0, 1]$. Finally, we sum up and normalise the maps of all relevant participants to obtain the aggregated saliency map per image.

Sequential saliency maps *(per image-participant pair)* A sequential saliency map consists of a sequence of saliency maps aligned with the words in a description, and represents the scan pattern of a given participant over the course of description production. Using the temporal intervals extracted from the audio files, we align each word with the image regions fixated by the participant right before the word was uttered. For each word w_t—using the same method described above for aggregated maps—we combine all the fixation windows that took place between w_{t-1} and the onset of w_t and normalise them to obtain a word-level saliency map.[2] This way, we obtain a sequence of saliency maps per participant description.

3.3 Masked images and image features

The saliency maps are used to keep visible only the image regions that were highly attended by participants and to mask the image areas that were never or rarely looked at (see Figure 1). We create each masked image by calculating the element-wise multiplication between the corresponding 2D saliency map and each RGB channel in the original image. We then extract image features from the masked images using ResNet-101 (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009). We take the output of the 2048-d average pooling layer as the image features to give as input to our models.

4 Evaluation Measures

We propose a novel metric to quantify the degree of both *semantic* and *sequential* alignment between two sentences. In our study, this metric will be leveraged in two ways: (1) to analyse cross-modal coordination in the DIDEC data (Section 5) and (2) to evaluate our generation models (Section 7). For context, we first briefly review several existing metrics for automatic image captioning.

Image Captioning metrics Image caption generation is evaluated by assessing some kind of similarity between the generated caption and one or more reference captions (i.e., those written by human annotators). One of the most commonly used metrics is CIDEr (Vedantam et al., 2015), which (a) computes the overlapping *n*-grams between the generated caption and the entire set of reference sentences for a given image, and (b) downweighs *n*-grams that are frequent in the entire corpus via *tf-idf* scores. Thus—regarding semantics and sequentiality—CIDEr scores can be affected by word order permutations, but not by the relative position of words in the entire caption nor

---

[1] `https://cmusphinx.github.io/`

[2] For the first word, we combine all the fixation windows that took place before its utterance. Some participants may look at an image before uttering the first word to obtain its gist (Oliva and Torralba, 2006). However, we do not encode these differences in behaviour explicitly.

by the presence of different but semantically similar words. Other metrics such as BLEU (which looks at n-gram precision; Papineni et al., 2002) and ROUGE-L (which considers n-gram recall; Lin, 2004) suffer from comparable limitations.

METEOR (Banerjee and Lavie, 2005) and SPICE (Anderson et al., 2016) also make use of n-grams (or tuples in a scene's graph, in the case of SPICE) and take into account semantic similarity by matching synonyms using WordNet (Pedersen et al., 2004). This allows for some flexibility, but can be too restrictive to grasp overall semantic similarity. To address this, Kilickaya et al. (2017) proposed using WMD, which builds on `word2vec` embeddings (Mikolov et al., 2013); more recently, several metrics capitalising on contextual embeddings (Devlin et al., 2019) were proposed, such as BERTScore (Zhang et al., 2020) and MoverScore (Zhao et al., 2019). However, these metrics neglect the sequential alignment of sentences.[3]

SSD We propose *Semantic and Sequential Distance* (SSD), a metric which takes into account both semantic similarity and the overall relative order of words. Regarding the latter, SSD is related to *Ordering-based Sequence Similarity* (OSS; Gómez-Alonso and Valls, 2008), a measure used by Coco and Keller (2010) to compare sequences of categories representing gaze patterns.[4] Given two sequences of words, i.e., a generated sentence G and a reference sentence R, SSD provides a single positive value representing the overall *dissimilarity* between G and R: the closer the value to 0, the higher the similarity between the two sentences (note that the value is unbounded). This single value is the average of two terms, *gr* and *rg*, which quantify the overall distance between G and R—the sum of their cosine (cos) and positional (pos) distance—from G to R and from R to G, respectively. The equation for *gr* is given below:

$$gr = \sum_{i=1}^{N} cos(G_{\mathrm{i}}, R_s(i)) + pos(G_{\mathrm{i}}, R_s(i)) \quad (1)$$

where $R_s(i)$ is the semantically closest element to G_i in R, and cos in our experiments is computed over `word2vec` embeddings trained on the 4B-token corpus in Dutch, COW (Tulkens et al., 2016).

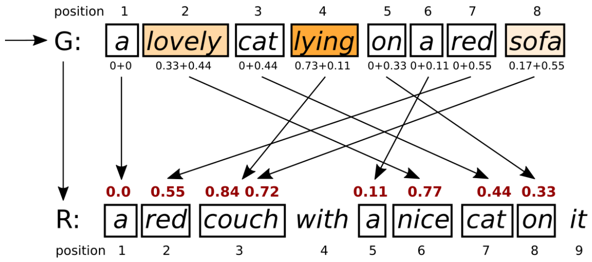

Figure 2: SSD. Computation of *gr* (Eq. 1). Sums below each word in G stand for $cos + pos$, darker shades of orange for higher cos distance. Value of gr is the sum of numbers in red (here 3.76). Best viewed in color.

Figure 2 illustrates how the metric works in practice. Full details are in Appendix B. For simplicity, the diagram only shows the computation in the gr direction. For example, consider the second element in G, 'lovely'. Its closest embedding in R is 'nice' ($cos = 0.33$). For each of these elements, we retrieve their position index (i.e., 2 for 'lovely' in G and 6 for 'nice' in R), compute their positional distance, and normalise it by the length of the longest sentence in the pair (here R), obtaining $|2 - 6|/9 \approx 0.44$. We then sum up the cosine distance and the positional distance to obtain a score for 'lovely': $0.33 + 0.44 = 0.77$. To obtain the overall *gr* value, we add up the scores for all words in G. We compute *rg* in a similar manner and obtain SSD as follows: $SSD = (gr + rg)/2$.

5 Cross-Modal Coordination Analysis

To empirically motivate our generation models, as a preliminary experiment we investigate the level of coordination between visual attention and linguistic production in the DIDEC dataset. In particular, we test whether scanpath similarity and sentence similarity are correlated and whether taking into account the sequential nature of the two modalities results in higher cross-modal alignment.

We transform gaze data into time-ordered sequences of object labels, i.e., scanpaths, (e.g., *S* = 'cat', 'person', 'cat', 'table') using the annotations of object bounding boxes in the MS COCO image dataset. On average, scanpaths have a length of 23.4 object labels. As for captions, we simply take the full sentences and treat them as sequences of words (e.g., *C* = 'a cute cat cuddled by a boy'). Descriptions contain an average of 12.8 tokens.

Order-sensitive analysis (*sequential*) For each image, we take the set of produced descriptions and compute all pairwise similarities by using SSD (see

---

[3] Moreover, metrics based on contextual embeddings have been shown to suffer with languages other than English.

[4] Despite its name, OSS is a *distance* measure. Note that it accounts for relative position, but not for semantic similarity.

Section 4). Similarly, we take the corresponding scanpaths and compute all pairwise similarities by using OSS (Gómez-Alonso and Valls, 2008). We then calculate Spearman's rank correlation (one-tailed) between the two similarity lists. This way, we obtain a correlation coefficient and p-value for each of the 307 images in the dataset.

Bag of Words analysis (*BoW*) We compare the correlation observed in the order-sensitive analysis with a BoW approach. Here, we represent a sentence as the average of the `word2vec` embeddings of the words it contains and a scanpath as a term-frequency vector. We then perform the same correlation analysis described above.

Random baseline (*random*) As a sanity check, using the stricter order-sensitive measures, for each image we re-compute the correlation between the two lists of similarities after randomly shuffling the sentences and corresponding scanpaths per image. We repeat this analysis 3 times.

Results As shown in Table 1, the highest level of alignment is observed in the *sequential* condition, where a significant positive correlation between scanpath and sentence similarities is found for 81 images out of 307 (26%). In BoW, the level of alignment is weaker: a positive correlation is found for 73 images (24%), with lower maximum correlation coefficients (0.65 vs. 0.49). Substantially weaker results can be seen in the *random* condition. These outcomes are in line with those obtained by Coco and Keller (2012) in a small dataset of 576 English sentences describing 24 images.

Overall, the results of the analysis indicate that the product of content and sequentiality better captures the coordination across modalities compared to content alone. Yet, the fact that positive correlations are present for only 26% of the images suggests that coordination across modalities is (not surprisingly) more complex than what can be captured by the present pairwise similarity computation, confirming the intricacy of the cross-modal temporal alignment (Griffin and Bock, 2000; Vaidyanathan et al., 2015). We take this aspect into account in our proposed generation models.

	sequential	*BoW*	*random*
# positively corr.	**81**	73	52.3 ± 5.774
% positively corr.	**0.26**	0.24	0.17 ± 0.015
Spearman's ρ (min)	0.15	0.15	0.15 ± 0.002
Spearman's ρ (max)	**0.65**	0.49	0.50 ± 0.042

Table 1: Results of the correlation analysis: number and percentage of images with statistically significant (p<0.05) positive correlations and range of coefficients in the three conditions. For random, avg. over 3 runs.

6 Models

The starting point for our models is the one by Anderson et al. (2018).[5] The main aspect that distinguishes this model from other image captioning systems is the use of Faster R-CNN (Ren et al., 2015) as image encoder, which identifies regions of the image that correspond to objects and are therefore more salient—the authors refer to this type of saliency detection as "bottom-up attention". Each object region i is transformed into an image feature vector v_i. The set of region vectors $\{v_1, \ldots, v_k\}$ is utilised in two ways by two LSTM modules: The first LSTM takes as input the mean-pooled image feature $\bar{\boldsymbol{v}}$ (i.e., the mean of all salient regions) at each time step, concatenated with the two standard elements of a language model, i.e., the previous hidden state and an embedding of the latest generated word. The hidden state of this first LSTM is then used by an attention mechanism to weight the vectors in $\{v_1, \ldots, v_k\}$—the authors refer to this kind of attention as "top-down". Finally, the resulting weighted average feature vector $\hat{v}_t$ is given as input to the second LSTM module, which generates the caption one word at a time. Note that the set of region vectors $\{v_1, \ldots, v_k\}$ and the mean-pooled vector $\bar{\boldsymbol{v}}$ are constant over the generation of a caption, while the weights over $\{v_1, \ldots, v_k\}$ and hence the weighted average feature vector $\hat{v}_t$ do change dynamically at each time step since they are influenced by the words generated so far.

We take the original model as our baseline and modify it to integrate visual attention defined by gaze behaviour. In particular, we replace the mean-pooled vector $\bar{\boldsymbol{v}}$ by a gaze vector g computed from masked images representing fixation patterns as explained in Section 3. We do not directly modify the set of object regions $\{v_1, \ldots, v_k\}$ present in the original model (i.e., bottom-up attention is still present in our proposed models). However, the top-down attention weights learned by the models

---

[5] The original implementation of this model can be found at: `https://github.com/peteanderson80/bottom-up-attention`. We developed our models building on the PyTorch re-implementation of the model available at: `https://github.com/poojahira/image-captioning-bottom-up-top-down`.

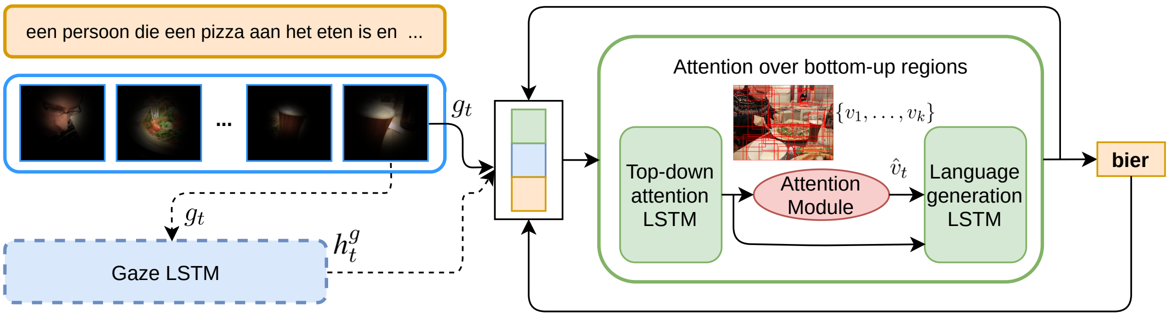

Figure 3: Architecture of the GAZE-SEQ and GAZE-2SEQ models. Dashed lines indicate that the connections to and from the Gaze LSTM are only present in the GAZE-2SEQ model.

are influenced by the gaze patterns given as input. Concretely, we test the following model conditions:

- NO-GAZE: The original model as described above, with exactly the same image feature vectors used by Anderson et al. (2018).
- GAZE-AGG: The mean-pooled vector $\overline{\boldsymbol{v}}$ in the original model is replaced with a gaze image vector $\overline{g}$ computed on the image masked by the aggregated gaze saliency map. As explained in Section 3.2, this corresponds to the combination of all participants' fixations per image and hence remains constant over the course of generation.
- GAZE-SEQ: As depicted in Figure 3, we replace $\overline{\boldsymbol{v}}$ with g_t, which are features computed for the image that was masked by the participant-specific sequential gaze saliency map at time t. Hence, g_t differs at each time step t. Building on the results of the correlation analysis, this sequential condition thus offers a model of the production process of a speaker where visual processing and language production are time-aligned.
- GAZE-2SEQ: Cross-modal coordination processes seem to go beyond simplistic content and temporal alignment (Griffin and Bock, 2000; Vaidyanathan et al., 2015). To allow for more flexibility, we add an extra gaze-dedicated LSTM component (labelled 'Gaze LSTM' in Figure 3), which processes the sequential gaze vector g_t and produces a hidden representation h_t^g. This dynamic hidden representation goes through a linear layer and then replaces $\overline{\boldsymbol{v}}$ at each time step t.

For the three GAZE models, we also considered a version where $\overline{\boldsymbol{v}}$ is concatenated with $\overline{g}$ or g_t as appropriate, rather than being replaced by the gaze vectors. Since they did not bring in better results, we do not discuss them further in the paper.

7 Experiments

We experiment with the proposed models using the DIDEC dataset and report results per model type.

7.1 Setup

We randomly split the DIDEC dataset at the image level, using 80% of the 307 images for training, 10% for validation, and 10% for testing. Further details are available in Appendix C.

Pre-training Since DIDEC is a relatively small dataset, we pre-train all our models using a translated version of train/val annotations of MS COCO 2017 version. We translated all the captions in the training and validation sets of MS COCO from English to Dutch using the Google Cloud Translation API.[6] We exclude all images present in our DIDEC validation and test sets from the training set of the translated MS COCO. We randomly split the original MS COCO validation set into validation and test. The final translated dataset in Dutch used for pre-training includes over 118k images for training, and 2.5k images for validation and testing, respectively, with an average of 5 captions per image.

Manual examination of a subset of translated captions showed that they are of good quality overall. Indeed, pre-training the NO-GAZE model with the translated corpus results in an improvement of about 21 CIDEr points (from 40.81 to 61.50) in the DIDEC validation set. Given that the MS COCO dataset is comprised of written captions compared to DIDEC, which includes spoken descriptions, these two datasets can have distinct characteristics. We expect the transfer learning approach to help mitigate this by allowing our models to learn the

Table 2: Test set results (average over 5 runs, with standard deviations in brackets) for the models selected with SSD and with CIDEr. Scores for BLEU-4 and SSD/CIDEr when not used for model selection are shown for reference only. For SSD, lower is better; for CIDEr and BLEU-4, higher is better.

features of spontaneous spoken descriptions during the fine-tuning phase.

All results reported below were obtained with pre-training (i.e., by initialising all models with the weights learned by the NO-GAZE model on the translated dataset and then fine-tuning on DIDEC).

Vocabulary and hyperparameters We use a vocabulary of 21,634 tokens consisting of the union of the entire DIDEC vocabulary and the translated MS COCO training set vocabulary. For all model types, we perform parameter search focusing on the learning rate, batch size, word embedding dimensions and the type of optimiser. The reported results refer to models trained with a learning rate of 0.0001 optimising the Cross-Entropy Loss with the Adam optimiser. The batch size is 64. The image features have 2048 dimensions and the hidden representations have 1024. The generations for the validation set were obtained through beam search with a beam width of 5. Best models were selected via either SSD or CIDEr scores on the validation set, with an early-stopping patience of 50 epochs.

More information regarding reproducibility can be found in Appendix D.

7.2 Results

The results obtained with different models are shown in Table 2. We report results on the test set, averaging over 5 runs with different random seeds. These scores are obtained with the best models selected on the validation set with either SSD or CIDEr.[7] For reference, we also include scores for other metrics not used for model selection. This allows us to check whether scores for other metrics are reasonably good when the models are optimised for a certain metric; however, only scores in the shaded columns allow us to extract conclusions on the relative performance of different model types.

On average, the best GAZE models outperform the NO-GAZE model: 5.81 vs. 5.86 for SSD (lower is better) and 55.74 vs. 52.45 for CIDEr (higher is better). This indicates that eye-tracking data encodes patterns of attention that can contribute to the enhancement of image description generation. Zooming into the different gaze-injected conditions, we find that among the models selected with SSD, the sequential models perform better than GAZE-AGG (5.81 and 5.82 vs. 5.93). This shows that the proposed models succeed (to some extent) in capturing the *sequential* alignment across modalities, and that such alignment can be exploited for description generation. Interestingly, GAZE-2SEQ is the best-performing gaze model: it has the best average SSD across runs and the best absolute single run (5.70 vs. 5.79 and 5.80 by GAZE-SEQ and GAZE-AGG, respectively). This suggests that the higher flexibility and abstraction provided by the gaze-dedicated LSTM component offers a more adequate model of the intricate ways in which the two modalities are aligned.

As for the CIDEr-selected models, on average the gaze-injected models also perform better than NO-GAZE. The best results are obtained with GAZE-AGG (55.74). This is consistent with what CIDEr captures: it takes into account regularities across different descriptions of a given image; therefore, using a saliency map that combines the gaze patterns of several participants leads to higher scores than inputting sequential saliency maps, which model the path of fixations of each speaker independently. This variability seems to have a negative effect on CIDEr scores of sequential models, which are lower than GAZE-AGG; yet higher than NO-GAZE (53.59 and 52.94 vs. 52.45).

It is worth noting that CIDEr and BLEU-4 scores obtained with the SSD-selected models are sensible, which indicates that the generated descriptions do not suffer with respect to distinct aspects evaluated by other metrics when the models are optimised with SSD. Indeed, the highest CIDEr score

	specificity	**disfluency**	**compression**	**repetition**
NO-G	een vrouw die in de keuken staat. . . *(a woman who is standing in the kitchen. . .)*	een foto van een straat met een aantal vogels *(a photo of a street with a number of birds)*	een rode bus en een bus *(a red bus and a bus)*	een straat met **auto's** en **auto's** *(a street with **cars** and **cars**)*
2SEQ	een vrouw in een keuken met **donuts** *(a woman in the kitchen with **donuts**)*	**uh uh uh uh** met een aantal vogels *(**uh uh uh uh** with some birds)*	**twee** bussen die geparkeerd staan *(**two** buses that are parked)*	een straat in de stad met **auto's** en **auto's** *(a street in the city with **cars** and **cars**)*

Figure 4: Phenomena that are either particular to gaze models (specificity, disfluency, and compression) or common to all (repetition). Abbreviations NO-G and 2SEQ refer to NO-GAZE and GAZE-2SEQ, respectively.

obtained among models selected via SSD (GAZE-SEQ: 56.16) is even higher than that obtained by the best CIDEr-selected one (GAZE-AGG: 55.74). However, this is likely due to CIDEr being sensitive to lexical differences between the test set and the validation set used for model selection, which could lead to slightly different patterns.

8 Analysis

This section presents an analysis of the descriptions generated by the models on the test set (446 descriptions). We focus on one single run per model.

Cross-modal sequential alignment Given what SSD captures, our results indicate that the captions generated by GAZE-2SEQ are better aligned—in terms of semantic content and order of words—with the human captions than the ones generated by non-sequential models. Arguably, this enhanced alignment is driven by the specific information provided by the scanpath of each speaker. If this information is used effectively by the sequential models, then we should see more variation in their output. By definition, the non-sequential models generate only one single caption per image. Are the sequential models able to exploit the variation stemming from the speaker-specific scanpaths? Indeed, we find that GAZE-2SEQ generates an average of 4.4 different descriptions per image (i.e., 30% of the generated captions per image are unique).

Furthermore, we conjecture that tighter coordination between scanpaths and corresponding descriptions should give rise to more variation, since presumably the scanpath has a stronger causal effect on the description in such cases. To test this, we take the 30 images in the test set and divide them into two groups: (A) images for which a significant positive correlation was found in the cross-modal coordination analysis of Section 5; (B) all the others. These groups include, respectively, 10 and 20 images. As hypothesised, we observe a higher percentage of unique captions per image in A (35%) compared to B (27%).

Quantitative analysis We explore whether there are any quantitative differences across models regarding two aspects, i.e., the average length in tokens of the captions, and the size of the vocabulary produced. No striking differences are observed regarding caption length: NO-GAZE produces slightly shorter captions (avg. 7.5) compared to both GAZE-2SEQ (avg. 7.7) and GAZE-AGG (avg. 8.1). The difference, however, is negligible. Indeed, it appears that equipping models with gaze data does not make sentence length substantially closer to the length of reference captions (avg. 12.3 tokens).

In contrast, there are more pronounced differences regarding vocabulary. While GAZE-AGG has a similar vocabulary size (68 unique tokens produced) to NO-GAZE (63), GAZE-2SEQ is found to almost double it, with 109 unique tokens produced. Though this number is still far from the total size of the reference vocabulary (813), this trend suggests that a more diverse and perhaps 'targeted' language is encouraged when specific image regions are identified through gaze-based attention. The following qualitative analysis sheds some light on this hypothesis.

Qualitative analysis Manual inspection of all the captions generated by the models reveals interesting qualitative differences. First, captions generated by gaze-injected models are more likely to refer to objects—even when they are small and/or in the background—which are image-specific and thus very relevant for the caption. For example, when describing the leftmost image in Fig. 4, NO-GAZE does not mention the word *donuts*, which is produced by both GAZE-AGG and GAZE-2SEQ. Second, gaze-injected models produce language that seems to reflect uncertainty present in the visual input. For the second image of Fig. 4, e.g., both GAZE-AGG and GAZE-2SEQ generate disfluencies such as *uh* (interestingly, several participants' descriptions include similar disfluencies for this same image, which suggests some degree of uncertainty at the visual level); in contrast, in the entire test set no disfluencies are produced by NO-GAZE.

Finally, we find that GAZE-2SEQ is able to produce captions that somehow 'compress' a repetitive sequence (e.g., *a red bus and a bus*) into a shorter one, embedding a number (e.g., *two buses that are parked*; see third example in Fig. 4). This phenomenon is never observed in the output of other models (crucially, not even in GAZE-SEQ). We thus conjecture that this ability is due to the presence of the gaze-dedicated LSTM, which allows for a more abstract processing of the visual input. However, the presence of gaze data does not fully solve the issue of words being repeated within the same caption, as illustrated by the rightmost example in Fig. 4. Indeed, this weakness is common to all models, including the best performing GAZE-2SEQ.

9 Conclusions

We tackled the problem of automatically generating an image description from a novel perspective, by modelling the sequential visual processing of a speaker concurrently with language production. Our study shows that better descriptions—i.e., more aligned with speakers' productions in terms of content and order of words—can be obtained by equipping models with human gaze data. Moreover, this trend is more pronounced when gaze data is fed *sequentially*, in line with cognitive theories of sequential cross-modal alignment (e.g., Coco and Keller, 2012).

Our study was conducted using the Dutch language dataset DIDEC (van Miltenburg et al., 2018), which posed the additional challenges of dealing with a small amount of data and a low resource language. We believe, however, that there is value in conducting research with languages other than English. In the future, our approach and new evaluation measure could be applied to larger eye-tracking datasets, such as the English dataset by He et al. (2019). Since different eye-tracking datasets tend to make use of different gaze encodings and formats, the amount of pre-processing and analysis steps required to apply our method to other resources was beyond the scope of this paper. We leave testing whether the reported pattern of results holds across different languages to future work.

Despite the challenges mentioned above, our experiments show that a state-of-art image captioning model can be effectively extended to encode cognitive information present in human gaze behaviour. Comparing different ways of aligning the gaze modality with language production, as we have done in the present work, can shed light on how these processes unfold in human cognition. This type of computational modelling could help, for example, study the interaction between gaze and the production of filler words and repetitions, which we have not investigated in detail. Taken together, our results open the door to further work in this direction and support the case for computational approaches leveraging cognitive data.

Acknowledgments

We are grateful to Lieke Gelderloos for her help with the Dutch transcriptions, and to Jelle Zuidema and the participants of EurNLP 2019 for their feedback on a preliminary version of the work. Lisa Beinborn worked on the project mostly when being employed at the University of Amsterdam. This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No. 819455 awarded to Raquel Fernández).

Appendices

A Audio-Caption Alignment

In this appendix, we provide details on the pipeline used to time-align audio and descriptions. After processing a transcribed caption, we insert it as a grammar rule into a Java Speech Grammar Format (JSGF) file to be fed into CMUSphinx. As CMUSphinx supports English by default, we incorporated into the tool the phonetic and language models and the dictionary for Dutch as provided by the developers of CMUSphinx.[8]

Some words in our JSGF files were not in the VoxForge Dutch phonetic dictionary of CMUSphinx, which lists lexical items and their corresponding pronunciations in a format similar to ARPABET, adapted for Dutch.[9] To overcome this problem, we used eSpeak[10] to obtain the International Phonetic Alphabet (IPA) transcriptions of such out-of-vocabulary words. We obtained the set of IPA symbols existing in the transcriptions of out-of-vocabulary words and the set of ARPABET symbols in the dictionary. Then, a native speaker of Dutch, who is also a linguist, manually produced a mapping from these IPA symbols to ARPABET symbols of Dutch phonemes.[11] Given this mapping, we automatically converted out-of-vocabulary tokens into the required format and appended to the dictionary. A similar approach was also followed for numbers in numeric notation and certain English words.

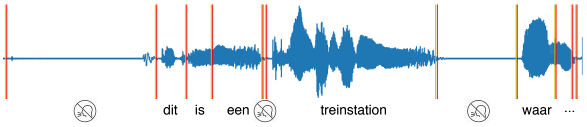

Figure 5: Temporal alignment of words in a transcribed caption and the corresponding audio file.

For some audio-caption pairs, the tool could not find an alignment matching the grammar. We turned off noise- and silence-removal and experimented with parameters related to beam-decoding in CMUSphinx to allow for a maximal number of complete alignments. However, we had to exclude some captions where there were unintelligible words in particular at the beginning or in the middle of the audio, since such an issue disrupts the alignment procedure.

Considering possible inter-participant differences in terms of pronunciation, the quality of audio files, and possible noise in the background of recordings, we assume that the time intervals of the words we obtained after these pre-processing steps are approximate indicators. Although there might be a few cases where the alignment is not quite accurate, we find this way of obtaining utterance timestamps reliable in general. An example audio-caption alignment is shown in Figure 5.

B SSD: Further Details

SSD is the average of two terms, *gr* and *rg*, which quantify the overall distance between a generated sentence (G) and a reference sentence (R). Eq. 2 (identical to Eq. 1 in Section 4) shows the calculation from G to R and Eq. 3 from R to G:

$$gr = \sum_{i=1}^{N} cos(G_{\mathrm{i}}, R_s(i)) + pos(G_{\mathrm{i}}, R_s(i)) \quad (2)$$

$$rg = \sum_{j=1}^{M} cos(R_{\mathrm{j}}, G_s(j)) + pos(R_{\mathrm{j}}, G_s(j)) \quad (3)$$

N and M refer to number of tokens in G and R, respectively. Cosine and positional distances are

Type	**Description**	**SSD**	gr	rg
R G	een dubbeldekker bus een dubbeldekker bus in een stad	1.41	2.82	0.00
R G	een dubbeldekkerbus in uh in engeland een dubbeldekker bus in een stad	2.64	2.72	2.55
R G	een rustige straat met een bus tegemoetkomend naar <unk> nummer 43 een dubbeldekker bus die op een weg rijdt	5.87	4.31	7.43
R G	een bus met lijn 43 die aan het rijden is waarvan uh de bus uit twee <unk> bestaat een dubbeldekker bus	8.62	0.43	16.81

Table 3: Examples of SSD scores for several descriptions generated (G) by GAZE-2SEQ compared to the reference description (R). gr and rg indicate the direction of the calculation. Lower SSD scores are better.

computed between the i_{th} element of G and another token, which is the most semantically similar word to G_i in R. $R_s(i)$ is the most semantically similar word to G_i and $G_s(j)$ is the most semantically similar word to R_j:

$$R_s(i) = \underset{j}{\operatorname{argmin}}(cos(G_{\text{i}}, R_{\text{j}})) \tag{4}$$

$$G_s(j) = \underset{i}{\operatorname{argmin}}(cos(R_{\text{j}}, G_{\text{i}})) \tag{5}$$

Table 3 shows some example descriptions generated by the GAZE-2SEQ model and corresponding references for a single image. We report the overall SSD scores along with gr and rg values separately.

C Data Split Statistics

Table 4 lists the number of images belonging to each split after we divide the DIDEC corpus (description-view partition) with respect to the images. In addition, the total number of captions in each split is provided.

	train	**val**	**test**	**total**
Images	247	30	30	307
Captions	3658	444	446	4548

Table 4: Number of images and captions.

The number of human descriptions per image varies in DIDEC and as we also removed some captions during preprocessing, images do not have an equal number of captions. Therefore, we report the average number of captions per image for each split, as well as their range, in Table 5.

	train	**val**	**test**	**overall**
Avg	14.81	14.80	14.87	14.81
Min	11	12	13	11
Max	16	16	16	16

Table 5: Number of captions per image.

D Reproducibility

We implemented and trained our models in Python version 3.6[12] and PyTorch version 0.4.1.[13] All models were run on a computer cluster with Debian Linux OS. Each model used a single GPU GeForce 1080Ti, 11GB GDDR5X, with NVIDIA driver version: 418.56 and CUDA version: 10.1.

Pre-training with the translated MS COCO dataset took approximately 5 days. NO-GAZE and GAZE-AGG took around 1.5 hours and GAZE-SEQ and GAZE-2SEQ models took 2 hours to fine-tune over the pre-trained model.

Since the pre-trained model and the fine-tuned NO-GAZE, GAZE-AGG and GAZE-SEQ models use essentially the same architecture, they have an equal number of parameters: 85 million. GAZE-2SEQ has more parameters due to the addition of the Gaze LSTM: 100 million.

In all the models, the biases in linear layers were set to 0 and the weights were uniformly sampled from the range (-0.1, 0.1). Embedding weights were initialised uniformly in the range (-0.1, 0.1). LSTM hidden states were initialised to 0.

Below we give details regarding the manually-tuned hyperparameters.

D.1 Hyperparameters for Pre-Training

We experimented with learning rate (0.001, 0.0001), dimensions for the word embeddings and

---

[12] https://www.python.org/downloads/release/python-360/

[13] https://pytorch.org/

hidden representations (512, 1024) and batch size (64, 128). The best pre-trained model is selected based on its CIDEr score on the validation split of our translated MS COCO dataset, with an early-stopping patience of 20 epochs. We use a learning rate of 0.0001 optimising the Cross-Entropy Loss with the Adam optimiser. The batch size is 128. The image features have 2048 dimensions and the hidden representations 1024. The generations for the validation set are obtained through beam search with a beam width of 5.

D.2 Hyperparameters for Fine-tuning

We experimented with the same set of hyperparameters as in pre-training. The details of the hyperparameters for the selected models were given in the main text. We select the models separately based on CIDEr scores and SSD scores. We train each model type with their selected configuration with 5 different random seeds to set the random behaviour of PyTorch and NumPy. We also turn off the cuDNN benchmark and also set cuDNN to deterministic.

OPTIMUS: Organizing Sentences via Pre-trained Modeling of a Latent Space

Abstract

When trained effectively, the Variational Autoencoder (VAE) (Kingma and Welling, 2013; Bowman et al., 2016) can be both a powerful generative model and an effective representation learning framework for natural language. In this paper, we propose the first large-scale language VAE model OPTIMUS [1]. A universal latent embedding space for sentences is first pre-trained on large text corpus, and then fine-tuned for various language generation and understanding tasks. Compared with GPT-2, OPTIMUS enables guided language generation from an abstract level using the latent vectors. Compared with BERT, OPTIMUS can generalize better on low-resource language understanding tasks due to the smooth latent space structure. Extensive experimental results on a wide range of language tasks demonstrate the effectiveness of OPTIMUS. It achieves new state-of-the-art on VAE language modeling benchmarks.

1 Introduction

Pre-trained language models (PLMs) have substantially advanced the state-of-the-art across a variety of natural language processing (NLP) tasks (Peters et al., 2018; Devlin et al., 2019; Yang et al., 2019; Radford et al., 2019; Liu et al., 2019; Keskar et al., 2019; Shoeybi et al., 2019). PLMs are often trained to predict words based on their context on massive text data, and the learned models can be fine-tuned to adapt to various downstream tasks.

PLMs can generally play two different roles: (i) a generic *encoder* such as BERT (Devlin et al., 2019) to provide contextualized representations for language understanding tasks, and (ii) a powerful *decoder* such as GPT-2 (Radford et al., 2019) to generate text sequences in an auto-regressive manner. In a bid to combine language understanding and generation tasks in one unified framework, several model variants have been proposed, including UniLM (Dong et al., 2019), BART (Lewis et al., 2019), and T5 (Raffel et al., 2019). Although significant performance improvement has been reported on a wide range of NLP tasks, these models lack of explicit modeling of structures in a compact latent space, rendering it difficult to control language generation/representation from an abstract level.

Variational Autoencoders (VAEs) (Kingma and Welling, 2013; Rezende et al., 2014) provide a tractable method to train latent-variable generative models. In NLP, latent variables may assume the role of higher-level sentence representations, which govern a lower-level word-by-word generation process, thus facilitating controlled text generation (Bowman et al., 2016; Hu et al., 2017). By representing sentences in a low-dimensional latent space, VAEs allow easy manipulation of sentences using the corresponding *compact* vector representations, such as feature regularization specified by prior distributions, and guided sentence generation with interpretable vector operators. Despite the attractive theoretical strengths, the current language VAEs are often built with shallow network architectures, such as two-layer LSTMs (Hochreiter and Schmidhuber, 1997). This limits the model's capacity and leads to sub-optimal performance.

In this paper, we propose OPTIMUS, the first large-scale pre-trained deep latent variable models for natural language. OPTIMUS is pre-trained using the sentence-level (variational) auto-encoder objectives on large text corpus. This leads to a universal latent space to organize sentences (hence named OPTIMUS). OPTIMUS enjoys several favorable properties: (i) It combines the strengths of VAE, BERT and GPT, and supports both natural language understanding and generation tasks. (ii) Comparing to BERT, OPTIMUS learns a more structured semantic space due to the use of the prior distri-

[1] **O**rganizing sentences via **P**re-**T**ra**i**ned **M**odeling of a **U**niversal **S**pace

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4678–4699,
November 16–20, 2020.

bution in training. As a result, the language representations learned by OPTIMUS are more universal / general in that they can be more easily adapted to a new domain/task. (*iii*) Different from GPT-2, which generates human-like text but may lack effective means of controlling its high-level semantics (such as tense, topics, sentiment), OPTIMUS can be easily deployed for guided text generation. The effectiveness of OPTIMUS has been demonstrated with extensive experiments on language modeling, dialog response generation, text style transfer and low-resource language understanding. It achieves lower perplexity than GPT-2 on standard benchmarks, produces strong performance on guided text generation, and improves BERT on feature-based language understanding tasks. The code and pre-trained models are released on Github[2].

Along the way to build the first big VAE language model, there are several technical contributions/implications that are novel: (*i*) Latent vector injection: this work demonstrates two schemes to discuss how to effectively inject conditioning vectors into GPT-2 without re-training it. (*ii*) The design idea to combine BERT/GPT-2 serves as a practical recipe to inspire people to integrate and reuse existing PLMs for larger and complex models. (*iii*) Pre-training on massive datasets itself is an effective approach to reduce KL vanishing, as demonstrated by the state of-the-art performance on four VAE language modeling datasets. (*iv*) The proof of VAE objective from the lens of IB, showing that VAE is a principled approach to balance the compactness and usability of learned representations. (*v*) Improved performance on several language tasks shows the importance and necessity of pre-training a latent space.

2 Related Work

Difference with prior PLMs. Large-scale Transformer-based PLMs have recently achieved state-of-the-art performance on various natural language understanding and generation tasks (Devlin et al., 2019; Yang et al., 2019; Radford et al., 2019; Liu et al., 2019; Keskar et al., 2019). Prior to Transformer-based PLMs, non-generative methods have seen some early success in pre-training sequence models for supervised downstream tasks including standard sequence auto-encoders (Dai and Le, 2015; Li et al., 2015), skip-thought models (Kiros et al., 2015) and paragraph vector models (Le and Mikolov, 2014) *etc.* However, all of these models do not generally learn a smooth, interpretable feature space for sentence encoding, or generating novel sentences. In this work, we aim to fill the gap to learn such a universal latent space in the field of Transformer-based PLMs.

Latent variable language modeling. Language VAEs have inspired new applications in NLP, via exploiting many interesting properties of the model's latent space (Bowman et al., 2016; Kim et al., 2018b). Its modeling capacity and empirical performance is somewhat limited, partially due to the KL vanishing issue described in Section 4.3. Several attempts have been made to alleviate this issue, including different KL annealing/thresholding schemes (Bowman et al., 2016; Fu et al., 2019; Higgins et al., 2017; Li et al., 2019), decoder architectures (Yang et al., 2017; Dieng et al., 2018), auxiliary loss (Zhao et al., 2017), semi-amortized inference (Kim et al., 2018a), aggressive encoder training schedule (He et al., 2019), batch normalized inference (Zhu et al., 2020) and flexible posterior (Fang et al., 2019). Subramanian et al. (2018) have shown some promise that general encoder can benefit language generation. Transformers (Vaswani et al., 2017) are recently considered in VAEs for classification (Gururangan et al., 2019) and storytelling (Wang and Wan, 2019). Pre-training VAEs has been recently considered in conditional text generation to amortize the training of decoders and to allow easy adaptation in new generation tasks (Duan et al., 2019).

All these efforts utilize simple LSTM (Hochreiter and Schmidhuber, 1997) and shallow Transformer (Vaswani et al., 2017) architectures, thus with limited capacity. Our paper is the first big VAE model at the same scale of recent PLMs such as BERT and GPT-2. More importantly, we show that pre-training a meaningful latent space on a large text corpus can largely reduce the KL vanishing issue, and lead to new state-of-the-art performance.

3 Background on NLMs & GPT-2

To generate a text sequence of length T, $\boldsymbol{x} = [x_1, \cdots, x_T]$, neural language models (NLM) (Mikolov et al., 2010) generate every token x_t conditioned on the previous word tokens:

$$p(\boldsymbol{x}) = \prod_{t=1}^{T} p_{\boldsymbol{\theta}}(x_t | x_{<t}), \tag{1}$$

---

[2] `https://github.com/ChunyuanLI/Optimus`

where $x_{<t}$ indicates all tokens before t, and $\boldsymbol{\theta}$ is the model parameter. In NLMs, each one-step-ahead conditional in (1) is modeled by an expressive family of neural networks, and is typically trained via maximum likelihood estimate (MLE). Perhaps the most well-known NLM instance is GPT-2 (Radford et al., 2019), which employs Transformers (Vaswani et al., 2017) for each conditional, and $\boldsymbol{\theta}$ is learned on a huge amount of OpenWeb text corpus. GPT-2 has shown surprisingly realistic text generation results, and low perplexity on several benchmarks. GPT-3 (Brown et al., 2020) was recently proposed to further scale up NLMs to 175 billion parameters, showing impressive results on few-shot learning on multiple language tasks.

However, the only source of variation in NLMs, GPT2 and GPT3 is modeled in the conditionals at every step: the text generation process only depends on previous word tokens, and there is limited capacity for the generation to be guided by the higher-level structures that are likely presented in natural language, such as tense, topics or sentiment.

4 Pre-trained Latent Space Modeling

4.1 Pre-training Objectives

To facilitate high-level guidance in sentence generation, OPTIMUS organizes sentences in a universal latent (or semantic) space, via pre-training on large text corpora. Each sample in this space can be interpreted as outlines of the corresponding sentences, guiding the language generation process performed in the symbolic space (Subramanian et al., 2018). This naturally fits within the learning paradigm of latent variable models such as VAEs (Kingma and Welling, 2013; Bowman et al., 2016), where the latent representations capture the high-level semantics/patterns. It consists of two parts, generation and inference, enabling a bidirectional mapping between the latent space and symbolic space.

Generation The *generative model* (*decoder*) draws a latent vector $\boldsymbol{z}$ from the continuous latent space with prior $p(\boldsymbol{z})$, and generates the text sequence $\boldsymbol{x}$ from a conditional distribution $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$; $p(\boldsymbol{z})$ is typically assumed a multivariate Gaussian, and $\boldsymbol{\theta}$ represents the neural network parameters. The following auto-regressive decoding process is usually used:

$$p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) = \prod_{t=1}^{T} p_{\boldsymbol{\theta}}(x_t|x_{<t}, \boldsymbol{z}). \tag{2}$$

Intuitively, VAE provides a "hierachical" generation procedure: $\boldsymbol{z} \sim p(\boldsymbol{z})$ determines the high-level semantics, followed by (2) to produce the output sentences with low-level syntactic and lexical details. This contrasts with (1) in the explicit dependency on $\boldsymbol{z}$.

Inference Similar to GPT-2, parameters $\boldsymbol{\theta}$ are typically learned by maximizing the marginal log likelihood $\log p_{\boldsymbol{\theta}}(\boldsymbol{x}) = \log \int p(\boldsymbol{z}) p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \mathrm{d}\boldsymbol{z}$. However, this marginal term is intractable to compute for many decoder choices. Thus, variational inference is considered, and the true posterior $p_{\boldsymbol{\theta}}(\boldsymbol{z}|\boldsymbol{x}) \propto p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) p(\boldsymbol{z})$ is approximated via the variational distribution $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ is (often known as the *inference model* or *encoder*), implemented via a $\boldsymbol{\phi}$-parameterized neural network. It yields the *evidence lower bound objective* (ELBO):

$$\log p_{\boldsymbol{\theta}}(\boldsymbol{x}) \geq \mathcal{L}_{\text{ELBO}} = \tag{3}$$
$$\mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})} \big[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \big] - \mathrm{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) || p(\boldsymbol{z}))$$

Typically, $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ is modeled as a Gaussian distribution, and the re-parametrization trick is used for efficient learning (Kingma and Welling, 2013).

A Taxonomy of Autoencoders There is an alternative interpretation of the ELBO: the VAE objective can be viewed as a regularized version of the autoencoder (AE) (Goodfellow et al., 2016). It is thus natural to extend the negative of $\mathcal{L}_{\text{ELBO}}$ in (3) by introducing a hyper-parameter β to control the strength of regularization:

$$\mathcal{L}_{\beta} = \mathcal{L}_E + \beta \mathcal{L}_R, \quad \text{with} \tag{4}$$
$$\mathcal{L}_E = -\mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})} \big[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}) \big] \tag{5}$$
$$\mathcal{L}_R = \mathrm{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) || p(\boldsymbol{z})) \tag{6}$$

where $\mathcal{L}_E$ is the reconstruction error (or negative log-likelihood (NLL)), and $\mathcal{L}_R$ is a KL regularizer. The cost function $\mathcal{L}_{\beta}$ provides a unified perspective for understanding various autoencoder variants and training methods. We consider two types of latent space with the following objectives:

- **AE**. Only $\mathcal{L}_E$ is considered ($\beta = 0$), while the Gaussian sampling in $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$ remains. In other words, the regularization is removed, and a point-estimate is likely to be learned to represent the text sequence's latent feature. Note our reconstruction is on sentence-level, while other PLMs (Devlin et al., 2019; Yang et al., 2019) employ masked LM loss, performing token-level reconstruction.

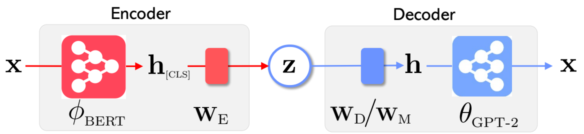

Figure 1: Illustration of OPTIMUS architecture.

- **VAE**. The full VAE objective is considered ($\beta > 0$). It tends to learn a smooth latent space due to $\mathcal{L}_R$.

Information Bottleneck Principle From an information theory perspective, *information bottleneck* (IB) provides a principled approach to find the trade-off between *predictive power* and *complexity (compactness)* when summarizing observed data in learned representations. We show that our OPTIMUS pre-training objectives effectively practice the IB principle as follows.

The objective in (4) shows the β-VAE loss for one single sentence $\boldsymbol{x}$. The training objective over the dataset $q(\boldsymbol{x})$ can be written as:

$$\mathcal{F}_\beta = -\mathcal{F}_E + \beta \mathcal{F}_R \tag{7}$$

where $\mathcal{F}_E = E_{q(\boldsymbol{x}),\boldsymbol{z}\sim q(\boldsymbol{z}|\boldsymbol{x})}[\log p(\tilde{\boldsymbol{x}}|\boldsymbol{z})]$ is the aggregated reconstruction term ($\tilde{\boldsymbol{x}}$ is the reconstruction target), and $\mathcal{F}_R = \mathbb{E}_{q(\boldsymbol{x})}[\mathrm{KL}(q(\boldsymbol{z}|\boldsymbol{x})||p(\boldsymbol{z}))]$ is the aggregated KL term. With the detailed proof shown in Section A of Appendix, we see that $\mathcal{F}_\beta$ is an upper bound of IB:

$$\mathcal{F}_\beta \geq -I_q(\boldsymbol{z}, \tilde{\boldsymbol{x}}) + \beta I_q(\boldsymbol{z}, \boldsymbol{x}) = \mathcal{L}_{\mathrm{IB}}, \tag{8}$$

where $\mathcal{L}_{\mathrm{IB}}$ is the Lagrange relaxation form of IB presented by Tishby et al. (2000), $I_q(\cdot,\cdot)$ is the mutual information (MI) measured by probability q. The goal of IB is to maximize the predictive power of $\boldsymbol{z}$ on target $\tilde{\boldsymbol{x}}$, subject to the constraint on the amount of information about original $\boldsymbol{x}$ that $\boldsymbol{z}$ carries. When $\beta = 0$, we have the AE variant of our OPTIMUS, the model fully focuses on maximizing the MI to recover sentences from the latent space. As β increases, the model gradually transits towards fitting the aggregated latent distribution $q(\boldsymbol{z}) = \int_{\boldsymbol{x}} q(\boldsymbol{z}|\boldsymbol{x})q(\boldsymbol{x})d\boldsymbol{x}$ to the given prior $p(\boldsymbol{z})$, leading the VAE variant of our OPTIMUS.

4.2 Model Architectures

The model architecture of OPTIMUS is composed of multi-layer Transformer-based encoder and decoder, based on the original implementation described in (Vaswani et al., 2017). The overall architecture is illustrated in Figure 1. To leverage the expressiveness power of existing PLMs, we initialize our encoder and decoder with weights of BERT $\boldsymbol{\phi}_{\mathrm{BERT}}$ and GPT-2 $\boldsymbol{\theta}_{\mathrm{GPT\text{-}2}}$, respectively. This procedure is seamless, as all of these models are trained in a self-supervised/unsupervised manner.

We denote the number of layers (*i.e.,* Transformer blocks) as L, the hidden size as H, and the number of self-attention heads as A. Specifically, we consider BERT$_{\mathrm{BASE}}$ (L=12, H=768, A=12, Total Parameters=110M) and GPT-2 (L=12, H=768, A=12, Total Parameters=117M). We hope that our approach can provide a practical recipe to inspire future work to integrate larger pre-trained encoder and decoder for higher performance models.

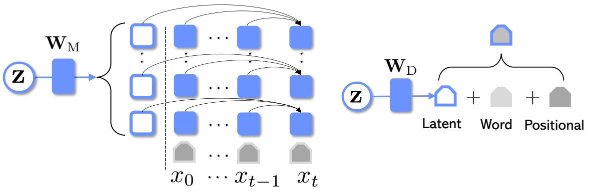
Connecting BERT & GPT-2 Two technical questions remain, when pre-training OPTIMUS from BERT & GPT-2: (*i*) How to represent sentences, since the two PLMs employ different tokenization schemes? (*ii*) How to adapt a pre-trained GPT-2 to arbitrary conditional input without re-training the model again? Controllable GPT-2 models have been studied in (Keskar et al., 2019; Zellers et al., 2019; Peng et al., 2020a,b) when prescribed control codes/tokens are provided, but it is still unknown how to ground GPT-2 to arbitrary conditional inputs.

Tokenization In BERT, WordPiece Embeddings (WPE) is used for tokenization (vocabulary size is 28996 for the cased version). In GPT-2, the modified Byte Pair Encoding (BPE) (Radford et al., 2019) is used for tokenization (vocabulary size is 50260). A given token is represented as $\boldsymbol{h}_{\mathrm{Emb}}$, by summing the corresponding token, position and segment embeddings [3]. For a sentence, we present it in both types of tokenization: the input of encoder is WPE, and the output of decoder is BPE to compute the reconstruction loss.

Latent Vector Injection Similar to BERT, the first token of every sentence is always a special classification token (`[CLS]`). The last-layer hidden state $\boldsymbol{h}_{\texttt{[CLS]}} \in \mathbb{R}^H$ corresponding to this token is used as the sentence-level representation. It further constructs the latent representation $\boldsymbol{z} = \mathbf{W}_{\mathrm{E}}\boldsymbol{h}_{\texttt{[CLS]}}$, where $\boldsymbol{z} \in \mathbb{R}^P$ is a P-dimensional vector and $\mathbf{W}_{\mathrm{E}} \in \mathbb{R}^{P\times H}$ is the weight matrix. To facilitate $\boldsymbol{z}$ in GPT-2 decoding without re-training the weights, we consider two schemes, illustrated in Figure 2:

---

[3] OPTIMUS does not require segment embeddings, but we remain it due to BERT initialization.



(a) Memory (b) Embedding

Figure 2: Illustration of two schemes to inject latent vector. (a) Memory: x_t attends both $x_{<t}$ and $\boldsymbol{h}_{\texttt{Mem}}$; (b) Embedding: latent embedding is added into old embeddings to construct new token embedding $\boldsymbol{h}'_{\texttt{Emb}}$.

- `Memory`: $\boldsymbol{z}$ plays the role of an additional *memory* vector $\boldsymbol{h}_{\texttt{Mem}}$ for GPT2 to attend. Specifically, $\boldsymbol{h}_{\texttt{Mem}} = \mathbf{W}_\mathrm{M}\boldsymbol{z}$, where $\mathbf{W}_\mathrm{M} \in \mathbb{R}^{LH \times P}$ is the weight matrix. $\boldsymbol{h}_{\texttt{Mem}} \in \mathbb{R}^{LH}$ is separated into L vectors of length H, each of which is attended by GPT-2 in one layer.
- `Embedding`: $\boldsymbol{z}$ is added on the original *embedding* layer, and directly used in every decoding step. The new embedding representation is $\boldsymbol{h}'_{\texttt{Emb}} = \boldsymbol{h}_{\texttt{Emb}} + \mathbf{W}_\mathrm{D}\boldsymbol{z}$, where $\mathbf{W}_\mathrm{D} \in \mathbb{R}^{H \times P}$.

We study their empirical performance in Section B.1 of Appendix, and observe that `Memory` is significantly more effective than `Embedding`, and the integration of both schemes yields slightly better results. We hypothesize that the reason why `Memory` is superior is because it allows the decoder to attend the latent information at every layer of the network directly, while the `Embedding` method only allows the decoder to see the latent information at the input and output layer. In our experiments, we use the integration scheme by default. In summary, the encoder parameters $\boldsymbol{\phi} = \{\boldsymbol{\phi}_{\text{BERT}}, \mathbf{W}_\mathrm{E}\}$, and decoder parameters $\boldsymbol{\theta} = \{\boldsymbol{\theta}_{\text{GPT-2}}, \mathbf{W}_\mathrm{M}, \mathbf{W}_\mathrm{D}\}$.

4.3 Learning Procedures

We train the model parameters $\{\boldsymbol{\phi}, \boldsymbol{\theta}\}$ using two objectives: AE and VAE, discussed in Section 4.1. Pre-training AE using (5) is straightforward. However, pre-training VAE can be challenging due to the notorious *KL vanishing* issue (Bowman et al., 2016), where (i) an encoder that produces posteriors almost identical to the Gaussian prior for all sentences (rather than a more interesting posterior); and (ii) a decoder that completely ignores $\boldsymbol{z}$ in (2), and a learned model that reduces to a simpler NLM.

To reduce this issue, we follow the intuition that if the encoder is providing useful information from the beginning of decoder training, the decoder is more likely to make use of $\boldsymbol{z}$ (Fu et al., 2019; He et al., 2019). Specifically, we use the cyclical schedule to anneal β for 10 periods (Fu et al., 2019). Within one period, there are three consecutive stages: Training AE ($\beta = 0$) for 0.5 proportion, annealing β from 0 to 1 for 0.25 proportion, and fixing $\beta = 1$ for 0.25 proportion. When $\beta > 0$, we use the KL thresholding scheme (Li et al., 2019; Kingma et al., 2016), and replace the KL term $\mathcal{L}_R$ in (6) with a hinge loss term that maxes each component of the original KL with a constant λ:

$$\mathcal{L}'_R = \sum_i \max[\lambda, \mathrm{KL}(q_{\boldsymbol{\phi}}(z_i|\boldsymbol{x})||p(z_i))] \qquad (9)$$

Here, z_i denotes the ith dimension of $\boldsymbol{z}$. Using the thresholding objective causes learning to give up driving down KL for dimensions of $\boldsymbol{z}$ that are already beneath the target compression rate.

Pre-training data The pre-training procedure largely follows the existing literature on language model pre-training. We use English Wikipedia to pre-train our AE and VAE objectives. As our main interest is to model sentences (rather than text sequences of a fixed length), we pre-process Wikipedia with maximum sentences length 64. It leads to 1990K sentences, which accounts 96.45% Wikipedia sentences used in BERT. More data preprocessing details are in Section B.2 of Appendix.

5 Experimental Results

We consider to apply the pre-trained OPTIMUS models to three types of downstream tasks: (i) language modeling, where OPTIMUS is compared with SoTA VAE methods and GPT-2. (ii) Guided language generation, where OPTIMUS shows its unique advantage in producing controllable sentences in contrast to GPT-2. (iii) Low-resource language understanding, where the learned structured latent features can be used for fast adaptation in new tasks.

5.1 Language Modeling

Fine-tuning LM on new datasets is straightforward. We load the pre-trained OPTIMUS, and update the model with one additional β scheduling cycle for one epoch. The semantic latent vectors are first pre-trained off-the-shelf, and then easily leveraged to train the decoder on downstream datasets. From this perspective, our pre-training can be viewed as an effective approach to reduce KL vanishing.

Table 1: Comparison on language modeling tasks on four datasets. "Small VAEs" indicate all previous language VAEs, which are built with two-layer LSTMs. All results for Small VAEs, LSTM-LM, LSTM-AE are quoted from literature, and GPT-2 results are produced by us. Best values are in blue. $\lambda = 0.50$ is a good trade-off to achieve the best values on all metrics compared with small VAEs. "-" indicates the models are improper to report these values; Empty cells indicate the results were not reported in the literature.

We consider four datasets: the Penn Treebank (`PTB`) (Marcus et al., 1993), `SNLI` (Bowman et al., 2015), `Yahoo`, and `Yelp` corpora (Yang et al., 2017; He et al., 2019).

Metrics There are two types of metrics to evaluate language VAEs. (*i*) Generation capability: we use *perplexity* (PPL). Note that NLM and GPT-2 has exactly PPL, while VAEs does not. Following (He et al., 2019), we use the importance weighted bound in (Burda et al., 2015) to approximate $\log p(\boldsymbol{x})$, and report PPL. (*ii*) Representation learning capability: Active units (AU) of $\boldsymbol{z}$ and its Mutual Information (MI) with $\boldsymbol{x}$. We report the full results with ELBO, KL and Reconstruction in Appendix, but note that higher ELBO does not necessarily yield better language modeling.

Baseline Methods (*i*) *GPT-2*. A large-scale LM trained on OpoenWebText (Radford et al., 2019). We load the pre-trained GPT-2 weights, and refine the model for 1 epoch on the new datasets. (*ii*) *Annealing*. β is gradually annealed from 0 to 1. This annealing procedure can be used once (M.A.) (Bowman et al., 2016) or multiple times (C.A.) (Fu et al., 2019). (*iii*) *Aggressive Training* (He et al., 2019). Training the encoder multiple times per decoder update. (*iv*) *AE-FB* (Li et al., 2019). Training AE, and then VAE using the KL thresholding in (9), the results on $\lambda = 0.50$ are reported as a good trade-off.

The results are shown in Table 1. Various λ values are used, we observe a trade-off between language modeling and representation learning, controlled by λ. Compared with existing VAE methods, Optimus achieve significantly lower perplexity, and higher MI/AU. This indicates that our pre-training method is an effective approach to reduce KL vanishing issue and training VAEs, especially given the fact that we only fine-tune on these datasets for one epoch. Optimus achieves lower perplexity compared with GPT-2 on three out of four datasets. Intuitively, this is because the model can leverage the prior language knowledge encoded in $\boldsymbol{z}$. This gap is larger, when the sentences in the dataset exhibit common regularities, such as `SNLI`, where the prior plays a more important/effective role in this scenario. Though the form of our model is simple, Optimus shows stronger empirical performance than sophisticated models that are particularly designed for long-text, such as hVAE in (Shen et al., 2019). For example, the KL and PPL of Optimus (15.09 and 22.79) are much better than hVAE (6.8 and 45.8) on Yelp dataset. This verifies the importance of pre-training a latent space. The full experimental results are shown in Table 8, 9, 10 and 11 of Appendix.

5.2 Guided Language Generation

Different from the traditional NLMs or GPT-2, VAEs learns bidirectional mappings between the

Source $\boldsymbol{x}_A$	**Target** $\boldsymbol{x}_B$
a girl makes a silly face	two soccer players are playing soccer
Input $\boldsymbol{x}_C$	**Output** $\boldsymbol{x}_D$
• a girl poses for a picture	• two soccer players are at a soccer game.
• a girl in a blue shirt is taking pictures of a microscope	• two football players in blue uniforms are at a field hockey game
• a woman with a red scarf looks at the stars	• two men in white uniforms are field hockey players
• a boy is taking a bath	• two baseball players are at the baseball diamond
• a little boy is eating a bowl of soup	• two men are in baseball practice

Table 2: Sentence transfer via arithmetic $\boldsymbol{z}_D = \boldsymbol{z}_B - \boldsymbol{z}_A + \boldsymbol{z}_C$. The output sentences are in blue.

latent and symbolic space. It enables high-level sentence editing as arithmetic latent vector operations, and thus allows guided language generation. The reason that Optimus supports arithmetic operations are two-fold: (1) Pre-training on large datasets with large networks allows all sentences to be densely and faithfully represented in the latent space. (2) The continuity property of neural nets and KL regularization of VAE encourage latent vectors with similar semantics are smoothly organized together.

This is demonstrated with two simple schemes to manipulate pre-trained latent spaces: sentence transfer and interpolation, with results in Table 2 and Table 3, respectively. Details and more results are shown in Appendix. They showcase that OPTIMUS enables new ways that one can play with language generation using pre-trained models, compared with GPT-2 that can only fulfill text sequences with given prompts. A website demo[4] is released to the public to interact with the model, exhibiting the power of latent-vector-based controllable text generation. We demonstrate more sophisticated ways to manipulate pre-trained latent spaces in three real applications as follows.

Metrics	Seq2Seq	CVAE	WAE	iVAE$_{\text{MI}}$	OPTIMUS
Recall↑	0.232	0.265	0.289	0.355	**0.362**
Precision↑	0.232	0.222	0.266	0.239	**0.313**
F1↑	0.232	0.242	0.277	0.285	**0.336**

Table 4: Dialog response generation on `DailyDialog` dataset. All numbers are from (Gu et al., 2019) except that iVAE$_{\text{MI}}$ is from (Fang et al., 2019).

Table 6: Label-conditional text generation on `Yelp`.

Dialog response generation The open-domain dialog response generation task is considered: generating responses $\boldsymbol{x}$ given a dialog history $\boldsymbol{c}$. Following (Gao et al., 2019a), we embed the history and response in a joint latent space as $\boldsymbol{z}_{\text{S2S}}$ and $\boldsymbol{z}_{\text{AE}}$, respectively. A fusion regularization is used to match the responses to the context. We consider `Dailydialog` (Li et al., 2017c) used in (Gu et al., 2019), which has 13,118 daily conversations. Each utterance is processed as the response of previous 10 context utterances from both speakers. The baseline methods are described in Appendix. We measure the performance using Bleu (Chen and Cherry, 2014), and compute the precision, recall and F1 in Table 4. OPTIMUS shows higher Bleu scores than all existing baselines.

Stylized response generation Following StyleFusion (Gao et al., 2019b), we consider generating responses for `Dailydialog` in the style of Holmes. The comparison is shown in Table 5. In addition to Bleu, we use neural and N-gram classifier scores

to evaluate the accuracy of the generated responses that belong to the desired style. Optimus achieves better performance on all metrics.

Label-conditional text generation The short `Yelp` dataset collected in (Shen et al., 2017) is used. It contains 444K training sentences, and we use separated datasets of 10K sentences for validation/testing, respectively. The goal is to generate text reviews given the positive/negative sentiment. We fine-tune Optimus using the VAE objective on the dataset, then freeze backbone weights. A conditional GAN (Mirza and Osindero, 2014) is trained on the fixed latent space. The generation process is to first produce a latent vector $\boldsymbol{z}_y$ based on a given label y using conditional GAN, then generate sentences conditioned on $\boldsymbol{z}_y$ using the decoder. The baselines are described in Appendix. G-score computes the geometric mean of Accuracy and Bleu, measuring the comprehensive quality of both content and style. Self-Bleu measures the diversity of the generated sentences. The results are shown in Table 6, Optimus achieves the best performance on all metrics. This verifies the importance of learning a smooth and meaningful latent space. The conditional generated sentences are shown in Appendix.

5.3 Low-resource Language Understanding

Due to the regularization term $\mathcal{L}_R$, Optimus can organize sentences in the way specified by the prior distribution. For basic VAEs, a smooth feature space is learned, which is specifically beneficial for better generalization when the number of task-specific labeled data is low. To have a fair comparison, we follow the BERT paper, where the hidden feature of `[CLS]` is used as the sentence-level representation. In this way, the linear classifiers for both models have the same number of trainable parameters. Though the latent vector $\boldsymbol{z}$ is typically used as sentence-level representation in VAE literature, we argue that the KL regularization applied on $\boldsymbol{z}$ has a large impact on the preceding layer feature $\boldsymbol{h}_{\texttt{[CLS]}}$. Specifically, $\boldsymbol{h}_{\texttt{[CLS]}}$ is fed into an linear classifier $\mathbf{W}_{\text{C}} \in \mathbb{R}^{K\times H}$, where K is the number of classes, with objective $-\log(\text{softmax}(\boldsymbol{h}_{\texttt{[CLS]}}\mathbf{W}_{\text{C}}^{\top}))$. Two schemes are used: (i) *Fine-tuning*, where both the pre-trained model and the classifier are updated; (ii) *Feature-based*, where pre-trained model weights are frozen to provide embeddings for the classifier update.

Sentiment classification on Yelp dataset. A varying number of training samples are randomly chosen, ranging from 1 to 10K per class. 10 trials are used when the number of available training samples are small, each is trained in 100 training epochs. The results are shown in Figure 3. When pre-trained models are used to provide sentence embeddings, the proposed Optimus consistently outperforms BERT. It demonstrates that the latent structure learned by Optimus is more separated, and helps generalize better. When the entire network is fine-tuned, Optimus can adapt faster than BERT, when the available number of training samples is small. The two methods perform quite similarly when more training data is provided. This is because the pre-trained backbone network size is much larger than the classifier, where the performance is dominated by the backbone networks.

Visualization of the latent space. We use tSNE (Maaten and Hinton, 2008) to visualize the learned feature on a 2D map. The validation set of Yelp is used to extract the latent features. Compared with BERT, Optimus learns a smoother space and more structured latent patterns, which explains why Optimus can yield better classification performance and faster adaptation.

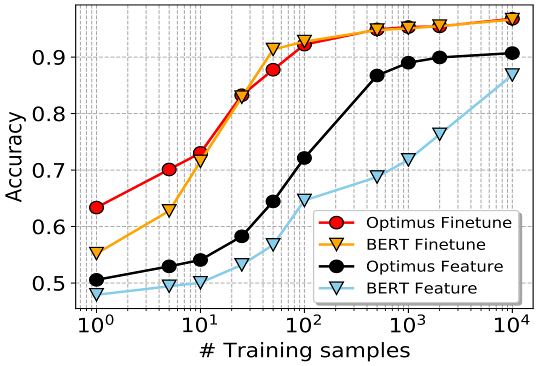

Figure 3: Testing accuracy with a varying number of labeled training samples per class on the `Yelp` dataset.

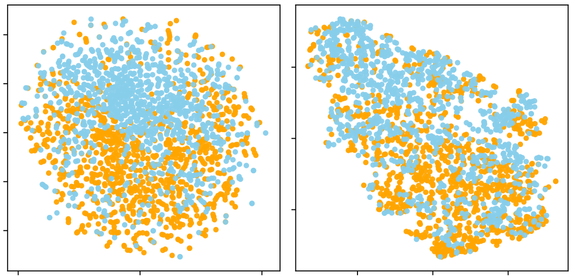

(a) OPTIMUS (b) BERT

Figure 4: Comparison of tSNE visualization for the learned features. The colors indicate different labels.

GLUE. We further consider the GLUE benchmark (Wang et al., 2019), which consists of nine datasets for general language understanding. Following the finetuning schedule in (Devlin et al., 2019), we use learning rate $[2, 3, 4, 5] \times 10^{-5}$ and train the model for 3 epochs. We select the best performance among different runs. We show the results on the validation set in Table 7. With the feature-based scheme, OPTIMUS yields higher performance than BERT, especially on the large datasets such as MNLI, QQP and QNLI. When the full models are fine-tuned, the two methods perform quite similarly.

In summary, the scenarios that OPTIMUS fit the low-resource settings are two-fold: (1) The required computing resource is low: the feature-based approach only updates the classifier, whose computing requirement is much lower than full-model fine-tuning; (2) The number of required labelled data is low: when labelled data is rare, OPTIMUS adapts better. The results confirm that OPTIMUS can maintain and exploit the structures learned in pre-training, and presents a more general representation that can be adapted to new tasks more easily than BERT – feature-based adaption is much faster and easier to perform than fine-tuning.

6 Discussion

We present OPTIMUS, a large-scale pre-trained deep latent variable model for natural language. It introduces a smooth and universal latent space, by combining the advantages of VAEs, BERT and GPT-2 in one model. Experimental results on a wide range of tasks and datasets have demonstrated the strong performance of OPTIMUS, including new state-of-the-art for language VAEs.

There are several limitations in current OPTIMUS. First, our pre-trained language VAE is still under-trained due to limited compute resource, as the training reconstruction loss can still decrease. One may further train the models with higher latent dimension and longer time to fully release the power of pre-trained latent spaces. Second, the current model can only control sentences of moderate length. One future direction is to consider more sophisticated mechanisms to gain stronger controllability over longer sentences while maintaining the compactness of latent representations.

While deep generative models (DGMs) such as VAEs are theoretically attractive due to its principle nature, it is now rarely used by practitioners in the modern pre-trained language modeling era where BERT/GPT dominate with strong empirical performance. That's why this paper makes a timely contribution to making DGMs practical for NLP. We hope that this paper will help renew interest in DGMs for this purpose. Hence, we deliberately keep a simple model, believing that the first pre-trained big VAE model itself and its implications are novel: it helps the community to recognize the importance of DGMs in the pre-training era, and revisit DGMs to make it more practical. Indeed, OPTIMUS is uniquely positioned to learn a smooth latent space to organize sentences, which can enable guided language generation compared with GPT-2, and yield better generalization in low-resource language understanding tasks than BERT.

Acknowledgments

The authors gratefully acknowledge Jason Yosinski, Changyou Chen, Yang Zhao and Le Fang for helpful discussion. Additional thanks go to the entire Project Philly team inside Microsoft, who provided us the computing platform for our research. The implementation in our experiments depends on open source GitHub repositories; we acknowledge all the authors who made their code public, which tremendously accelerates our project progress.

A Information Bottleneck and VAEs

Definition of IB Tishby et al. (2000) presented the Information Bottleneck (IB) method via solving the Lagrange relaxation of the optimization problem:

$$\min \mathcal{L}_{\text{IB}} = -I(\boldsymbol{z}; \tilde{\boldsymbol{x}}) + \beta I(\boldsymbol{z}; \boldsymbol{x}) \tag{10}$$

where $\boldsymbol{z}$ is the representation of $\boldsymbol{x}$, and β is a positive parameter that controls the trade-off between the compression of input $\boldsymbol{x}$ and preserved information about target $\tilde{\boldsymbol{x}}$.

In the following, we first show that the KL and reconstruction terms of VAE are the bounds of MI, respectively. Further, we put the bounds together, and show that VAE objective can optimize IB.

KL upper bounds MI Following (Makhzani et al., 2016), we refer to $q(\boldsymbol{z}) = \int_{\boldsymbol{x}} q(\boldsymbol{z}|\boldsymbol{x})q(\boldsymbol{x})d\boldsymbol{x}$ as the aggregated posterior. This marginal distribution captures the aggregated $\boldsymbol{z}$ over the entire dataset. The KL term (6) in can be decomposed into two refined terms (Chen et al., 2018; Hoffman and Johnson, 2016):

$$\begin{aligned}\mathcal{F}_R &= \mathbb{E}_{q(\boldsymbol{x})}[\text{KL}(q(\boldsymbol{z}|\boldsymbol{x})||p(\boldsymbol{z}))] \\ &= \underbrace{I_q(\boldsymbol{z}, \boldsymbol{x})}_{\mathcal{F}_1\text{: Mutual Info.}} + \underbrace{\text{KL}(q(\boldsymbol{z})||p(\boldsymbol{z}))}_{\mathcal{F}_2\text{: Marginal KL}} \\ &\geq I_q(\boldsymbol{z}, \boldsymbol{x})\end{aligned} \tag{11}$$

where $\mathcal{F}_1$ is the mutual information (MI) measured by q. Higher MI can lead to a higher correlation between the latent variable and data variable, and encourages a reduction in the degree of KL vanishing. The marginal KL is represented by $\mathcal{F}_2$, and it measures the fitness of the aggregated posterior to the prior distribution.

Reconstruction lower bounds MI The reconstruction term in (5) provides a lower bound for MI measured by q, based on Corollary 3 in (Li et al., 2017a):

$$\begin{aligned}\mathcal{F}_E &= E_{q(\boldsymbol{x}),\boldsymbol{z}\sim q(\boldsymbol{z}|\boldsymbol{x})}(\log p(\tilde{\boldsymbol{x}}|\boldsymbol{z}))] + H_q(\tilde{\boldsymbol{x}}) \\ &\leq I_q(\boldsymbol{z}, \tilde{\boldsymbol{x}})\end{aligned} \tag{12}$$

where $\tilde{\boldsymbol{x}}$ is the reconstruction target in our auto-encoder setting, and $H(\tilde{\boldsymbol{x}})$ is a constant.

VAE recovers BI When scheduled with β, the training objective over the dataset can be written as:

$$\mathcal{F}_\beta = -\mathcal{F}_E + \beta\mathcal{F}_R \tag{13}$$

$$\geq -I_q(\boldsymbol{z}, \tilde{\boldsymbol{x}}) + \beta I_q(\boldsymbol{z}, \boldsymbol{x}) \tag{14}$$

This recovers IB principle in (10). When $\beta = 0$, we have the AE variant of our OPTIMUS, the model fully focuses on maximizing the MI to recover sentence from the latent space. As β increases, the model gradually transits towards fitting the aggregated latent codes to the given prior, leading the VAE variant of our OPTIMUS.

B Pre-training Details

B.1 Latent Vector Injection Schemes

We compare three different schemes to inject latent vector into GPT2 in Figure 5:

- **Mem**. Latent vector $\boldsymbol{z}$ is used as additional *memory* token for GPT2 to attend.
- **Emb**. Latent vector $\boldsymbol{z}$ is used as additional *embedding* to add into other embeddings.
- **Mem+Emb**. The integration of the above two schemes.

On both Yelp and PTB datasets, 5 training epochs are considered. Yelp generally has longer sentences than PTB. The encoder is initialized with BERT, and decoder is initialized with GPT-2. Lower reconstruction error per word indicates a more effective approach to pass the information flow from encoder to decoder. We see that it is significantly more efficient to use $\boldsymbol{z}$ as a memory vector for GPT-2 to attend, than as the additional embedding. The combined scheme yields slightly better performance in the late stage of training. In the paper, we use the combined scheme in default.

B.2 Wikipedia Dataset

We illustrate the statistics of Wikipedia dataset in Figure 6. Since we focus on modeling natural sentences (rather than text sequences of a fixed length as in GPT-2 (Radford et al., 2019)) in a latent space, we pre-process Wikipedia into a set of natural sentences, with maximum sequence length as 64. This leads to 1990K sentences, which is 96.45% of entire Wikipedia dataset.

C Experiment Details

C.1 Language Modeling

In addition to generating high-quality sentences as in the traditional language models that only, VAEs also aim to learn a good posterior distribution in the latent space. The language modeling performance

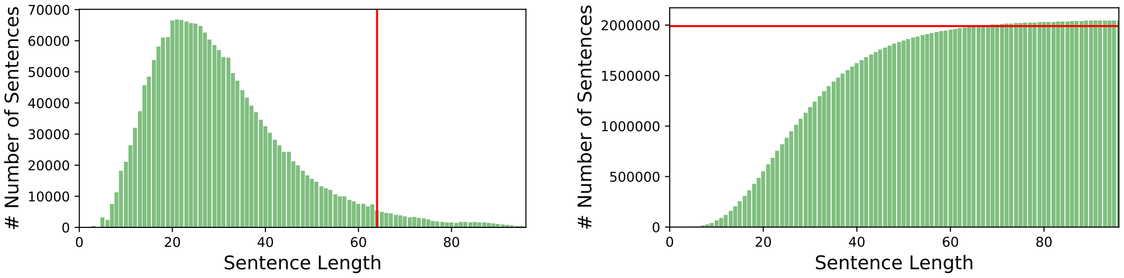
(b) PTB

Figure 5: Illustration of three different schemes to inject latent vector into GPT-2 for guided language generation: (a) Yelp and (b) PTB. The learning curves for reconstruction error per word is considered. `Emb` indicates latent vector is used as additional embedding to add into other embeddings, and `Mem` indicates latent vector is used as additional memory token for GPT2 to attend. `Mem+Emb` indicates the integration of two schemes.



(a) Frequency distribution

(b) Cumulative frequency distribution

Figure 6: Illustration of sentence distribution in Wikipedia dataset: (a) Frequency distribution and (b) Cumulative Frequency distribution. We choose maximum length as 64 to construct the pre-training dataset. It leads to 1990K sentences, which is 96.45% of entire Wikipedia dataset.

is evaluated with ELBO, perplexity (PPL) or importance weighted perplexity (He et al., 2019), which provides a tighter bound to $\log p(\boldsymbol{x})$. Higher ELBO and lower PPL indicate the model fits the observed sentences better. The pre-training takes around 50 hours for one epoch on eight V100 DGX2 GPU's.

- **ELBO**: The sum of KL divergence and reconstruction loss.
- **Perplexity.** $\text{PPL} = p(x_1, \cdots, x_N)^{-1/N}$, where N is the number of words. For latent variable models, we use a lower bound on the marginal log-likelihood $\log p(\boldsymbol{x})$, as follows from Jensen's Inequality and the fact that the average importance weights are an unbiased estimator of $p(\boldsymbol{x})$:

$$\mathcal{L}_k = \mathbb{E}\big[\log \frac{1}{k}\sum_{i=1}^{k} w_i\big]$$
$$\leq \log\big[\mathbb{E}\frac{1}{k}\sum_{i=1}^{k} w_i\big] = \log p(\boldsymbol{x}). \qquad (15)$$

where $w_i = p(\boldsymbol{x}, \boldsymbol{z}_i)/q(\boldsymbol{z}_i|\boldsymbol{x})$.

More importantly, we are interested in the learned $\boldsymbol{z}$, which is evaluated using the following three metrics:

- **AU**: The total number of active units in $\boldsymbol{z}$, defined as $A_z = \text{Cov}_{\boldsymbol{x}}(\mathbb{E}_{z\sim q(z|\boldsymbol{x})}[z]) > 0.01$ (Burda et al., 2015);
- **MI**: The mutual information $I(\boldsymbol{x}, \boldsymbol{z})$;
- **KL**: The posterior-prior KL divergence

The full experimental results on shown in Table 8, 9, 10 and 11.

C.2 Dialog response generation

Dialog response generation: SpaceFusion We interpolate samples $\boldsymbol{z}_\tau$ between the context and response as $\boldsymbol{z}_\tau = \tau\boldsymbol{z}_{\text{S2S}} + (1-\tau)\boldsymbol{z}_{\text{AE}}$, where $\tau \sim \text{Uniform}(0,1)$. We fix the first 11 layers of encoder, and fine-tune from last layer to $\boldsymbol{z}$: $\{\phi_{\text{AE}}, \phi_{\text{E}}\}$. An additional network path $\{\phi_{\text{S2S}}, \phi'_{\text{E}}\}$ is introduced

corresponding loss for the biased target is $\mathcal{L}'_{\boldsymbol{x}} = -[\tau \log p(\boldsymbol{x}|\boldsymbol{z}_{\text{Style}}) + (1-\tau) \log p(\boldsymbol{x}|\boldsymbol{z}_{\text{AE}})]$, which is added into $\mathcal{L}_{\text{dialog}}$ for training.

Evaluation Two type of *Accuracy* are reported, based on text sequence (*i.e.,* neural) and its N-gram information. The accuracy is assessed by an oracle classifier to correctly predict whether generated response belongs the style-reference dataset.

C.2.1 Label-Conditional Text Generation

The goal of this task is to generate sentences conditioned on a given label. We consider a two-stage algorithm to adapt OPTIMUS for this task. First, we fine-tune a VAE language model on the downstream dataset, and freeze the model parameters. In another word, the latent space is fixed. Second, we build a conditional GAN for the latent space. Let's denote the latent vectors for ground-truth sentences as $\boldsymbol{z}_{\text{true}}$. We build a generator G to produce $\boldsymbol{z}_{\text{fake}} = G(\epsilon, y)$, where ϵ is the random noise, and y is the label. A discriminator D is trained simultaneously to distinguish $\boldsymbol{z}_{\text{true}}$ and $\boldsymbol{z}_{\text{fake}}$. The learning objectives for conditional GAN is:

$$\min_G \max_D \mathcal{L}_{\text{cGAN}}$$
$$= \mathbb{E}_{\boldsymbol{x},y\sim q(\boldsymbol{x},y)} \left[\mathbb{E}_{\boldsymbol{z}\sim q(\boldsymbol{z}|\boldsymbol{x})} [\log p_D(d=1|E(\boldsymbol{x}))]\right.$$
$$\left. + \mathbb{E}_{\epsilon\sim p_0(\epsilon)} [\log p_D(d=0|G(\epsilon,y))]\right] \quad (16)$$

To make the model work effectively, it is key to learn a smooth and meaningful latent space of target sentences. The text generation procedure conditioned on label y is:

$$\boldsymbol{x} \sim p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z}), \quad \text{with} \quad \boldsymbol{z} = G(\epsilon, y) \quad (17)$$

This mimics the process to produce the outlines of the sentences using conditional GAN, and fill in details using the decoder. We show some generated sentences in Table 20.

We compare with three baselines: (1) *Ctrl-Gen* (Hu et al., 2017); We use their released code to reproduce the results. (2) *ARAE* (Zhao et al., 2018) proposes to learn an auto-encoder first, and then train a GAN to produce the latent vectors. (3) *NN-Outlines* (Subramanian et al., 2018) proposes the use of a general purpose encoder for text generation, and we implement it using BERT. Note that our two-stage fine-tuning scheme borrows the ideas from ARAE and NN-Outlines. The key difference is that we employ our pre-trained OPTIMUS model, and work on a better latent space.

Evaluation We consider three metrics: (1) *Bleu* for sentence quality, (2) *Accuracy* for conditional generation capability. The accuracy is assessed by an oracle classifier to correctly predict the attributes that generated sentences are conditioned on. (3) *G-score* is reported as the geometric mean of Accuracy and Bleu. This is the most important metric, as it evaluates the overall performance. For label-conditional text generation, Bleu of each generated sentence is computed by comparing with all sentences in the test set, as there are no source sentences. We further report Self-Bleu (Zhu et al., 2018) to evaluate the diversity of generated sentences.

C.3 Latent space interpolation & arithmetic operation

Arithmetic operation The universal latent space learned by OPTIMUS supports arithmetic operations. Given source sentence $\boldsymbol{x}_A$ and target $\boldsymbol{x}_B$, the goal is to re-write the input sentence $\boldsymbol{x}_C$ as output $\boldsymbol{x}_D$ in analogy to the transition from $\boldsymbol{x}_A$ to $\boldsymbol{x}_B$. We first encode $\boldsymbol{x}_{A,B,C}$ into the latent vectors $\boldsymbol{z}_{A,B,C}$, respectively, then apply the arithmetic operator $\boldsymbol{z}_D = \boldsymbol{z}_B - \boldsymbol{z}_A + \boldsymbol{z}_C$, and generate $\boldsymbol{x}_D$ conditioned on $\boldsymbol{z}_D$. One example is shown in Table 2. Interestingly, we observe consistent style transfer from $\boldsymbol{x}_C$ to $\boldsymbol{x}_D$, to analogize the relation from $\boldsymbol{x}_A$ to $\boldsymbol{x}_B$. For example, the subject is revised from singular to plural forms, the topic changes from daily-life to sport. In another word, OPTIMUS supports sentence arithmetic operator $\boldsymbol{x}_D \approx \boldsymbol{x}_B - \boldsymbol{x}_A + \boldsymbol{x}_C$ at the semantic level. More latent vector arithmetic operation examples are shown in Table 17, 18, 19.

Latent space interpolation One favorable property of VAEs is to provide a smooth space that captures sentence semantics. We demonstrate linear interpolating between latent vectors. We take two sentences $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, and use their posterior mean as the latent features $\boldsymbol{z}_1$ and $\boldsymbol{z}_2$, respectively. We interpolate a path $\boldsymbol{z}_\tau = \boldsymbol{z}_1 \cdot (1-\tau) + \boldsymbol{z}_2 \cdot \tau$ with τ increased from 0 to 1 by a step size of 0.1. Table 3 shows generated sentences using greedy decoding conditioned on $\boldsymbol{z}_\tau$. The interpolated sentences exhibit smooth semantic evolution. More interpolation examples are shown in Appendix. Note that we have observed smooth & meaningful interpolation results for almost arbitrary input sentences pairs. This demonstrates the promise that OPTIMUS learns a universal latent space. More latent space interpolation examples are shown in Table 13, 14, 15.

Limitations. While OPTIMUS shows the potentials of latent-vector-based controllable language generations, it has several limitations: (1) The compactness of latent vectors restricts the amount of encoded information, thus the model has difficulties in representing with long or complex sentences. This can be improved with more sophisticated design of latent space. (2) The model generates repeated interpolated sentences when intrinsic language variations are limited. (3) When doing interpolation, though the model knows the basic trend of numbers, it does not fully understand how to count numbers; For example, it jumps from one to five, then to twenty, instead of outputting the smoothly changing numbers such as one, five, ten, fifth, twenty.

For more user interaction with OPTIMUS, we have released a demo website to allows users to input sentences, and the system will provide controllable generated sentences with arithmetic or interpolating operations.

C.4 Ablation study on VAE & AE objectives

We compare the interpolation examples in Table 16, and generally observe that VAE can produce smoother sentences interpolation results than AE. We compare the two pre-training objectives on the GLUE benchmark using the feature-based approach. The results are shown in Table 7. We see that both objectives outperform than BERT on large datasets, and VAE objective performs better than AE objective. This verifies the effectiveness of smooth regularization on the latent space for the classification performance.

Metrics	Seq2Seq	SeqGAN	CVAE	VHRED	VHCR	WAE	iVAE$_{\text{MI}}$	Optimus

$\tau = 0.9$	there are children watching a train.	there are children watching a train.
$\tau = 1.0$	there are children watching a train.	there are children watching a train.

Table 16: Comparison of VAE and AE objective for latent space interpolation. VAE shows smoother interpolation results than AE.

Source $\boldsymbol{x}_A$	**Target** $\boldsymbol{x}_B$
two soccer players are playing soccer	the people are building a machine
Input $\boldsymbol{x}_C$	**Output** $\boldsymbol{x}_D$
• people walking in the street	• the people were going to build the city
• the man was waiting for his wife to come home	• the man was going to get the job done
• two women preparing food for a table	• the people carefully prepared a piece of equipment
• two dogs chase each other through the water	• the vehicles get to work
• a person sitting in a library reading	• a person working on the building
• a tall human walking	• a construction project was made
• a young boy and a young girl play in a grassy field	• a child is building a house for the future to see
• men playing music in the rain	• they were making a construction work

Table 17: Sentence transfer via arithmetic operation in the latent space. The output sentences are in blue. In this example, we see content transition from *relaxing* to *working*.

Source x_A	**Target x_B**
a girl makes a silly face	two soccer players are playing soccer
Input x_C	**Output x_D**
• a girl poses for a picture	• two soccer players are at a soccer game.
• a girl in a blue shirt is taking pictures of a microscope	• two football players in blue uniforms are at a field hockey game
• a woman with a red scarf looks at the stars	• two men in white uniforms are field hockey players
• a boy is taking a bath	• two baseball players are at the baseball diamond
• a little boy is eating a bowl of soup	• two men are in baseball practice
• a mother is feeding her baby	• football players are at home
• a black dog is running across a field in the middle of a snowy field	• two white and black soccer players are in the field in a soccer field
• some dogs are traveling to their owners	• dogs are in the field playing baseball
• the men were sitting on the bench at the gym for a long time	• men on the field are playing in the league championship game

Table 18: Sentence transfer via arithmetic operation in the latent space. The output sentences are in blue. In this example, we see two type of style transition: (1) from singular to plural subject, and (2) from daily-life activity to sport.

Source x_A	**Target x_B**
people are walking near a road.	a girl is riding a small white horse in a park with a large group of people
Input x_C	**Output x_D**
• some people are holding cameras	• a girl in a black and white costume is performing a trick on a toy gun.
• people are attending church	• a young girl is participating in a martial arts competition in the middle of the night.
• people eat at a restaurant.	• a girl plays a `[UNK]` in a carnival in a city.
• the dancers are asleep	• the female ballet dancer is performing a ballet in the middle of a ballet class.
• two dogs are reunited	• a young girl is the first to capture a black and white dog in a black and white toy.
• a person is fishing for water.	• a girl is flying a kite into a tropical storm with a tropical storm.
• a mother and daughter laugh as they walk home	• a young blond-haired girl is rescued from a sad death by a young blond-haired girl in a karate ballet costume.
• a female gymnast is performing for a crowd	• a young girl is a solo performer in a karate ballet ballet performance in a ballet performance
• a small dog is in water	• a little girl is a golden retriever in a blue and white striped striped swimsuit

Table 19: Sentence transfer via arithmetic operation in the latent space. The output sentences are in blue. In this example, we see two type of style transition: (1) from plural/old to singular/young subject, or and (2) sentences are expended.

Positive
our favorite place to get great coffee and taterts.
the best brunch you will find in vegas.
the best breakfast with meats is awesome!
great samosas and serve as a regular!
great place to meet up with a custom bean & wine.
a great selection of chinese food and always happy.
the free wi-fi is amazing as well!
great staff and freshly made latte is a must.
love the fresh staff as well!
highly recommend the place and sunbeams!
the staff is always great with homemade paesadillas.

Negative
not only did you get a headache upstairs, they were disgusting.
once i realized the pizza wasn’t decent, i cancelled.
instead of going to the bathroom you couldn’t find anything.
tonight i was unable to give the pizza any less.
i didn’t even bother to find a $ [num] frozen pizza.
no wonder i was dropped off at laundry.
not only was this place freezing, but the salad sucked.
then [num] bucks was ruined in my mouth.
love the fresh staff as well!
once you asked for chipotle its out of control.
another thing i refused to eat.

Abstract

There has been an influx of biomedical domain-specific language models, showing language models pre-trained on biomedical text perform better on biomedical domain benchmarks than those trained on general domain text corpora such as Wikipedia and Books. Yet, most works do not study the factors affecting each domain language application deeply. Additionally, the study of model size on domain-specific models has been mostly missing. We empirically study and evaluate several factors that can affect performance on domain language applications, such as the sub-word vocabulary set, model size, pre-training corpus, and domain transfer. We show consistent improvements on benchmarks with our larger BioMegatron model trained on a larger domain corpus, contributing to our understanding of domain language model applications. We demonstrate noticeable improvements over the previous state-of-the-art (SOTA) on standard biomedical NLP benchmarks of question answering, named entity recognition, and relation extraction. Code and checkpoints to reproduce our experiments are available at `github.com/NVIDIA/NeMo`.

1 Introduction

Effectively transferring the success of BERT (Devlin et al., 2018) to the biomedical domain, most notably Lee et al. (2019) (BioBERT) and Beltagy et al. (2019) (SciBERT) inspired a large number of similar works last year. For example, Peng et al. (2019); Alsentzer et al. (2019); Huang et al. (2019) added clinical text to the PubMed biomedical pre-training corpus and tested on standard biomedical and clinical NLP benchmarks. Many other similar works appeared at the ACL BioNLP Workshop (Demner-Fushman et al., 2019).

More recently, Gu et al. (2020) performed a comprehensive study on the pre-training corpus domain, language model masking method, and adversarial training, benchmarking on a number of different datasets for *token classification*, *sequence classification*, and *sequence regression*.

Compared to the previous works, we perform a more detailed study on *(1)* subword vocabulary, *(2)* labeling method, *(2)* model size, and *(3)* domain transfer, showing gains in *token classification*, *sequence classification*, and *question answering*.

2 Related Works

A prime example of Language Models (LMs) in the biomedical domain is BioBERT (Lee et al., 2019). It is a transformer LM pre-trained on the PubMed (`www.ncbi.nlm.nih.gov/pubmed`) biomedical text corpus comprised of biomedical literature abstracts. Their pre-training started from the checkpoint of Devlin et al. (2018) trained on Wikipedia and Books-Corpus. Independently, Beltagy et al. (2019) (SciBERT) pre-trained BERT from scratch using their vocabulary set on scientific text corpora, including PubMed abstracts and computer science papers. Both demonstrated increased performance over the previous non-BERT SOTA on biomedical benchmarks, including Named Entity Recognition (NER), Relation Extraction (RE), and Question Answering (QA). BioBERT and SciBERT report similar results on NER and RE, while only BioBERT report QA results.

They inspired other follow-up works (Alsentzer et al., 2019; Huang et al., 2019; Peng et al., 2019), most notably translating their success to the clinical domain, adding the MIMIC-III (Johnson et al., 2016) clinical text corpus. Gu et al. (2020) (PubMedBERT) used the PubMed full-text for pre-training in addition to the abstracts, and use a domain vocabulary set learned from PubMed corpus.

Meanwhile, they mostly report similar NER and RE tests and results, and only BioBERT reports QA

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4700–4706,
November 16–20, 2020.

results. Additionally, most use a $\text{BERT}_{\text{Base}}$ with 110M parameters. Peng et al. (2019) report slightly improved performance on RE using $\text{BERT}_{\text{Large}}$ while reporting worse results on NER, compared to $\text{BERT}_{\text{Base}}$. These results on biomedical tasks do not benefit from scaling model size to the same degree as standard NLP benchmarks such as GLUE or SQuAD (Shoeybi et al., 2019; Raffel et al., 2019).

3 Language Model Pre-training

$\text{BERT}_{\text{Base \& Large}}$ We compare our models to the pre-trained $\text{BERT}_{\text{Base \& Large}}$ models of BioBERT (Lee et al., 2019) and PubMedBERT (Gu et al., 2020) ($\text{BERT}_{\text{Base}}$) for fine-tuning and evaluation. For QA we use the $\text{BERT}_{\text{Large}}$ variant of BioBERT following the authors' recommendation.

BioMegatron Megatron-LM (Shoeybi et al., 2019) was introduced for efficient model parallel training of large LMs, with up to 8.3B parameters. Shoeybi et al. (2019) showed that rearranging the order of the layer normalization and the residual connections is critical to enabling the scaling of the BERT-style models beyond 336m parameters, and we use the same architecture.

Megatron-LM also used a larger pre-training text corpus, comprised of Wikipedia (Devlin et al., 2018), CC-Stories (Trinh and Le, 2018), RealNews (Zellers et al., 2019), and OpenWebtext (Radford et al., 2019). For our LM training, we use the 4.5 billion-word PubMed abstract set and the 1.6 billion-word CC0-licensed Commercial Use Collection of the PMC full-text corpus (`www.ncbi.nlm.nih.gov/pmc`).

We train three sizes of BioMegatron: with 345 million, 800 million, and 1.2 billion number of parameters. We compare four pre-training scenarios in the smallest 345m model - using BERT-cased/uncased vocabularies, each pre-trained from scratch and fine-tuned from general domain LM. We also compare two sets of domain vocabularies learned on PubMed text corpus using `SentencePiece` (github.com/google/sentencepiece) library, each containing 30k and 50k subword units.

We train the larger BioMegatron models with less variation: 800m models from scratch on PubMed with BERT -cased/-uncased vocabularies; and 1.2b model starting from general domain LM checkpoint using BERT-uncased vocabulary.

4 Downstream Benchmark Tasks

We use the most widely used downstream biomedical benchmark datasets for NER, RE, and QA.

Named Entity Recognition The BC5CDR (Li et al., 2016) NER dataset annotated *disease* and *chemical* terms with IOB tagging (Ramshaw and Marcus, 1999). In NCBI-disease (Doğan et al., 2014), only *disease* entities are IOB-tagged.

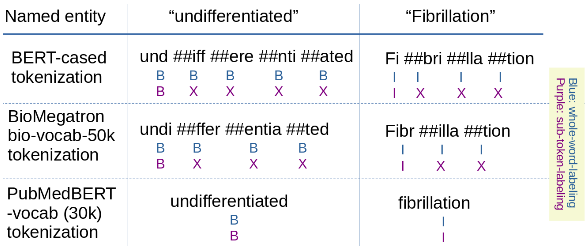
Relation Extraction The ChemProt (Krallinger et al., 2015) dataset contains sentences from PubMed abstracts, where chemical-protein interaction types are annotated as five categories. Relation Extraction is essentially a sequence classification task, classifying a set of sentences into a category.

Question Answering The BioASQ-7b factoid task (Tsatsaronis et al., 2015) is a biomedical QA dataset whose format is similar to the SQuAD dataset (Rajpurkar et al., 2016). In this task, context-snippet, question and answer triplets, and factoid question/answers are evaluated with *strict accuracy (SAcc)*, *lenient accuracy (LAcc)*, and *mean reciprocal rank (MRR)*.

5 Results and Discussion

The evaluation results on NER and RE are shown in Table 1, and QA are shown in Table 2. We perform entity-level F1 NER using the official CoNLL evaluation script translated into Python (`github.com/spyysalo/conlleval.py`). RE uses micro-level F1, and QA uses the BioASQ evaluation script (`github.com/BioASQ/Evaluation-Measures`).

5.1 Named Entity Recognition



Named entity	"undifferentiated"	"Fibrillation"
BERT-cased tokenization	und ##iff ##ere ##nti ##ated B B B B B B X X X X	Fi ##bri ##lla ##tion I I I I I X X X
BioMegatron bio-vocab-50k tokenization	undi ##ffer ##entia ##ted B B B B B X X X	Fibr ##illa ##tion I I I I X X
PubMedBERT -vocab (30k) tokenization	undifferentiated B B	fibrillation I I

Figure 1: Examples of tokenization with different subword vocabularies. Under each token, blue and purple text shows the word-level and subtoken-level labeling, respectively.

While the NER benchmark datasets appear saturated due to the small sample size, we find that the subword vocabulary is the most critical factor.

	Benchmark	Model	#Parameters	Vocabulary	Prec	Rec	F1
NER	BC5CDR-chem	BioBERT	110m	BERT-cased	90.0	93.4	91.7
		PubMedBERT	110m	PubMedBERT-vocab (30k)	92.1	93.2	92.6
		BioMegatron	**345m**	**Bio-vocab-30k**	92.1	**93.6**	**92.9**

		BioMegatron	**345m**	**Bio-vocab-50k**	86.1	**91.0**	**88.5**
		BioMegatron	800m	BERT-cased	85.8	90.1	87.9
		BioMegatron	1.2b	BERT-uncased	83.8	89.2	86.4
	NCBI-disease	BioBERT	110m	BERT-cased	85.0	90.0	87.5
		PubMedBERT	110m	PubMedBERT-uncased (30k)	85.9	87.7	86.8
		BioMegatron	345m	Bio-vocab-30k	85.6	88.6	87.1
		BioMegatron	345m	Bio-vocab-50k	83.7	**90.4**	87.0
		BioMegatron	**800m**	**BERT-cased**	**87.0**	88.8	**87.8**
		BioMegatron	1.2b	BERT-uncased	83.5	90.1	86.7
RE	ChemProt	BioBERT	110m	BERT-cased	76.5	73.3	74.8
		PubMedBERT	110m	PubMedBERT-uncased (30k)	73.6	77.7	75.6
		BioMegatron	345m	Bio-vocab-30k	77.8	72.5	75.1
		BioMegatron	**345m**	**Bio-vocab-50k**	74.5	**79.7**	**77.0**
		BioMegatron	800m	BERT-cased	80.4	68.9	74.3
		BioMegatron	1.2b	BERT-uncased	**82.0**	65.6	72.9

Table 1: Evaluation results on NER and RE after fine-tuning for 30 epochs with hyper-parameter settings of: `num-fc-layers`: {1, 2}; `fc-hidden-size`: {512, 1024}; `fc-dropout`: 0.5; `max-seq-length`: 128; `learning-rate`: 5e-5; cross-entropy loss, with Adam optimizer. BioMegatron models are pre-trained from scratch on PubMed, except 1.2b model which is fine-tuned from a general domain model checkpoint.

	Benchmark	Model	#Parameters	Vocabulary	SAcc	LAcc	MRR
QA	BioASQ-7b-factoid	BioBERT-Base	110m	BERT-cased	30.8	64.1	41.1
		BioBERT-Large	345m	BERT-cased	42.8	62.8	50.1
		BioMegatron	**345m**	**BERT-uncased**	46.2	**62.6**	**52.5**
		BioMegatron	800m	BERT-uncased	45.2	58.6	50.4
		BioMegatron	1.2b	BERT-uncased	**47.4**	60.9	52.4

Table 2: Evaluation results on QA after fine-tuning for 30 epochs on checkpoints fine-tuned on SQuAD dataset with fixed hyper-parameter settings as `num-fc-layers`: 2; `fc-hidden-size`: 2048; `fc-dropout`: 0.1; `max-seq-length`: 512; `learning-rate`: 3e-5; cross-entropy loss, using Adam optimizer. BioMegatron models are pre-trained from scratch on PubMed, except 1.2b model which is fine-tuned from a general domain model checkpoint.

Examples of tokenization with different vocabularies are shown in Figure 1. Representing named entities as single terms is more helpful than breaking them into several subtokens. Table 3 shows the rate named entities break into sub-tokens for each benchmark training set with different sub-word vocabularies. PubMedBERT vocabulary set is good with a low break-out rate while being smaller in size than our 50k-size vocabulary. A lower break-out rate with smaller vocabulary size probably helps achieve better NER performance despite smaller model size.

Sub-word vocabulary	BC5-chem	BC5-disease
BERT-cased	3.012	2.42
PubMedBERT-uncased (30k)	1.654	1.236
BioMegatron-bio-30k-cased	1.753	1.272
BioMegatron-bio-50k-cased	**1.478**	**1.116**

Table 3: The rate of named entities breaking into subtokens (#tokens/#words) in NER training sets.

There are two ways to label entities for NER training: *(1)* labeling the whole entity as a single label, and *(2)* labeling sub-tokens separately. Figure 1 shows examples of these labeling methods. We find that these different schemes can result in as much as ∼2% difference in the F1-score on NER evaluation, possibly indicating that the datasets are too small. We report NER results by labeling sub-tokens separately, except for the NCBI-disease dataset, where we observe better results with whole-entity labeling across all models.

5.2 Relation Extraction

Since RE is a classification task, albeit on sequences rather than on tokens, the choice of subword vocabulary has a notable effect.

We can also observe that larger models result in higher precision for lower recall, both for NER and RE. More hyper-parameter tuning could achieve higher F1-scores, even the generalization ability of such result may be questionable.

5.3 Question Answering

Table 2 show evaluation results after fine-tuning on SQuAD for 10 epochs and BioASQ for 30 epochs each, following the recipe found to work best by Lee et al. (2019). We found a large batch size to be beneficial, as Q&A pairs repeat up to 88 times. We use a batch size of 64 per GPU with data parallelism on 16 GPUs. Here, using biomedical vocabularies result in much worse results, possibly due to its low relevance in the first SQuAD fine-tuning task.

Larger models tend to perform better in QA, though it levels off after 345m parameters. The larger model size effect is more evident when fine-tuning on BioASQ directly, as shown in Table 4.

Model	SAcc	LAcc	MRR
BioMegatron-345m	33.1	50.4	39.8
BioMegatron-800m	37.7	56.3	45.1
BioMegatron-1.2b	**40.6**	**53.7**	**45.6**

Table 4: Results on BioASQ-7b factoid, without fine-tuning on SQuAD dataset first. The other models, including those using domain vocabularies, could not achieve any comparable results. A consistent pattern of improvement over model size noticeable on par with findings in general domain LM on SQuAD.

5.4 Domain Transfer and Generalization

We examine how well a general- or domain- specific LM generalizes across domains related to the model size. Gu et al. (2020) studied the effect of "domain-specific" vs. "mixed-domain" pre-training, i.e., pre-training on PubMed from scratch vs. pre-training starting from a general domain LM (fine-tuning). They found that pre-training on PubMed from scratch is better for biomedical NLP benchmarks, but we analyze its effect with further pre-training (fine-tuning) steps. In other words, if starting from a general domain LM, does sufficient fine-tuning make it as good as a fully domain-specific model? Can such model have any advantage for cross-domain or cross-discipline generalization?

	Benchmark	Fine-tuning steps	F1
NER	BC5CDR-chem	10^3 steps	63.2
		10^4 steps	74.3
		10^5 steps	89.7
		$2 \cdot 10^5$ steps	89.37
		$3 \cdot 10^5$ steps	91.8
		$4 \cdot 10^5$ steps	**92.1**
		$5 \cdot 10^5$ steps	91.2
	BC5CDR-disease	10^3 steps	39.4
		10^4 steps	63.6
		10^5 steps	79.8
		$2 \cdot 10^5$ steps	81.2
		$3 \cdot 10^5$ steps	79.2
		$4 \cdot 10^5$ steps	**81.9**
		$5 \cdot 10^5$ steps	81.8
RE	ChemProt	10^3 steps	0.00
		10^4 steps	34.1
		10^5 steps	63.4
		$2 \cdot 10^5$ steps	**71.1**
		$3 \cdot 10^5$ steps	70.4
		$4 \cdot 10^5$ steps	69.7
		$5 \cdot 10^5$ steps	68.3

Table 5: Comparison of fine-tuning steps for NER and RE benchmark when pre-training general-domain Megatron-1.2b model on PubMed. Cross-domain LMs should be trained sufficiently long on domain text to achieve comparable performance as LM pre-trained on domain text only.

Table 5 shows F1-score evaluation on NER and RE benchmarks using a general-domain BioMegatron-1.2b with additional fine tuning. It shows that even for a large LM that was pre-trained on a large text corpus, it needs sufficient further pre-training on domain text (PubMed). After sufficient pre-training on domain text, it can be as good as an LM pre-trained on domain-text only, except that vocabulary has more significant effect on NER.

Model	SAcc	LAcc	MRR
Megatron-345m (general LM)	**38.5**	**52.6**	**43.7**
Megatron-1.2b (general LM)	29.3	39.7	32.7

Table 6: Fine-tuning and evaluating on BioASQ-7b using general domain LMs that was not trained on PubMed corpus. Larger model does not perform better.

Table 6 shows the results of general-domain LMs fine-tuned on BioASQ-7b-factoid. Larger models do not perform better, which may indicate overfitting is occuring on the small training set.

Model	SQuAD-v1.1	SQuAD-v2.0
BioMegatron-345m	90.4	84.2
BioMegatron-345m-ft	86.5	77.9
BioMegatron-800m	91.6	86.1
BioMegatron-1.2b-ft	91.8	86.4
BERT$_{\text{LARGE}}$	90.9	81.8
RoBERTa	94.6	89.4
Megatron-3.9b	**95.8**	**91.2**

Table 7: Fine-tuning on SQuAD -v1.1/-v2.0 using BioMegatron and evaluating on F1-score on dev-set. BioMegatron with '-ft' are pre-trained from general domain checkpoints (fine-tuned). Results of other general domain LMs are compared: RoBERTa (Liu et al., 2019), Megatron-LM (Shoeybi et al., 2019).

Table 7 shows the generalization ability of BioMegatron models on SQuAD datasets. Here, a large biomedical LM pre-trained on large text corpus performs better than smaller general domain LMs such as BERT$_{\text{LARGE}}$, even when pre-trained on the biomedical text.

5.5 Other Domain-Specific Factors

Size and Bias in Biomedical Datasets Annotating biomedical data requires in-depth domain knowledge. Besides, data often have substantial label bias as the occurrences of "abnormal" or "findings" are rare by nature. As a result, biomedical benchmark data tend to be smaller and highly biased than their general domain counterparts.

Task	Dataset	# Samples	Bias %
NER	CONLL-2003	14987	0.18
	BC5CDR	5235	0.08
CLS	MRPC	3668	0.48
	ChemProt	19461	0.27
QA	SQuAD-v1.0	87599	0.4
	BioASQ-7b	5537	0.02

Table 8: Label bias in general and biomedical benchmark dataset. CONLL-2003 (Sang and De Meulder, 2003), MRPC (Dolan et al., 2005), and SQuAD (Rajpurkar et al., 2016) are general domain dataset for NER, CLS (RE), and QA, respectively, for comparison against biomedical domain dataset. Label bias is computed as [*sum of the #samples of minority labels*]/[*#samples of majority label*], for NER and RE (CLS), and [*#minimum repeat of the same answer*]/[*#maximum repeat of the same answer*] for QA.

Table 8 shows a comparison of benchmark datasets for NER, RE (CLS), and QA in the biomedical domain and their general-domain counterparts. The SQuAD Q&A set is 15 times larger than the BioASQ data, where the same question-answer combinations appear up to 88 times in BioASQ. Question-answer pairs are seldom repeated in SQuAD data, at most twice. The BC5CDR NER dataset is 1/3 size of CONLL-2003 and the ratio of `I`/`O` to `O` tags 0.08, compared to 0.18 for CONLL.

Methods to circumvent data imbalance issues such as oversampling the minority classes (Chawla et al., 2002; Chen et al., 2010) and using weighted cross-entropy gave minor effects on our NER and RE benchmarks. Recently, Li et al. (2019) proposed dice-loss for data-imbalance issues in NLP, with SOTA results on NER and QA, which could be a future avenue to explore for domain LMs. Transfer learning showed effectiveness in the biomedical QA task. However, it is somewhat unclear how to apply it to NER and RE tasks.

Model	PubMed Corpus	#Words
BioBERT	abstracts	4.5 billion
PubMedBERT	abstracts + full-text	16.8 billion
BioMegatron	abstracts + full-text-CC	6.1 billion

Table 9: Pre-training text corpus of each biomedical LM. We pre-train on PubMed abstracts and full-text commercial-collection (CC) that are free of copyrights.

Pre-training Corpus and Duration PubMedBERT is pre-trained on a much larger text corpus, as shown in Table 9. It is a performant domain-LM with a larger pre-training corpus and adequate domain vocabulary compared to its model size. We pre-train our LMs for about one epoch, reaching a masked-LM loss of about 1.2 (Devlin et al., 2018). Further pre-training may be helpful, but it is challenging to have strictly controlled experiments with many different settings.

6 Conclusion

We review and test several factors that can affect the performance of domain language models. We find that a language model targeted for a domain and application performs best. For example, model size is a secondary factor to vocabulary set for token classification task. Larger model size does not necessarily translate to better performance on a cross-domain benchmark task.

This probably indicates that there is no master model that can "do it all", at least well enough as a targeted one. The model size is a secondary factor; larger model size can probably further improve the performance of a a domain- and application-specific language model.

Abstract

Document and discourse segmentation are two fundamental NLP tasks pertaining to breaking up text into constituents, which are commonly used to help downstream tasks such as information retrieval or text summarization. In this work, we propose three transformer-based architectures and provide comprehensive comparisons with previously proposed approaches on three standard datasets. We establish a new state-of-the-art, reducing in particular the error rates by a large margin in all cases. We further analyze model sizes and find that we can build models with many fewer parameters while keeping good performance, thus facilitating real-world applications.

1 Introduction

Text segmentation is a traditional NLP task that breaks up text into constituents, according to predefined requirements. It can be applied to documents, in which case the objective is to create logically coherent sub-document units. These units, or segments, can be any structure of interest, such as paragraphs or sections. This task is often referred to as *document segmentation* or sometimes simply *text segmentation*. In Figure 1 we show one example of document segmentation from Wikipedia, on which the task is typically evaluated (Koshorek et al., 2018; Badjatiya et al., 2018).

Documents are often multi-modal, in that they cover multiple aspects and topics; breaking a document into uni-modal segments can help improve and/or speed up down stream applications. For example, document segmentation has been shown to improve information retrieval by indexing sub-document units instead of full documents (Llopis et al., 2002; Shtekh et al., 2018). Other applications such as summarization and information extraction can also benefit from text segmentation (Koshorek et al., 2018).

Early life and marriage:
Franklin Delano Roosevelt was born on January 30, 1882, in the Hudson Valley town of Hyde Park, New York, to businessman James Roosevelt I and his second wife, Sara Ann Delano. (...) Aides began to refer to her at the time as “the president’s girlfriend”, and gossip linking the two romantically appeared in the newspapers.

(...)

Legacy:
Roosevelt is widely considered to be one of the most important figures in the history of the United States, as well as one of the most influential figures of the 20th century. (...) Roosevelt has also appeared on several U.S. Postage stamps.

Figure 1: Illustration of text segmentation on the example of the Wikipedia page of President Roosevelt. The aim of document segmentation is breaking the raw text into a sequence of logically coherent sections (e.g., “Early life and marriage” and “Legacy” in our example).

A related task called *discourse segmentation* breaks up pieces of text into sub-sentence elements called Elementary Discourse Units (*EDUs*). EDUs are the minimal units in discourse analysis according to the Rhetorical Structure Theory (Mann and Thompson, 1988). In Figure 2 we show examples of EDU segmentations of sentences. For example, the sentence “Annuities are rarely a good idea at the age 35 because of withdrawal restrictions” decomposes into the following two EDUs: “Annuities are rarely a good idea at the age 35” and “because of withdrawal restrictions”, the first one being a statement and the second one being a justification in the discourse analysis. In addition to being a key step in discourse analysis (Joty et al., 2019), discourse segmentation has been shown to improve a number of downstream tasks, such as text summarization, by helping to identify fine-grained sub-sentence units that may have different levels of importance when creating a summary (Li et al., 2016).

Multiple neural approaches have been recently proposed for document and discourse segmentation. Koshorek et al. (2018) proposed the use of

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4707–4716,
November 16–20, 2020.

Sentence 1:
Annuities are rarely a good idea at the age 35 || because of withdrawal restrictions

Sentence 2:
Wanted: || An investment || that's as simple and secure as a certificate of deposit || but offers a return || worth getting excited about.

Figure 2: Example discourse segmentations from the RST-DT dataset (Carlson et al., 2001). In the segmentations, the EDUs are separated by the || character.

hierarchical Bi-LSTMs for document segmentation. Simultaneously, Li et al. (2018) introduced an attention-based model for both document segmentation and discourse segmentation, and Wang et al. (2018) obtained state of the art results on discourse segmentation using pretrained contextual embeddings (Peters et al., 2018). Also, a new large-scale dataset for document segmentation based on Wikipedia was introduced by Koshorek et al. (2018), providing a much more realistic setup for evaluation than the previously used small scale and often synthetic datasets such as the Choi dataset (Choi, 2000).

However, these approaches are evaluated on different datasets and as such have not been compared against one another. Furthermore they mostly rely on RNNs instead of the more recent transformers (Vaswani et al., 2017) and in most cases do not make use of contextual embeddings which have been shown to help in many classical NLP tasks (Devlin et al., 2018).

In this work we aim at addressing these limitations and make the following contributions:

1. We compare recent approaches that were proposed independently for text and/or discourse segmentation (Li et al., 2018; Koshorek et al., 2018; Wang et al., 2018) on three public datasets.
2. We introduce three new model architectures based on transformers and BERT-style contextual embeddings to the document and discourse segmentation tasks. We analyze the strengths and weaknesses of each architecture and establish a new state-of-the-art.
3. We show that a simple paradigm argued for by some of the earliest text segmentation algorithms can achieve competitive performance in the current neural era.
4. We conduct ablation studies analyzing the importance of context size and model size.

2 Literature review

Document segmentation Many early research efforts were focused on unsupervised text segmentation, doing so by quantifying lexical cohesion within small text segments (Hearst, 1997; Choi, 2000). Being hard to precisely define and quantify, lexical cohesion has often been approximated by counting word repetitions. Although computationally expensive, unsupervised Bayesian approaches have also been popular (Utiyama and Isahara, 2001; Eisenstein, 2009; Mota et al., 2019). However, unsupervised algorithms suffer from two main drawbacks: they are hard to specialize for a given domain and in most cases do not naturally deal with multi-scale issues. Indeed, the desired segmentation granularity (paragraph, section, chapter, etc.) is necessarily task dependent and supervised learning provides a way of addressing this property. Therefore, supervised algorithms have been a focus of many recent works.

In particular, multiple neural approaches have been proposed for the task. In one, a sequence labeling algorithm is proposed where each sentence is encoded using a Bi-LSTM over tokens, and then a Bi-LSTM over sentence encodings is used to label each sentence as ending a segment or not (Koshorek et al., 2018). Authors consider a large dataset based on Wikipedia, and report improvements over unsupervised text segmentation methods. In another work, a sequence-to-sequence model is proposed (Li et al., 2018), where the input is encoded using a BiGRU and segment endings are generated using a pointer network (Vinyals et al., 2015). The authors report significant improvements over sequence labeling approaches, however on a dataset composed of 700 artificial documents created by concatenating segments from random articles from the Brown corpus (Choi, 2000). Lastly, Badjatiya et al. (2018) consider an attention-based CNN-Bi-LSTM model and evaluate it on three small-scale datasets.

Discourse Segmentation Contrary to document segmentation, discourse segmentation has historically been framed as a supervised learning task. However, a challenge of applying supervised approaches for this type of segmentation is the fact that the available dataset for the task is limited (Carlson et al., 2001). For this reason, approaches for discourse segmentation usually rely on external annotations and resources to help the models generalize. Early approaches to discourse segmentation were based on features from linguistic annotations such as POS tags and parsing trees (Soricut and Marcu, 2003; Xuan Bach et al., 2012; Joty et al., 2015). The performance of these systems was highly dependent on the quality of the annotations.

Recent approaches started to rely on end-to-end neural network models that do not need linguistic annotations to obtain high-quality results, relying instead on pretrained models to obtain word or sentence representations. An example of such work is by Li et al. (2018), which proposes a sequence-to-sequence model getting a sequence of GloVe (Pennington et al., 2014) word embeddings as input and generating the EDU breaks. Another approach utilizes ELMO pretrained embeddings in the CRF-Bi-LSTM architecture and achieves state-of-the-art results on the task (Wang et al., 2018).

3 Architectures

We propose three model architectures for segmentation. One uses only local context around each candidate break, while the other two leverage the full context from the input (by candidate break, we mean any potential segment boundary).

All our models rely on the same preprocessing technique and simply feed the raw input into a word-piece (sub-word) tokenizer (Wu et al., 2016). We use the word-piece tokenizer implementation that was open-sourced as part of the BERT release (Devlin et al., 2018), more precisely its English, uncased variant, which has a vocabulary size of 30,522 word-pieces.

3.1 Cross-segment BERT

For our first model, we represent each candidate break by its left and right local contexts, i.e., the sequences of word-piece tokens that come before and after, respectively, the candidate break. The main motivation for this model is its simplicity; however, using only local contexts might be sub-optimal, as longer distance linguistic artifacts are likely to help locating breaks. Using such a simple model is a departure from recent trends favoring hierarchical models, which are conceptually appealing to model documents. However, it is also interesting to note that using local context was a common approach with earlier text segmentation models, such as (Hearst, 1997), which were studying semantic shift by comparing the word distributions before and after each candidate break.

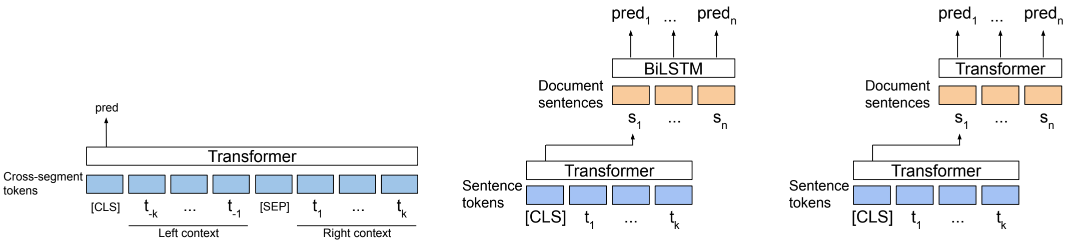
In Figure 3(a) we illustrate the model. The input is composed of a *[CLS]* token, followed by the two contexts concatenated together, and separated by a *[SEP]* token. When necessary, short contexts are padded to the left or to the right with *[PAD]* tokens. *[CLS]*, *[SEP]* and *[PAD]* are special tokens introduced by BERT (Devlin et al., 2018). They stand for, respectively, ”classification token” (since it is typically for classification tasks, as a representation of the entire input sequence), ”separator token” and ”padding token”. The input is then fed into a transformer encoder (Vaswani et al., 2017), which is initialized with the publicly available $\text{BERT}_{\text{LARGE}}$ model. The $\text{BERT}_{\text{LARGE}}$ model has 24 layers, uses 1024-dimensional embeddings and 16 attention heads. The model is then fine-tuned on each task. The released BERT checkpoint supports sequences of up to 512 tokens, so we keep at most 255 word-pieces for each side. We study the effect of length of the contexts, and denote the context configuration by n-m where n and m are the number of word piece tokens before and after the *[SEP]* token.

3.2 BERT+Bi-LSTM

Our second proposed model is illustrated in Figure 3(b). It starts by encoding each sentence with $\text{BERT}_{\text{LARGE}}$ independently. Then, the tensors produced for each sentence are fed into a Bi-LSTM that is responsible for capturing a representation of the sequence of sentences with an indefinite size.

When encoding each sentence with BERT, all the sequences start with a *[CLS]* token. If the segmentation decision is made at the sentence level (e.g., document segmentation), we use the *[CLS]* token as input of the LSTM. In cases in where the segmentation decision is made at the word level (e.g., discourse segmentation), we obtain BERT's full sequence output and use the left-most word-piece of each word as an input to LSTM. Note that, because the context is short for the discourse segmentation task, it is fully encoded in a single pass using BERT. Alternatively, one could encode each word independently; considering that many words consist of a single word-piece, encoding them with a deep transformer encoder would be somewhat wasteful of computing resources.

With this model, we reduce the BERT's inputs to a maximum sentence size of 64 tokens. Keeping this size small helps reduce training and inference times, since the computational cost of transformers



(a) Cross-Segment BERT (b) BERT+Bi-LSTM (c) Hierarchical BERT

Figure 3: Our proposed segmentation models, illustrating the document segmentation task. In the cross-segment BERT model (left), we feed a model with a local context surrounding a potential segment break: k tokens to the left and k tokens to the right. In the BERT+Bi-LSTM model (center) we first encode each sentence using a BERT model, and then feed the sentence representations into a Bi-LSTM. In the hierarchical BERT model (right), we first encode each sentence using BERT and then feed the output sentence representations in another transformer-based model.

(and self-attention in particular) increases quadratically with the input length. Then, the LSTM is responsible for handling the diverse and potentially large sequence of sentences with linear computational complexity. In practice, we set a maximum document length of 128 sentences. Longer documents are split into consecutive, non-overlapping chunks of 128 sentences and treated as independent documents.

In essense, the hierarchical nature of this model is close to the recent neural approaches such as (Koshorek et al., 2018).

3.3 Hierarchical BERT

Our third model is a hierarchical BERT model that also encodes full documents, replacing the document-level LSTM encoder from the BERT+Bi-LSTM model with a transformer encoder. This architecture is similar to the HIBERT model used for document summarization (Zhang et al., 2019), encoding each sentence independently. The $[CLS]$ token representations from sentences are passed into the document encoder, which is then able to relate the different sentences through cross-attention, as illustrated in Figure 3(c).

Due to the quadratic computational cost of transformers, we use the same limits as BERT+Bi-LSTM for input sequence sizes: 64 word-pieces per sentence and 128 sentences per document.

To keep the number of model parameters comparable with our other proposed models, we use 12 layers for both the sentence and the document encoders, for a total of 24 layers. In order to use the $\text{BERT}_{\text{Base}}$ checkpoint for these experiments, we use 12 attention heads and 768-dimensional word-piece embeddings.

We study two alternative initialization procedures:

- initializing both sentence and document encoders using $\text{BERT}_{\text{Base}}$
- pre-training all model weights on Wikipedia, using the procedure described in (Zhang et al., 2019), which can be summarized as a ”masked sentence” prediction objective, analogously to the ”masked token” pre-training objective from BERT.

We call this model hierarchical BERT for consistency with the literature.

4 Evaluation methodology

4.1 Datasets

We perform our experiments on datasets commonly used in the literature. Document segmentation experiments are done on Wiki-727K and Choi, while discourse segmentation experiments are done on the RST-DT dataset. We summarize statistics about the datasets in Table 1.

Wiki-727K The Wiki-727K dataset (Koshorek et al., 2018) contains 727 thousand articles from a snapshot of the English Wikipedia, which are randomly partitioned into train, development and test sets. We re-use the original splits provided by the authors. While several segmentation granularities are possible, the dataset is used to predict *section* boundaries. The average number of segments per document is 3.5, with an average segment length of 13.6 sentences.

We found that the preprocessing methodology used on the Wiki-727K dataset can have a noticeable effect on the final numerical results, in particular when filtering lists, code snippets and other special elements. We used the original preprocessing script (Koshorek et al., 2018) for a fair comparison.

Choi Choi's dataset (Choi, 2000) is an early dataset containing 700 synthetic documents made of concatenated extracts of news articles. Each document is made of 10 segments, where each segment was created by sampling a document from the Brown corpus and then sampling a random segment length up to 11 sentences.

This dataset was originally used to evaluate unsupervised segmentation algorithms, so it is somewhat ill-designed to evaluate supervised algorithms. We use this dataset as a best-effort attempt to allow comparison with some of the previous literature. However, we had to create our own splits as no standard splits exist: we randomly sampled 200 documents as a test set and 50 documents as a validation set, leaving 450 documents for training, following evaluation from Li et al. (2018). Since the Brown corpus only contains 500 documents, the same documents are sampled over and over, necessarily resulting in data leakage between the different splits. Its use should therefore be discouraged in future research.

RST-DT We perform experiments on discourse segmentation on the RST Discourse Treebank (RST-DT) (Carlson et al., 2001). The dataset is composed of 385 Wall Street Journal articles that are part of the Penn Treebank (Marcus et al., 1994), and is split into the train set composed of 347 articles and the test set composed of 38 articles. We found that the choice of a validation set (held out from the train set) has a large impact on model performance. For this reason, we conduct 10-fold cross validation and report the average over test set metrics.

Since this dataset is used for discourse segmentation, all the segmentation decisions are made at the intra-sentence level (i.e., the context that is used in the decisions is just a sentence). In order to make the evaluation consistent with other systems from the literature we decided to use the sentence splits that are available in the dataset, even though they are not human annotated. For this reason, there are cases in which some EDUs (which were manually annotated) overlap between two sentences. In such cases, we merge the two sentences.

	Docs	Sections	Sentences
Wiki-727K Train	582,146	2,025,358	26,988,063

RST-DT Train	347	7,028	19,443
RST-DT Test	38	864	2,346

Table 1: Statistics about the datasets.

4.2 Metrics

Following the trend of many studies on text segmentation (Soricut and Marcu, 2003; Li et al., 2018), we evaluate our approaches using Precision, Recall and F1-score with regard to the internal boundaries of the segments only. In our evaluation we do not include the last boundary of each sentence/document, because it would be trivial to categorize it as a positive boundary, which would lead to an artificial inflation of the results.

To allow comparison with the existing literature, we also use the P_k metric (Beeferman et al., 1999) to evaluate our results on the Choi's dataset (note that lower P_k scores indicate better performance). k is set, as is customary, to half the average segment size over the reference segmentation. The P_k metric is less harsh than the F1-score in that it takes into account near misses. It is important to note that P_k metric is known to suffer from biases, for example penalizing false negatives more than false positives and discounting errors close to the document extremities (Pevzner and Hearst, 2002).

5 Results

In Table 2, we report results from the document and discourse segmentation experiments on the three datasets presented in Section 4.1. We include several state-of-the-art baselines which had not been compared against one another before, as they have been proposed independently over a short time period: hierarchical Bi-LSTM (Koshorek et al., 2018), SEGBOT (Li et al., 2018) and Bi-LSTM+CRF+ELMO (Wang et al., 2018). We also include the human annotation baseline from (Wang et al., 2018), providing an additional reference point on the RST-DT dataset to the trained models. We estimate standard deviations for our proposed models and were able to calculate them from

	Wiki-727K			RST-DT			Choi

Table 2: Test set results on text segmentation and discourse segmentation for baselines and our models. Where possible, we estimate standard deviations by bootstrapping the test set 100 times.

the hierarchical Bi-LSTM, whose code and trained checkpoint were publicly released.

To train our models, we used the AdamW optimizer (Loshchilov and Hutter, 2017) with a 10% dropout rate as well as a linear warmup procedure. Learning rates are set between 1e-5 and 5e-6, chosen to maximize the F1-score on the validation sets from each dataset. For the more expensive models, and especially on the Wiki-727K dataset, we trained our models using Google Cloud TPUs.

We can see from the table that our models outperform the baselines across all datasets, reducing the relative error margins from the best baseline by 20%, 16% and 79% respectively on the Wiki-727K, RST-DT and Choi datasets. The improvements are statistically significant for all datasets. The errors are impressively low on the Choi dataset, but it is important to point out that it is a small-scale synthetic dataset, and as such limited. Since each document is a concatenation of extracts from random news articles, it is an artificially easy task for which a previous neural baseline achieved an already low error margin. Moreover, on this dataset, the cross-segment BERT model obtains very good results compared to the hierarchical models which do not attend across the candidate break. This aligns with the expectation that locally attending across a segment break is sufficient here, as we expect large semantic shifts due to the artificial nature of the dataset.

Hierarchical models, with a sentence encoder followed by a document encoder, perform well on the RST-DT dataset. As a reminder, this discourse segmentation task is about segmenting individual sentences so there is no notion of document context. In order to study whether the hierarchical structure is really necessary for discourse segmentation, we also trained a model without the Bi-LSTM (that is, making predictions directly using BERT): this decreased the F1-score by 0.4%. It is also worth noting that several known LSTM downsides were particularly apparent on the Wiki-727K dataset: the model was harder to train and significantly slower during both training and inference.

Regarding the hierarchical BERT model, different initialization methods were used for the two document segmentation datasets. On the Choi dataset, a HIBERT initialization (a model fully pre-trained end-to-end for hierarchical BERT, similarly to (Zhang et al., 2019) was necessary to get good results, due the small dataset size. On the contrary, we obtained slightly better results initializing both levels of the hierarchy with $\text{BERT}_{\text{Base}}$ on the Wiki-727K dataset, even though the model took longer to converge. Other initializations, e.g., random for both levels of the hierarchy or $\text{BERT}_{\text{Base}}$ at the lower level and random at the upper level, gave worse results.

Perhaps the most surprising result from Table 2 is the good performance of our cross-segment BERT model across all datasets, since it only relies on local context to make predictions. And while the BERT checkpoints were pre-trained using (among other things) the next-sentence prediction task, it was not clear a priori that our cross-segment BERT model would be able to detect much more subtle semantic shifts. To further evaluate the effectiveness of this model, we tried using longer contexts. In particular, we considered using a cross-segment BERT with 255-255 contexts, achieving 67.1 F1, 73.9 recall and 61.5 precision scores. Therefore, we can see that encoding the full document in a hierarchical manner using transformers does not improve over cross-segment BERT on this dataset. This suggests that BERT self-attention mechanism applied across candidate segment breaks, with a limited context, is in this case just as powerful as separately encoding each sentence and then allowing a flow of information across encoded sentences. In the next section we further analyze the impact of context length on the results from the cross-segment BERT model.

6 Analyses

In this section we perform additional analyses and ablation studies to better understand our segmentation models.

Experiments revolve around the cross-segment BERT model. We choose this model because it has several advantages over its alternatives:

- It outperforms all baselines previously reported as state-of-the-art, and its results are competitive with the more complex hierarchical approaches we considered.
- It is conceptually close to the original BERT model (Devlin et al., 2018), whose code is open-source, and is as such simple to implement.
- It only uses local document context and therefore does not require encoding an entire document to segment a potentially small piece of text of interest.

One application for text segmentation is in assisting a document writer in composing a document, for example to save them time and effort. The task proposed by Lukasik and Zens (2018), aligned with what industrial applications such as Google Docs Explore provide, was to recommend related entities to a writer in real time. However, text segmentation could also help authors in structuring their document better by suggesting where a section break might be appropriate. Motivated by this application, we next analyze how much context is needed to reliably predict a section break.

6.1 Role of trailing context size

For the aforementioned application, it would be helpful to use as little trailing (after-the-break) context as possible. This way, we can suggest section breaks sooner. Reducing the context size also speeds up the model (as cost is quadratic in sequence length). To this end, we study the effect of trailing context size, going from 128 word-piece tokens down to 0. For this set of experiments, we held the leading context size fixed at 128 tokens, and tuned $\text{BERT}_{\text{BASE}}$ with a batch size of 1536 examples and a learning rate of 5e-5. The results for these 128-n experiments are shown in Figure 4.

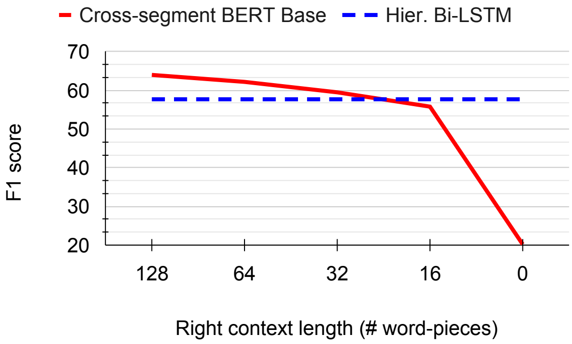

Figure 4: Analysis of the importance of the right context length (solid red line). Dashed blue line denotes the hierarchical Bi-LSTM baseline encoding the full context (Koshorek et al., 2018).

While the results are intuitive, it is not clear whether the performance drops because of smaller trailing context or because of smaller overall context. To answer this, we ran another experiment with 256 tokens on the left and 0 tokens on the right (256-0). With all else being the same, this 256-0 experiment attains F1 score of 20.2. This is much smaller than 64.0 F1 with 128 tokens on each side of the proposed break. Clearly, it is crucial that the model sees both sides of the break. This aligns with the intuition that word distributions before and after a true segment break are typically quite different (Hearst, 1997). However, presenting the model with just the distributions of tokens on either side of the proposed break leads to poor performance: in another experiment, we replaced the running text on either side with a sorted list of 128 most frequent tokens seen in a larger context (256 tokens) on either side, padding as necessary, and tuned $\text{BERT}_{\text{BASE}}$ with all else the same. This 128-128 experiment attains 39.1 F1 score, compared to 64.0 with 128-128 running text on either side. This suggests that high-performing models are doing more than just counting tokens on each side to detect semantic shift.

6.2 Role of Transformer architecture

The best cross-segment BERT model relies on $\text{BERT}_{\text{Large}}$. While powerful, this model is slow and expensive to run. For large-scale applications such as offline analysis for web search or online document processing such as Google Docs or Microsoft Office, such large models are prohibitively expensive. Table 3 shows the effect of model size on performance. For these experiments, we initialized the training with models pre-trained as in the

Architecture	Parameters	F1

Table 3: Effect of model architecture on Wiki-727K results.

BERT paper (Devlin et al., 2018). The first two experiments are initialized with $\text{BERT}_{\text{LARGE}}$ and $\text{BERT}_{\text{BASE}}$ respectively.

Overall, the larger the model, the better the performance. These experiments also suggest that, in addition to the size, the configuration also matters. A 128-dimensional model with more layers can outperform a 256-dimensional model with fewer layers. While the new state-of-the-art is several standard deviations better than the previous one (as reported in Table 2), this gain came at a steep cost in the model size. This is unsatisfactory, as large size hinders the possibility of using the model at scale and with low latency, which is desirable for this application (Wang et al., 2018). In the next section, we explore smaller models with better performance using model distillation.

6.3 Model distillation

As can be seen from the previous section, performance degrades quite quickly as smaller and therefore more practical networks are used. An alternative to the pre-training/fine-tuning approach used above is distillation, which is a popular technique to build small networks (Bucila et al., 2006; Hinton et al., 2015). Instead of training directly a small model on the segmentation data with binary labels, we can instead leverage the knowledge learnt by our best network —called in this context the 'teacher'— as follows. First, we record the predictions, or more precisely the output logits, from the teacher model on the full dataset. Then, a small 'student' model is trained using a combination of a cross-entropy loss with the true labels, and a MSE loss to mimick the teacher logits. The relative weight between the two objectives is treated as a hyperparameter.

Distillation results are presented in Table 4. We can see that the distilled models perform better than models trained directly on the training data without a teacher, increasing F1-scores by over 4 points. We notice that distillation allows much more compact models to significantly outperform the previous state-of-the-art. Unfortunately, we cannot directly compare model sizes with (Koshorek et al., 2018) since they rely on a subset of the embeddings from a public word2vec archive that includes over 3M vocabulary items, including phrases, most of which are likely never used by the model. It is however fair to say their hierarchical Bi-LSTM model relies on dozens of millions of embedding parameters (even though these are not fine-tuned during training) as well as several million LSTM parameters.

Architecture	Parameters	F1

7 Conclusion

In this paper, we introduce three new model architectures for text segmentation tasks: a cross-segment BERT model that uses only local context around candidate breaks, as well as two hierarchical models, BERT+Bi-LSTM and hierarchical BERT. We evaluated these three models on document and discourse segmentation using three standard datasets, and compared them with other recent neural approaches. Our experiments showed that all of our models improve the current state-of-the-art. In particular, we found that a cross-segment BERT model is extremely competitive with hierarchical models which have been the focus of recent research efforts (Chalkidis et al., 2019; Zhang et al., 2019). This is surprising as it suggests that local context is sufficient in many cases. Due to its simplicity, we suggest at least trying it as a baseline when tackling other segmentation problems and datasets.

Naturally these results do not imply that hierarchical models should be disregarded. We showed they are strong contenders and we are convinced there are applications where local context is not sufficient. We tried several encoders at the upper-level of the hierarchy. Our experiments suggest that deep transformer encoders are useful for encoding long and complex inputs, e.g., documents for document segmentation applications, while Bi-

LSTMs proved useful for discourse segmentation. Moreover, RNNs in general may also be useful for very long documents as they are able to deal with very long input sequences.

Finally, we performed ablation studies to better understand the role of context and model size. Consequently, we showed that distillation is an effective technique to build much more compact models to use in practical settings.

In future work, we plan to further investigate how different techniques apply to the problem of text segmentation, including data augmentation (Wei and Zou, 2019; Lukasik et al., 2020b) and methods for regularization and mitigating labeling noise (Jiang et al., 2020; Lukasik et al., 2020a).

Abstract

In this paper, we introduce an advanced Russian general language understanding evaluation benchmark – RussianGLUE.

Recent advances in the field of universal language models and transformers require the development of a methodology for their broad diagnostics and testing for general intellectual skills - detection of natural language inference, commonsense reasoning, ability to perform simple logical operations regardless of text subject or lexicon. For the first time, a benchmark of nine tasks, collected and organized analogically to the SuperGLUE methodology (Wang et al., 2019), was developed from scratch for the Russian language. We provide baselines, human level evaluation, an open-source framework for evaluating models and an overall leaderboard of transformer models for the Russian language.

Besides, we present the first results of comparing multilingual models in the adapted diagnostic test set and offer the first steps to further expanding or assessing state-of-the-art models independently of language.

1 Introduction

With the development of technologies for text processing and then deep learning methods for obtaining better text representation, language models went through the increasingly advanced stages of natural language modelling.

Modern scientific methodology is beginning to gradually explore universal transformers as an independent object of study - furthermore, such models show the ability to extract causal relationships in texts (natural language inference), common sense and world knowledge and logic (textual entailment), to generate coherent and correct texts. An actively developing field of model interpretation develops testing procedures comparing their performance to a human level and even the ability to reproduce some mechanisms of human brain functions.

NLP is gradually absorbing all the new areas responsible for the mechanisms of thinking and the theory of artificial intelligence.

Benchmark approaches are being developed, testing general intellectual "abilities" in a text format, including complex input content, but having a simple output format. Most of these benchmarks (for more details see Section 2) make the development of machine intelligence anglo-centric, while other, less widespread languages, in particular Russian, have other characteristic linguistic categories to be tested.

In this paper, we expand the linguistic diversity of the testing methodology and present the first benchmark for evaluating universal language models and transformers for the Russian language, together with a portable methodology for collecting and filtering the data for other languages.

The contribution of RussianGLUE is two-fold. First, it provides nine novel datasets for the Russian language covering a wide scope of NLU tasks. The choice of the tasks are justified by the design of prior NLU benchmarks (Wang et al., 2018, 2019). Second, we evaluate two widely used deep models to establish baselines.

The remainder is structured as follows. We overview multiple prior works on developing NLU benchmarks, including those designed for languages other than English, in Section 2. Section 3.1 lists the tasks and novel datasets, proposed for the Russian NLU. Section 4 presents with the baselines, established for the tasks, including a human level baseline. We overview compare achieved results in Section 2 to the current state of English NLU. We discuss future work directions and emphasize the importance of NLU benchmarks for languages other than English in Section 6. Section 7 concludes.

November 16–20, 2020.

2 Related Work

Several benchmarks have been developed to evaluate and analyze word and sentence embeddings over the past few years.

SentEval (Conneau and Kiela, 2018) is one of the first frameworks intended to evaluate the quality of sentence embeddings. A twofold set of transfer tasks is used to assess the generalization power of sentence embedding models. The transfer tasks comprise downstream tasks, in which the sentence embedding is used as a feature vector, and probing tasks, which are aimed to evaluate the capability of sentence embeddings to encode linguistic properties. The choice of the downstream tasks is limited to sentiment classification, natural language inference, paraphrase detection and image captioning tasks. The probing tasks are meant to analyse morphological, syntactical and semantical information encoded in sentence embeddings.

The General Language Understanding Evaluation (GLUE) (Wang et al., 2018) benchmark is a collection of tools for evaluating the performance of language models across a diverse set of existing natural language understanding (NLU) tasks, adopted from different sources. These tasks are divided into two parts: single sentence classification tasks and sentence pair classifications tasks subdivided further into similarity and inference tasks. GLUE also includes a hand-crafted diagnostic test, which probes for complex linguistic phenomena, such as the ability of the model to express lexical semantics and predicate-argument structure, to pose logical apparatus and knowledge representation. GLUE is recognized as a de-facto standard benchmark to evaluate transformer-derived language models. Last but not least GLUE informs on human baselines for the tasks, so that not only submitted models are compared to the baseline, but also to the human performance. The SuperGLUE (Wang et al., 2019) follows GLUE paradigm for language model evaluation based on NLU tasks, providing with more complex tasks, of which some require reasoning capabilities and some are aimed at detecting ethical biases. A few recent projects reveal that GLUE tasks may be not sophisticated enough and do not require much tasks-specific linguistic knowledge (Kovaleva et al., 2019; Warstadt et al., 2019). Thus SuperGLUE benchmark, being more challenging, becomes much more preferable for evaluation of language models.

decaNLP (McCann et al., 2018) widens the scope for language model evaluation by introducing ten disparate natural language tasks. These tasks comprise not only text classification problems, but sequence tagging and sequence transformation problems. The latter include machine translation and text summarization, while the former include semantic parsing and semantic role labelling. Although decaNLP along with the associated research direction focuses on multi-task learning as a form of question answering, it supports zero-shot evaluation.

To evaluate models for languages other than English, several monolingual benchmarks were developed, such as FLUE (Le et al., 2019) and CLUE (Liang, 2020), being French and Chinese versions of GLUE. These benchmarks include a variety of tasks, ranging from part-of-speech tagging and syntax parsing to machine reading comprehension and natural language inference.

To the best of our knowledge, LINSPECTOR (Eichler et al., 2019) is a first multi-lingual benchmark for evaluating the performance of language models. LINSPECTOR offers 22 probing tasks to analyse for a single linguistic feature such as case marking, gender, person, or tense for 52 languages. A part of these 22 probing tasks are static, i.e. are aimed at evaluation of word embeddings, and the rest are contextual and should be used to evaluate language models. Released in early 2020 two multilingual benchmarks, (Liang et al., 2020) and XTREME (Hu et al., 2020), aim at evaluation of cross-lingual models. XGLUE includes 11 tasks, which cover both language understanding and language generation problems, for 19 languages. XGLUE provides with several multilingual and bilingual corpora that allow of cross-lingual model training. As for the Russian language, XGLUE provides with four datasets for POS tagging, a part of XNLI (Conneau et al., 2018) and two datasets, crawled from commercial news website, used for news classification and news headline generation. XTREME consists of nine tasks which cover classification, sequence labelling, question answering and retrieval problems for 40 languages. Almost a half of the datasets were translated from English to the target languages with the help of professional translators. XTREME offers for the Russian language five datasets, including NER and two question-answering datasets. Both XGLUE and XTREME offer tasks that are much simpler than SuperGLUE and are aimed at evaluation of cross-lingual models rather than at comparison of mono-lingual models in similar setups. Thus the need for novel datasets targeted at mono-lingual model evaluation for languages other than English is still not eliminated.

3 RussianGLUE Overview

We have intenooed to have the same task set in the framework as one in the SuperGLUE. There is no one-to-one mapping, but the corpora we use could be considered close to the specified tasks in the SuperGLUE framework.

We divided the tasks into six groups, covering the general diagnostics of language models and different core tasks: common sense understanding, natural language inference, reasoning, machine reading and world knowledge.

3.1 Tasks

The tasks description is provided below. The samples from the tasks are presented at figs. 1 to 7.

3.1.1 Diagnostics

LiDiRus: Linguistic Diagnostic for Russian is a diagnostic dataset that covers a large volume of linguistic phenomena, while allowing you to evaluate information systems on a simple test of textual entailment recognition. This dataset was translated from English to Russian with the help of professional translators and linguists to ensure that the desired linguistic phenomena remain. This dataset corresponds to AX-b dataset in SuperGLUE benchmark.

3.1.2 Common Sense

RUSSE: Word in context is a binary classification task, based on word sense disambiguation problem. Given two sentences and a polysemous word, which occurs in both sentences, the task is to determine, whether the word is used in the same sense in both sentences, or not. For this task we used the Russian word sense disambiguation dataset **RUSSE** (Panchenko et al., 2015) and converted it into WiC dataset format from SuperGLUE.

RUSSE

Context 1: *Бурые ковровые дорожки заглушали шаги.* **Context 2:** *Приятели решили выпить на дорожку в местном баре.*
Sense match: `False`

Figure 1: A sample from RUSSE dataset.

PARus: The choice of Plausible Alternatives for Russian language evaluation provides researchers with a tool for assessing progress in open-domain commonsense causal reasoning. Each question in PARus is composed of a premise and two alternatives, where the task is to select the alternative that more plausibly has a causal relation with the premise. The correct alternative is randomized so that the expected performance of randomly guessing is 50%. PARus is constructed as a translation of COPA dataset from SuperGLUE and edited by professional editors. The data split from COPA is retained.

PARus

Premise: *Гости вечеринки прятались за диваном.*
Question: *Почему это произошло?*
Alternative 1: *Это была вечеринка-сюрприз.*
Alternative 2: *Это был день рождения.*
Correct Alternative: 1

Figure 2: A sample from PARus dataset.

3.1.3 Natural Language Inference

TERRa: Textual Entailment Recognition for Russian is a dataset which is devoted to capture textual entailment. The task of textual entailment has been proposed recently as a generic task that captures major semantic inference needs across many NLP applications, such as Question Answering, Information Retrieval, Information Extraction, and Text Summarization. This task requires to recognize, given two text fragments, whether the meaning of one text is entailed (can be inferred) from the other text. The corresponding dataset in SuperGLUE is RTE, which in its place is constructed from NIST RTE challenge series corpora. To collect TERRa we filtered out the large scale Russian web-corpus, Taiga (Shavrina and Shapovalova, 2017) with a number of rules to extract suitable sentence pairs and manually corrected them. The rules had the following structures: there should be a mental verb in the first sentence and the second sentence should be attached to the first one by a subordinate conjunction. To ensure the literary language of the extracted sentences, we processed only news and fiction parts of Taiga and made sure, that the sentences contain only frequently used words (i.e. number instances per million, IPM is higher than 1). The word frequencies were estimated according to Russian National Corpus[1].

RCB: The Russian Commitment Bank is a corpus of naturally occurring discourses whose final sentence contains a clause-embedding predicate

TERRA

Text: *Автор поста написал в комментарии, что прорвалась канализация.*
Hypothesis: *Автор поста написал про канализацию.* **Entailment:** `True`

Figure 3: A sample from TERRa dataset.

under an entailment canceling operator (question, modal, negation, antecedent of conditional). Similarly to the design of TERRa dataset, we filtered out Taiga with a number of rules and manually post processed the extracted passages. Final labelling was conducted by three of the authors. This dataset corresponds to CommonBank dataset.

RCB

Text: *Сумма ущерба составила одну тысячу рублей. Уточняется, что на место происшествия выехала следственная группа, которая установила личность злоумышленника. Им оказался местный житель, ранее судимый за подобное правонарушение.*
Hypothesis: *Ранее местный житель совершал подобное правонарушение.*
Entailment: `Yes`

Figure 4: A sample from RCB dataset.

3.1.4 Reasoning

RWSD: Winograd Schema task is devoted to coreference resolution in specifically designed experiment, where reference could be resolved only using the common sense. The Russian Winograd Schema Dataset (**RWSD**) is constructed as translation of the Winograd Schema Challenge[2].

RWSD

Text: *Кубок не помещается в коричневый чемодан, потому что он слишком большой.* **Coreference:** `True`

Figure 5: A sample from RWSD dataset.

3.1.5 Machine Reading

MuSeRC: Russian Multi-Sentence Reading Comprehension is a reading comprehension challenge in which questions can only be answered by taking into account information from multiple sentences. The dataset is the first to study multi-sentence inference at scale, with an open-ended set of question types that requires reasoning skills. The task is actually a binary classification, whether the answer to the question is correct or not. Each example consists of numerated passage, question and answers. Our dataset contains approximately 6000 questions for more than 800 paragraphs across 5 different domains, namely: 1) elementary school texts, 2) news, 3) fiction stories, 4) fairy tales, 5) brief annotations of TV series and books. First, we have collected open sources data from different domains and automatically preprocessed them, filtered only those paragraphs that corresponds to the following parameters: 1) paragraph length 2) number of named entities 3) number of coreference relations. Afterwords we have checked the correct splitting on sentences and numerate each of them. Next, in Toloka[3] we have generated the crowd sourcing task to get the following information: 1) generate questions 2) generate answers 3) check that to solve every question a human needs more than one sentence in the text. Collecting the dataset we adhere the principles of MultiRC (Khashabi et al., 2018): a) We exclude any question that can be answered based on a single sentence from a paragraph; b) Answers are not written in the full match form in the text; c) Answers to the questions are independent from each other.

MuSeRC

Paragraph: *(1) Мужская сборная команда Норвегии по биатлону в рамках этапа Кубка мира в немецком Оберхофе выиграла эстафетную гонку. (2) Вторыми стали французы, а бронзу получила немецкая команда. (3) Российские биатлонисты не смогли побороться даже за четвертое место, отстав от норвежцев более чем на две минуты. (4) Это худший результат сборной России в текущем сезоне. (5) Четвёртыми в Оберхофе стали австрийцы. (6) В составе сборной Норвегии на четвёртый этап вышел легендарный Уле-Эйнар Бьорндален. (7) Впрочем, Норвегия с самого начала гонки была в числе лидеров, успешно проведя все четыре этапа. (8) За сборную России в Оберхофе выступали Иван Черезов, Антон Шипулин, Евгений Устюгов и Максим Чудов. (9) Гонка не задалась уже с самого начала: если на стрельбе из положения лежа Черезов был точен, то из положения стоя он допустил несколько промахов, в результате чего ему пришлось бежать один дополнительный круг. (10) После этого отставание российской команды от соперников только увеличивалось. (11) Напомним, что днем ранее российские биатлонистки выиграли свою эстафету. (12) В составе сборной России выступали Анна Богалий-Титовец, Анна Булыгина, Ольга Медведцева и Светлана Слепцова. (13) Они опередили своих основных соперниц - немок - всего на 0,3 секунды.*
Question: *На сколько секунд женская команда опередила своих соперниц?*
Candidate answers:
Всего на 0,3 секунды. (`T`),
На 0,3 секунды. (`T`),
На секунду. (`F`),
На секунды. (`F`)

Figure 6: A sample from MuSeRC dataset.

RuCoS: Russian reading comprehension with Commonsense reasoning is a large-scale dataset for machine reading comprehension requiring commonsense reasoning. The dataset construction is based on ReCoRD methodology (Zhang et al., 2018). RuCoS consists of passages and cloze-style queries automatically generated from Russian news articles, namely Lenta[4] and Deutsche Welle[5]. Each sample from the dev and test sets was validated by crowd workers. The answer to each query is a text

---

[2] `https://cs.nyu.edu/faculty/davise/papers/WinogradSchemas/WS.html`

[3] `https://toloka.yandex.ru`

[4] `https://lenta.ru/`

[5] `https://www.dw.com/ru/`

span that corresponds to one or more referents of the answer entity in the context. The answer entity may be expressed by an abbreviation, an acronym or a set of surface forms. Hence, the task requires understanding of rich inflectional morphology and lexical variability of Russian. The goal of RuCoS is to test a machine's ability to infer the answer based on the commonsense reasoning and knowledge.

RuCoS

Paragraph: Мать двух мальчиков, брошенных отцом в московском аэропорту *Шереметьево*, забрала их. Об этом сообщили *ТАСС* в пресс-службе министерства образования и науки *Хабаровского края*. Сейчас младший ребенок посещает детский сад, а старший ходит в школу. В учебных заведениях с ними по необходимости работают штатные психологи. Также министерство социальной защиты населения рассматривает вопрос о бесплатном оздоровлении детей в летнее время. Через несколько дней после того, как *Виктор Гаврилов* бросил своих детей в аэропорту, он явился с повинной к следователям в городе *Батайске* Ростовской области.
Query 26 января <placeholder> бросил сыновей в возрасте пяти и семи лет в Шереметьево.
Correct Entities: `Виктор Гаврилов`

Figure 7: A sample from RuCoS dataset.

3.1.6 World Knowledge

DaNetQA: This question-answering corpus follows BoolQ (Clark et al., 2019) design: it comprises natural yes/no questions. Each question is paired with a paragraph from Wikipedia and an answer, derived from the paragraph. The task is to take both the question as input and a paragraph and come up with a yes/no answer, i.e. to produce a binary output. DaNetQA was collected in a few steps: 1) we used crowd workers to compose candidate yes/no questions; 2) we used Google API to retrieve relevant Wikipedia pages by treating each question as a search query; 3) we queried a pre-trained BERT-based model for SQuAD (Kuratov and Arkhipov, 2019) to extract relevant paragraphs from Wikipedia pages, using candidate questions; 4) finally, we used crowd workers to evaluate each question and paragraph pair and provide the desired yes/no answers. We ensure high quality of the dataset by using a high overlap for annotation at the last step and a number of control gold-standard control questions, labelled by two of the authors. The core difference of DaNetQA to BoolQ is that some question may occur multiple times in the dataset, as at the step 3) we may retrieve more than one relevant paragraph. To make the dataset more challenging, we admit contradictory answers to a question if these answers are implied from the passages.

3.1.7 Statistics for the Tasks

Table 1 below presents the characteristics of the collected datasets - examples partitioning by train/val/test, as well as the total volume in tokens and sentences. As one can see, the size of the RuCoS task significantly exceeds the rest of the tasks due to the articles included in the task.

Task	Samples	Sents	Tokens
LiDiRus	0/0/1104	2210	$3.6 \cdot 10^4$
Common Sense			
RUSSE	19845/8508/12151	90862	$1.1 \cdot 10^6$
PARus	500/100/400	1000	$5.4 \cdot 10^3$

3.2 Scoring

Following (Wang et al., 2019), we calculate scores for each of the tasks based on their individual metrics. All metrics are scaled by 100x (i.e., as percentages). These scores are then averaged to get the final score. For the tasks with multiple metrics, the metrics are averaged.

4 Experiments

4.1 Baselines

In this section, we provide a two-step baseline design. At first we have developed a naïve baseline based on the TF-IDF model (section 4.1.1), and then evaluate state-of-the-art models for Russian language (section 4.1.2).

4.1.1 Naïve Baseline

We used Scikit-learn package (Pedregosa et al., 2011) to train a TF-IDF model. We used a 20 thousand sample from Wikipedia, from Russian and English sites equally. We restricted a vocabulary to 10 thousand most common words. Then for each task set a logistic regression was trained to predict an answer.

Dataset	**Metrics**	`RuBERT`	`MultiBERT`	TF-IDF	Human
LiDiRus	MCC	0.186	0.157	0.059	**0.626**
RCB	F_1/Acc.	0.432/0.468	0.383/0.429	0.45	**0.68/0.702**

Table 2: Results of the human benchmark and the baseline models. MCC stands for Matthews Correlation Coefficient; Acc - Accuracy; EM - Exact Match.

4.1.2 Advanced Baselines

We leverage two BERT-derived models as baseline. Multilingual BERT (`MultiBERT`), released by (Devlin et al., 2019), is a single language model pre-trained from monolingual corpora in 104 languages, Russian texts being a part of training data. `MultiBERT` uses a shared vocabulary for all languages. The capabilities of `MultiBERT` for zero-shot cross-lingual tasks have been recently studied by (Pires et al., 2019). Russian BERT (`RuBERT`) was trained on large-scale corpus of news and Wikipedia in Russian. To alleviate the training all weights except sub-word embeddings were borrowed from `MultiBERT`. The sub-word vocabulary was obtained from the same training corpus and the new mono-lingual embeddings were transformed from the multi-lingual ones. This allowed to incorporate longer Russian sub-word units into the vocabulary. This model is part of DeepPavlov framework (Kuratov and Arkhipov, 2019).

4.2 Human Evaluation

We include human performance estimates for all provided benchmark tasks, including the diagnostic set. We estimate human performance by hiring crowd workers via Toloka platform to re-annotate a sample from each task test set. We suggest a two step procedure: 1) a crowd worker is provided with an instruction and completes a short training phase before proceeding to the annotation phase, 2) a crowd worker that passed through the training phase solves the original test set.

For the annotation phase we ask crowd workers to annotate the full test sets except for the RUSSE and the RuCoS datasets, where we randomly sampled only 5000 and 1000 examples from the tasks' test sets, respectively. For each sample, we collect annotations from three to five crowd workers and take a majority vote to estimate human performance. In annotation phase we add control questions to prevent the crowd workers from cheating. As a result, we reject the annotations from the crowd workers that fail the training phase and do not include the results of those who achieved low performance on the control tasks. The results of human evaluation are presented in Table 2. The example of a Toloka task is provided in Appendix.

5 Results

The analysis of Table 2 can give an exact representation of the baseline model performance, which still remains significantly different from the human level. Nevertheless, the task of resolving the ambiguity of the word meaning in context (RUSSE) was solved by both monolingual and multilingual BERT at a level significantly exceeding the human one (0.89 vs 0.74). Besides, the monolingual model is showing a slightly higher quality than that of the multilingual one, especially prevailing textual entailment tasks (RCB, TERRA, PARus), disambiguating word meaning (RUSSE) and reading comprehension (MuSeRC). The multilingual model shows the most excellent result on the smallest dataset on commonsense QA task (DaNetQA) and also on commonsense-related task on machine reading (RuCoS).

We hope that our benchmark will help to excel the performance of models for the Russian language in the future, and will favour achieving comparably high results.

Can the results of a multilingual BERT on Russian and English data be considered analogous? Based on the results of the assessment, `MultiBERT` in English gets an overall score of 60.8 [6], while on RussianGLUE task set an overall score of 54.2 is achieved– 6% lower, but noting that the English benchmark includes additionally Winograd Gender Parity (Levesque et al., 2012) dataset, giving SOTA models from 90 to 93% of accuracy added to the overall assessment. In the next section, a detailed comparison of the multilingual model performance is provided.

5.1 Comparison to SuperGLUE

As mentioned in Section 3.1, the diagnostic dataset has been obtained by professional translation with preservation of the original linguistic features mentioned. Thus being said, this diagnostic data is the first of its kind that allows drawing a multilingual analogy of comparable models.

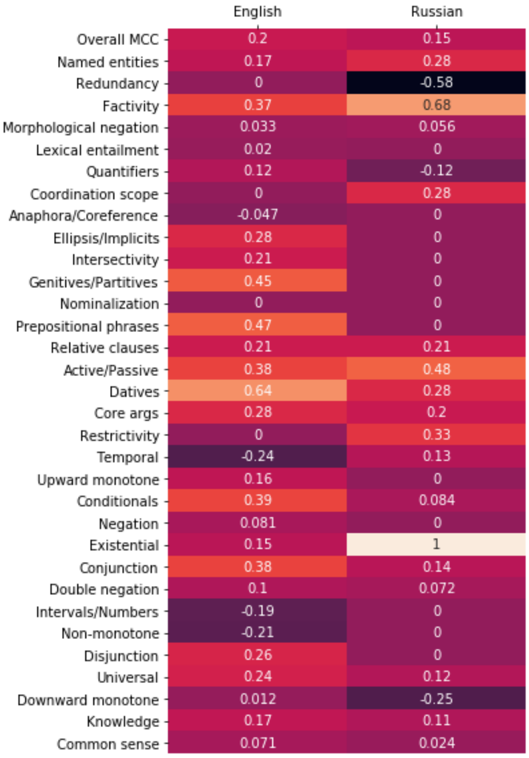

Figure 8: Russian and English Diagnostic Evaluation on Multilingual transformer, scored using Matthews' correlation (MCC).

Procedure: using the original `MultiBERT` (Devlin et al., 2019), we conducted sequential model pretraining in English and Russian using the RTE dataset, and then tested the models on the diagnostic set, as long as the task requires exactly the same format. Predictions were further scored using Matthews' correlation (MCC), and correlation for different linguistic features was computed. The results are presented in Figure 8.

First of all, it could be noticed that the English variant of the model performs slightly better and shows a higher overall correlation of 0.2 compared to 0.15 for the Russian variant. This could be due to an asymmetry of the quality of the multilingual model and its better understanding of the English language in general.

As for the models' performance in the context of different linguistic features, the results generally coincide. For those categories for which correlation is low in English, the result in Russian is in most cases poor as well (for instance, *Redundancy, Nominalization, Intervals/Numbers*). However, there exist several categories which are much better solved in English than in Russian such as *PA Structure, Ellipsis/Implicits, Genetives/Partitives, Prepositional phrases, Datives* – mostly low-level and/or syntactically driven categories, that may indicate that optimal hyperparameters of BERT architecture are much more suitable for English syntax and may not be linguistically universal. Similarly, we could find categories which show an extremely high correlation in Russian and low correlation in English (*Factivity, Coordination scope, Restrictivity* and *Existential*) – high-level logical and semantic categories.

These numbers compared to the ones for English could be explained by the fact that the language features now included in the diagnostics are not exactly linguistically universal in different languages and are mostly focused on the English language (at least those syntactic ones). Thus, for the comprehensive cross-linguistic typological analysis of possible linguistic features should be reviewed.

6 Discussion

We hope that our project will give a start to new research in the application of universal language models and transformers, including multilingual ones. Our example of an analysis of translated diagnostics shows that even in languages of the same European family (which Russian and English belong to), significant differences in the influence of linguistic categories on model performance are possible. One of the directions of the next studies, we consider detailed experiments on the influence of model parameters and language categories in data on the quality of the model in different languages.

---

[6] Jiant, full SuperGLUE task set

An independent problem for the English original leaderboard is that a gradual improvement in the quality of models allows us to exceed the human performance level in individual tasks, as happened with the T5 (Raffel et al., 2019) model. We expect that a similar situation will soon happen on Russian data, which means that when releasing straight off with complex SuperGLUE tasks, we will still be focused on adding tasks of a higher level of complexity in the future. Such tasks can become those that are obviously inaccessible to models for the "understanding" of long texts and documents, seq2seq tasks, tasks that require knowledge graphs.

In the further development of our leaderboard, we also see the possibility of adding an industrial assessment of models: for fair ranking and ease of use, all models could receive an estimate of the required memory resources, an estimate of performance, and so on.

7 Conclusion

In this paper we present the first benchmark on general language understanding evaluation for the Russian language. The benchmark including nine task sets is aimed to test BERT-like models for their ability to perform entailment recognition, commonsense reasoning and machine reading while denoising various linguistic features added on the level of semantics, logical and syntactic structure.

We invite developers, researchers, and AI experts to join our project. Further development of the benchmark includes areas such as evaluation of industrial performance of models on the leaderboard and multilingual diagnostics.

An Empirical Study of Pre-trained Transformers for Arabic Information Extraction

Wuwei Lan[1], Yang Chen[2], Wei Xu[2], Alan Ritter[2]
[1] Department of Computer Science and Engineering, Ohio State University
[2] School of Interactive Computing, Georgia Institute of Technology
`lan.105@osu.edu {yang.chen, wei.xu, alan.ritter}@cc.gatech.edu`

Abstract

Multilingual pre-trained Transformers, such as mBERT (Devlin et al., 2019) and XLM-RoBERTa (Conneau et al., 2020a), have been shown to enable the effective cross-lingual zero-shot transfer. However, their performance on Arabic information extraction (IE) tasks is not very well studied. In this paper, we pre-train a customized bilingual BERT, dubbed GigaBERT, that is designed specifically for Arabic NLP and English-to-Arabic zero-shot transfer learning. We study GigaBERT's effectiveness on zero-short transfer across four IE tasks: named entity recognition, part-of-speech tagging, argument role labeling, and relation extraction. Our best model significantly outperforms mBERT, XLM-RoBERTa, and AraBERT (Antoun et al., 2020) in both the supervised and zero-shot transfer settings. We have made our pre-trained models publicly available at `https://github.com/lanwuwei/GigaBERT`.

1 Introduction

Fine-tuning pre-trained Transformer models (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019) has recently achieved state-of-the-art results on a wide range of NLP tasks where supervised training data is available. When trained on multilingual corpora, BERT-based models have demonstrated the ability to learn multilingual representations that support zero-shot cross-lingual transfer learning surprisingly effectively (Wu and Dredze, 2019; Pires et al., 2019; Lample and Conneau, 2019).

Without access to any parallel text or target language annotations, multilingual BERT (mBERT; Devlin et al., 2019) even supports cross-lingual transfer for language pairs that are written in different scripts, for example, English-to-Arabic. However, the transfer learning performance still lags far behind where supervised data is available in the target language. In this paper, we explore to what extent it is possible to improve performance in the zero-shot scenario by building a customized bilingual BERT for English and Arabic, a particularly challenging language pair for cross-lingual transfer learning.

We present GigaBERT, a customized BERT for English-to-Arabic cross-lingual transfer that is trained on newswire text in the Gigaword corpus (Graff et al., 2003; Parker et al., 2009) in addition to Wikipedia and web crawl data. We systematically compare our pre-trained models of different configurations against the mBERT (Devlin et al., 2019) and XLM-RoBERTa (XLM-R; Conneau et al., 2020a). By using a customized vocabulary and code-switched data specifically created for English-to-Arabic transfer learning, our GiagBERT outperforms mBERT and XLM-$\mathrm{R}_{\mathrm{base}}$ (both support more than 100 languages) on a range of IE tasks, including named entity recognition, part-of-speech tagging, argument role labeling, and relation extraction. Further performance gains are demonstrated by augmenting the pre-training corpus with synthetically generated code-switched data. This demonstrates the usefulness of anchor points for zero-shot cross-lingual transfer learning. GigaBERT also performs well when annotated Arabic data is available, outperforming AraBERT (Antoun et al., 2020), the state-of-the-art Arabic-specific BERT model, on various Arabic IE tasks.

2 Related Work

The existing Arabic pre-trained models are either monolingual, such as hULMonA (ElJundi et al., 2019) and AraBERT (Antoun et al., 2020); or multilingual with several or over a hundred languages, such as mBERT (Devlin et al., 2019), XLM (Lample and Conneau, 2019), and XLM-RoBERTa (Conneau et al., 2020a). There is no bilingual pre-

trained language model designed specifically for English-Arabic. K et al. (2020) pre-trained small-scale (e.g., 1GB data and 2M training steps) bilingual BERT for English-Hindi, English-Spanish, and English-Russian to study the impact of linguistic properties of the languages, the architecture of the model, and the learning objectives on cross-lingual transfer. Kim et al. (2019) presented a bilingual BERT using multi-task learning for translation quality estimation with regards to English-Russian and English-German. Conneau et al. (2020b) focused on the bilingual XLM for English-French, English-Russian, and English-Chinese to analyze the cross-lingual transfer ability with domain similarity, anchor points, parameter sharing, and language similarity.

3 GigaBERT

We present five versions of GigaBERT pre-trained using the Transformer encoder (Vaswani et al., 2017) with BERT$_{\text{base}}$ configurations: 12 attention layers, each has 12 attention heads and 768 hidden dimensions, which attributes 110M parameters. Table 1 shows a detailed summary of the training data and model parameters.

3.1 Training Data

We pre-train our GigaBERT models using the fifth edition of English and Arabic Gigaword corpora.[1] The Gigaword data consists of 13 million news articles[2] and matches the domain of many NLP tasks. We split English and Arabic sentences without tokenization by a modified version of the Stanford CoreNLP tool (Manning et al., 2014).[3] We also add Wikipedia data processed by WikiExtractor[4] for better coverage. As the English Wikipedia (total 2.5B tokens) is much larger than the Arabic Wikipedia (total 0.15B tokens), we balance the pre-training data by (1) up-sampling the Arabic data by repeating the Wikipedia portion five times and the Gigaword portion three times; (2) adding the Arabic section of the Oscar corpus (Ortiz Suárez et al., 2019), a large-scale multilingual dataset filtered from the Common Crawl.

Code-Switched Data Augmentation. To further improve cross-lingual transfer capability, we leverage English-Arabic dictionaries to create synthetic code-switched training data (Conneau et al., 2020a). We experimented with three dictionaries: PanLex (Kamholz et al., 2014), MUSE (Conneau et al., 2018), and Wikipedia parallel titles. We extract parallel article titles in Wikipedia based on the inter-language links and the entities based on the Wikidata (Jiang et al., 2020).[5] The dictionaries of PanLex, MUSE, Wikipedia contain 24K, 44K, 2M entries, respectively, and on overage 4.6, 1.4 and 1 translations per entry (English or Arabic). For training GigaBERT-v4, we code-switch up to 50% random sentences for both English and Arabic and up to 30% of tokens for each sentence. During the replacement process, we prioritize substitutions based on the Wikipedia titles, then PanLex and MUSE if the proportion of tokens being replaced has not reached 30% for a given sentence.

3.2 Vocabulary

The vocabulary size is critical to the performance of pre-training models, as it directly impacts the subword granularity and the number of parameters. The original English BERT (Devlin et al., 2019) uses a 30k vocabulary size for ∼3B tokens of training data, while the multilingual BERT and XLM-R have ∼5k and ∼14k Arabic subwords in their vocabularies respectively (Table 1).[6] We choose a vocabulary size of 50k for our GigaBERT models based on preliminary experiments. For GigaBERT-v0, we use the unigram language model in the SentencePiece (Kudo and Richardson, 2018) to create 30k cased English subwords and 20k Arabic subwords separately.[7] For GigaBERT-v1/2/3/4, we did not distinguish Arabic and English subword units, instead, we train a unified 50k vocabulary using WordPiece (Wu et al., 2016).[8] The vocabulary is cased for GigaBERT-v1 and uncased for GigaBERT-v2/3/4, which use the same vocabulary.

3.3 Optimization

We use the official implementation of BERT (Devlin et al., 2019) in TensorFlow for pre-training. We use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 1e-4, $\beta_1 = 0.9$, $\beta_2 = 0.999$, L2 weight decay of 0.01. The learning rate is warmed up over the first 100,000 steps to a peak value of 1e-4, then linearly decayed. The dropout is set to 0.1 for all layers. We use the whole word mask for GigaBERT-v0 and the regular subword mask for v1/2/3/4. The batch size is set to 512. GigaBERT-v0/1/2 are trained for 1.2 million steps on Google Cloud TPUs with a max sequence length of 128. GigaBERT-v3 is additionally trained for 140k steps with a max sequence length of 512. The maximum number of masked LM predictions per sequence is set to 20 when max sequence length is 128 and set to 80 when max sequence length is 512. GigaBERT-v4 is trained from the GigaBERT-v3 checkpoint for another 140K steps on the code-switched data. We also experiment with different thresholds for the code-switched data augmentation, as well as training models from scratch on the code-switched data (Appendix A).

Table 2: Statistics of the datasets for IE tasks.

4 Experiments

4.1 Downstream IE Tasks

We demonstrate the effectiveness of GigaBERT on named entity recognition (NER), part-of-speech tagging (POS), argument role labeling (ARL), and relation extraction (RE) tasks. We use the ACE 2005 corpus (Walker et al., 2006) in the NER, ARL, and RE evaluations, and use the Universal Dependencies Treebank v1.4 (Nivre et al., 2016) in the POS experiments. All of these datasets are from the news domain, as summarized in Table 2. For NER, we use the same English document splits as Lu and Roth (2015) and randomly shuffle Arabic documents into train/dev/test (80%/10%/10%). For ARL and RE, we randomly shuffle both English and Arabic documents into train/dev/test (80%/10%/10%). For POS, we follow the train/dev/test split by Wu and Dredze (2019). In the ARL fine-tuning experiment, we pair each trigger with its argument mentions as positive instances and with other entities in the sentence as negative instances. As for RE, we use gold relation mentions as positive examples and create negative examples by randomly pairing two entities in a sentence. We perform these tasks following the same fine-tuning pipeline as BERT (Devlin et al., 2019). We feed input sentences into a pre-trained model, then extract the necessary hidden representations, i.e., all token representations for NER/POS and argument/entity spans for ARL/RE, before applying one linear layer for classification. We evaluate for each language in the standard supervised learning setting, as well as the zero-shot transfer learning setting from English to Arabic, where the model is trained on the annotated English training data and evaluated on the Arabic test set.

4.2 Implementations

We implement the fine-tuning experiments with the PyTorch framework (Paszke et al., 2019) and choose hyperparameters by grid search.[9] We set the

---

[6] We check the Unicode range of characters to classify word pieces as English or Arabic.

[7] There are 633 word pieces shared by both languages. We add 633 unused symbols (e.g., unused-1, unused-2, etc.) to make up the 50k combined vocabulary.

[8] We use Hugging Face's implementation: `https://github.com/huggingface/tokenizers`

[9] The search range includes learning rate (1e-5. 2e-5. 5e-5. 1e-4), batch size (4, 8, 16, 32) and epoch number (3, 7, 10).

Table 3: Evaluation on four Arabic IE tasks that compares AraBERT (Antoun et al., 2020), multilingual BERT (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020a), GigaBERT/GigaXLM-R (this work). All models use $BERT_{base}$ architecture except XLM-R_{large}. GigaBERT-v4 is continued pre-training of GigaBERT-v3 on code-switched data. GigaXLM-R is domain adapted pre-training of XLM-R on Gigaword data.

learning rate to 2e-5, batch size to 8, max sequence length to 128, and the number of fine-tuning epochs to 7. Some exceptions include a learning rate of 1e-4 in NER experiments, max sequence length of 512, and batch size of 4 in RE experiments. For RE, we also use gradient accumulation to simulate the larger batch size of 32 when using models based on $BERT_{large}$ architecture.

4.3 Results and Analysis

Table 3 shows experimental results for the pre-trained models on both English and Arabic IE tasks. For the zero-shot transfer (en → ar), we report two scores on the Arabic test set, where the best checkpoint is selected based on the English dev set and the Arabic dev set, respectively. In summary, we find the key factors of improved pre-training performance are a large amount of training data in the target language, customized vocabulary, longer max length of sentence, and more anchor points from code-switched data. We also add experiments with XLM-R_{large} models as a reference, but the comparison focuses on the pre-trained models with $BERT_{base}$ configuration for fairness.

Single-language Performance. All versions of GigaBERT perform very competitively, especially the GigaBERT-v3/4. After adding Wikipedia and Oscar data, GigaBERT-v2 starts to outperform mBERT and XLM-R_{base} on most tasks. We find it crucial to continue training GigaBERT-v2 with a longer max sentence length of 512 word pieces, as the resulting GigaBERT-v3 model shows improvements in all four IE tasks. GigaBERT-v3 also outperforms AraBERT (Antoun et al., 2020), the state-of-the-art Arabic-specific BERT model by a large margin, showing that our bilingual GigaBERT does not sacrifice per-language performance. It is worth noting that GigaBERT-v4 also has competitive single-language performance after training on the synthetically created code-switched data.

Cross-lingual Zero-shot Transfer Learning. All pre-trained models show varied performance when we select checkpoints based on the English dev set and Arabic dev set, indicating that the best single-language performance does not necessarily imply the best cross-lingual performance. Compared to GigaBERT-v0, additional data used to train GigaBERT-v1/2 helps improve zero-shot transfer capability, even though the added data is not from the news domain. Different from previous works (Wu and Dredze, 2019; Pires et al., 2019) that attribute cross-lingual ability to shared subwords, GigaBERT-v3 has nearly no shared word pieces or scripts between English and Arabic, but still shows strong cross-lingual performance. We hypothesize the Transformer encoder projects similar contextual representations and enables cross-lingual transfer (Conneau et al., 2020b).

Code-Switched Pre-training. We show that we can further improve GigaBERT's cross-lingual transfer capability with a carefully designed code-switching procedure. Our GigaBERT-v4 pre-trained with code-switched data shows significant improvement over GigaBERT-v3, achieving

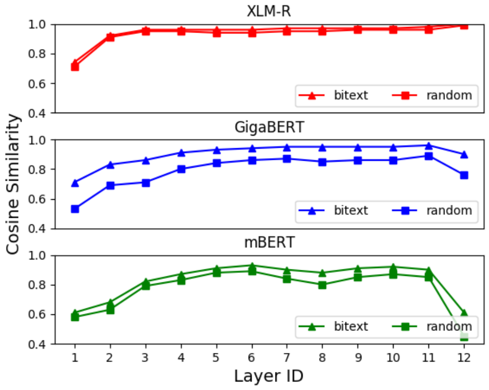

Figure 1: Cosine similarity between sentence representations of parallel sentences (bitext) and randomly paired sentences (random).

new state-of-the-art for zero-shot transfer from English to Arabic on NER, ARL, and RE. Our code-switched pre-training differs from Conneau et al. (2020b) in two aspects: 1) we explored multiple bilingual dictionaries, including PanLex (Kamholz et al., 2014), MUSE (Conneau et al., 2018) and Wikipedia titles, while MUSE appears to be the most effective; 2) we keep at least half of the sentences unchanged to balance between real data and artificial data. In practice, the generated data for GigaBERT-v4 has 47.4% of the sentences code-switched. We present more comparison experiments using varied code-switching mixes and different bilingual lexicons in Appendix A.

Domain-adapted Pre-training. We also explore whether XLM-RoBERTa can be improved by additional pre-training on Gigaword data, as Gururangan et al. (2020) have shown that the continued pre-training with in-domain data is helpful. We create GigaXLM-R models by continuing pre-training from XLM-$\mathrm{R}_{\mathrm{base}}$ and XLM-$\mathrm{R}_{\mathrm{large}}$ checkpoints in the Fairseq toolkit (Ott et al., 2019) for 500k steps on shuffled Arabic and English Gigaword corpus (max sequence length 512 and batch size 4). Although only $\sim$1% of the Gigaword corpus is used in this continued training step due to computing resource limit, GigaXLM-R still improves zero-shot transfer performance for NER, POS, and RE over the original XLM-R models as shown in Table 3. We could expect more performance improvement with a larger batch size and longer training time.

Embedding Space Analysis. We further analyze the semantic similarity of parallel English-Arabic sentence representations and find that GigaBERT is able to distinguish parallel sentences from randomly paired sentences more effectively compared to its counterparts. Our hypothesis is that cross-lingual representations for parallel English-Arabic sentences should be similar, but randomly paired sentences should be dissimilar. To evaluate cross-lingual similarity, we extract sentence representation of 5340 English-Arabic parallel sentences from the GALE corpus[10] and the same number of randomly paired sentences with pre-trained models across all 12 layers. We use the average of hidden representations, excluding [CLS] and [SEP], as a sentence representation. Cosine similarity is calculated for each sentence pairs and averaged across the whole corpus. In Figure 1, GigaBERT shows high similarity between parallel sentences and low similarity between randomly paired sentences. A clear separation for two types of paired sentences is shown across all the layers. In contrast, XLM-R is not able to distinguish between them but shows high similarity scores. mBERT shows low similarity in both cases. This suggests that our GigaBERT preserves language independent semantic information in the sentence representations, which might contribute to the competitive performance in downstream IE tasks.

5 Conclusions

In this paper, we show that the performance of zero-shot cross-lingual transfer can be improved by training customized bilingual BERT for a given language pair and text domain. We pre-trained several masked language models (GigaBERTs) for Arabic-English and conducted a focused study on information extraction tasks in the newswire domain. The experiments show that our GigaBERT model outperforms multilingual BERT, XLM-RoBERTa, and the monolingual AraBERT on NER, POS, ARL and RE tasks. We also achieve the new state-of-the-art performance fro zero-shot transfer learning from English to Arabic. We additionally studied code-switched pre-training for GigaBERT and domain-adapted pre-training for XLM-RoBERTa.

A Comparison Experiments for Code-Switched Pre-training

Given the English and Arabic monolingual corpus and the bilingual lexicons, we have different thresholds to control the code-switched data generation: 1) the percentage of sentences being code-switched within the whole corpus, we set sentence replacement threshold to limit the changed sentences; 2) the percentage of tokens being replaced within the sentence, we set token replacement threshold to limit the changed tokens; 3) the choice of bilingual lexicons, where we explore different combinations of PanLex, MUSE and Wiki titles. With the generated code-switched data, we can pre-train GigaBERT from scratch or load the existing checkpoint (GigaBERT-v3) for continued pre-training, which are s1 and s2 in Table 4, respectively.

As shown in Table 4, it's better to keep some sentences unchanged for code-switched pre-training. The continued pre-training (s2) shows slightly better performance than that training from scratch (s1). During the data augmentation, we need to keep a relatively low ratio for token replacement. The results also reveal that the MUSE dictionary is very promising, which outperforms the combinations of all dictionaries in some cases.

Abstract

In this work, we present a new language pre-training model TNT (Text Normalization based pre-training of Transformers) for content moderation. Inspired by the masking strategy and text normalization, TNT is developed to learn language representation by training transformers to reconstruct text from four operation types typically seen in text manipulation: substitution, transposition, deletion, and insertion. Furthermore, the normalization involves the prediction of both operation types and token labels, enabling TNT to learn from more challenging tasks than the standard task of masked word recovery. As a result, the experiments demonstrate that TNT outperforms strong baselines on the hate speech classification task. Additional text normalization experiments and case studies show that TNT is a new potential approach to misspelling correction.

1 Introduction

Language model pre-training (self-supervised or unsupervised learning) has been a popular thread in Natural Language Understanding (NLP) studies recently due to its universal representation capacity (Radford et al., 2018; Devlin et al., 2019; Radford et al., 2019; Brown et al., 2020). It has been thus widely used in a multitude of language processing tasks such as named entity recognition, sentiment analysis, question answering and content moderation (Bodapati et al., 2019). In addition, the masking pre-training paradigm introduced by BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019) has been employed for other tasks such as image processing (Trinh et al., 2019), optical flow (Liu et al., 2019a), and audio-visual co-segmentation (Rouditchenko et al., 2019).

Recently, many variants have been proposed to further improve the pre-training procedure (Liu et al., 2019b; Wang et al., 2019; Sun et al., 2019). They have also advanced the state-of-the-art performance on multiple downstream natural language understanding tasks (Leaderboard) consistently. Almost all these studies train language models by predicting the masked words in different manners. The underlying mechanism is *Cloze task* (Taylor, 1953). The pre-training model itself, however, has not been fully exploited to address complicated yet feasible tasks. It is reasonable to expect that models can learn a better universal language representation if the pre-training procedure can be aligned with more challenging tasks.

In this article, we attempt to improve the language representation by proposing TNT: **T**ext **N**ormalization based pre-training of **T**ransformers. TNT enhances the language learning by utilizing text normalization pre-training objective, inspired by misspelling correction. Specifically, TNT randomly manipulates tokens from the input text. The objective is then to reconstruct the original tokens of the manipulated words based on the context by predicting both recovery operation type and original token labels as illustrated in Fig. 1. Unlike the masked language model, TNT has to offer two predictions to reconstruct the original text. In addition, TNT does not have to be given the prediction positions in advance. This aligns with the fact that misspelling correction needs to perform the position-agnostic prediction for both aspects.

Perpetrators often intentionally obfuscate certain words about groups, or abusive words, by misspelling, or leetspeak (e.g.,“f@ggot”,“ph*ck”, “w.e.t.b.a.c.k.”) (Perea et al., 2008). This could sidestep the content moderation algorithms easily as exemplified in Table 5. To assess the learning capacity of TNT for obfuscated text and reduce the training cost, it is pre-trained only on one dataset and then applied to three datasets related to a hate speech detection task. TNT achieves better results

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4735–4741,
November 16–20, 2020.

compared to strong baselines on these datasets. Furthermore, we conduct an experiment on misspelling correction, and demonstrates that TNT has appealing language understanding capacity.

Our contributions are summarized as follows: (1) we introduce text normalization into the language training paradigm, which involves challenging tasks of predicting both operation types and token labels; (2) we show that TNT advances the challenging downstream text classification task, which benefits the content moderation; (3) TNT offers a new perspective on misspelling correction.

2 Related Works

BERT (Devlin et al., 2019) is developed by introducing the bidirectional encoder of well-known transformers to learn the contextual representation of text, which is underpinned by the attention mechanism (Vaswani et al., 2017). It randomly masks a certain portion of tokens from the input and then learns to predict these masked words. This cloze task based pre-training strategy enables BERT to advance the state-of-the-art performance on various key NLP tasks. It also inspires the community with a plethora of subsequent works (Yang et al., 2019; Sun et al., 2019; Wang et al., 2019; Liu et al., 2019b). Among them several are closely related to our approach: XLNet (Yang et al., 2019) and StructBERT (Wang et al., 2019) improve the masking by imposing the permutation and shuffling among words and sentences. StructBERT is one of the current state-of-the-art algorithms topping the GLUE leaderboard[1] (Leaderboard), and is most similar to this work. TNT differs from StructBERT in that it is inspired by the need for misspelling correction, and therefore not only allows permutation of words, but also deletion and insertion.

For online abusive language moderation, BERT has also been shown effective and advances the overall performance largely (Bodapati et al., 2019). In addition, early works formulate the hate speech detection as the generic text classification, alternatively focus on certain ethnic groups or building up blacklists of swear words (Nobata et al., 2016a; Badjatiya et al., 2017). Misspelling correction is also a long-standing problem in NLP (Hirst and Budanitsky, 2005; Bassil, 2012; Islam and Inkpen, 2009) and has been widely used in real-word scenarios like word processing system and email spell checking.

Table 1: Real user manipulated text examples. 0, 1, 2 and 3 in the bracket correspond to recovery operation types: substitution, transposition, deletion and insertion. Identity (4) is also exemplified here for completeness

Manipulation	Text	Normalization
substitution	I damn sure didn't vote for the Marxist 8astard!	$8 \rightarrow b(0)$
transposition	mario= dumb cutn	t $\leftrightarrow n(1)$
deletion	Don Lemon is a shthead.	i (3)
insertion	Pi–ss on Putin !!!!!!!!!!___!!!!!!!!!!	$\not-$ (2)
identity	She is a nice lady.	c(4)

3 Pre-training

3.1 Architecture

We develop TNT based on a multi-layer bidirectional Transformer network as encoder used in popular language models like BERT (Devlin et al., 2019). The well-known masking strategy employed in BERT and subsequent works is inspired by cloze task for human-level language understanding. People are required to fill out the omitted words from a passage based on context.

Unlike the cloze procedure, text normalization involves more diversified and challenging tasks. The goal is to rewrite a sentence that was not properly formed, either due to misspelling, or due to intentional manipulation. A perpetrator would misspell on purpose, with the intention of evade detection, through *substitution*, *transposition*, *deletion* and *insertion* as exemplified in Table 1. The task of text normalization is to understand the manipulated sentence, and normalize it to the correct form. Therefore in TNT, motivated by the task of text normalization, we propose the pre-training tasks of substitution, transposition, deletion and insertion. The masking procedure could be viewed as a special case of the text normalization objective, under substitution.

For substitution (e.g., masking) and insertion, the corresponding *token label* predictions alongside *operation type* is required to reconstruct text. Specifically, we have normalization type $o \in \mathcal{O} = \{0, 1, 2, 3, 4\}$, where o is the operation type with values 0 (substitution), 1 (transposition), 2 (deletion), 3 (deletion) or 4 (identity), as exemplified in Table 1. The normalized token labels $l \in \mathcal{V}$

---

[1] The General Language Understanding Evaluation (GLUE) benchmark is a collection of resources for training, evaluating, and analyzing natural language understanding systems. It consists of 9 sentence- or sentence-pair language understanding tasks.

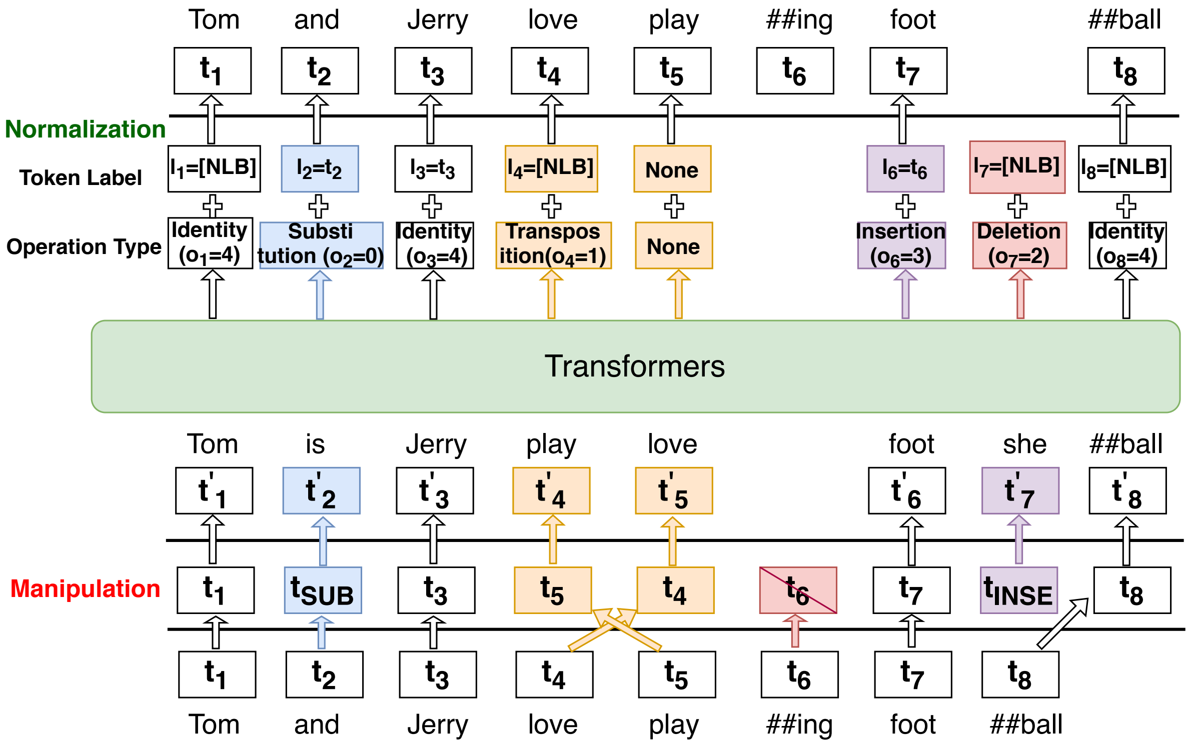

Figure 1: Wordpiece illustration of two pre-training subtasks in TNT. “None” means no prediction as the preceding transposition covers it already. [CLS], [SEP], positional and segment embedding are omitted for brevity.

are ground-truth tokens for corresponding types, where $\mathcal{V}$ is the vocabulary. It is noted that for transposition, deletion and identity, no token labels are required to reconstruct the original text. Thus, we introduce a special token symbol [NLB] as the placeholder. Fig. 1 illustrates the generation procedure of pre-training instances and the joint training of two subtasks.

3.2 Objective

Given an input sequence with manipulated tokens, the operation type and token label objectives can be denoted simply as $\mathcal{O}_{operation} = \arg\max_{\boldsymbol{\theta_o}} \sum_{i=1}^{M} w_i^o \log \mathrm{P}(o_i|t'_i;\boldsymbol{\theta_o})$ and $\mathcal{O}_{label} = \arg\max_{\boldsymbol{\theta_l}} \sum_{i=1}^{M} w_i^l \log \mathrm{P}(l_i|t'_i;\boldsymbol{\theta_l})$, respectively. t'_i is the observed token from the input sentence. o_i and l_i are ground-truth operation type and token label as illustrated in Fig. 1. M is the maximum length of input sequence. $\boldsymbol{\theta_o}$ and $\boldsymbol{\theta_l}$ are sets of trainable parameters. w_i^o and w_i^l are weights for operation type and token label, respectively. The overall pre-training objective is $\mathcal{O} = \mathcal{O}_{operation} + \mathcal{O}_{label}$.

4 Experiments

We perform the hate speech classification and misspelling correction tasks based on the pre-trained model.

4.1 Datasets

Our primary dataset is extracted from user comments on Yahoo News and Finance, and consisted of 1.43M labeled comments. Among them, 7% of the comments are labelled as abusive (including hatespeech and profanity). The labeled data were collected as follows: comments that are reported as “abusive” for any reason by users of Yahoo properties are sent to in-house trained raters for review, and the decisions of the raters form the labels. Further details can be found at (Nobata et al., 2016b). In addition, we experimented on two publicly available hatespeech datasets: Twitter, and Wikipedia (Wiki) (Agrawal and Awekar, 2018). Wiki set here is a collection of discussions among editors on talk pages for improving Wiki articles, which includes inflammatory posts. The statistics of three datasets are shown in Table 2.

We split the dataset into train/development/test sets with a ratio 70%/10%/20%. We generate vocabulary, pretrain the language modeling tasks, and train the hate speech prediction task using only the training set. We tune hyper-parameters on the development set, and report final results on the test set.

Table 2: Basic statistics of datasets

Source	# Abusive	# Clean	Total	% Abusive
Yahoo	100,652	1,328,486	1,429,138	7.04%
Twitter	5,054	11,036	16,090	31.4%
Wiki	13,590	102,274	115,864	11.7%

4.2 Experiment Setups

For TNT pre-training, the substitution follows the masking setting in BERT. We also set up 5% manipulation rate for transposition, deletion and insertion, respectively. The rest of the tokens remain unchanged.

The vocabulary generation, wordpiece tokenization, learning rate, weight decay, warm-up and other training settings follow BERT. The model size is reduced to quarter of the original BERT. The maximum length of input sequence M is set to 256. Parameter scale is $O = (V + M + S) \times H + L \times 12H^2 + H^2$ where V, S are vocabulary size $|\mathcal{V}|$, segment type size. H and L are the hidden layer dimension and the number of transformer block layers, respectively.

We mainly report two models with wordpiece and character inputs as detailed in Table 3. The main difference is that manipulation and normalization are performed on different levels. Wordpiece- and character-level operations are exemplified in Fig. 1 and Table 1, respectively.

Table 3: Parameter scale and weight settings, character for misspelling correction. Tuples of w_i^o and w_i^l are weights associated with operation type {0,1,2,3,4}

Model	V	F	S	L	H	O	w_i^o	w_i^l
Wordpiece	40K	256	1	3	192	9.09M	(1,1,1,1,0)	(1,0,0,1,0)
Character	6.8K	512	1	3	192	2.77M	(1,1,1,1,1)	(1,0,0,1,0)

For both TNT models, we run the pre-training procedure for 64 epochs. We pre-train quarter size of BERT (wordpiece) and StructBERT (wordpiece) with the same dataset, epochs and wordpiece vocabulary. In the fine-tuning phase, batch size, the number of batches and learning rate are set to 64, 10 and 2e-5. For all models, we discard the sentence-pair training objective.

4.3 Results

For the downstream hate speech classification, we do fine-tuning on top of aggregate embedding [CLS] of wordpiece TNT as BERT does. Threshold-free AUC@ROC and AUC@PR[2] (Davis and Goadrich, 2006) and threshold (0.5 used here) based F1 score and Matthews correlation coefficient (MCC) are adopted. MCC and AUC@PR are generally regarded as balanced metrics.

Table 4: Performance comparisons on wordpiece TNT for hate speech classification

Source	Method	AUC@ROC	AUC@PR	MCC	F1 Score
Yahoo	BERT	93.92	69.56	60.34	61.10
	StructBERT	94.04	70.22	60.66	61.15
	TNT	94.30 (↑0.26)	70.91 (↑0.69)	62.04 (↑1.38)	63.18 (↑2.03)
Twitter	BERT	89.52	81.10	62.38	73.99
	StructBERT	89.96	82.77	62.58	74.09
	TNT	90.42 (↑0.46)	82.81 (↑0.04)	63.99 (↑1.41)	75.29 (↑1.20)
Wiki	BERT	97.10	87.07	76.04	78.67
	StructBERT	97.10	87.07	75.59	78.37
	TNT	97.30 (↑0.20)	87.86 (↑0.79)	76.32 (↑0.73)	79.10 (↑0.73)

Table 5: Case studies for different models

Case	BERT	StructBERT	TNT	Text
1	0.0434	0.0653	0.7401	If njjjjgers are killing more people daily..why in the world would anyone want gun control.
2	0.421	0.9275	0.9651	Buyout Announced - $45/share massfaggot
3	0.2445	0.4729	0.8083	Good, we don't want a foggat President anyway
4	0.0925	0.0902	0.622	Dey BigFatAceNeggirBeach be's LOUD!!! lol!!!

We first report the comparison results on Yahoo set. As shown in Table 4, our TNT outperforms BERT and StructBERT on test set. Particularly, it achieves more than 1% and 2% improvement in terms of MCC and F1 score, respectively. The performance gain could be reasonably attributed to the new training objective. We further do fine-tuning based on pre-trained models directly for Twitter and Wikipedia sets, respectively. The advantage of TNT over baselines still holds. The superiority of TNT on classification task over multiple datasets signalizes that text normalization based training strategy is a promising direction for better universal language representation learning. Although all three sets are user generated content, Wiki users are somewhat different. As Wiki itself is a collaborative knowledge repository, editors are likely to attack others due to disputes on specific domain knowledge. However, the users are the general public who post comments and tweets more casually for Yahoo and Twitter. In this context, text misspellings in Wiki are likely to be less severe and intentional than others. The way we develop the model enables it to learn better representations especially for garbled text compared to standard masking schemes. Thus, the performance gain is more salient in Yahoo and Twitter.

To better understand their performance difference intuitively, we illustrate in Table 5 some specific error case analysis, where toxic comments are created by users to attack a certain group of people. The key parts are all intentionally manipulated to

---

[2] Precision-Recall

Table 6: Misspelling correction comparison examples. For Bing Spell Check, we render the best results from Proof and Spell modes. The corrected results of Google Docs and Grammarly are based on their top suggestions

Case	Text	Autocorrect	Bing Spell Check	Google Docs	Grammarly	TNT
1	M ke Y*h0! Graet Aga 1n	M he Y*h0! Great Age 1n	M ke Y*h0! Graet Aga 1n	M ke Y*h0! Great Aga 1n	M ke Y*h0! Great Aga 1n	Make Yahoo Great Again
2	T Ⓡump anf B*!den	T Ⓡump and B*!den	Trump and Biden	T Ⓡump and B*!den	T Ⓡump and B*!den	Trump and Biden
3	UAS is a great county	Was is a great county	USA is a great county	UAS is a great county	UAS is a great county	USA is a great country
4	UAS stands for Unmanned Aircraft Systems	Was stands for Unmanned Aircraft Systems	UAS stands for Unmanned Aircraft Systems	UAS stands for Unmanned Aircraft Systems	UAS stands for Unmanned Aircraft Systems	UAS stands for Unmanned Aircraft Systems
5	she recieved her prize	she received her prize	she received her prize	she received her prize	she received her prize	she received her prize
6	we had heard from you more definately	we had heard from you more definitely	we had heard from you more definitely	we had heard from you more definitely	we had heard from you more definitely	we had heard from you more definately

obfuscate moderation algorithms. For case 1 with substitution, TNT functions well but others work poorly. Both StructBERT and TNT work better than BERT for case 2 involving white space deletion. Case 3 comes out with a subtle transposition, TNT performs robust than the other two. Regarding the most challenging case 4 with combination of white space deletion, transposition and substitution, only TNT still works well overall.

5 Misspelling Correction

Misspelling correction is a long-standing research topic (Islam and Inkpen, 2009; Whitelaw et al., 2009; Bassil, 2012) and has been widely commercialized as a service such as Bing Spell Check (Bing) and Grammarly (Grammarly). TNT can be readily employed in misspelling correction. We here evaluate TNT using its character-level[3] variant without additional fine-tuning.

We aggressively misspell the test set of Yahoo in Table 2 by 15% for each sample. Then we employ the pre-trained TNT model to recover the text. As a comparison, we also examine an open-source[4] tool autocorrector (Autocorrect) for reference. Edit distance (Distance), and BLEU (BLEU) are adopted to measure the distance and similarity between corrected samples and original ones as detailed in Table 7. TNT performs significantly better than the dictionary look-up algorithm.

Table 7: Misspelling correction comparison

Metric	Misspelling	Autocorrect	TNT
Edit Distance (↓)	16.9391	16.0261	**4.0115**
Normalized Edit Distance (↓)	0.1295	0.1259	**0.0307**
BLEU (↑)	0.3818	0.4609	**0.8309**

In addition, we cross-check the results between TNT and popular commercial spell check products through case studies as reported in Table 6. Among all tools, Bing leads the performance, followed by Google Docs and Grammarly, and Autocorrect performs the worst. Overall, TNT functions very well particularly for case 1 as a combination of multiple challenging misspellings. It is noted that *received* and *definitely* are two of most commonly misspelled words (Words), but TNT fails on the correction of "definately". Overall, "definitely" is not a strongly contextual word derived from the whole sentence here. The limited training set might restrict the correction capacity as well.

6 Discussions and future work

We conducted experiments on three classification tasks. The data size for Yahoo Finance and News, while being one of the largest in the context of hate-speech classification, is nevertheless small in the context of language modeling. We plan to perform large-scale pre-training and evaluation on GLUE datasets for the comprehensive analysis.

This work targets sentence level language understanding. As far as we know, no data available for misspelled words in the context of sentences, we thus have to generate the evaluation set by ourselves. The main goal here is not to develop a more powerful misspelling corrector, but rather to propose a new and stronger language modeling approach. We thus don't set up the strict and comprehensive evaluation for apples-to-apples comparison on spelling correction. We will continue to explore this line in the future.

7 Conclusion

In this work, we propose a new language representation training strategy TNT. TNT improves language modeling by training a transformer to reconstruct text from four operation types typically seen in text manipulation. We show that when fine-tuned for the content moderation task of detecting hatespeech, the new model performed better than the state of the art baselines. We also demonstrate its effectiveness in misspelling correction.

---

[3] As misspelling usually involves with many subtle changes, we resort to character sets as the vocabulary with much flexibility.

Abstract

Word embedding models are typically able to capture the semantics of words via the distributional hypothesis, but fail to capture the numerical properties of numbers that appear in a text. This leads to problems with numerical reasoning involving tasks such as question answering. We propose a new methodology to assign and learn embeddings for numbers. Our approach creates Deterministic, Independent-of-Corpus Embeddings (referred to as DICE) for numbers, such that their cosine similarity reflects the actual distance on the number line. DICE outperforms a wide range of pre-trained word embedding models across multiple examples of two tasks: (i) evaluating the ability to capture numeration and magnitude; and (ii) to perform list maximum, decoding, and addition. We further explore the utility of these embeddings in downstream applications by initializing numbers with our approach for the task of magnitude prediction. We also introduce a regularization approach to learn model-based embeddings of numbers in a contextual setting.

1 Introduction

Word embeddings capture semantic relationships between words by operationalizing the distributional hypothesis (Harris, 1954; Firth, 1957). They can be learned either non-contextually (Mikolov et al., 2013b; Pennington et al., 2014; Bojanowski et al., 2017) or contextually (Devlin et al., 2018; Peters et al., 2018). Non-contextual embeddings have worked well on various language understanding and semantic tasks (Rumelhart et al., 1988; Mikolov et al., 2013a,b). More recently, they have also been used as pre-trained word embeddings to aid more sophisticated contextual models for solving rigorous natural language processing (NLP) problems, including translation, paraphrasing, and sentence-similarity tasks (Kiros et al., 2015; Wieting et al., 2015).

While word embeddings effectively capture semantic relationships between *words*, they are less effective at capturing numeric properties associated with *numbers*. Though numbers represent a significant percentage of tokens in a corpus, they are often overlooked. In non-contextual word embedding models, they are treated like any other word, which leads to misinterpretation. For instance, they exhibit unintuitive similarities with other words and do not contain strong prior information about the magnitude of the number they encode. In sentence similarity and reasoning tasks, failure to handle numbers causes as much as 29% of contradictions (De Marneffe et al., 2008). In other data-intensive tasks where numbers are abundant, like neural machine translation, they are masked to hide the translation models inefficiency in dealing with them (Mitchell and Lapata, 2009).

There are a variety of tests proposed to measure the efficiency of number embeddings. For instance, Naik et al. (2019) shows that GloVe (Pennington et al., 2014), word2vec (Mikolov et al., 2013b), and fastText (Joulin et al., 2016; Bojanowski et al., 2017) fail to capture *numeration* and *magnitude* properties of a number. Numeration is the property of associating numbers with their corresponding word representations (“3” and “three”) while magnitude represents a number’s actual value ($3 < 4$). Further, Wallace et al. (2019) proposes several tests for analyzing numerical reasoning of number embeddings that include list maximum, decoding, and addition.

In this paper, we experimentally demonstrate that if the cosine similarity between word embeddings of two numbers reflects their actual distance on the number line, the resultant word embeddings are useful in downstream tasks. We first demonstrate how *Deterministic, Independent-of-Corpus Embeddings* (DICE) can be constructed such that they almost perfectly capture properties of numera-

November 16–20, 2020.

tion and magnitude. These non-contextual embeddings also perform well on related tests for numeracy (Wallace et al., 2019).

To demonstrate the efficacy of DICE for downstream tasks, we explore its utility in two experiments. First, we design a DICE embedding initialized Bi-LSTM network to classify the magnitude of masked numbers in the 600K dataset (Chen et al., 2019). Second, given the popularity of modern contextual model-based embeddings, we devise a regularization procedure that emulates the hypothesis proposed by DICE and can be employed in any task-based fine-tuning process. We demonstrate that adding such regularization helps the model internalize notions of numeracy while learning task-based contextual embeddings for the numbers present in the text. We find promising results in a numerical reasoning task that involves numerical question answering based on a sub-split of the popular SQuAD dataset (Rajpurkar et al., 2016).

Our contribution can be summarized as follows:

- We propose a deterministic technique to learn numerical embeddings. DICE embeddings are learned independently of corpus and effectively capture properties of numeracy.
- We prove experimentally that the resultant embeddings learned using the above methods improve a model's ability to reason about numbers in a variety of tasks, including numeration, magnitude, list maximum, decoding, and addition.
- We also demonstrate that properties of DICE can be adapted to contextual models, like BERT (Devlin et al., 2018), through a novel regularization technique for solving tasks involving numerical reasoning.

2 Related Work

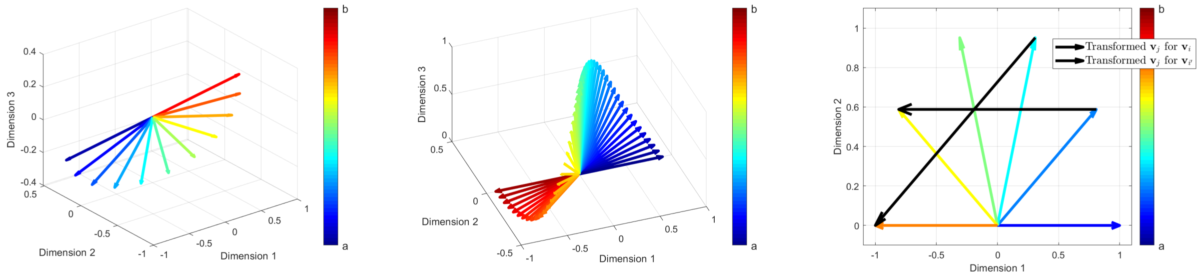
The major research lines in this area have been dedicated to (i) devising probing tests and curating resources to evaluate the numerical reasoning abilities of pre-trained embeddings, and (ii) proposing new models that learn these properties.

Naik et al. (2019) surveyed a number of non-contextual word embedding models and highlighted the failure of those models in capturing two essential properties of numbers – *numeration* and *magnitude*. Chen et al. (2019) created a novel dataset named Numeracy-600k, a collection of approximately 600,000 sentences from market comments with a diverse set of numbers representing age, height, weight, year, etc. The authors use neural network models, including a GRU, BiGRU, CRNN, CNN-capsule, GRU-capsule, and BiGRU-capsule, to classify the magnitude of each number. Wallace et al. (2019) compares and contrasts the numerical reasoning ability of a variety of non-contextual as well as contextual embedding models. The authors also proposed three tests – list maximum, decoding, and addition – to judge the numerical reasoning ability of embeddings of numerals. They infer that word embedding models that perform the best on these three tests have captured the numerical properties of numbers well. Therefore, we consider these proposed tests in our evaluation. (Spithourakis and Riedel, 2018) used a variety of models to distinguish numbers from words, and demonstrated that this ability reduces model perplexity with neural machine translation. Weiss et al. (2018) found that neural networks are capable of reasoning numbers with explicit supervision.

Numerically Augmented QANet (NAQANet) (Dua et al., 2019) was built by adding an output layer on top of QANet (Yu et al., 2018) to predict answers based on addition and subtraction over numbers in the DROP dataset. Our work, in contrast, offers a simple methodology that can be added to any model as a regularization technique. Our work is more similar to Jiang et al. (2019), where embedding of a number is learned as a simple weighted average of its prototype embeddings. Such embeddings are used in tasks like word similarity, sequence labeling and have been proven to be effective.

3 Methods

To overcome NLP models inefficiency in dealing with numbers, we consider our method DICE to form embeddings. To begin, we embed numerals and word forms of numbers as vectors $\mathbf{e}_i \in \mathbb{R}^D$, where i indexes numerals identified within a corpus. We first preprocess by parsing the corpora associated with each of our tasks (described below) for numbers in numeral and word forms to populate a number vocabulary. Then, the dimensionality of the embeddings required for that task is fixed. We explicitly associate the embeddings of a numeral and word forms of numbers to have the same embedding.



(a) DICE-2 embedding (b) DICE-D embedding (c) Addition of DICE vectors

Figure 1: Proposed DICE embeddings. Vectors are colored according to numeral magnitude. Note that addition of two numbers in this embedding is performed by a shift, scaling, and rotation. Scaling depends only on the vector being added, as illustrated in sub-figure (c) in which the two black lines, corresponding to identical $\mathbf{e}_j$, have the same length.

3.1 DICE embeddings

In designing embeddings that capture the aforementioned properties of numeration and magnitude, we consider a deterministic, handcrafted approach (depicted in Figures 1a and 1b). This method relies on the fact that tests for both numeration and magnitude are concerned with the correspondence in similarity between numbers in token space and numbers in embedding space. In token space, two numbers $x, y \in \mathbb{R}$, in numeral or word form (with the latter being mapped to its corresponding numeral form for comparison), can be compared using absolute difference, $i.e.$:

$$d_n(x, y) = |x - y| \tag{1}$$

The absolute value ensures that two numbers are treated as equally distant regardless of whether $x \geq y$ or $y \geq x$. On the other hand, two embeddings $\mathbf{x}, \mathbf{y} \in \mathbb{R}^D$ are typically compared via cosine similarity, given by:

$$s_e(\mathbf{x}, \mathbf{y}) = \frac{\mathbf{x}^T\mathbf{y}}{||\mathbf{x}||_2||\mathbf{y}||_2} = \cos(\theta) \tag{2}$$

$$d_e(\mathbf{x}, \mathbf{y}) = 1 - \cos(\theta) \tag{3}$$

where θ is the angle between $\mathbf{x}$ and $\mathbf{y}$ and $d_e(\mathbf{x}, \mathbf{y})$ is their cosine distance. Normalization by the vector lengths ensures that the metric is independent of the lengths of the two vectors.

Note that numerals are compared in terms of distance while their embeddings are compared by similarity. As cosine distance increases, the angle between $\mathbf{x}$ and $\mathbf{y}$ increases monotonically. A distance of zero is achieved when $\mathbf{x}$ and $\mathbf{y}$ are oriented in the same direction. When $\mathbf{x} \perp \mathbf{y}$, the cosine distance is 1; and when $\mathbf{x}$ and $\mathbf{y}$ are antiparallel, cosine distance is 2.

We seek a mapping $(x, y) \mapsto (\mathbf{x}, \mathbf{y})$ such that d_e monotonically increases as d_n increases. We first bound the range of numbers for which we wish to compute embeddings by $[a, b] \subset \mathbb{R}$ and, without loss of generality, restrict $\mathbf{x}$ and $\mathbf{y}$ to be of unit length ($i.e.$, $||\mathbf{x}||_2 = ||\mathbf{y}||_2 = 1$). Since the cosine function decreases monotonically between 0 and π, we can simply employ a linear mapping to map distances $s_n \in [0, |a - b|]$ to angles $\theta \in [0, \pi]$:

$$\theta(s_n) = \frac{s_n}{|a - b|}\pi \tag{4}$$

This mapping achieves the desired direct relationship between s_n and d_e. Since there are infinitely many choices for $\mathbf{x}$ and $\mathbf{y}$ with angle θ, we simply fix the direction of the vector corresponding to the numeral a. Numbers that fall outside $[a, b]$ are mapped to a random angle in $[-\pi, \pi]$. In the corpora we considered, a and b are chosen such that numbers outside $[a, b]$ represent a small fraction of the total set of numbers (approximately 2%).

We employ this mapping to generate numeral embeddings in $\mathbb{R}^D$. Figure 1a shows deterministic, independent-of-corpus embeddings of rank 2 (DICE-2). In this approach we represent angles as vectors in $\mathbb{R}^2$ using the polar-to-Cartesian coordinate transformation:

$$[r, \theta] \mapsto [x_1, x_2] = [r\cos(\theta), r\sin(\theta)]\mathbf{v} \tag{5}$$

where we choose $r = 1$ without loss of generality. We then sample a random matrix $\mathbf{M} \in \mathbb{R}^{D \times D}$ where $D \geq 2$ and $m_{ij} \sim \mathcal{N}(0, 1)$ and perform a QR decomposition on $\mathbf{M}$ to obtain a matrix $\mathbf{Q}$

Table 1: Performance (% accuracy) on numeracy tests.

whose columns $\mathbf{q}_i, i = 1, \ldots, D$ constitute an orthonormal basis for $\mathbb{R}^D$. The DICE-2 embedding $\mathbf{e} \in \mathbb{R}^D$ of each numeral is then given by $\mathbf{e} = \mathbf{Q}_{1:2}\mathbf{v}$, where the subscript on $\mathbf{Q}$ indicates taking the first two columns of $\mathbf{Q}$.

In Figure 1b we consider DICE-D, in which we generate vectors in $\mathbb{R}^D$ by applying a polar-to-Cartesian transformation in D dimensions (Blumenson, 1960):

$$v_d = \begin{cases} [\sin(\theta)]^{d-1}\cos(\theta), & 1 \leq d < D \\ [\sin(\theta)]^D, & d = D \end{cases} \qquad (6)$$

where the subscripts indicate the coordinate in $\mathbf{v}$. We again apply a QR-decomposition on a random matrix $\mathbf{M}$ generated as above, except here we project $\mathbf{v}$ using all D basis vectors. This allows for a random rotation of the embeddings to avoid bias due to choosing $e_{a1} = 1, e_{ai} = 0 \ \forall i \neq 1$. We employ DICE-D embeddings throughout this paper as word embeddings are practically not 2 dimensional.

4 Experiments

To observe the numerical properties of DICE, we consider two tasks: **Task 1** deals with the *numeration (NUM)* and *magnitude (MAG)* properties as proposed by (Naik et al., 2019); **Task 2** performs *list maximum*, *decoding*, and *addition* as proposed by (Wallace et al., 2019). We then experiment on two additional tasks to demonstrate the applications of DICE.

4.1 Task 1: Exploring Numeracy

In this task, proposed by Naik et al. (2019), there are three tests for examining each property of numeration (NUM, 3 = "three") and magnitude (MAG, $3 < 4$). For each of these tests, target numbers in its word or numeral form are evaluated against other numbers as follows:

- *One-vs-All (OVA):* The distance between the embedding vector of the target and its nearest neighbor should be smaller than the distance between the target and any other numeral in the data.
- *Strict Contrastive (SC):* The distance of the embedding vector of the target from its nearest neighbor should be smaller than its second nearest neighbor numeral.
- *Broad Contrastive (BC):* The distance of the embedding vector of the target numeral from its nearest neighbor should be smaller than its furthest neighbor.

Training Details. We use the Gigaword corpus obtained from the Linguistic Data Consortium to populate the list of numbers from the dataset. Parsing was performed using the text2digits[1] Python module. As done by Naik et al. (2019), we employ $D = 300$ for the DICE-D embeddings. Embeddings of numerals are assigned using the principle explained in Section 3.1, while the embedding of words that denote numbers (word form) simply points to the embedding of that numeral itself. We then perform the six tests (OVA-NUM / OVA-MAG, SC-NUM/ SC-MAG, BC-NUM / BC-MAG) on 130 combinations of numbers for NUM and $31,860$ combinations of numbers for MAG.

Evaluation. Following Naik et al. (2019), we use accuracy to measure the efficiency of the embeddings. These tests require the fulfillment of certain clauses which are defined in Naik et al. (2019).

Results. Table 1 shows comparisons of the performance of embeddings created by each of the DICE methods on the MAG tests. Compared to the baselines, both DICE methods outperform all commonly employed non-contextual word embedding models in OVA, SC, and BC tests. This is attributed to the cosine distance property addressed in the DICE embeddings. Specifically, because the magnitude of the number is linearly related to its angle, sweeping through numbers in order guarantees an increase in angle along each axis. Numbers that are close to each other in magnitude are rotated further but in proportion to their magnitude. Thus, small and large numbers are ensured to lie

near other small and large numbers, respectively, in terms of cosine distance.

On the NUM tests, DICE achieves perfect accuracy. The primary reason DICE embeddings perform so well on numeracy tasks is that the preprocessing steps taken allow us to parse a corpus for word forms of numbers and explicitly set matching embeddings for both word and numeral forms of numbers. Each of these embeddings is guaranteed to be unique since a number's embedding is based on its magnitude, $i.e.$, the larger the magnitude, the greater the angle of the embedding, with a maximum angle of π. This ensures that the numeral form of a number is always able to correctly identify its word form among all word forms in the corpus as that with the smallest cosine distance (which equals zero). Performance on OVA-NUM is a lower bound on the performance of SC-NUM and BC-NUM, so those tests are guaranteed to pass under our approach.

4.2 Task 2: List Maximum, Decoding, and Addition

This task considers the operations proposed by (Wallace et al., 2019) – list maximum, decoding, and addition. List maximum deals with the task of predicting the maximum number given the embedding of five different numbers. Decoding deals with regressing the value of a number given its embedding. An additional task involves predicting the sum of two numbers given their embeddings.

Training Details. The list-maximum test presents to a Bi-LSTM neural network a set of five numbers of the same magnitude, and the network is trained to report the index of the maximum number. In the decoding test, a linear model and a feed-forward network are each trained to output the numeral corresponding to the word form of a number based on its embedding. Finally, in the addition test, a feed-forward network is trained to take in the embeddings of two numbers as its input and report the sum of the two numbers as its output. Each test is performed on three ranges of integers $[0, 99]$, $[0, 999]$, and $[0, 9999]$, with an 80/20 split of training and testing data sampled randomly. The neural network is fed with the embedding of numbers; the task is either classification (in the case of list maximum) or prediction of a continuous number (in case of addition and decoding). We replicate the exact experimental conditions and perform the three tests with DICE embeddings. For the sake of consistency with the tests proposed by (Wallace et al., 2019), we also only deal with positive in this experiment.

Evaluation. List maximum again uses accuracy as its metric while decoding and addition use root mean squared error (RMSE), since predictions are continuous.

Results. Given the strong performance of the DICE-D method on the NUM and MAG tests, we next consider its performance on tasks involving neural network models. In their empirical study, (Wallace et al., 2019) compared a wide range of models that included a random baseline; character level models such as a character-CNN and character-LSTM, which were both untrained and trained; a so-called value embedding model in which numbers are embedded as their scalar value; traditional non-contextual word embedding models including Word2Vec and GloVe; contextual word embedding models including ELMo and BERT; and the Numerically Aware Question Answering (NAQA) Network, a strong numerical reasoning model proposed on the Discrete Reasoning over Paragraphs (DROP) dataset.

We compare the performance of our DICE-D embedding to that of the other models on each of the three tasks proposed by (Wallace et al., 2019). Results are presented in Table 2. We find that our DICE embedding exceeds the performance of more sophisticated models by large margins in all but four cases. In two of those four, our model fell short by only a few percentage points. We attribute the success of the DICE-D approach to the fact that the model is, by design, engineered to handle numeracy. Just as the value embedding model – which proved to be reasonably successful in all three tasks across a wide range of numbers – captures numeracy through the magnitude of embeddings, our model captures numeracy through the angle corresponding to the embeddings.

The value embedding model, however, breaks down as the range of the processed numbers grows. This is likely because, as demonstrated by Trask et al. (2018), networks trained on numeracy tasks typically struggle to learn an identity mapping. We reason that our model outperforms the value embedding model because the network learns to associate features between the set of inputs such that the input vectors can be scaled, rotated, and translated in D dimensions to achieve the desired goal.

More precisely, for a neural network to learn addition, numbers must be embedded such that their vector embeddings can be consistently shifted, rotated, and scaled to yield the embedding of another number (see Figure 1c). The choice of embedding is essential as it may be impractical for a network to learn a transformation for all embeddings that obeys this property (without memorization).

DICE is quite similar to the value embedding system, which directly encodes a number's value in its embeddings. However, DICE performs better due to its compatibility with neural networks, whose layers are better suited for learning rotations and scaling than identity mappings.

Finally, both the value embedding models for a small number range and the character level models remain somewhat competitive, suggesting again that exploring a digit-by-digit embedding of numerals may provide a means of improving our model further.

5 Applications of DICE

5.1 Magnitude Classification

We examine the importance of good initialization for number embedding vectors (Kocmi and Bojar, 2017), particularly for better contextual understanding. In particular, we experiment on the magnitude classification task, which requires the prediction of magnitudes for masked numbers. The task is based on the 600K dataset proposed by Chen et al. (2019), which requires classification into one of seven categories corresponding to powers of 10 in $\{0, 1, 2, 3, 4, 5, 6\}$.

Training Details. We use a bi-LSTM (Hochreiter and Schmidhuber, 1997) with soft attention (Chorowski et al., 2015) to classify the magnitude of masked numbers. Numerals are initialized with corresponding DICE embeddings, and the target number is masked by substituting a random vector. Each token x_n in a sequence of length N is associated with a forward and backward LSTM cell. The hidden state $\mathbf{h_n}$ of each token is given by the sum of the hidden states of the forward and backward cells: $\mathbf{h}_n = \overleftarrow{\mathbf{h}}_n + \overrightarrow{\mathbf{h}}_n$. To generate a context vector $\mathbf{c}$ for the entire sentence, we compute attention scores α_n by taking the inner product of each hidden state $\mathbf{h}_n$ with a learned weight vector $\mathbf{w}$. The resulting scores are passed through a softmax function, and the weights are used to form a convex combination of the $\mathbf{h}_n$ that represents the context $\mathbf{c}$ of the sentence. Logits are obtained by taking the inner product of $\mathbf{c}$ with trained embeddings for each of the seven categories, and cross-entropy loss is minimized. More details on training can be found in Appendix A.

Evaluation. Following Chen et al. (2019), we use micro and macro F1 scores for classifying the magnitude of a number.

Results. Table 3 shows significant improvements in the F1 score achieved by the model. To investigate the effects of dimensions of the embedding

Model	Micro-F1	Macro-F1

Table 4: Performance (%) of BiLSTM-attention with DICE model on the Numeracy-600k dataset by varying the embedding dimensions of input tokens.

and hidden vectors within the LSTM cells on the performance of the BiLSTM-attention model, we perform ablation experiments. We vary the embedding size of tokens while keeping other hyperparameters constant, and observe the results on Tables 4. From Table 4 the BiLSTM with DICE model achieves the best micro-F1 score when the embedding dimension is 256. However, the macro-F1 score peaks when the embedding dimension is 512.

These results suggest that while DICE embeddings yield superior performance in non-contextual numerical tasks, such as computing the maximum and performing basic mathematical operations, data agnostic embeddings such as DICE may not be ideal for textual reasoning tasks in which words surrounding a number provide important information regarding the magnitude of the number. Hence, we introduce a model-based regularization method that utilizes the DICE principles to learn number embeddings in 5.2.

5.2 Model-Based Numeracy Embeddings

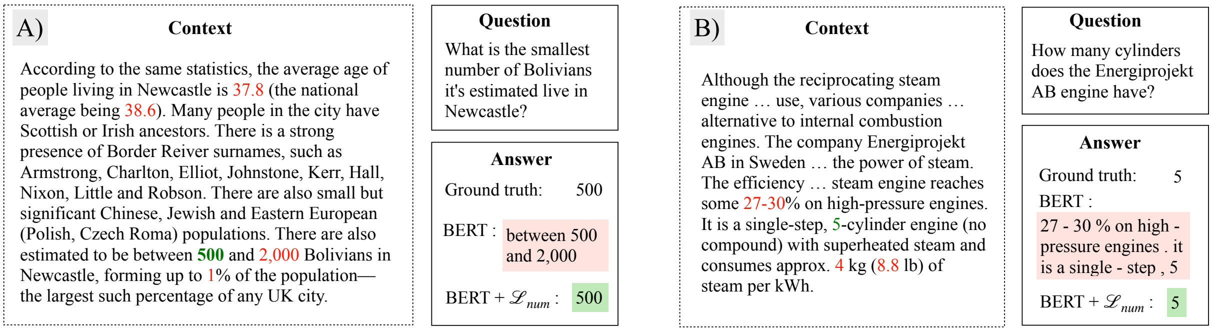
In the previous section, we demonstrated how DICE could be explicitly incorporated for numbers in the text. Here, we propose a methodology that help models implicitly internalize the properties of DICE. Our approach involves a regularization method (an auxiliary loss) that can be adopted in the fine-tuning of any contextual NLP model, such as BERT. Auxiliary losses have shown to work well for a variety of NLP downstream tasks (Shen et al., 2019).

During the task-specific training of any model, the proposed auxiliary loss $\mathcal{L}_{num}$ can be applied to the input embeddings of numbers available in a minibatch. For any two contextual numerical embeddings $\mathbf{x}, \mathbf{y}$ obtained from the final hidden layer of the model, the $\mathcal{L}_{num}$ loss for the pair of numbers (x, y) is calculated as:

$$\mathcal{L}_{num} = \left\| 2\frac{|x-y|}{|x|+|y|} - d_{\cos}(\mathbf{x},\mathbf{y}) \right\|_2 \qquad (7)$$

where $d_{\cos}(\mathbf{x},\mathbf{y}) = 1 - \frac{\mathbf{x}^T\mathbf{y}}{\|\mathbf{x}\|_2\|\mathbf{y}\|_2}$ is the cosine distance between the embeddings $\mathbf{x}$ and $\mathbf{y}$. In essence, $\mathcal{L}_{num}$ follows the same motivation as DICE where cosine distance between the embeddings of two numbers are encouraged to be proportional to their (scaled) absolute magnitude distance on the number line.

Training Details. To evaluate the proposed $\mathcal{L}_{num}$, we test the regularization on the task of question answering (QA) involving numerical answers. In particular, we take the popular Stanford Question Answering Dataset (SQuAD 1.1) (Rajpurkar et al., 2016) dataset and create sub-splits (ranges from [1, 30000]) where the (i) training QA pairs have answers strictly containing numerical digits (Sub-split 1, less than 10K examples), and (ii) training QA pairs have answers containing a number as one of their tokens, for e.g. “10 apples” (Sub-split 2, slightly more than 10K examples). We create these splits to evaluate BERT model’s reasoning involving numbers to pick these answers. We choose `BERT-base-uncased` as baseline model and train it on both the datasets. Within each batch, we calculate $\mathcal{L}_{num}$ by randomly sampling a pair of numbers x, y from the available numbers in the contexts. The corresponding embeddings of the numbers are $\mathbf{x}$ and $\mathbf{y}$, which are extracted from the last hidden layer of the BERT model. We then enforce the distance of embeddings to match the difference between number values by $\mathcal{L}_{num}$. The scores are reported on the development set (less than 1000 examples) as the test set cannot be pruned for our purpose. The assumption here is that the BERT model needs to perform numerical reasoning to come up with answers for these particular kinds of QA pairs. The models were trained on Nvidia Tesla P100 GPU. More details on choosing



A)

Context

According to the same statistics, the average age of people living in Newcastle is 37.8 (the national average being 38.6). Many people in the city have Scottish or Irish ancestors. There is a strong presence of Border Reiver surnames, such as Armstrong, Charlton, Elliot, Johnstone, Kerr, Hall, Nixon, Little and Robson. There are also small but significant Chinese, Jewish and Eastern European (Polish, Czech Roma) populations. There are also estimated to be between **500** and 2,000 Bolivians in Newcastle, forming up to 1% of the population—the largest such percentage of any UK city.

Question

What is the smallest number of Bolivians it's estimated live in Newcastle?

Answer

Ground truth: 500

BERT : between 500 and 2,000

BERT + $\mathscr{L}_{num}$: 500

B)

Context

Although the reciprocating steam engine … use, various companies … alternative to internal combustion engines. The company Energiprojekt AB in Sweden … the power of steam. The efficiency … steam engine reaches some 27-30% on high-pressure engines. It is a single-step, 5-cylinder engine (no compound) with superheated steam and consumes approx. 4 kg (8.8 lb) of steam per kWh.

Question

How many cylinders does the Energiprojekt AB engine have?

Answer

Ground truth: 5

BERT :

27 - 30 % on high - pressure engines . it is a single - step , 5

BERT + $\mathscr{L}_{num}$: 5

Figure 2: Qualitative examples where BERT + $\mathcal{L}_{num}$ performed better than BERT-base

hyper-parameter for BERT + $\mathcal{L}_{num}$ is discussed in Appendix B.

Evaluation. Exact Match is a binary measure ($i.e.$, true/false) of whether the predicted output matches the ground truth answer exactly. This evaluation is performed after the string normalization (uncased, articles removed, etc.). F1 is the harmonic mean of precision and recall.

Results. Results in Table 5 show that the BERT model with numeracy objective achieves an improvement of 0.48 F1 points when the answers are purely numerical digits. When the BERT model is trained on QA pairs with answers containing at least a number with several words, and evaluated on pairs with answers containing only numbers, we see an improvement of 1.12 F1 points over the baseline model.

The BERT-base model on the original SQuAD data was finetuned for 3 epochs owing to its complexity. However, we find that 1 epoch is sufficient to capture the complexity of the pruned SQuAD data. Table 5 shows BERT + $\mathcal{L}_{num}$ consistently performs better than BERT-base across epochs.

Interestingly, BERT-base performs worse when finetuned with QA pairs containing a mix of words and numbers as answers (sub-split 2). This informs us that the baseline model learns to pick numbers better but fails to do as well when fine-tuned with a mix of words and numbers. In both the cases, the evaluation set consists of pruned SQuAD dev set QA pairs with answers strictly containing numerical digits only. We find that BERT + $\mathcal{L}_{num}$ gives the maximum improvement on sub-split 2 data highlighting the efficiency of our regularization technique to learn numerical embeddings.

Figure 2 shows some qualitative examples where the BERT + $\mathcal{L}_{num}$ performs better than BERT-base (Sub-split 2). In this analysis, we found that the baseline model picks the whole sentence or paragraph involving the numerical value (Figure 2 B) as the answer. Our method picks numbers within the classification span (Figure 2 B) and sometimes helps the BERT model to accurately pick up correct numbers (Figure 2 A), contributing to exact match and F1. More such examples are shown in Appendix C.

Model	Epochs	Sub-split 1		Sub-split 2	
		F1	Exact	F1	Exact
BERT	1	89.75	89.40	89.03	86.50
	2	90.71	90.66	90.32	88.09
	3	91.12	91.04	90.28	88.02
BERT + $\mathcal{L}_{num}$	1	**90.23**	90.16	**89.90**	87.26
	2	**91.05**	90.92	**90.49**	88.52
	3	**91.46**	91.29	**91.40**	89.15

Table 5: F1 scores of BERT-base model on SQuAD 1.1 sub-splits (all scores are statistically significant with a variance of 0.01). **Sub-split 1**: both training and testing splits contains only numerical answers; **Sub-split 2**: train split contains atleast one number in the answer and testing split contains only numerical answers.

During our experiments, we observed the potential issue of weak signals from the loss when the availability of numerical pairs is sparse. In the future, our efforts would be to overcome this issue to ensure further gains.

6 Conclusion

In this work, we methodologically assign and learn embeddings for numbers to reflect their numerical properties. We validate our proposed approach with several experiments that test number embeddings. The tests that evaluate the numeral embeddings are fundamentally applicable to all real numbers. Finally, we introduced an approach to jointly learn embeddings of numbers and words that preserve numerical properties and evaluated them on a contextual word embedding based model. In our future work, we would like to extend this idea to unseen numbers in vocabulary as a function of seen ones.

A Training details for Magnitude Classification Experiment

The Bi-LSTM with attention model initialized with DICE embeddings were trained on the market comments data. The model was trained for a fixed number of 9 epochs. We found that the micro and macro F1 scores peaked for a certain epoch and then flattened out. We picked the best micro and macro pair the model obtained in that certain epoch.

B Hyperparameter for BERT + $\mathcal{L}_{num}$

Our model involves a regularization method (an auxiliary loss) that can be adopted in the fine-tuning of BERT. This loss was finetuned with a hyperparameter λ and added to the existing BERT classification loss for detecting the correct span. The hyperparameter search space is between $0, 1$. We sweeped through the values manually within the search space and found that the best model that gave the maximum improvement in F1 scores had a hyperparameter value of 10^{-3}. The values were sweeped based on the observed performance. The performance faded as the hyperparameter was set to a higher value (closer to 1).

C Examples for BERT vs. BERT + $\mathcal{L}_{num}$

Figure 3 provides additional samples where BERT + $\mathcal{L}_{num}$ outperformed the baseline BERT model. Similar to previous observations, our regularized approach is able to pinpoint the correct number as opposed to selecting a substring via pattern matching.

An Empirical Investigation of Contextualized Number Prediction

Taylor Berg-Kirkpatrick
UC San Diego
`tberg@ucsd.edu`

Daniel Spokoyny
Carnegie Mellon University
`dspokoyn@cs.cmu.edu`

Abstract

We conduct a large scale empirical investigation of contextualized number prediction in running text. Specifically, we consider two tasks: (1) *masked number prediction* – predicting a missing numerical value within a sentence, and (2) *numerical anomaly detection* – detecting an errorful numeric value within a sentence. We experiment with novel combinations of contextual encoders and output distributions over the real number line. Specifically, we introduce a suite of output distribution parameterizations that incorporate latent variables to add expressivity and better fit the natural distribution of numeric values in running text, and combine them with both recurrent and transformer-based encoder architectures. We evaluate these models on two numeric datasets in the financial and scientific domain. Our findings show that output distributions that incorporate discrete latent variables and allow for multiple modes outperform simple flow-based counterparts on all datasets, yielding more accurate numerical prediction and anomaly detection. We also show that our models effectively utilize textual context and benefit from general-purpose unsupervised pretraining.

1 Introduction

Pretraining large neural architectures (e.g. transformers (Devlin et al., 2019; Raffel et al., 2019)) on vast amounts of unlabeled data has lead to great improvements on a variety of NLP tasks. Typically, such models are trained using a masked language modeling (MLM) objective and the resulting contextualized representations are finetuned for a particular downstream task like question answering or sentence classification (Devlin et al., 2019; Lan et al., 2020). In this paper, we focus on a related modeling paradigm, but a different task. Specifically, we investigate contextualized number prediction: predicting a real numeric value from its textual context using an MLM-style modeling objective. We conduct experiments on two specific variants: (1) *masked number prediction* (MNM), in which the goal is to predict the value of a masked number token in a sentence, and (2) *numerical anomaly detection* (NAD), with the goal of deciding whether a specific numeric value in a sentence is errorful or anomalous. In contrast with more standard MLM training setups, here we specifically care about the accuracy of the trained masked conditional distributions rather than the contextualized representations they induce. While successful models for these tasks are themselves useful in applications like typo correction and forgery detection (Chen et al., 2019), better models of numeracy are essential for further improving downstream tasks like question answering, numerical information extraction (Mirza et al., 2017; Saha et al., 2017) or numerical fact checking (Thorne and Vlachos, 2017), as well as for processing number-heavy domains like financial news, technical specifications, and scientific articles. Further, systems that detect anomalous numbers in text have applications in practical domains – for example, medicine (Thimbleby and Cairns, 2010) – where identification of numerical entry errors is critical.

Our modeling approach to contextualized number prediction combines two lines of past work. First, following Chen et al. (2019), we treat number prediction as a sentence-level MLM problem where only numerical quantities are masked. However, Chen et al. (2019) focused on predicting the discrete exponent of masked numbers as a classification problem. In contrast, Spithourakis and Riedel (2018) demonstrate the utility of predicting full numerical quantities in text, represented as real numbers, but do so in a language modeling framework, conditioned only on left context. Here, we

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4754–4764,
November 16–20, 2020.

propose a novel setup that combines full-context encoding (i.e. both left and right contexts) with real-valued output distributions for modeling numerical quantities in text. In Figure 1, we illustrate an example where we aim to predict "2 trillion" as a quantity on the real number line.

We expand upon past work by conducting a large scale empirical investigation that seeks to answer three questions: (1) Which encoding strategies yield more effective representations for numbers in surrounding context? (2) Which encoding architectures provide the best representations of surrounding context? (3) What are the most effective real-valued output distributions to model masked number quantities in text? To answer these questions, we propose a suite of novel real-valued output distributions that add flexibility through the use of learned transformation functions and discrete latent variables. We conduct experiments for both MNM and NAD tasks on two large datasets in different domains, combining output distributions with both recurrent and transformer-based encoder architectures, as well as different numeric token encoding schemes. Further, while Chen et al. (2019) studied a specific type of NAD (detecting exaggerated numbers in financial comments), we examine several NAD variants with different types of synthetic anomalies that are found to arise in practice across different domains of data. Finally, we further compare results with a strong discriminative baseline.

2 Models

Our goal is to predict numbers in their textual contexts. The way we approach this is similar to masked language modeling (MLM), but instead of masking and predicting all token types, we only mask and predict tokens that represent numeric values. For example in Figure 1 we wish to predict that the value of the masked number `[#MASK]` should be $2 \times 10^{12} \in \mathbb{R}$ given the surrounding context.

For notational simplicity, we describe our model as predicting a single missing numeric value in a single sentence. However, like other MLMs (see section 4.3), during training we will mask and predict multiple numeric values simultaneously. Let $\boldsymbol{X}$ be a sentence consisting of N tokens where the kth token is a missing numerical value, y. The goal of our model is to predict the value of y conditioned on $\boldsymbol{X}$. We will use common notation for from similar setups and simply treat the kth token in X as a masked numeric value, `[#MASK]`.

Our models $P_{\theta,\gamma}(y|\boldsymbol{X})$ consist of three main components: an input representation of the sentence, a contextual encoder with parameters γ which summarizes the sentence, and an output distribution with parameters θ over the real number line. In this section we will describe our strategies for numerical input representation, the two types of contextual encoders we use, along with different formulations of numerical output distributions.

2.1 Input Context Representation

We first describe the input representation for the textual context $\boldsymbol{X}$ that will be passed into our model's encoder. We let x_i represent the ith token in the input sequence. Like related MLMs that leverage transformers (which is one type of encoder we consider in experiments) we separate the representation of x_i into several types of embeddings. We include a positional embedding e^{Pos} and a word-piece token embedding e^{Tok} like the original BERT. We also introduce our new numeric value embedding e^{Num} to help us learn better numerical representations. Finally, as shown in Figure 1, the input representation for token x_i is the sum of these three H-dimensional embeddings.

If the token at position i represents a numerical quantity, we replace it with a special symbol `[#MASK]`, and represent its numerical value using e_i^{Num}.[1] We use the extraction rules detailed in Section 3.1 to find the numbers in our input sequence. In the next section we will describe two strategies for numerical representation e^{Num}.

2.1.1 Digit-RNN Embedding

The large range ($[1, 1e^{16}]$ in our data) of numerical values prevents them from being used directly as inputs to neural network models as this results in optimization problems due to the different scales of parameters. One strategy to learn embeddings of numerical values has been shown by Saxton et al. (2019) which used character-based RNNs to perform arithmetic operations such as addition and multiplication. We conduct experiments with a similar strategy and represent each number in scientific notation (d.ddde+d) with 6 digits of precision as a string. We then use a digit-RNN to encode the

---

[1] We exclude segment type embeddings since we do not perform next sentence prediction. We also found it helpful to use the zero vector as the numerical embedding for e_i^{Num} if position i is not a quantity.

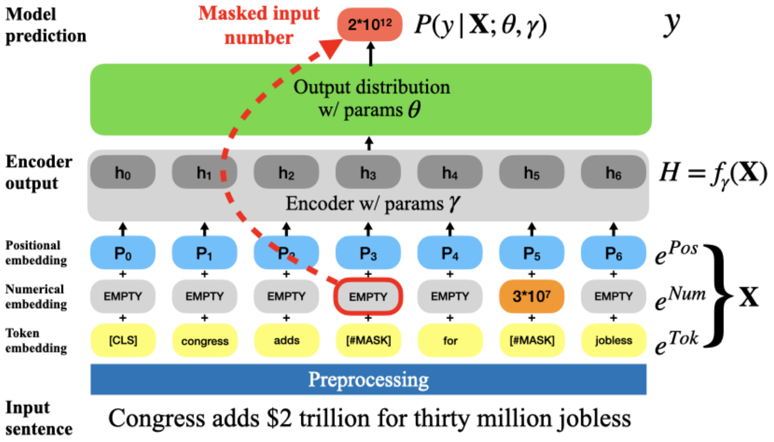

Figure 1: Outline of our model architecture consisting of a sentence representation $\boldsymbol{X}$ which is fed to the encoder with parameters γ and an output distribution over the real number line with parameters θ. In this example our masked numerical objective is to predict the masked out "2 trillion" quantity y. Note that our model is able to use a numerical embedding of the unmasked input $3 * 10^7$ value ("thirty million") as part of the context.

string and use the last output as e^{NUM}.

2.1.2 Exponent Embedding

A simpler approach to represent numbers would be to explicitly learn embeddings for their magnitudes. Magnitudes have been shown to be a key component of the internal numerical representation of humans and animals (Ansari, 2016; Whalen et al., 1999; Dehaene et al., 1998). We conduct experiments with an encoding scheme that learns embeddings for base-10 exponents.

2.2 Context Encoder

The encoder's goal is to summarize the surrounding text, along with other numbers that appear therein. We define $\boldsymbol{H} = f_\gamma(\boldsymbol{X})$ where the encoder f_γ is a function of the context $\boldsymbol{X}$, and $\boldsymbol{H}$ is the hidden representation of the encoder's last layer. Next, we describe two encoder architectures: a transformer and a recurrent approach.

2.2.1 Transformer Encoder

Transformer architectures pretrained on vast amounts of data have led to breakthroughs in textual representation learning (Yang et al., 2019; Liu et al., 2019; Lan et al., 2020; Raffel et al., 2019). We use the 12-layer BERT-base architecture (Devlin et al., 2019) with the implementation provided by Huggingface (Wolf et al., 2019). We use the original BERT's word-piece vocabulary with 30,000 tokens and add a new `[#MASK]` token.

2.2.2 BiGru Encoder

Previous methods focusing on the related task of predicting the order of magnitude of a missing number in text showed that RNNs were strong models for this task (Chen et al., 2019). In our real-valued output task we use a bidirectional Gated Recurrent Unit (*BiGRU*), the best performing model from Chen et al. (2019). We use a one-layer BiGRU with a 64-dimensional hidden state and a dropout layer with a 0.3 dropout rate. We use the same pretrained word-piece embeddings from BERT as this allows us to directly compare the two encoders.

2.3 Real-valued Output Distributions

In early experiments, we observed that simple continuous distributions (e.g. Gaussian or Laplace) performed poorly. Since numbers can have ambiguous or underspecified units, and further, since numbers in text are heavy-tailed, asymmetric or multi-modal output distributions may be desirable. For this reason, we propose several more flexible output distributions, some which include learned transforms and others which include latent variables (both well-known methods for adding capacity to real-valued distributions), to parameterize $P(y|\boldsymbol{X})$.

2.3.1 Log Laplace

A common method for constructing expressive probability density functions is to pass a simple density through a transformation (e.g. a flow or invertible mapping function). As an initial example (and our first output distribution), we describe the log Laplace distribution as a type of flow. Since numbers in text are not distributed evenly on the number line due to a long tail of high magnitudes, a simple trick is to instead model the log of nu-

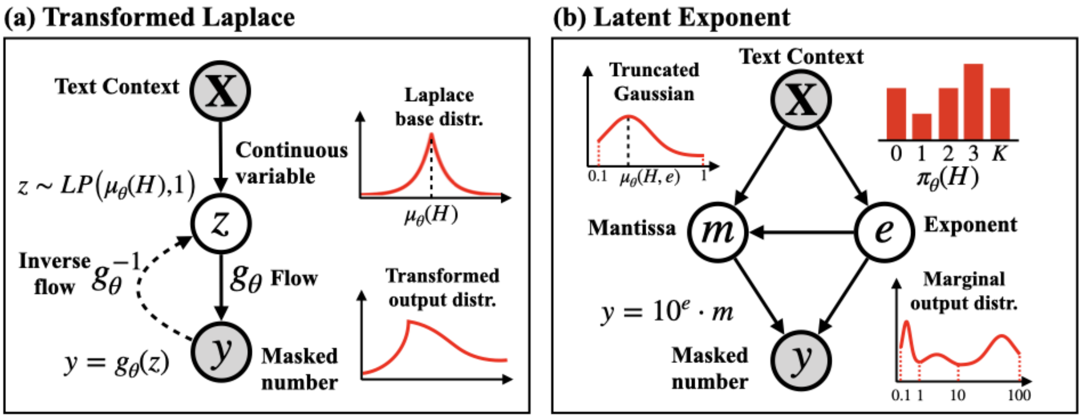

Figure 2: *Left (a):* We depict our *LogLP* and *FlowLP* graphical models along with the latent and output distributions. *Right (b):* Probabilistic graphical model of our latent *DExp* model.

meric values. If the base distribution is Laplace, this yields a log Laplace distribution, which we describe next as an exponential transformation.

In Figure 2, we illustrate our *LogLP* model with a continuous intermediate variable z, encoder f_γ, with exp as the transformation, g_θ , and consequently log as g_θ^{-1}. In equation 1 we show our generative process and training objective where both g_θ and g_θ^{-1} are deterministic functions with no parameters. We let $\mu_\theta(\boldsymbol{H})$ denote a single layer MLP that outputs the location parameter of the base Laplace distribution on z, which is transformed to produce the output variable, y. More precisely:

Generative Process:

$$z \sim Laplace(\mu_\theta(H), 1)$$

$$y = g_\theta(z) = \exp z$$

Training Objective:

$$g_\theta^{-1}(y) = \log y$$

$$\log P(y\,|\,\mathbf{X}) = -\left|g_\theta^{-1}(y) - \mu_\theta(H)\right| - C + \log J_{det}(y)$$

$$\log J_{det}(y) = \log \left|\frac{dg^{-1}}{dy}(y)\right| = \log \left|\frac{1}{y}\right| \tag{1}$$

2.3.2 Flow-transformed Laplace

The exp transformation may not be the ideal choice for our data. For this reason we consider a parameterized transform (flow) to add further capacity to the model. For our purposes, we are restricted to 1-dimensional transformations $g : \mathbb{R} \rightarrow \mathbb{R}$. Further, by restricting the class of functions, we ensure an efficient way of computing the log-derivative of the inverse flow, which allows us to efficiently compute likelihood. We conduct experiments with the simple parameterized flow described in Equation 2. We use a single layer MLP to independently predict each parameter *a*,*b*,*c* from $\boldsymbol{H}$, the output of $f_\gamma(\boldsymbol{X})$. We also scale the range of b, c to be between [0.1, 10] using a Sigmoid activation. Similarly to the *LogLP* setting, $\mu_\theta(\boldsymbol{H})$ is a single layer MLP which predicts the location parameter of the Laplace.

Generative Process:

$$z \sim Laplace(\mu_\theta(H), 1)$$

$$y = g_\theta(z) = \frac{\exp(\frac{z-a}{b})}{c}$$

Training Objective:

$$g_\theta^{-1}(y) = a + b \log cy$$

$$\log P(y\,|\,\mathbf{X}) = -\left|g_\theta^{-1}(y) - \mu_\theta(H)\right| - C + \log J_{det}(y)$$

$$\log J_{det}(y) = \log \left|\frac{dg^{-1}}{dy}(y)\right| = \log \left|\frac{b}{y}\right| \tag{2}$$

This parameterization of flow is designed to allow for (1) re-centering of the input variable (via parameter a), (2) re-scaling of the input (via parameter b), and (3) re-scaling of the output (via parameter c). Together, this leads to a family of inverse flows that are all log-shaped (i.e. they compress higher values), yet have some flexibility to change intercept and range.

2.3.3 Discrete Latent Exponent

While *FlowLP* adds flexibility over the *LogLP* model, both have the drawback of only being able to produce unimodal output distributions.[2] A well-established approach to parameterizing multimodal densities is to use a mixture model. The mixture component is determined by a discrete latent variable in contrast with the continuous intermediate variable introduced in the flow-based models.

---

[2] In principle, more complicated flows could also have multiple modes – though they are more challenging to construct and optimize.

In Figure 2 we show our *DExp* model where e represents an exponent sampled from a multinomial distribution, and m is the mantissa sampled from a truncated Gaussian.

Prior work has shown the effectiveness of cross-entropy losses on numerical training (Saxton et al., 2019; Chen et al., 2019). For this reason we use a truncated Gaussian on the range of [0.1,1] to generate m, which effectively restricts back-propagation to a single mixture component for a given observation. The combination of exponent and mantissa prediction allows us to benefit from the effectiveness of cross-entropy losses, while at the same time getting more fine-grained signal from the mantissa loss. In Equation 3 we show the *DExp* generative process and training objective. We let $\pi_\theta(\boldsymbol{H})$ denote a single layer MLP that outputs the multinomial parameters of $P(e|X)$. Similarly, we let $\mu_\theta(\boldsymbol{H}, e)$ denote a two layer MLP with a [.1,1] scaled Sigmoid that outputs the mean parameter of the mantissa normal distribution.

Generative Process:

$$e \sim Mult(\pi_\theta(H))$$

$$y \sim \mathcal{N}_{trunk[0.1,1]}(\mu_\theta(H, e), 0.05)$$

Training Objective:

$$e^*(y) = \lfloor log_{10}(y) \rfloor$$

$$\log P(y\,|\,\mathbf{X}) = \log\Big[P\big(e = e^*(y)\big) \cdot \frac{1}{C}\exp\Big(-10\Big(\frac{y}{10^{e^*(y)}} - \mu_\theta\big(H, e^*(y)\big)\Big)^2\Big)\Big] \tag{3}$$

2.3.4 Gaussian Mixture Model

Inspired by the best performing model from Spithourakis and Riedel (2018) we also compare with a Gaussian mixture model (*GMM*). This model assumes that numbers are sampled from a weighted mixture of K independent Gaussians. During training the mixture from which a particular point was sampled from is not observed and so it is treated as a latent variable. We can optimize the marginal log-likelihood objective by summing over the K mixtures. In equation 4, *GMM* has K mixtures parameterized by K means and variances $\boldsymbol{\mu}, \boldsymbol{\sigma}$, respectively. Following Spithourakis and Riedel (2018), we pre-train the parameters $\boldsymbol{\mu}, \boldsymbol{\sigma}$ on all the numbers in our training data $\mathcal{D}$ using EM. The means and variances are then fixed and our masked number prediction model only predicts mixture weights during training and inference. We let $\pi_\theta(\boldsymbol{H})$ denote a single layer MLP that outputs the mixture weights $P(e|X)$.

Generative Process:

$$\mu = [\mu_1, \mu_2, \ldots \mu_k]; \sigma = [\sigma_1, \sigma_2, \ldots \sigma_k]$$

$$e \sim Mult(\pi_\theta(H))$$

$$y \sim \mathcal{N}(\mu_e, \sigma_e)$$

Training Objective:

$$\log P(y\,|\,\mathbf{X}) = \log \sum_{k=1}^{K} \Big[P(e = k) \cdot \frac{1}{C}\exp\Big(\frac{-(y-\mu_k)^2}{2\sigma_k^2}\Big)\Big] \tag{4}$$

3 Data

Financial news Financial news documents are filled with many different ratios, quantities and percentages which make this domain an ideal testbed for MNM. The **FinNews** is a collection of 306,065 financial news and blog articles from websites like Reuters[3]. We randomly break the documents into [train, valid, test] splits with [246065, 30000, 30000] respectively.

Since **FinNews** has many occurrences of dates and years, we also evaluate on a subset corpus, **FinNews-$** , to measure effectiveness at modeling only dollar quantities in text. **FinNews-$** is constructed exactly as **FinNews** , with the added requirement that the number is preceded by a dollar sign token ($). For all training and testing on **FinNews-$** , we only predict dollar values.

Academic papers Academic papers have diverse semantic quantities and measurements that make them an interesting challenge numeracy modeling. For this reason, we also use S2ORC, a newly constructed dataset of academic papers (Lo et al., 2020). We use the first 24,000 full text articles, randomly splitting into [20000, 2000, 2000] [train, valid, test] splits. [4] We refer to this dataset as **Sci**. All three datasets follow the same preprocessing discussed below and summary statistics are provided in Table 1.

3.1 Preprocessing

Financial news, academic papers, and Wikipedia articles all have different style-guides that dictate how many digits of precision to use or whether certain quantities should be written out as words. While such stylistic queues might aid models in better predicting masked number *strings*, we are specifically focused on modeling actual numeric

---

[3] www.kaggle.com/jeet2016/us-financial-news-articles

[4] We also filter articles from only these categories {Geology, Medicine, Biology, Chemistry, Engineering, Physics, Computer science, Materials science, Economics, Business, Environmental science}.

values for two reasons: (1) reduced dependence on stylistic features of the text domain leads to better generalization to new domains, and (2) the numerical value of a numeric token conveys its underlying meaning and provides a finer-grained learning signal. For example currencies are usually written as a number and magnitude like *$32 million* however, many quantities can be written out as cardinals *sixty thousand trucks*. We normalize our input numbers so that changing the style from *five* to *5* does not change our output predictions.

As exemplified in Figure 1, the aim of our approach is to incorporate both numbers as context and numbers as predictions (i.e. 2 trillion and thirty million in the example). For this reason, before tokenization we employ heuristics to combine numerals, cardinals and magnitudes into numerical values, whilst removing their string components. We also use heuristics to change ordinals into numbers. By following this normalization preprocessing procedure we get higher diversity of naturally occurring quantitative data and mitigate the bias towards some particular style guide.

For both **FinNews** and **Sci** we lowercase the text and ignore signs $(+, -)$, so all numbers are positive and restrict magnitudes to be in $[1, 1e^{16}]$. We discard sentences that do not have numbers or where the numbers are outside of our specified range. We also filter out sentences that have less than eight words and break up sentences longer than 50 words.[5] We do not use the special token *[SEP]* and all examples are truncated to a maximum length of 128 tokens.

4 Experiments

In this section we explain our experimental setup, starting with our evaluation metrics, implementation details, results, and ablation analyses. We use the following naming convention for models: we specify the encoder (*BiGRU*, *BERT*) first, followed by one of our four output distributions (*LogLP*, *FlowLP*, *DExp*, *GMM*).

4.1 Evaluation

For the MNM task on $\mathcal{D}_{\text{valid}}$ and $\mathcal{D}_{\text{test}}$ splits we randomly select a single number to mask out from the input and predict. We let $\hat{y}$ denote the model's $\arg\max$ prediction from $P(y|\boldsymbol{X})$ and y as the actual observed number. In equation 5 and 6 we show how we calculate log-MAE (*LMAE*) and exponent accuracy (*E-Acc*), both of which use log base 10.

$$\textit{LMAE} = \frac{1}{|\mathcal{D}_{\text{test}}|} \sum_{\mathcal{D}_{\text{test}}} |\log y - \log \hat{y}| \tag{5}$$

$$\textit{E-Acc} = \frac{1}{|\mathcal{D}_{\text{test}}|} \sum_{\mathcal{D}_{\text{test}}} = \begin{cases} 1 & if \lfloor \log y \rfloor = \lfloor \log \hat{y} \rfloor \\ 0 & otherwise \end{cases} \tag{6}$$

4.2 Numerical Anomaly Detection

Both *LMAE* and *E-Acc* metrics test the model's argmax prediction and not the entire $P(y|\boldsymbol{X})$ distribution. We next consider the NAD task where our models need to discern the true number versus some anomaly. We let $\tilde{y}$ denote an anomaly and describe two different ways, [*string, random*], we construct an anomalous example. For *string* we use the true y and randomly perform one of three operations [*add, del, swap*]: inserting a new digit, deleting an existing digit, and swapping the first two digits respectively. For *random*, we randomly sample a number from the training data $\mathcal{D}$ as our anomaly. We choose these string functions as they constitute a large part of numerical entry errors (Thimbleby and Cairns, 2010; Wiseman et al., 2011). Further, *random* mimics a copy-paste error. We report the AUC of a ROC curve for both types as random-anomaly (*R-AUC*) and string-anomaly (*S-AUC*) respectively, using the model's output density to rank the true value against the anomaly.

4.3 Implementation Details

We train all models with stochastic gradient descent using a batch-size of 32 for 10 epochs. We use early stopping with a patience of three on the validation loss. For pretrained *BERT* encoder experiments, we use two learning rates $\{3e^{-5}, 1e^{-2}\}$ for all pretrained parameters and newly added parameters respectively. For all non-pretrained *BERT* experiments and all *BiGRU* encoders we use a single learning rate of $2e^{-2}$.

Devlin et al. (2019) propose a two step process to generate masked tokens. First, select tokens for masking with an independent probability of 15%. Second, for a selected token: With 80% probability replace it with a `[MASK]`, 10% replace it with a random token, and 10% leave it unchanged. Since there are fewer numbers than text tokens, we use a higher probability of 50% for selection. We follow a similar strategy for masking numbers: 80% of the time masking out the number, 10% of the time randomly substituting it with a number from train, and 10% of the time leaving it unchanged.

---

[5] Sentences under eight words in length tended to be titles of articles with the date as the only numeric quantity.

Table 1: Statistics on our datasets. The top half of the table reveals the number of examples per data split, the average length of sentences, and the fraction of tokens that are numbers. The bottom half shows summary statistics for number values in both datasets.

Baselines: We also consider a fully discriminative baseline trained to predict real vs. fake numbers with binary cross entropy loss. The negative numerical samples are randomly drawn from training set numbers to match exactly the random-anomaly task. During training each positive datum has one negative example and is trained in the same batch-wise fashion. When this model uses exponent embeddings for output numbers, emb_{exp} , we can also calculate the exponent accuracy by selecting the exponent embedding with highest model score as a predicted value. We include this approach in experiments as a non-probabilistic alternative to our four output distributions.

4.4 Results

We ran all combinations of encoders and output distributions using input exponent embeddings on **FinNews** and show the results in Table 2. We train the *GMM* model with four different settings of *K* $\in \{31, 63, 127, 255\}$ and report results for the highest-performing setting.

Comparing the two encoders, we find that *BERT* results in stronger performance across all metrics and all output distributions. Although both settings share the same pretrained embedding layers, the pretrained transformer architecture has higher capacity and is able to extract more relevant numerical information for both MNM and NAD.

We find that the parameterized *FlowLP* model was generally better across all metrics under both encoders compared to the *LogLP* model. With the weaker *BiGRU* encoder, the *LogLP* model's *S-AUC* is only 0.04 better than random guessing.

The *DExp* model was the best performing output distribution across all metrics and both encoders, yielding on average 10% higher *E-Acc* and a gain of 0.13 on *AUC*. This means that *DExp* had the best overall fit in terms of the predicted mode $(\arg\max)$ as well as the overall density $P(y|\boldsymbol{X})$.

In contrast, *GMM* , which is also a discrete latent variable model capable of outputting a multimodal distribution, underperformed across all metrics. There was little effect from adjusting the number of mixture components, with slight improvements using more mixtures. One possible reason for the *GMM* model's worse performance is that the mixtures are fit and fixed before training without any of the surrounding textual information. Quantities such as dates and years have many textual clues, but the model's initial clustering may group them together with other quantities. We also found that, empirically, optimization for this model was somewhat unstable.

Finally the *Disc* baseline was the second best performing model on NAD , though on MNM it showed worse *E-Acc* than *LogLP* and *FlowLP* models. This baseline benefited from being directly trained for NAD , which may explain it's underperformance on MNM metrics. Due to the comparatively worse performance of both the *BiGRU* encoder and the *GMM* output distribution, we exclude them from the remainder of our experiments.

4.5 Ablations

Ablations on Numerical Embedding We select our best performing model, *BERT-DExp*, and ablate the numerical input representation on **FinNews**. We compare using emb_{dig}, emb_{exp} , and a version of *ExpBert* which has no numerical input representation. The top half of Table 3 displays the results. We see that emb_{dig} and emb_{exp} perform equally well. Using no input number embeddings reduces performance by 8% on *E-Acc* and 0.03 *AUC* on

Model	**LMAE**↓	***E-Acc*** ↑	**r-AUC**↑	**s-AUC**↑

Table 3: Ablation on **FinNews** dataset. The top half of the table shows the effect of the numerical input representation. The bottom half shows performance for models trained from scratch, without leveraging pretrained BERT parameters.

both anomaly metrics. We also see that there is no benefit from combining both of these input representations, which implies that the model is able to extract similar information from each.

Ablations One-vs-All To measure our model's effectiveness at using the other numbers in the input we construct an ablated evaluation *All* , where all input numbers are masked out.[6] In Table 3 we see that all models that have a numerical embedding suffer a performance drop of around 12% *E-Acc* and an increase of 0.4 on *LMAE*. This suggests that the model is in fact using the other quantities for its predictions. We also find that the model with no input number embeddings does better on the *All* setting since it was effectively trained with fully masked input numbers.

Ablations on Pretraining In the bottom half of Table 3, we compare the effect of starting from a pretrained transformer versus training from scratch. We see that training from scratch hurts all models by around 6% on *E-Acc* and 0.02 on *R-AUC*. We also note that *BERT-LogLP* seems least affected, dropping only 1% on *E-Acc*.

Modeling Additional Domains In this section we explore how different models behave on the alternative domain of academic papers, and how modeling is affected by focusing only dollar quantities in financial news. In Table 4, we show results for pretrained BERT encoder models with input exponent embeddings, trained and evaluated on **Sci** and **FinNews-$** datasets.

On the **Sci** data, the generative models have similar performance on *LMAE* and *E-Acc* . We further find that *BERT-DExp* is still the best performing model across most metrics on both **Sci** and **FinNews-$** data. The *BERT-Disc* baseline, which is directly trained to predict anomalies, is consistently the second best across all datasets on NAD. Finally, we find that the **FinNews-$** is the most challenging of the three datasets, with *BERT-DExp* dropping on *E-Acc* by 20% compared to **FinNews** data. This supports our initial reasoning that the distribution of dollar amounts is more difficult to characterize than other quantities, such as dates, which tend to cluster to smaller ranges.

algebraic word problems (Ling et al., 2017; Roy and Roth, 2016; Zhang et al., 2019), building novel neural modules to directly learn numerical operations (Trask et al., 2018; Madsen and Johansen, 2020) and solving a variety of challenging mathematical problems (Saxton et al., 2019; Lee et al., 2020; Lample and Charton, 2020). In these tasks, numbers can be treated as symbolic variables and computation based on these values leverages a latent tree of arithmetic operations. This differs from our task setting since there is no “true” latent computation that generates all the quantities in our text given the available context.

Numerical Question Answering The DROP dataset (Dua et al., 2019) is a new dataset that requires performing discrete numerical reasoning within a traditional question answering framework. Andor et al. (2019) treat DROP as a supervised classification problem, while recent work by Geva et al. (2020) show how synthetic mathematical training data can build better numerical representations for DROP. Unlike work on DROP, our primary focus is on the task of contextualized number prediction and numerical anomaly detection in text, which involve correlative predictions based on lexical context rather than concrete computation.

String Embeddings Recently, word and token embeddings have been analyzed to see if they record numerical properties (for example, magnitude or sorting order) (Wallace et al., 2019; Naik et al., 2019). This work finds evidence that common embedding approaches are unable to generalize to large numeric ranges, but that character-based embeddings fare better than the rest. However, this line of work also found mixed results on overall numeracy of existing embedding methods and further investigation is required.

Numerical Prediction Spithourakis and Riedel (2018) trained left-to-right language models for modeling quantities in text as tokens, digits, and real numbers using a *GMM*. Our empirical investigation focuses on MNM and considers both left and right contexts of numbers, along with a broader class of generative output distributions. Chen et al. (2019) predict magnitudes of numbers in text and also consider a type of NAD to detect numerical exaggerations on financial data. However, this modeling approach is restricted: it can only distinguish anomalies that result in a change of exponent. In contrast, our real-valued distributions allow us to focus on a broader suite of harder anomaly detection tasks, such as random substitutions and string input error.

6 Conclusion

In this work we carried out a large scale empirical investigation of masked number prediction and numerical anomaly detection in text. We showed that using the base-10 exponent as a discrete latent variable outperformed all other competitive models. Specifically, we found that learning the exponent representation using pretrained transformers that can incorporate left and right contexts, combined with discrete latent variable output distributions, results is the most effective way to model masked number quantities in text. Future work might explore combining more expressive flows with discrete latent variables.

Modeling the Music Genre Perception across Language-Bound Cultures

Abstract

The music genre perception expressed through human annotations of artists or albums varies significantly across language-bound cultures. These variations cannot be modeled as mere translations since we also need to account for cultural differences in the music genre perception. In this work, we study the feasibility of obtaining relevant cross-lingual, culture-specific music genre annotations based only on language-specific semantic representations, namely distributed concept embeddings and ontologies. Our study, focused on six languages, shows that unsupervised cross-lingual music genre annotation is feasible with high accuracy, especially when combining both types of representations. This approach of studying music genres is the most extensive to date and has many implications in musicology and music information retrieval. Besides, we introduce a new, domain-dependent cross-lingual corpus to benchmark state of the art multilingual pre-trained embedding models.

1 Introduction

A prevalent approach to culturally study music genres starts with a common set of music items, *e.g.* artists, albums, tracks, and assumes that the same music genres would be associated with the items in all cultures (Ferwerda and Schedl, 2016; Skowron et al., 2017). However, music genres are subjective. Cultures themselves and individual musicological backgrounds influence the music genre perception, which can differ among individuals (Sordo et al., 2008; Lee et al., 2013). For instance, a Westerner may relate *funk* to *soul* and *jazz*, while a Brazilian to *baile funk* that is a type of *rap* (Hennequin et al., 2018). Thus, accounting for cultural differences in music genres' perception could give a more grounded basis for such cultural studies. However, ensuring both a common set of music items and culture-sensitive annotations with broad coverage of music genres is strenuous (Bogdanov et al., 2019).

To address this challenge, we study the feasibility of cross-culturally annotating music items with music genres, without relying on a parallel corpus. In this work, culture is related to a community speaking the same language (Kramsch and Widdowson, 1998). The specific research question we build upon is: assuming consistent patterns of music genres association with music items within cultures, can a mapping between these patterns be learned by relying on language-specific semantic representations? It is worth noting that, since music genres fall within the class of Culture-Specific Items (Aixelá, 1996; Newmark, 1988), cross-lingual annotation, in this case, cannot be framed as standard translation, as one also needs to model the dissimilar perception of music genres across cultures.

Our work focuses on four language families, Germanic (English-**en** and Dutch-**nl**), Romance (Spanish-**es** and French-**fr**), Japonic (Japanese-**ja**), Slavic (Czech-**cs**), and on two types of language-specific semantic representations, ontologies and multi-word expression embeddings.

First, ontologies are often used to represent music genres, showing how they relate conceptually (Schreiber, 2016). We identify Wikipedia[1], the online multilingual encyclopedia, to be particularly relevant to our study. It extensively documents worldwide music genres relating them through a coherent set of relation types across languages (*e.g. derivative genre*, *sub-genre*). Though the relations types are the same per language, the actual music genres and the way they are related can differ. Indeed, Pfeil et al. (Pfeil et al., 2006) have shown that Wikipedia contributions expose cultural differences aligned with the ones in the physical world.

Second, music genres can be represented from a distributional semantics perspective. Word vector

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4765–4779,
November 16–20, 2020.

spaces are generated from large corpora following the distributional hypothesis, *i.e.* words with similar contexts have akin meanings. As languages are passed on culturally, we assume that the language-specific corpora used to create these spaces are sufficient to convey concepts' cultural specificity into their vector representations. In our study, we focus on multiple recent multilingual pre-trained models to generate word or sentence[2] embeddings (Arora et al., 2017; Grave et al., 2018; Artetxe and Schwenk, 2019; Devlin et al., 2019; Lample and Conneau, 2019), to account for variances in the used corpora or model designs.

Lastly, we combine the semantic representations by retrofitting distributed music genre embeddings to music genre ontologies. Retrofitting (Faruqui et al., 2015) modifies each concept embedding such that the representation is still close to the distributed one, but also encodes ontology information. Initially, we retrofit music genres per language, using monolingual ontologies. Then, by partially aligning these ontologies, we apply retrofitting to learn multilingual embeddings from scratch.

The results show that we can model the cross-lingual music genre annotation with high accuracy by combining both types of language-specific semantic representations. When comparing the representations derived from multilingual pre-trained models, the smooth inverse frequency averaging (Arora et al., 2017) of aligned word embeddings outperforms the state of the art approaches. To our knowledge, this simple method has been rarely used to embed multilingual sentences (Vargas et al., 2019), and we hypothesize its potential as a strong baseline on other cross-lingual datasets and tasks too. Finally, embedding learning based on retrofitting leads to better multilingual music genre representations than when inferred with pre-trained embedding models. This opens the possibility to learn embeddings for rare music genres or languages when aligned music genre ontologies are available.

Summing up, our contributions are: 1) a study on how effective language-specific semantic representations of music genres are for modeling cross-lingual annotation, without relying on a parallel music item corpus; 2) an extensive evaluation of multilingual pre-trained embedding models to derive representations for multi-word concepts in the music domain. Our study can enable complete musicological research, but also localized music information retrieval. This latter application is crucial for online music streaming platforms that leverage music genre annotations to provide worldwide, user-personalized music recommendations.

Our domain-specific study complements other works benchmarking general-language sentence representations (Conneau et al., 2018). Finally, we provide an in-depth formal analysis of the retrofitting part of our method. We prove the strict convexity of retrofitting and show that the ontology concepts' final embeddings converge to the same values despite the order in which concepts are iteratively updated, on condition that we know a single initial node embedding in each connected component of the ontology.

2 Related Work

Music genres are conceptual representations encompassing a set of conventions between the music industry, artists, and listeners about individual music styles (Lena, 2012). From a cultural perspective, it has been shown that there are differences in how people listen to music genres. (Ferwerda and Schedl, 2016; Skowron et al., 2017). Average listening habits in some countries span across many music genres and are less diverse in other countries (Ferwerda and Schedl, 2016). Also, cultural dimensions proved strong predictors for the popularity of specific music genres (Skowron et al., 2017).

Despite the apparent agreement on the music style for which the music genres stand, conveyed in the earlier definition and implied in the related works too, music genres are subjective concepts (Sordo et al., 2008; Lee et al., 2013). To address this subjectivity, Bogdanov et al. (2019) proposed a dataset of music items annotated with English music genres by different sources. In this line of work, we address the divergent perception of music genres. Still, we focus on multilingual, unsupervised music genre annotation without relying on content features, *i.e.* audio or lyrics. We also complement similar studies in other domains (art: Eleta and Golbeck, 2012) with another research method.

Then, in the literature, there are other works that benchmark pre-trained word and sentence embedding models. van der Heijden et al. (2019) compares multilingual contextual language models for

---

[2] Music genres can be multi-word expressions. Previous work (Shwartz and Dagan, 2019a) successfully embed phrases with sentence embedding models. In particular, contextualized language models result in more meaningful representations for diverse composition tasks.

named-entity recognition and part-of-speech tagging. Shwartz and Dagan (2019b) use multiple static and contextual word embeddings to represent multi-word expressions and assess their capacity to capture meaning shift and implicit meaning in compositionality. Conneau et al. (2018) formulate a new task to evaluate cross-lingual sentence representation centered on natural language inference.

Compared to these works, our benchmark is aimed at cross-lingual annotation; we target a specific domain, music, for which we try concept embedding adaptation with retrofitting; and we also test a multilingual sentence representation obtained with smooth inverse frequency averaging of multilingual word embeddings. As discussed in a recent survey on cross-lingual word embedding models (Ruder et al., 2019), there is a need to unlock domain-specific data to assess if general-language sentence representations are also accurate across domains. Our work builds towards this goal.

3 Cross-lingual Music Genre Annotation

Further, we formalize the cross-lingual annotation task and the strategy to evaluate it in Section 3.1. We describe the test corpus used in this work, together with its collection procedure in Section 3.2.

3.1 Problem Formalization

The cross-lingual music genre annotation consists of inferring, for music items, tags in a target language L_t, knowing tags in a source language L_s. For instance, knowing the English music genres of *Fatboy Slim* (*big beat*, *electronica*, *alternative rock*), the goal is to predict *rave* and *rock alternativo* in Spanish. As shown in the example, but also Section 1, the problem goes beyond translation and instead targets a model able to map concepts, potentially dissimilar, across languages and cultures.

Formally, given S a set of tags in language L_s, $\mathcal{P}$ the partitions of S and T a set of tags in language L_t, a mapping scoring function $f : \mathcal{P}(S) \rightarrow \mathbb{R}^{|T|}$ can attribute a prediction score to each target tag, relying on subsets of source tags drawn from S (Hennequin et al., 2018; Epure et al., 2019, 2020). The produced score incorporates the degree of relatedness of each particular input source tag to the target tag. A common approach to compute relatedness in distributional semantics relies on cosine similarity. Thus, for $\{s_1, ..., s_K\}$ source tags and any target tag t, f can be defined as:

$$f_t(\{s_1, s_2, \dots, s_K\}) = \frac{1}{K}\sum_{k=1}^{K}\frac{\mathbf{s}_k{}^T\mathbf{t}}{||\mathbf{s}||_2||\mathbf{t}||_2}, \quad (1)$$

where $||\cdot||_2$ is the Euclidean norm.

3.2 Test Corpus

Wikipedia records worldwide music artists and their discographies, with a frequent mentioning of their music genres. By manually checking the Wikipedia pages of miscellaneous music items, we observed that their music genres vary significantly across languages. For instance, *Knights of Cydonia*, a single by *Muse*, was annotated in Spanish as *progressive rock*, while in Dutch as *progressive metal* and *alternative rock*. In Figure 1, we show another example of different annotations in English, Spanish, and Japanese from Wikipedia infoboxes. As Wikipedia writing is localized, contributors' culture can lead to differences in the multilingual content on the same topic (Pfeil et al., 2006), particularly for subjective matters. Thus, Wikipedia was a suitable source for assembling the test corpus.

Using DBpedia (Auer et al., 2007) as a proxy to Wikipedia, we collected music items such as artists and albums, annotated with music genres in at least two of the six languages (**en**, **nl**, **fr**, **es**, **cs** and **ja**). We targeted *MusicalWork*, *MusicalArtist* and *Band* DBpedia resource types, and we only kept music items that were annotated with music genres which appeared at least 15 times in the corpus. Our final corpus includes 63246 music items. The number of annotations for each language pair is presented in Table 1. We also show in Table 2 the number of

Figure 1: Wikipedia infoboxes of Puerto Rican artist *Milton Cardona*, in English (**en**), Spanish (**es**) and Japanese (**ja**) languages. Some music genre annotations are culture-specific, such as *World*/ワールドミュージック which is present for **en** and **ja** but not for **es**, or 実験音楽 (*Experimental Music*) for **ja** only.

unique music genres per language in the corpus and the average number of tags for each music item.

The **en** and **es** languages use the most diverse tags. This can be because more annotations exist in these languages, in comparison to **cs**, which has the least annotations and least diverse tags. However, the mean number of tags per item appears relatively high for **cs**, while **ja** has the smallest mean number of tags per item.

4 Language-specific Semantic Representations for Music Genres

This work aims to assess the possibility of obtaining relevant cross-lingual music genre annotations, able to capture cultural differences too, by relying on language-specific semantic representations. Two types of semantic representations are investigated given their popularity: ontologies to represent music genre relations (presented in Section 4.1) and distributed embeddings to represent multiword expressions in general (presented in Section 4.2). In contrast to this unsupervised approach, mapping patterns of associating music genres with music items across cultures could have also been enabled with a parallel corpus. However, gathering a corpus that includes all music genres for each pair of languages is challenging.

4.1 Music Genre Ontology

Conceptually, music genres are interconnected entities. For example, *rap west coast* is a sub-genre of *hiphop* or *música electrónica* is the origin of *synthpunk*. Academic and practitioner communities often use ontologies or knowledge graphs to represent music genre relations and enrich the music genre definitions (Schreiber, 2016; Lisena et al., 2018). As mentioned in Section 1, we use in this study Wikipedia-based music genre ontologies because the multilingual Wikipedia contributions on the same topic can differ and these differences have been proven aligned with the ones in the physical world (Pfeil et al., 2006).

We further describe how we crawl the Wikipedia-based music genres ontologies for the six languages by relying on DBpedia. For each language, first, we constitute the seed list using two sources: the DBpedia resources of type *MusicGenre* and their aliases linked through the *wikiPageRedirects* relation; the music genres discovered when collecting the test corpus (introduced in Section 3.1) and their aliases. Then, music genres are fetched by visiting the DBpedia resources linked to the seeds through the relations *wikiPageRedirects*, *musicSubgenre*, *stylisticOrigin*, *musicFusionGenre* and *derivative*[3]. The seed list is updated each time, allowing the crawling to continue until no new resource is found.

In DBpedia, resources are sometimes linked to their equivalents in other languages through the relation *sameAs*. For most experiments, we rely on monolingual music genres ontologies. How-

---

[3] We present these relations by their English names, which may be translated in the DBpedia versions in other languages.

ever, we also collect the cross-lingual links between music genres to include a translation baseline for cross-lingual annotation, *i.e.* for each music genre in a source language, we predict its equivalent in a target language using DBpedia. Besides, we try to learn aligned embeddings from scratch by relying on these partially aligned music genre ontologies, as will be discussed in Section 4.3.

The number of unique Wikipedia music genres discovered in each language is presented in Table 2. Let us note that the graph numbers are much larger than the test corpus numbers, emphasizing the challenge to constitute a parallel corpus that covers all language-specific music genres.

4.2 Music Genre Distributed Representations

As music genres are multi-word expressions, we make use of existing sentence representation models. We also inquire into word vector spaces and obtain sentence embeddings by hypothesizing that music genres are generally compositional, *i.e.* the sense of a multi-word expression is conveyed by the sense of each composing word (*e.g. West Coast rap*, *jazz blues*; there are also non-compositional examples like *hard rock*). We set our investigation scope to multilingual pre-trained embedding models, and we consider both static and contextual word/sentence representations as described next.

Multilingual Static Word Embeddings. The classical word embeddings we study are the multilingual fastText word vectors trained on Wikipedia and Common Crawl (Grave et al., 2018). The model is an extension of the Common Bag of Word Model (CBOW, Mikolov et al., 2013), which includes subword and word position information. The fastText word vectors are trained in distinct languages. Thus, we must ensure that the monolingual word vectors are projected in the same space for cross-lingual annotation. We perform the alignment with the method proposed by Joulin et al. (2018), which treats word translation as a retrieval task and introduces a new loss relying on a relaxed cross-domain similarity local scaling criterion.

Multilingual Contextual Word Embeddings . Contextual word embeddings (Peters et al., 2017; Devlin et al., 2019), in contrast to the classical ones, are dynamically inferred based on the given context sentence. This type of embedding can address polysemy as the word sense is disambiguated through the surrounding text. In our work, we include two recent contextualized language models compatible with the multilingual scope: multilingual Bidirectional Encoder Representations from Transformers (BERT, Devlin et al., 2019) and Cross-lingual Language Model (XLM, Lample and Conneau, 2019).

BERT (Devlin et al., 2019) is trained to jointly predict a masked word in a sentence and whether sentences are successive text segments. Similar to fastText (Grave et al., 2018), subword and word position information is also used. An input sentence is tokenized against a limited token vocabulary with a modified version of the byte pair encoding algorithm (BPE, Sennrich et al., 2016). Multilingual BERT is trained as a single-language model, fed with 104 concatenated monolingual Wikipedias (Pires et al., 2019; Wu and Dredze, 2019).

XLM (Lample and Conneau, 2019) has a similar architecture to BERT. Also, it shares with BERT one training objective, the masked word prediction, and the tokenization using BPE, but applied on sentences differently sampled from each monolingual Common Crawl corpus. Compared to BERT, two other objectives are introduced, to predict a word from previous words and a masked word by leveraging two parallel sentences. Thus, to train XLM, several multilingual aligned corpora are used (Lample and Conneau, 2019).

Multilingual Sentence Embeddings. Contextualized language models can be exploited in multiple ways. First, as Lample and Conneau (2019) show, by training the transformers on multi-lingual data, cross-lingual word vectors are obtained in an unsupervised way. The word vectors can be accessed through the model lookup table. These embeddings are merely aligned but not contextual, thus directly comparable to fastText. For these three types of cross-lingual non-contextual word embeddings, fastText (**FT**), the multilingual BERT's lookup table (**mBERT**) and the XLM's lookup table (**XLM**), we compute the sentence embedding using the standard average (*avg*) or the smooth inverse frequency averaging (*sif*) introduced by Arora et al. (2017).

Formally, let c denote a music genre composed of multiple tokens $\{t_1, t_2, \ldots, t_M\}$, $\mathbf{t}_m$ the embedding of each token t_m initialized from a given pretrained embedding model or to d-dimensional[4] null vector $\mathbf{0}_d$ if t_m is absent from the model vocabulary, and $\hat{\mathbf{q}}_i \in \mathbb{R}^d$ the representation of c which we want to infer. The *avg* strategy computes $\hat{\mathbf{q}}_i$ as

---

[4] In Appendix B, we report d for each embedding type.

$\frac{1}{M}\sum_{m=1}^{M}\mathbf{t}_m$. The *sif* strategy computes $\hat{\mathbf{q}}_i$ as:

$$\overline{\mathbf{q}}_i = \frac{1}{M}\sum_{m=1}^{M}\frac{a}{a+f_{t_m}}\mathbf{t}_m \quad (2)$$

$$\hat{\mathbf{q}}_i = \overline{\mathbf{q}}_i - \mathbf{u}\mathbf{u}^T\overline{\mathbf{q}}_i \quad (3)$$

where f_{t_m} is the frequency of t_m, a is a hyperparameter usually fixed to 10^{-3} (Arora et al., 2017) and $\mathbf{u}$ is the first singular vector obtained through the singular value decomposition (Golub and Reinsch, 1971) of $\overline{\mathbf{Q}}$, the embedding matrix computed with the Equation 2 for all music genres. Vocabulary tokens of pre-trained embedding models are usually sorted by decreasing frequency in the training corpus, *i.e.* the higher the rank, the more frequent the token. Thus, based on the Zipf's law (Zipf, 1949), f_{w_m} can be approximated by $1/z_{t_m}$, z_{t_m} being the rank of t_m. The intuition of this simple sentence embedding method is that uncommon words are semantically more informative.

Second, contextualized language models can be used as feature extractors representing sentences from the contextual embeddings of the associated tokens. Multiple strategies exist to retrieve contextual token embeddings: to use the embeddings layer or the last hidden layer or to apply min or max pooling over time (Devlin et al., 2019). To infer a fixed-length representation of a multi-word music genre, we try max and mean pooling over token embeddings (Lample and Conneau, 2019; Reimers and Gurevych, 2019), obtained with the diverse strategies mentioned before. We denote these sentence embeddings **XLM**$_{Ctxt}$ and **mBERT**$_{Ctxt}$.

The contextualized language models can be further fine-tuned for particular downstream tasks, yielding better sentence representations (Eisenschlos et al., 2019; Lample and Conneau, 2019). Existing evaluations of cross-lingual sentence representations are centered on natural language inference (XNLI, Conneau et al., 2018) or classification (Eisenschlos et al., 2019). The cross-lingual music genre annotation would be closer to the XNLI task; hence we could fine-tune the pre-trained models on a parallel corpus of music genres translations or music genre annotations. However, our research investigates language-specific semantic representations. Also, using translated music genres would not model their different perception across cultures while obtaining an exhaustive corpus of cross-lingual annotations is challenging.

Last, we explore **LASER**, a universal language-agnostic sentence embedding model (Artetxe and Schwenk, 2019). The model is based on a BiLSTM encoder trained on corpora in 93 languages to learn multilingual fixed-length sentence embeddings. As in other models, sentences are tokenized against a fixed vocabulary, obtained with BPE from the concatenated multilingual corpora. **LASER** appears highly effective without requiring task-specific fine-tuning (Artetxe and Schwenk, 2019).

4.3 Retrofitting Music Genre Distributed Representations to Ontologies

Retrofitting (Faruqui et al., 2015) is a method to refine vector space word representations by considering the relations between words as defined in semantic lexicons such as WordNet (Miller, 1995). The intuition is to modify the distributed embeddings to become closer to the representations of the concepts to which they are related. Ever since the original work, many uses of retrofitting have been explored to semantically specialize word embeddings in relations such as synonyms or antonyms (Kiela et al., 2015; Kim et al., 2016), in other languages than a source one (Ponti et al., 2019) or in specific domains (Hangya et al., 2018).

Enhanced extensions of retrofitting exist, but they require supervision (Lengerich et al., 2018). The original method (Faruqui et al., 2015) is unsupervised and can simply yet effectively leverage distributed embeddings and ontologies for improved representations. Thus, we mainly rely on it, but we apply some changes as further described. Let $\Omega = (C, E)$ be an ontology including the concepts C and the semantic relations between these concepts $E \subseteq C \times C$. The retrofitting goal is to learn new concept embeddings, $\mathbf{Q} \in \mathbb{R}^{n \times d}$ with $n = |C|$ and d the embedding dimension. The learning starts with initializing each $\mathbf{q}_i \in \mathbb{R}^d$, the new embedding for concept $i \in C$, to $\hat{\mathbf{q}}_i$, the initial distributed embedding, and then iteratively updates $\mathbf{q}_i$ until convergence as follows:

$$\mathbf{q}_i \leftarrow \frac{\sum_{j:(i,j)\in E}(\beta_{ij}+\beta_{ji})\mathbf{q}_j + \alpha_i\hat{\mathbf{q}}_i}{\sum_{j:(i,j)\in E}(\beta_{ij}+\beta_{ji}) + \alpha_i} \quad (4)$$

α and β are positive scalars weighting the importance of the initial, respectively, the related concept embeddings in computation. The formula was reached through the optimization of the retrofitting objective using the Jacobi method (Saad, 2003).

Equation 4 is a corrected version of the original work, as for a concept i, not only β_{ij} appears in it, but also β_{ji}. That is to say that when computing the

Table 3: Macro-AUC scores (in %, best overall in bold, best locally underlined). The first part corresponds to the translation baselines; the second to the best distributed representations; the last to the retrofitted **FT**$_{sif}$ vectors.

partial derivative of the retrofitting objective concerning i, two non-zero terms are corresponding to the related concept j: when i is the source and j is the target and vice-versa (Bengio et al., 2006; Saha et al., 2016). The further modifications that we make regard the parameters α and β. For each $i \in C$, Faruqui et al. (2015) fix α_i to 1, and β_{ij} to $\frac{1}{degree(i)}$ for $(i, j) \in E$ or 0 otherwise; $degree(i)$ is the number of related concepts i has in Ω.

While many embedding models can handle unknown words nowadays, concepts may still have unknown initial distributed vectors, depending on the model's choice. For this case, expanded retrofitting (Speer and Chin, 2016) has been proposed, considering $\alpha_i = 0$, for each concept i with unknown initial distributed vector, and $\alpha_i = 1$ for the rest. Thus, $\mathbf{q}_i$ is initialized to $\mathbf{0}_d$ and updated by averaging the embeddings of its related concepts at each iteration. Let us notice that, through retrofitting, representations are not only modified but also learned from scratch for some concepts.

We adopt the same approach to initialize α. Moreover, we also adjust the parameters β to weight the importance of each related concept embedding depending on the relation semantics in our music genre ontology (Epure et al., 2020). Specifically, we distinguish between equivalence and relatedness as follows:

$$\overline{\beta}_{ij} = \begin{cases} 1 & : (i, j) \in E_\epsilon \subset E \\ \beta_{ij} & : (i, j) \in E - E_\epsilon \\ 0, & : (i, j) \notin E \end{cases}$$

where E_ϵ contains the equivalence relation types (*wikiPageRedirects*, *sameAs*); $E - E_\epsilon$ contains the relatedness relation types (*stylisticOrigin*, *musicSubgenre*, *derivative*, *musicFusionGenre*). We label this modified version of retrofitting as **Rfit**.

Finally, we want to highlight a crucial aspect of retrofitting. Previous works (Speer and Chin, 2016; Hayes, 2019; Fang et al., 2019) claim that, while the retrofitting updating procedure converges, the results depend on the order in which the updates are made. We prove in Appendix A that the retrofitting objective is strictly convex when at least one initial concept vector is known in each connected component. Hence, with this condition satisfied, retrofitting converges to the same solution always and independently of the updates' order.

5 Experiments

Cross-lingual music genre annotation, as formalized in Section 3, is a typical multi-label prediction task. For evaluation, we use the Area Under the receiver operating characteristic Curve (AUC, Bradley, 1997), macro-averaged. We report the mean and standard deviations of the macro AUC scores using 3-fold cross-validation. For each language, we apply an iterative split (Sechidis et al., 2011) of the test corpus that balances the number of samples and the tag distributions across the folds. We pre-process the music genres by either replacing special characters with space (*_-/,*) or removing them (*()’:.!$*). For Japanese, we introduce spaces between tokens obtained with Mecab[5]. Embeddings are then computed from pre-processed tags.

We test two translation baselines, one based on Google Translate[6] (**GTrans**) and one on the DBpedia *SameAs* relation (**DBpSameAs**). In this case, a source music genre is mapped on a single or no target music genre, its embedding being in the form $\{\mathbf{0,1}\}^{|T|}$. For **XLM**$_{Ctxt}$, we compute the sentence embedding by averaging the token embeddings obtained with mean pooling across all layers. For **mBERT**$_{Ctxt}$, we apply the same strategy, but by max pooling the token embeddings instead. We chose these representations as they showed the best performance experimentally compared to the other strategies described in Section 4.2.

When retrofitting language-specific music genre embeddings, we use the corresponding monolingual ontology (**Rfit**$_{u\Omega}$). When we learn multilingual embeddings from scratch with retrofitting, by knowing only music genre embeddings in one language (*la*), we use the partially aligned DBpedia ontologies which contain the *SameAs* relations (**Rfit**$^{la}_{a\Omega}$). For this case, we also propose a baseline representing a source concept embedding as a vector of geodesic distances in the partially aligned ontologies to each target concept (**DBp**$_{a\Omega}$**NNDist**).

Results. Table 3 shows the cross-lingual annotation results. The standard translation, **GTrans**, leads to the lowest results being over-performed by a knowledge-based translation, more adapted to this domain (**DBpSameAs**). Also, these results show that translation methods fail to capture the dissimilar cross-cultural music genre perception.

Pair	**DBp**$_{a\Omega}$**NNDist**	**Rfit**$^{en}_{a\Omega}$**FT**$_{sif}$
en-nl	83.7 ± 0.1	**90.7 ± 0.0**
en-fr	82.7 ± 0.3	**91.7 ± 0.1**
en-es	81.1 ± 0.3	**91.4 ± 0.2**
en-cs	86.6 ± 0.3	**91.6 ± 0.4**
en-ja	81.3 ± 0.1	**89.1 ± 0.2**
Pair	**DBp**$_{a\Omega}$**NNDist**	**Rfit**$^{ja}_{a\Omega}$**FT**$_{sif}$
ja-nl	68.5 ± 0.7	75.7 ± 0.3
ja-fr	71.9 ± 0.1	76.7 ± 0.5
ja-es	68.9 ± 0.4	76.1 ± 0.5
ja-cs	77.9 ± 0.8	**82.2 ± 0.8**
ja-en	70.4 ± 0.4	**82.3 ± 0.5**

Table 4: Macro-AUC scores (in %; those larger than **Rfit**$_{u\Omega}$**FT**$_{sif}$ in Table 3 in bold) with vectors learned by retrofitting to aligned monolingual ontologies.

The second part of Table 3 contains only the best[7] music genre embeddings computed with each word/sentence pre-trained model or method. When averaging static multilingual word embeddings, those from **mBERT** often yield the most relevant cross-lingual annotations, while when applying the *sif* averaging, the aligned **FT** word vectors are the best choice. Between the two contextual word embedding models, **XLM**$_{Ctxt}$ significantly outperforms **mBERT**$_{Ctxt}$, thus we report only the former.

We can notice that all distributed representations of music genres can model quite well the varying music genre annotation across languages. **FT**$_{sif}$ results in the most relevant cross-lingual annotations consistently for 5 out of 6 languages as a source. For **cs** though, the embeddings from **XLM**$_{Ctxt}$ are sometimes slightly better. **LASER** under-performs for most languages but **ja**, for which the vectors obtained with **mBERT**$_{avg}$ are less suitable.

The last column of Table 3 shows the results of cross-lingual annotation when using the **FT**$_{sif}$ vectors retrofitted to monolingual music genre ontologies. The domain adaptation of concept embeddings, inferred with general-language pre-trained models, significantly improves music genre annotation modeling across all pairs of languages.

Table 4 shows the results when using retrofitting to learn music genre embeddings from scratch. Here, distributed vectors are known for one language (**en**, respectively **ja**[8]) and the monolingual ontologies are partially aligned. Even though not necessarily all music genres are linked to their equivalents in the other language, the concept representations learned in this way are more relevant for cross-lingual annotation, for all pairs involving **en** as the source and for **ja**-**cs** and **ja**-**en**. In fact, the

[7] The complete results are presented in Appendix B.

[8] The results for the other languages are in Appendix B.

baseline (**DBp**$_{a\Omega}$**NNDist**) reveals that the aligned ontologies stand-alone can model the cross-lingual annotation quite well, in particular for **en**.

Discussion. The results show that using translation to produce cross-lingual annotations is limited as it does not consider the culturally divergent perception of music genres. Instead, monolingual semantic representations can model this phenomenon rather well. For instance, from *Milton Cardona*'s music genres in **es**, *salsa* and *jazz*, it correctly predicts the Japanese equivalent of *fusion* (フュージョン) in **ja**. Yet, while a thorough qualitative analysis requires more work, preliminary exploration suggests that larger gaps in perception might still be inadequately modeled. For instance, for *Santana*'s album *Welcome* tagged with *jazz* in **es**, it does not predict *pop* in **fr**.

When comparing the distributed embeddings, a simple method that relies on a weighted average of multilingual aligned word vectors significantly outperforms the others. Although rarely used before, we question if we can notice such high performance with other multilingual data-sets. The cross-lingual annotations are further improved by retrofitting the distributed embeddings to monolingual ontologies. Interestingly, the vector alignment does not appear degraded by retrofitting to disjoint graphs. Or, the negative impact is limited and exceeded by introducing domain knowledge in representations. Further, as shown in Table 4, joining semantic representations in this way proves very suitable to learn music genre vectors from scratch.

Regarding the scores per language, we obtained the lowest ones for **ja** as the source. We could explain this by either a more challenging test corpus or still incompatible embeddings in **ja**, possibly because of the quality of the individual embedding models for this language and the completeness of the Japanese music genre ontology. Also, we did not notice any particular improvement for pairs of languages from the same language family, *e.g.* **fr** and **es**. However, we would need a sufficiently sizeable parallel corpus exhaustively annotated in all languages to reliably compare the performance for pairs of languages from the same language family or different ones.

Finally, by closely analysing the results in Table 3, we noticed that given two languages L_1 and L_2, with more music genre embeddings in L_1 than in L_2 (from both ontology and corpus), the results of mapping annotations from L_1 to L_1 seems always better than the results from L_2 to L_1. This observation explains two trends in Table 3. First, the scores achieved for **en** or **es** as the source, the languages with the largest number of music genres, are the best. Second, the results for the same pair of languages could vary a lot, depending on the role each language plays, source, or target.

One possible explanation is that the prediction from languages with fewer music genre tags such as L_2 towards languages with more music genre tags such as L_1 is more challenging because the target language contains more specific or rare annotations. For instance, when checking the results per tag from **cs** to **en** we observed that among the tags with the lowest scores, we found *moombahton*, *zeuhl*, or *candombe*. However, other common music genres, such as *latin music* or *hard rock*, were also poorly predicted, showing that other causes exist too. Is the unbalanced number of music genres used in annotations a cultural consequence? Related work (Ferwerda and Schedl, 2016) seems to support this hypothesis. Then could we design a better mapping function that leverages the unbalanced numbers of music genres in cross-cultural annotations? We will dedicate a thorough investigation of these questions as future work.

6 Conclusion

We have presented an extensive investigation on cross-lingual modeling of music genre annotation, focused on six languages, and two common approaches to semantically represent concepts: ontologies and distributed embeddings[9].

Our work provides a methodological framework to study the annotation behavior across language-bound cultures in other domains too. Hence, the effectiveness of language-specific concept representations to model the culturally diverse perception could be further probed. Then, we combined the semantic representations only with retrofitting. However, inspired by paraphrastic sentence embedding learning, one can also consider the music genre relations as paraphrasing forms with different strengths (Wieting et al., 2016). Finally, the models to generate cross-lingual annotations should be thoroughly evaluated in downstream music retrieval and recommendation tasks.

A Strict Convexity of Retrofitting

Theorem. Let V be a finite vocabulary with $|V| = n$. Let $\Omega = (V, E)$ be an ontology represented as a directed graph which encodes semantic relationships between vocabulary words. Further, let $\hat{V} \subseteq V$ be the subset of words which have non-zero initial distributed representations, $\hat{\mathbf{q}}_i$. The goal of retrofitting is to learn the matrix $\mathbf{Q} \in \mathbb{R}^d$, stacking up the new embeddings $\mathbf{q}_i \in \mathbb{R}^d$ for each $i \in V$. The objective function to be minimized is:

$$\begin{aligned}\Phi(\mathbf{Q}) &= \textstyle\sum_{i\in\hat{V}} \alpha_i ||\mathbf{q}_i - \hat{\mathbf{q}}_i||_2^2 \\ &+ \textstyle\sum_{i=1}^{n} \sum_{(i,j)\in E} \beta_{ij} ||\mathbf{q}_i - \mathbf{q}_j||_2^2,\end{aligned}$$

where the α_i and β_{ij} are positive scalars. Assuming that each connected component of Ω includes at least one word from $\hat{V}$, the objective function Φ is strictly convex w.r.t. $\mathbf{Q}$.

Proof. First of all, let $\hat{\mathbf{Q}}$ denote the $n \times d$ matrix whose i-th row corresponds to $\hat{\mathbf{q}}_i$ if $i \in \hat{V}$, and to the d-dimensional null vector $\mathbf{0}_d$ otherwise. Let $\mathbf{A}$ denote the $n \times n$ diagonal matrix verifying $\mathbf{A}_{ii} = \alpha_i$ if $i \in \hat{V}$ and $\mathbf{A}_{ii} = 0$ otherwise. Let $\mathbf{B}$ denote the $n \times n$ symmetric matrix such as, for all $i, j \in \{1, ..., n\}$ with $i \neq j$, $\mathbf{B}_{ij} = \mathbf{B}_{ji} = -\frac{1}{2}(\beta_{ij} + \beta_{ji})$ and $\mathbf{B}_{ii} = \sum_{j=1, j\neq i}^{n} |\mathbf{B}_{ij}|$. With these notations, and with $Tr(\cdot)$ the trace operator for square matrices, we have:

$$\begin{aligned}&\textstyle\sum_{i\in\hat{V}} \alpha_i ||\mathbf{q}_i - \hat{\mathbf{q}}_i||_2^2 \\ &= Tr\Big((\mathbf{Q} - \hat{\mathbf{Q}})^T \mathbf{A} (\mathbf{Q} - \hat{\mathbf{Q}})\Big) \\ &= Tr\Big(\mathbf{Q}^T\mathbf{A}\mathbf{Q} - \hat{\mathbf{Q}}^T\mathbf{A}\mathbf{Q} - \mathbf{Q}^T\mathbf{A}\hat{\mathbf{Q}} + \hat{\mathbf{Q}}^T\mathbf{A}\hat{\mathbf{Q}}\Big).\end{aligned}$$

Also:

$$\sum_{i=1}^{n} \sum_{(i,j)\in E} \beta_{ij} ||\mathbf{q}_i - \mathbf{q}_j||_2^2 = Tr\Big(\mathbf{Q}^T\mathbf{B}\mathbf{Q}\Big).$$

Therefore, as the trace is a linear mapping, we have:

$$\begin{aligned}\Phi(\mathbf{Q}) &= Tr\Big(\mathbf{Q}^T(\mathbf{A} + \mathbf{B})\mathbf{Q}\Big) + \\ &Tr\Big(\hat{\mathbf{Q}}^T\mathbf{A}\hat{\mathbf{Q}} - \hat{\mathbf{Q}}^T\mathbf{A}\mathbf{Q} - \mathbf{Q}^T\mathbf{A}\hat{\mathbf{Q}}\Big).\end{aligned}$$

Then, we note that $\mathbf{A} + \mathbf{B}$ is a weakly diagonally dominant matrix (WDD) as, by construction, $\forall i \in \{1, ..., n\}$, $|(\mathbf{A} + \mathbf{B})_{ii}| \geq \sum_{j\neq i} |(\mathbf{A} + \mathbf{B})_{ij}|$. Also, for all $i \in \hat{V}$, the inequality is strict, as $|(\mathbf{A} + \mathbf{B})_{ii}| = \alpha_i + \sum_{j\neq i} |\mathbf{B}_{ij}| > \sum_{j\neq i} |(\mathbf{A} + \mathbf{B})_{ij}| = \sum_{j\neq i} |\mathbf{B}_{ij}|$, which means that, for all $i \in \hat{V}$, row i of $\mathbf{A} + \mathbf{B}$ is strictly diagonally dominant (SSD). Assuming that each connected component of graph G includes at least one node from $\hat{V}$, we conclude that $\mathbf{A}+\mathbf{B}$ is a weakly chained diagonally dominant matrix (Azimzadeh and Forsyth, 2016), *i.e.* that:

- $\mathbf{A} + \mathbf{B}$ is WDD;
- for each $i \in V$ such that row i is not SSD, there exists a *walk* in the graph whose adjacency matrix is $\mathbf{A} + \mathbf{B}$ (two nodes i and j are connected if $(\mathbf{A} + \mathbf{B})_{ij} = (\mathbf{A} + \mathbf{B})_{ji} \neq 0$), starting from i and ending at a node associated to a SSD row.

Such matrices are nonsingular (Azimzadeh and Forsyth, 2016), which implies that $\mathbf{Q} \rightarrow \mathbf{Q}^T(\mathbf{A} + \mathbf{B})\mathbf{Q}$ is a positive-definite quadratic form. As $\mathbf{A}+\mathbf{B}$ is a symmetric positive-definite matrix, there exists a matrix $\mathbf{M}$ such that $\mathbf{A} + \mathbf{B} = \mathbf{M}^T\mathbf{M}$. Therefore, denoting $||\cdot||_F^2$ the squared Frobenius matrix norm:

$$\begin{aligned}&Tr\Big(\mathbf{Q}^T(\mathbf{A} + \mathbf{B})\mathbf{Q}\Big) \\ &= Tr\Big(\mathbf{Q}^T\mathbf{M}^T\mathbf{M}\mathbf{Q}\Big) = ||\mathbf{Q}\mathbf{M}||_F^2\end{aligned}$$

which is strictly convex w.r.t. $\mathbf{Q}$ due to the strict convexity of the squared Frobenius norm (see *e.g.* 3.1 in Dattorro (2005)). Since the sum of strictly convex functions of $\mathbf{Q}$ (first trace in $\Phi(\mathbf{Q})$) and linear functions of $\mathbf{Q}$ (second trace in $\Phi(\mathbf{Q})$) is still strictly convex w.r.t. $\mathbf{Q}$, we conclude that the objective function Φ is strictly convex w.r.t. $\mathbf{Q}$.

Corollary. *The retrofitting update procedure is insensitive to the order in which nodes are updated.*

The aforementioned updating procedure for $\mathbf{Q}$ (Faruqui et al., 2015) is derived from Jacobi iteration procedure (Saad, 2003; Bengio et al., 2006) and converges for any initialization. Such a convergence result is discussed in Bengio et al. (2006). It can also be directly verified in our specific setting by checking that each irreducible element of $\mathbf{A}+\mathbf{B}$, *i.e.* each connected component of the underlying graph constructed from this matrix, is irreducibly diagonally dominant (see 4.2.3 in Saad (2003)) and then by applying Theorem 4.9 from Saad (2003) on each of these components. Besides, due to its strict convexity w.r.t. $\mathbf{Q}$, the objective function Φ admits a unique global minimum. Consequently, the retrofitting update procedure will converge to the same embedding matrix regardless of the order in which nodes are updated.

B Extended Results

The following Tables 5 and 6 provide more complete results from our experiments.

Abstract

Exposure to violent, sexual, or substance-abuse content in media increases the willingness of children and adolescents to imitate similar behaviors. Computational methods that identify portrayals of risk behaviors from audio-visual cues are limited in their applicability to films in post-production, where modifications might be prohibitively expensive. To address this limitation, we propose a model that estimates content ratings based on the language use in movie scripts, making our solution available at the earlier stages of creative production. Our model significantly improves the state-of-the-art by adapting novel techniques to learn better movie representations from the semantic and sentiment aspects of a character's language use, and by leveraging the co-occurrence of risk behaviors, following a multi-task approach. Additionally, we show how this approach can be useful to learn novel insights on the joint portrayal of these behaviors, and on the subtleties that film-makers may otherwise not pick up on.

1 Introduction

In one of the longest running movie franchises in history, fictional British Secret Service agent James Bond is more often than not portrayed as an extremely charming gentleman, a cold-blooded killer, a smoker, and a severe alcoholic (Wilson et al., 2018). This is not a unique character trait, as other critically acclaimed films—such as, The Exorcist (Friedkin, 1973), Pulp Fiction (Tarantino, 1994), and A Clockwork Orange (Kubrick, 1972)—follow narratives where the main characters engage in a similar collection of risk behaviors. The portrayals of these risk behaviors typically include acts of violence, sexual and substance-abusive behaviors in scenes of fighting, bloodshed, gunplay; intercourse and nudity; and alcohol, smoking and drug use, respectively. While these tend to attract audiences (Barranco et al., 2017) and facilitate a movie's global market reach (Sparks et al., 2005), they have long sparked concerns about the potential side effects of repeated exposure. Particularly, in the case of at-risk populations, such as children and adolescents, where this exposure has been linked to increased risk for engaging in violence (Anderson and Bushman, 2001; Bushman and Huesmann, 2001), smoke and alcohol consumption (Sargent et al., 2005; Dal Cin et al., 2008), and earlier sexual initiation (Brown et al., 2006).

Although various automated tools have been designed to recognize risk behaviors portrayals (e.g., (Chen et al., 2011; Liu et al., 2008)), many rely on cinematic principles from film theory such as illumination, rapid shot transitions or musical score selection (Brezeale and Cook, 2008). This limits their practical impact to an almost-final edition of the content, specifically where visual and sound effects have been added in, making it too late or expensive to implement any modifications. Hence, there is an opportunity on being able to identify these depictions from an earlier stage of content creation as to offer additional useful insights for film-makers and movie producers during the complex creative process.

To this end, our work leverages on two key insights: first, that while all of these works focus on a specific behavior, risk behaviors frequently co-occur with one another both in real-life (Brener and Collins, 1998) and in entertainment media (Bleakley et al., 2017, 2014; Thompson and Yokota, 2004). Second, that the language use in movie scripts can characterize portrayals of risk behaviors at the earliest form of content creation—even before production begins. For example, by identifying when Mr. Bond orders his usual alcoholic drink, Pulp Fiction's main characters plotting to kill someone, or the evil incarnated in The Exorcist cursing in a sexually explicit manner.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4780–4790,
November 16–20, 2020.

The present work, to the best of our knowledge, is the first to model the co-occurrence of risk behaviors from linguistic cues found in movie scripts. Our proposed model is a multi-task approach that predicts a movie script's violent, sexual and substance-abusive content from vectorial representations of the character's utterances. We hypothesize that this multi-task approach will help improve violent content classification, as well as in providing insights on their relation to other dimensions of risk behaviors depicted in film media.

Specifically, the contributions of this work are:

1. A multi-task model that significantly improves the state-of-the-art for violent content rating prediction by leveraging the co-occurrence of sexual and substance-abusive content
2. *MovieBERT*[1]: A domain-specific fine-tuned BERT model (Devlin et al., 2019) pre-trained over a large collection of film and TV scripts. We use this model to obtain better representations for the semantics of a character's language
3. A novel large-scale analysis on the joint portrayals, and their relation to other ratings, of violence, sex, and substance abuse in film.

2 Related Work

To understand the prevalence of risk behaviors in film and TV, social scientists have often relied on relatively small human annotated data sets (typically under a 100). This includes a study of portrayals of violence in 74 to 77 films from the last decade (Yokota and Thompson, 2000; Webb et al., 2007), as well as portrayals of teenage sex in 90 of the top-grossing films (Callister et al., 2011). Among other findings, these studies provide evidence that MPAA[2] ratings (the primary rating system used for films in the U.S.) are overly sensitive to sexual content, and less effective at identifying other types of risk behaviors (Tickle et al., 2009; Thompson and Yokota, 2004). However, most of these works are limited to the study of a particular behavior, even though risk behaviors frequently co-occur with one another in media (Bleakley et al., 2017, 2014; Thompson and Yokota, 2004).

The task of identifying risk behaviors from language is perhaps closely related to that of recognizing *Abusive Language* (AL; Waseem et al. 2017). AL is an umbrella term that includes offensive language, including sexist and racist language, and hate-speech. AL computational models are usually designed using popular document classification techniques (Mironczuk and Protasiewicz, 2018), based on features such as n-grams (Nobata et al., 2016); affective language (Wiegand et al., 2018) and distributed semantic representations (Wulczyn et al., 2017). Recent efforts (e.g., Mozafari et al., 2019) explore a supervised fine-tuning approach that start from pre-trained models of highly-contextualized word representations from transformers (Devlin et al., 2019).

Most similar to our work are efforts in predicting a single movie-level rating from language either in movie scripts (Martinez et al., 2019; Shafaei et al., 2019) or in transcripts (Mohamed and Ha, 2020). These works explore the use of recurrent neural networks (RNN) over sequences of vector representations, each composed by the concatenation of lexical, semantic and sentiment features, to learn a movie representation from which the target rating is predicted. There are two notable differences between these and our proposed model. First, our model incorporates additional information in the form of other prediction targets (i.e., multi-task paradigm) and multiple attention layers (Vaswani et al., 2017). The former is motivated by the previously mentioned notion that characters tend to engage in joint portrayals of risk behaviors (Bleakley et al., 2017); the latter allows the model to jointly attend to information from different representation sub-spaces. Second, these previous works explore an early-fusion method where linguistic features are concatenated and fed to a self-attention mechanism on top of the RNN layer. This assumes that in an effort to construct a meaningful interpretation of the features, the attention layer will be powerful enough to disentangle different aspects of language, such as semantic and sentiment. Instead, we use a late-fusion approach where we separate semantics from sentiment, and direct them through different pathways in our model—all the way up to independent attention layers. Thus, our attention layers have the relatively easier task of identifying what is of importance for a particular view of language in a particular task. This allows our model to attend to what is being said (semantic) and, independently, how it is being said (sentiment). We expect this

---

[2] Motion Picture Association of America

to be more informative about the content of each utterance, leading to a better representation construction.

3 Method

Our model learns to map sequences of character utterances' representations to overall movie-level ratings. Each representation is composed by two parts: one representing its semantics, and one for its sentiment. These representations are obtained from models trained on larger out-of-domain corpora but have been validated on related tasks in domains similar to those we study in this work (e.g., classification of movie review sentiment (Pagliardini et al., 2018)). Our decision to start from character utterance representation (as opposed to word representations) comes from the limited number of labeled expert curated content ratings in our dataset (see Section 4).

3.1 Semantic representations

The unique aspect of this work is the use of highly-contextualized vector representations for the particular domain of movie scripts to predict content ratings. These techniques have shown remarkable success on a variety of NLP tasks such as sentiment classification (Devlin et al., 2019) and identifying AL in social media (Mozafari et al., 2019).

A. Sentence embeddings: We obtain 700-dimensional Sent2Vec (Pagliardini et al., 2018) (a sentence-level extension of word2vec (Mikolov et al., 2013)) representations from either of two pre-trained sources: (a) BookCorpus (Zhu et al., 2015), and (b) our own collection of $6,000$ movie and TV scripts (see Sec. 4).

B. Highly-contextualized representations: Bidirectional Encoder Representations from Transformers (BERT; Devlin et al. 2019) is a novel language model that outperforms its predecessors due to an innovative architecture that incorporates information from both the left and right contexts. This is done through an interlacing of n fully-connected dense layers each with a multi-head attention layer (Vaswani et al., 2017). From BERT, we obtain vector representations for every utterance. These come from either of two pre-trained models: (a) *BERT-base* ($n = 12$; 768-dimensional), and (b) *BERT-large* ($n = 24$; 1024-dimension)—both trained on a large corpus of documents from Wikipedia and BookCorpus.

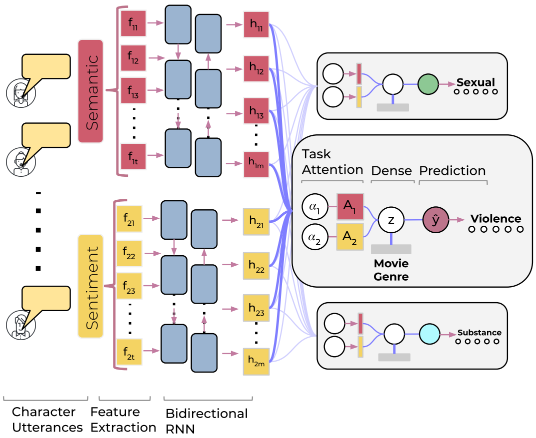

Figure 1: Multi-task model for content rating classification: Each utterance is represented by semantic and sentiment features, fed to independent RNN encoders. The sequence of hidden states from the encoders serve as input for task-specific layers (gray boxes).

C. MovieBERT: A common approach to implement models that produce near state-of-the-art results is to fine-tune large pre-trained models (such as BERT) for a particular task. This aims to keep the generalization power of the original model while also adapting its vocabulary for the language use in a particular domain. Following this idea, here we fine-tune a BERT-base model by continuing its training over the $6,000$ movie scripts dataset. Our adapted model, *movieBERT*, consists of 12 transformer layers that learn a 768-dimensional representation of a movie script. We train this model over a $85\% - 15\%$ train-test data split and, as in (Devlin et al., 2019), we optimize the model for two tasks: next-sentence prediction and masked language modeling. In the former, the model has to predict the sentence that follows a given sentence; in the latter, a random word in a sentence is masked with a token, and the model has to recover the original word. We initialize the weights of our model with those from the pre-trained BERT-base model, and continue training for $10,000$ steps, using the base model's parameters: learning rate of 2×10^{-5}, batch size of 32, and sequences length of 128. *MovieBERT* achieves 96.5% accuracy on the next sentence prediction task, and a 65.9% accuracy on the masked language model—an absolute improvement from the BERT-base model of 24.5% and 12.43%, respectively. To obtain sentence-level representations, we concatenate and then average-pooled the output of the last 2 layers.

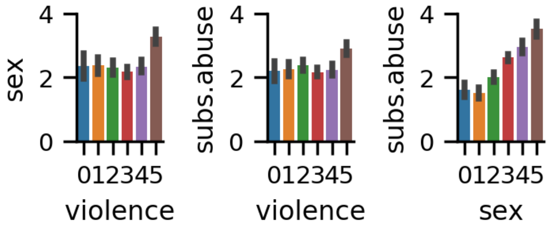

Figure 2: Risk behavior rating co-occurrence: on average, when one risk-behavior rating increases so does the others. Error bars denote 95% confidence intervals.

3.2 Sentiment representations

Previous works show the benefits of including lexical features that capture the expressed sentiment characteristics from language for media content prediction tasks (Martinez et al., 2019; Shafaei et al., 2019). However, most approaches to sentiment analysis on movie scripts rely on manually-constructed sentiment lexica (e.g., Gorinski and Lapata 2018, 2015). These lexica have a limited vocabulary, which is costly to scale or adapt to new domains. In contrast, here we explore neural-network-based sentiment models that learn representations from language used in the related task of movie reviews (Socher et al., 2013). While we are aware of the possible mismatch between the language use in movie reviews and that of movie scripts, our work relies on the assumption that these reviews provide a good initial step towards capturing sentiment expressed in movie scripts. These models not only learn how words are used from a larger vocabulary but also consider the relations between these words which may allow them to generalize better for unseen data. In this work, we experiment with two neural-based models: bidirectional long short-term memory models (Bi-LSTM; Tai et al. 2015), and bidirectional encoder representations from transformers (Devlin et al., 2019). We chose these models because they provide a good trade-off between the number of parameters and the performance on the sentiment prediction task (Barnes et al., 2017), and due to their outstanding performance in NLP tasks. Our sentiment representations are obtained from the last hidden state of the Bi-LSTM, and the previous to last layer of the BERT transformer.

3.3 Role of Movie Genre

Movie genres relate the elements of a story, plot, setting and characters to a specific category. Categorizing a movie indirectly assists in shaping the characters and the story of the movie, and determines the plot and best setting to use. Thus, movie genre contains information on the type of content one could expect in a movie (especially for the case of violent content (Martinez et al., 2019)). Thus, our models include movie genre as an additional feature. Genres for each movie were obtained from IMDb[3] and transformed into a multi-hot encoding.

3.4 Ratings Prediction Model

Our model (see Fig. 1) takes a sequence of utterance representations as input, and outputs predictions for target content ratings. Formally, let K be the number of content ratings to output (number of tasks), and $\{u_t\}_{t=1}^N$ be a sequence of N character utterances. For each u_t, we obtain features, f_{1t} and f_{2t} corresponding to the semantic and sentiment aspects of language respectively. These representations are input to separate bi-directional RNN layers. To improve model generalization, a dropout layer (probability p) was added after the feature extraction layer. Each RNN takes a sequence of representations and outputs a sequence of m hidden vectors $\{h_{j1}, \ldots, h_{jm}\}$; $h_{jl} \in \mathbb{R}^d$ where $j = 1, 2$ corresponds to semantic and sentiment features respectively. Each hidden vector represents a state of *conversational context*—i.e., what is being said in relation to what has been previously said. This context is important as it follows from the fact that most utterances are not independent of one another, but follow a conversation thread.

Both hidden-vector sequences $\{h_{1i}\}_{i=1}^m$ and $\{h_{2i}\}_{i=1}^m$ go through $k \in \{1 \ldots, K\}$ task-specific units, represented as gray boxes in Fig. 1. Each task-specific unit is composed of a sequence of four layers: (i) two separate self-attention mechanisms; (ii) a concatenation layer; (iii) a z-dimensional dense layer, and (iv) a softmax prediction layer. Self-attention (Bahdanau et al., 2014) aggregates the sequence of hidden vectors into a representation of what characters say during the movie. These attention layers, denoted by $\{\alpha_{kj} \in \mathbb{R}^m : j = 1, 2\}$, are not shared between the tasks to allow them to focus on what is important for their particular type of content. We chose this approach as it showed improved performance over our initial experiments with multi-head attention (Vaswani et al., 2017). Attention outputs corresponds to a weighted sum of the hidden states and the α_{kj} weights, $A_{kj} = \sum_{i=1}^m \alpha_{kji} \cdot h_{ji}$. In the concate-

nation layer, these aggregated representations are coupled with movie-genre $v_k = [A_{k1}; A_{k2}; g]$, and serve as inputs for a z-dimensional dense layer. This yields $s_k = \phi(W_k * v_k + b_k)$ where ϕ is a ReLu function, and W_k, b_k are the weight and bias matrix to be learned. We predict the ratings through a prediction layer as $\hat{y_k} = softmax(s_k)$. The complete model is trained by minimizing the aggregated loss $L = \sum_k l_k(y_k, \hat{y_k})$ where l_k is the cross-entropy loss associated with the k-th task.

4 Data

We collected a large number of movie scripts from three publicly available sources. The first source was related works who shared their movie scripts datasets (Gorinski and Lapata, 2018; Ramakrishna et al., 2017); the second source was online collections of produced scripts[4], and the final source was online communities where non-produced scripts are shared[5]. In total we collected $12,706$ scripts, some of which correspond to produced films or TV episodes. To improve the quality of this dataset, we clean it by extracting text, limiting to files with more than $1,000$ lines, and replacing non-ascii characters. In case of any error, we remove the file from the collection. This procedure resulted in $6,057$ movie scripts spanning 23 genres with an average of 1450.6 utterances per movie ($\sigma = 456.11, M = 1447.0$). We use this collection to fine-tune movieBERT.

To evaluate the performance of our model, and directly compare it to previous work, we manually align a subset of 989 movie scripts from our dataset to the content ratings found in (Martinez et al., 2019). These ratings come from Common Sense Media (CSM), a non-profit organization that promotes safe technology and media for children[6]. CSM experts rate movies from 0 (lowest) to 5 (highest) with each rating manually checked by the executive editor to ensure consistency across raters. A manual inspection of the dataset revealed that the movies with the least scores across all risk behaviors correspond to the romantic genre, whereas the movies with the most risky content were in the horror genre. Additionally, we investigate if CSM expert raters capture the co-occurrence of risk behavior portrayals. Figure 2 shows that, on average, when one risk-behavior rating increases so does the others. This was corroborated by significant positive Spearman's correlations between violence and sexual content ($r_s = 0.161$, $p < 0.001$); violence and substance-abuse ($r_s = 0.129$, $p < 0.001$), and sexual content and substance-abuse ($r_s = 0.467$, $p < 0.001$).

4.1 Preprocessing

We follow a procedure similar to that described in Martinez et al. (2019), which discards scene headers, actions and transitions to represent a movie script as a sequence of actors speaking one after another. This leads to a natural formulation of a sequence learning model for capturing the dialog narrative using recurrent neural networks. Additionally, we transformed the five-point ratings to three categories using a median split on each rating to counter class imbalance and to be consistent with previous work. The distribution of the ratings is shown in Table 1.

5 Experimental Setup

In this section we discuss the model implementation, parameter selection, baseline models and sensitivity analysis setup.

5.1 Model Implementation

Our model was implemented in Keras[7]. Although not common in most deep-learning approaches, we performed 10-fold cross-validation (CV) to obtain a more reliable estimation for our model's performance. In each fold, the model was trained until convergence (i.e. loss in consecutive epochs was less than 10^{-8} difference). To prevent over-fitting, we used Adam optimizer with a small learning rate (0.001), batch size of 16, and high dropout probability ($p = 0.5$). For the RNN layer, we used Gated Recurrent Units (GRU; Cho et al. 2014). For the sentiment models, Bi-LSTM parameters were informed by the work of Tai et al. (2015): 50-dimensional hidden representation, dropout ($p = 0.1$), trained with Adam optimizer on a batch size of 25 and a L_2 penalty of 10^{-4}. To allow for a fair comparison, all the BERT pre-trained models and *movieBERT*

Table 2: 10-fold cross validation multi-task classification performance. Precision (P), recall (R) and F1 macro average scores reported (percentages). Models trained independently for each task are denoted by double-line. The best model (shown in bold) performs significantly better than baseline for violence (perm. test $n = 10^5$, $p = 0.002$) and substance-abuse ($n = 10^5$, $p = 0.006$).

had the same set of parameters as the BERT-base model: 12 layers, 768 dimensions, learning rate of 2×10^{-5}, sequence length of 128 and batch size of 32. For the initial experiments, we set the model parameters to hidden dimension size of $d = 16$, to help prevent overfitting, and the sequence length $m = 500$, which is approximately the duration of one movie act (i.e., one third). This selection was informed by previous works (Martinez et al., 2019; Shafaei et al., 2019).

5.2 Experiments

In our first set of experiments, we compare the predictive power of each of the proposed features for predicting risk behavior content. In a second set, we explore how varying the number of dimensions ($d \in \{8, 16, 32, 64\}$) and the utterance sequence length ($m \in \{100, 300, 500, 1000\}$) impacts the performance of our model. Additionally, we explore the individual contribution of each feature to the overall prediction task using ablation studies. For all experiments, we report macro-average precision, recall and F-score (F_1) estimated through 10-fold cross validation.

5.3 Baselines

As baselines, we compare against: (i) AL classification (Nobata et al., 2016), since AL likely includes sexual and drug-related terms; (ii) the state-of-the-art for violence rating prediction from movie scripts (Martinez et al., 2019), and (iii) BERT-only document classification systems (Adhikari et al., 2019). Additionally, to measure whether the performance improves with the inclusion of co-occurring risk behaviors, we compare our model against the same architecture without the multi-task approach.

6 Results

6.1 Classification Results

Table 2 presents the classification performance for the baselines and our proposed model. In line with previous results (Martinez et al., 2019; Shafaei et al., 2019), we observe that including sentiment features (either in the form of lexica or neural network representations) greatly improves the model performance. Even without the multi-task framework, our model architecture shows significant improvement over the baselines (permutation test, $n = 10^5$, all $p < 0.05$). This is likely due to our design choice of reducing the model complexity by focusing just on the informative features (i.e., semantic, sentiment and genre) instead of dealing with redundant features (e.g., n-grams, word2vec, AL lexica). By including the co-occurrence information in the form of additional tasks, our proposed multi-task model with task-specific attention gained an average $F_1 = 1.22\%$ points. It also results in the best model (*movieBERT + sentiment + movie-genre*) with an $F_1 = 67.7\%$ for ($d = 16, m = 500$), performing significantly better than the previous state-of-the-art model for violent content rating prediction (perm. test $n = 10^5$, $p = 0.002$) as well as the AL baselines for violence (perm. test $n = 10^5$, $p = 0.005$) and substance-abuse content (perm. test $n = 10^5$,

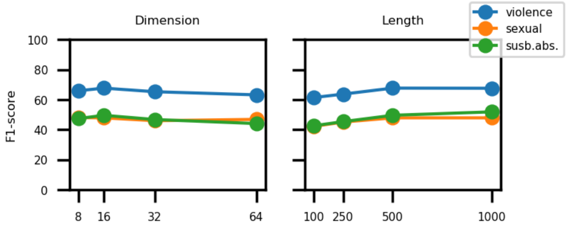

Figure 3: 10-fold cross validation multi-task classification performance based on GRU dimension (d) and sequence length (m).

$p = 0.006$).

While the proposed model also improves sexual content rating prediction, this improvement is non-significant ($p > 0.05$). As previously mentioned, this could be attributed to the fact that MPAA's ratings are particularly sensitive to sexual content (Thompson and Yokota, 2004). In fact, filmmakers are advised to avoid the repeated usage of sexually-derived words—either as an expletive or in a sexual context—as to avoid a non family-friendly rating (Myers, 2018). Thus, they might refer to sexual acts through the use of euphemisms or innuendos, which the model seems unable to pick up on. Our experiments in using BERT for sentiment representations (last row in Table 2) did not significantly improve performance any further ($p > 0.05$). Future work will explore further fine-tuning to better capture affective language.

6.2 Performance Analysis

Parameter Selection: We evaluate model performance under different selections of parameters, namely the number of hidden dimensions in the GRU layer (d) and the length of the character utterance sequences (m). The model performance for different dimensions is presented in the left section of Fig. 3. For all tasks, we notice an improvement in performance for $d = 16$, which drops for higher dimensions. This suggests that the larger models are overfiting the data. There is a slight improvement for sexual content estimation for $d = 8$ ($F_1 = 48.1$), but its performance is not significantly different from the original model (perm. test $p > 0.05$).

With respect to m, the right section of Fig. 3 presents the F_1 performance of the multi-task model. Overall, we see that longer sequences improve the model's performance. However, there was no significant difference between the performance of $m = 500$ and that of $m = 1000$ (perm.test, $p > 0.05$). Although we did not test sequences longer than 1000 utterances, the smaller performance gains between increments of m lead us to believe that the model is saturated, which suggests that any longer sequence length will not provide any significant performance gains.

Semantic	Sentiment	Genre	Violence	Sex	Subs. Abuse	Avg.
✓	✓	✓	67.6 (0.0)	47.9 (0.0)	49.6 (0.0)	0.0
–	✓	✓	60.8 (-6.8)	42.6 (-5.3)	38.2 (-11.4)	-7.83
✓	–	✓	65.2 (-2.4)	46.9 (-0.1)	49.0 (-0.6)	-0.96

Table 3: 10-fold CV ablation experiments using BiGRU (16). F1 macro average score (percentage) reported. In parenthesis: difference between full model and the individual ablation.

Ablation studies: Table 3 shows the individual contributions of each of the three representations. We find that semantic representations are the most important source of information. Removing this feature results in an average performance drop of $-7.83 F_1$. This difference in performance was significant for violence (perm.test $n = 10^5$, $p = 0.003$) and substance-abuse (perm.test $n = 10^5$, $p < 0.0001$) tasks. The second most informative feature was genre, closely followed by sentiment with average performance drops of -1.2 and -0.96 respectively. These results suggest that, while useful, our sentiment features still have scope for improvement. In particular, we note that a potential limiting factor might be the possible mismatch between the language used in movie reviews and that of the movie scripts. A study on how to bridge this possible mismatch will be part of our future work.

Attention Analysis: Finally, we verify our assumption that the attention layers are correctly identifying the important aspects of language with respect to each behavior. We do so by exploring how the attention weights are distributed across the movies scripts. Each of the 6 attention layers (two per task: one for semantic and one for sentiment) learns a m-dimensional weight vector, where each entry corresponds to a particular utterance in the sequence. The higher the weight, the more *importance* the model assigns to that particular utterance. For example, for the violent behavior task, we would expect utterances assigned a higher attention weight to be more reflective violent expressions than utterances with lower attention weights. To verify that each attention layer is correctly focusing on the behavior we are interested in, we set up a hypothesis test where we compare the maximum weight of each attention layer for movies rated HIGH against movies rated LOW on each behavior. Our null hypothesis is that there will be no difference in the way attention concentrates weights for different levels of the behavior. We reject this null hypothesis for the case of the semantics of the violence task (Mann-Whitney $U = 59377.5$, $n_1 = 356$, $n_2 = 304$, $p = 0.015$), and for the sentiment in the sexual content task (Mann-Whitney $U = 52937.5$, $n_1 = 214$, $n_2 = 446$, $p = 0.011$). These results suggest that our model picks up on violence by focusing on the content of the words, whereas identification of sexual behaviors is dependent on the emotional aspects of the language.

7 Co-Occurrence Analysis

In this section, we focus on some of the insights that our proposed model may provide film-makers and producers during the creative process. In particular, our analyses centers on three insights: first, on understanding how joint portrayals of risk behaviors appear on screen; second, in identifying temporal patterns that arise from these joint portrayals, and finally, in showcasing the relation between risk behaviors and MPAA ratings. For this analysis, we re-trained the best performing model over the complete movie script dataset ($n = 989$).

On the relation between joint portrayals of risk behaviors. We find a strong association between predictions of substance-abuse and sexual content: the odds for a movie script to be rated high on sexual content are twice as high when it has a high rating in substance-abuse compared to when it has a low rating (95% Confidence Interval [CI] 2.01 to 34.05). Moreover, we find that the odds of rating high on all three risk behaviors simultaneously are inversely proportional to the predicted violence rating (95% CI, HIGH:0.11 to 0.82 and MED:0.12 to 0.88). Hence, this suggests that *film-makers compensate low levels of violence with joint portrayals of sexual and substance-abuse behaviors.*

On the temporal patterns of the joint portrayals. If there is a temporal relation between the portrayals, when the model picks up a cue for a particular behavior at time t (i.e., a spike in the attention signal), we expect to see a corresponding spike in the attention signal of another task some time after t. To compute this relation, for each movie script we obtained the maximum correlation and its corresponding time lag ($\Delta \in [-m, m]$) by using sample cross correlation function (CCF) between the attention weights of each task. CCF is a measure of similarity between two time series as a function of the displacement of one relative to the other. As an example, Fig. 4 shows the co-evolution of attentions weights and the lags corresponding to their maximum correlation for two movies. On average, *attention to the sexual sentiment content precedes attention to violence semantics* by $\bar{\Delta} = 15.50$ utterances (95% CI, 10.88 to 17.4), with an average correlation coefficient of $r_z = 0.192 \pm 0.02$. This lag increases for movies with higher content ratings on both violence and sex ($\bar{\Delta} = 21.46$, $r_z = 0.202$), whereas movies with low sex and violent content have almost no temporal difference, and a significantly lower correlation coefficient ($\bar{\Delta} = 0.75$, $r_z = 0.172$, perm.test $n = 10^5, p = 0.034$). These results suggests, as Bleakley et al. (2014) points out, that characters engage in sexual and violent behaviors in a small time span from one another.

On the relation between risk behaviors and MPAA ratings. Finally, we measure the relation between the predicted risk behaviors and the movie's MPAA rating. We find that *as sexual content increases, the association between violent (or substance-abuse) content and MPAA rating decreases*. Specifically, movies with high sexual rating are more likely to be rated as R[8], irrespective of their violent or substance-abuse content (odds ratio $OR = 12.172$ (95% CI: 7.86 to 19.46)). In contrast, the MPAA rating of a movie with low sexual content is strongly associated with both their violent content rating ($\chi^2(6) = 18.595$, $p = 0.004$) and their substance-abuse content rating ($\chi^2(3) = 17.99$, $p < 0.001$). These results point out the overly sensitiveness of MPAA raters towards sexual content and corroborate previous findings from small manually-annotated samples of films (Tickle et al., 2009; Thompson and Yokota, 2004).

8 Conclusion

We designed a multi-task model to capture the co-occurrence of depictions of violent content as well as sexual and substance abuse risk behaviors in film through the language data available in scripts. Our proposed model achieves significant improvements

[8] R–Restricted: under 17 requires accompanying parent or adult guardian.

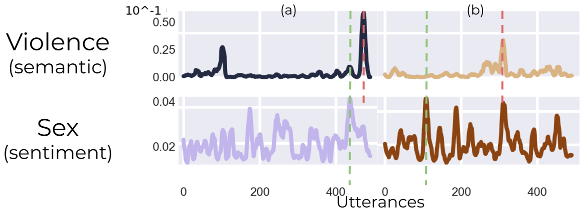

Figure 4: Attention weights for violence and sex for (a) The Exorcist (Friedkin, 1973), and (b) From Russia With Love (Young, 1963). Sex-sentiment (green) leads the violence-semantics (red) by 31 ($\rho = 0.23$) and 203 ($\rho = 0.29$) utterances respectively.

over previous state-of-the-art models for violent content rating prediction. While complementing audio-visual methods, our language-based models can be used to identify subtleties in the way risk behavior content is portrayed, before production begins, offering a valuable tool for content creators and decision makers in entertainment media.

8.1 Future Work

Our overarching goal is to identify when (and how often) are characters being portrayed as targets of risk behaviors—especially in the case where characters are women and minorities. The next step towards this goal would be to recognize when characters refer to one another, and how this contributes to the movie-level risk behavior rating. We hope this leads to tools that can be helpful during the creative process, rather than after the fact.

Abstract

Morphologically rich languages seem to benefit from joint processing of morphology and syntax, as compared to pipeline architectures. We propose a graph-based model for joint morphological parsing and dependency parsing in Sanskrit. Here, we extend the Energy based model framework (Krishna et al., 2020), proposed for several structured prediction tasks in Sanskrit, in 2 simple yet significant ways. First, the framework's default input graph generation method is modified to generate a multigraph, which enables the use of an exact search inference. Second, we prune the input search space using a linguistically motivated approach, rooted in the traditional grammatical analysis of Sanskrit. Our experiments show that the morphological parsing from our joint model outperforms standalone morphological parsers. We report state of the art results in morphological parsing, and in dependency parsing, both in standalone (with gold morphological tags) and joint morphosyntactic parsing setting.

1 Introduction

Morphology and syntax are often inextricably intertwined for morphologically rich languages (MRLs). For such languages, it might be unrealistic to design dependency parsers that expect correct morphological tags to be provided as input (More et al., 2019; Bohnet et al., 2013). Jointly modelling *morphological parsing* (MP) with *dependency parsing* (DP) has shown to be effective for several MRLs (More et al., 2019). In this work, we present *multigraph-EBM* (MG-EBM), a joint model for morphosyntactic parsing, i.e. joint MP and DP, in Sanskrit.

Morphosyntactic parsing has been successfully applied to several MRLs. Bohnet et al. (2013) proposed a transition based joint parser, extending the joint POS tagger and dependency parser of Bohnet and Nivre (2012). Similarly Seeker and Çetinoğlu (2015) proposed a joint graph based parser for Turkish. Here, two different models, one predicting a morphological path and the other a dependency tree, are made to reach an agreement using dual decomposition. More et al. (2019) proposed a transition based joint parser for Hebrew, where it aims to maximise a global score over both morphological and dependency transitions.

Sanskrit is an MRL which shows high degree of syncretism and homonymy in its morphological paradigm. About 90.96 % of the tokens in a dataset of 115,000 Sanskrit sentences (Krishna et al., 2017) show syncretism with an average of 3.62 morphological tags per token. Morphological features, especially *case*, are indicative of the syntactic roles that a word (nominal) can assume in a sentence. The interplay of morphological markers and syntactic roles has been formalised in the traditional grammatical analysis of Sanskrit, *Ashtādhyāyī* (Pāṇini, 500 BCE; Ramkrishnamacharyulu, 2009). Here, the joint modelling of syntactic and morphological information can help disambiguate each other (Tsarfaty, 2006). In MG-EBM, we use this information to prune the input search space.

Krishna et al. (2020) proposed an energy based-model (EBM) framework for multiple structured prediction tasks in Sanskrit. For all the models under EBM, the input search space is a graph which considers every unique morphological analysis of the input words to be a separate node (Figure 1a). Modeling morphosyntactic parsing over this input graph requires an approximation algorithm for inference as it needs to predict a structure containing only a subset of the nodes. We propose to modify the input space to be a multigraph where the number of nodes correspond to the number of tokens in a sentence. This enables us to use an exact search inference (Edmonds, 1967) akin to the first

The labels should not be confused as dependency relations. The graphs we use as input to the EBM are unlabelled graphs.

order dependency parsing model of McDonald et al. (2005).

MG-EBM achieves state of the art results (SOTA), improving the previous best results by 3 F-score points for MP and 2 UAS points for standalone DP (expects gold morph tags as input). We set new SOTA results for joint MP and DP. Further, we demonstrate that MP results obtained from our joint model outperforms standalone MP models. Our proposed pruning approach in itself report an improvement of 6 F-score (2 UAS) points with the original EBM configuration for MP (DP), and a further 2 F-Score (2 UAS) points improvement with the multigraph formulation for MP (DP).

2 Energy Based Model

Krishna et al. (2020) proposed an Energy based model (EBM) framework (LeCun et al., 2006) for multiple structured prediction tasks in Sanskrit. The framework is a generalisation of the joint word-segmentation (WS) and morphological parsing (MP) model by Krishna et al. (2018). The models under this framework are trained using multilayer perceptrons and are essentially first-order arc-factored graph-based parsing models. The dependency parsing (DP) model, similar to McDonald et al. (2005), makes use of a sequence level max-margin loss (Taskar et al., 2003) and Chu-Liu-Edmonds algorithm for the inference. However, the feature function for the task is learnt automatically, and differs from that of McDonald et al. (2005). A lexicon-driven shallow parser (Goyal and Huet, 2016; Huet, 2005) is used to enumerate all the morphological analyses, including cases of syncretism and homonymy, for the tokens in the input sequence. An input graph is constructed from this analysis, as shown in Figure 1a for the sequence “*śriyaḥ patiḥ śrīmati*”.[1] Here every node is a unique combination of three entities, namely, surface-form, stem and morphological tag. All the node pairs, which are not suggested as alternative solutions and hence can co-occur in a predicted solution, form an edge.

The framework uses an automated feature learning approach (Lao and Cohen, 2010; Meng et al., 2015) to generate a feature function consisting of 850 features. Using this feature set the framework achieves state of the art (SOTA) results in several tasks. This is significant, given several morphologically rich languages still rely on models that use hand-crafted features for SOTA results (More et al., 2019; Seeker and Çetinoğlu, 2015). Given the models are arc-factored, the edges are featurised. A feature would consider only one entity each from either of the nodes in the edge. The feature then calculates the distributional information between these entities conditioned on some specific morphological constraint. The type of the entities and the constraints, which constitute the features, are automatically learned as typed paths over a large morphologically tagged corpus. While the training and the feature function remain the same for all the tasks under the framework, the inference is task specific. It searches for a spanning tree with minimum energy (Edmonds, 1967) for DP. For tasks that require prediction of a subset of nodes from the input graph, such as WS and MP, and standalone MP, approximation algorithms were used for inference. Here the inference procedure searches for only a small percentage of all the possible candidates ($< 1\%$) (Krishna et al., 2018).

---

[1] gloss: *śriyaḥ* - Of godess Lakshmi, *patiḥ* - husband, *śrīmati* - prosperous

3 MG-EBM: The Proposed Model

Multigraph-EBM (MG-EBM) extends the EBM framework in two simple yet significant ways.

Multigraph formulation: Instead of the 'one node per unique morphological analysis', as shown in Figure 1a, we propose to use a 'one node per inflected surface-form' multigraph representation, as shown in Figure 1b. For instance, the surface form śriyaḥ, due to syncretism, has 2 possible morphological analyses *M1* and *M2*. In Figure 1a, these analyses are represented as separate nodes and are connected to the only analysis of *patiḥ* via the edges *e* and *g*. In Figure 1b, the cases of syncretism for *śriyaḥ* are merged as a single node, though the edges e and g to *patiḥ* are retained. This leads to a multigraph formulation.[2] The new representation retains all the edges, and their feature vectors, present in the original representation. The design of our feature function guarantees that every edge will have a unique feature vector. With this formulation, we simplify the search problem for the joint MP and DP task to that of searching for the spanning tree with minimum energy. This enables the use of the exact search Edmonds-Chu-Liu MST algorithm (Edmonds, 1967), rather than an approximation algorithm, for inference. It is straightforward to extend the algorithm to multigraph, as we just need to retain only the minimum energy edge and prune out all the other edges between a pair of nodes in the input graph (McDonald and Satta, 2007).

Linguistically Motivated Pruning: Linguistic constraints based on the traditional grammatical analysis and verbal cognition in Sanskrit (Kulkarni and Ramakrishnamacharyulu, 2013; Ramkrishnamacharyulu, 2009) have been previously employed in various deterministic dependency parsers for Sanskrit (Kulkarni et al., 2019; Kulkarni, 2013; Kulkarni et al., 2010). We use these constraints to prune the edges in our input graph. During pruning, we first exhaustively enumerate all the unlabelled directed spanning-trees in the input graph using Mayeda and Seshu (1965).[3] For each such tree, if every directed-edge in the spanning-tree can be assigned at least one label as per the rules of the grammar, it will be considered a valid candidate. Finally, all the edges which are not part of even one valid candidate-tree will be pruned from the input graph. This pruned unlabelled directed graph serves as the input for the inference procedure. This linguistically informed pruning can at best be seen as a rule-based deterministic delexicalised dependency parsing, which considers information only from the morphological tags.

Figure 2: Case information and possible dependency relations that a case is indicative of.

Morphology can signal dependency in various ways. The morphological marker of a word may not only index the properties of the word itself, but it may also index the agreement between its head or dependants (Nichols, 1986). The agreement between the subject and verb in terms of the number and person respectively is one such case. Similarly, the case, number, and gender agreement between the words in an adjectival modifier (*viśeṣaṇa*) relation is another example of this in Sanskrit. Further, morphological markers are indicative not only of the presence of syntactic dependency between the words in a sentence, but also of the type of the syntactic dependency shared between them (Nichols, 1986; Seeker and Kuhn, 2013). In Sanskrit, the *case* information of a nominal narrows down the possible relations it can have with a verb as the head. This is shown in Figure 2. We form constraints based on these morphosyntactic information and use it for pruning the edges.[4] The dependency relations shown in Figure 2 are rooted in the *Pāṇinian* grammar, i.e. traditional grammatical sys-

---

[2] It needs to be noted that the edge labels in Figure 1(a and b) are used for illustrative purposes. The graphs we use are unlabelled and do not contain any information related to dependency labels.

[3] The algorithm has an amortised runtime of $O(nm)$, where n and m are the number of nodes and edges, respectively (Smith, 1997).

tem followed for Sanskrit (Pāṇini, 500 BCE). The use of the relations from the *Pāṇinian* grammar, instead of other dependency tagsets such as Universal Dependencies (Nivre et al., 2016), enables us to incorporate the linguistic constraints for the pruning.

4 Experimental Framework

Systems: For DP, with gold morphology tags as input, we compare the performance of MG-EBM with 5 other parsers. The models are YAP (More et al., 2019): a transition based parser for MRLs, BiAff (Dozat and Manning, 2017): a neural biaffine classifier, DCST (Rotman and Reichart, 2019): a self-training based neural classifier, and two variants of EBM: T-EBM and T-EBM*. For MP, we use the current SOTA model, C-EBM, an EBM variant as the baseline. The EBM variants and the impact of these variations would be elaborated in Section 5. For the joint morphosyntactic setting, we propose DCST++ as a neural baseline. DCST++ is our augmentation over DCST which integrates encoder outputs from a neural morphological tagger (Gupta et al., 2020) by a gating mechanism (Sato et al., 2017).[5]

Metric: All the results we report are macro averaged at a sentence level. For DP, we use UAS and LAS and for MP, we use F-Score. For joint MP and DP, all the EBM models other than MG-EBM may predict a tree that has a different vertex set than that of the ground truth. Since UAS cannot be used here, we use (unlabelled and labelled) F-Score for those systems. For MG-EBM UAS/LAS and Unlabelled/Labelled F-Score would be the same.

Dataset[6]: We use a test set of 1,300 sentences, where 1,000 come from the Sanskrit Tree Bank Corpus (Kulkarni, 2013, STBC) and 300 from *Sisupāla-vadha*, a work from classical Sanskrit poetry (Ryali, 2016). 1,500 and 1,000 sentences from STBC, other than the ones in test data, were used as the training and validation data respectively for DCST, DCST++, and BiAFF. However all the EBM models and YAP were trained on 12,320 sentences obtained by augmenting the training data in STBC (Krishna et al., 2020, §4.1).[7]

5 Results

MG-EBM achieves the state of the art (SOTA) results in MP and in DP, both in standalone (with gold morphological tags as input) and joint morphosyntactic parsing setting. Table 1a shows that MG-EBM reports a 2 point improvement in UAS as compared to T-EBM*, the previous SOTA model for DP in Sanskrit. Both MG-EBM and T-EBM* differ only in terms of how the pruning of the input graph is performed. The pruning decisions in T-EBM* are made by considering a maximum of 3 nodes at a time, instead of the context from the entire tree. However, MG-EBM considers a tree in its entirety for applying the constraints. This leads to more than 300 fold reduction in the number of possible candidates for MG-EBM as compared to T-EBM*, with just about 40 % increase in wall time (on test data).[8] Since, both the models use the same label predictor (Krishna et al., 2020), they perform similar, with a small improvement of 0.77 points for MG-EBM .

Table 1b shows that MG-EBM outperforms C-EBM, the previous SOTA model for morphologi-

---

[5] Refer to the supplementary material §2 for more experiments with this model

[6] The dataset can be downloaded from `http://bit.ly/KISSData`

[7] BiAFF, DCST and DCST++ performed worse, when used with the sentences from the augmented training data.

[8] The increase is due to the use of the spanning tree enumeration algorithm by Mayeda and Seshu (1965).

cal parsing. Similarly MG-EBM achieves SOTA results for DP in the joint setting, followed by DCST++. In the joint setting, gold morphological tags are not provided as input. All the EBM models, other than MG-EBM, use the one node per analysis (Figure 1a) input formulation and approximation algorithms for inference. For morphological parsing, the inference in C-EBM searches for a maximal clique, considering pairwise interaction between all the nodes in the clique, while P-EBM searches for a Steiner Tree. Both JP-EBM* and JP-EBM-Prune extend P-EBM for joint morphosyntactic parsing, by introducing linguistically informed pruning. JP-EBM* uses the same pruning approach as T-EBM*, while JP-EBM-Prune uses our proposed pruning approach. The models report a 5 point and 11 point F-Score increase respectively for morphological parsing as compared to P-EBM. In fact, JP-EBM-Prune outperforms C-EBM. MG-EBM and JP-EBM-Prune use the same pruning approach proposed in this work. They differ in terms of the input space formulation and as a consequence, MG-EBM uses an exact search inference. This difference has led to nearly 2 point increase in both UAS and F-Score, and a 3 Point increase in LAS between both. YAP (More et al., 2019), the SOTA joint morphosyntactic parser proposed originally for Hebrew can perform joint prediction. However it is observed that YAP's performance would typically degrade in the joint setting as compared to its performance in the standalone setting (with gold-morphological tag; Table 1a). All the joint models for morphological parsing and DP outperform YAP even when YAP uses gold morphological tags. Finally, all the joint models for morphological parsing and DP outperform the pipeline EBM model C-EBM + T-EBM*, which validates that joint morphosyntactic parsing benefits an MRL like Sanskrit than a pipeline model.

6 Conclusion

In this work, we proposed MG-EBM, a model for joint morphological parsing and DP in Sanskrit. It extends the EBM framework from Krishna et al. (2020) by 1) incorporating a linguistically motivated pruning approach resulting in a substantial reduction in the input search space, and 2) modifying the input graph formation to a multigraph resulting in the use of Edmonds-Chu-Liu algorithm (Edmonds, 1967), an exact search algorithm, as inference. While the multigraph formulation is language agnostic the linguistically motivated pruning is rooted on the grammatical tradition of Sanskrit. Experiments validate that the joint morphosyntactic-parsing hypothesis, i.e., morphological information can benefit syntactic disambiguation and vice versa (Tsarfaty, 2006), holds true for Sanskrit. We find that the MG-EBM reports state of the art results (SOTA) for morphological parsing, outperforming standalone morphological parsing models, similar to what is observed for Hebrew (More et al., 2019). Further, all the joint morphological parsing and DP variants of EBM, we experimented here, result in a superior performance than the pipeline morphological parsing and DP EBM model. We also establish SOTA results in Sanskrit for DP, both in standalone and joint setting.

Unsupervised Parsing via Constituency Tests

Abstract

We propose a method for unsupervised parsing based on the linguistic notion of a constituency test. One type of constituency test involves modifying the sentence via some transformation (e.g. replacing the span with a pronoun) and then judging the result (e.g. checking if it is grammatical). Motivated by this idea, we design an unsupervised parser by specifying a set of transformations and using an unsupervised neural acceptability model to make grammaticality decisions. To produce a tree given a sentence, we score each span by aggregating its constituency test judgments, and we choose the binary tree with the highest total score. While this approach already achieves performance in the range of current methods, we further improve accuracy by fine-tuning the grammaticality model through a refinement procedure, where we alternate between improving the estimated trees and improving the grammaticality model. The refined model achieves 62.8 F1 on the Penn Treebank test set, an absolute improvement of 7.6 points over the previous best published result.

1 Introduction

When developing a phrase structure grammar for a language, one powerful tool that linguists use is constituency tests. Given a sentence and some span within it, one type of constituency test involves modifying the sentence via some transformation (e.g. replacing the span with a pronoun) and then judging the result (e.g. checking if it is grammatical). If a span passes constituency tests, then linguists have evidence that it is a constituent. Motivated by this idea, as well as recent advancements in neural acceptability (grammaticality) models via pre-training (Warstadt et al., 2018; Devlin et al., 2019; Liu et al., 2019), in this paper we propose a method for unsupervised parsing that operationalizes the way linguists use constituency tests.

Focusing on constituency tests that are judged via grammaticality, we begin by specifying a set of transformations that take as input a span within a sentence and output a new sentence (Section 3). Given these transformations, we then describe how to use a (potentially noisy) grammaticality model for parsing (Section 4). Specifically, we score the likelihood that a span is a constituent by applying the constituency tests and averaging their grammaticality judgments, i.e. the probability that the transformed sentence is grammatical under the model. We then parse via minimum risk decoding, where we score each binary tree by summing the scores of its contained spans, with the interpretation of maximizing the expected number of constituents. Importantly, this scoring system accounts for false positives and negatives because it allows some spans in the tree to have low probability if the model is confident about the rest of the tree.

To learn the grammaticality model, we note that given gold trees, we can train the model to accept constituency test transformations of gold constituents and reject those of gold distituents. On the other hand, given the model parameters, we can estimate trees via the parsing algorithm in Section 4. Therefore, we learn the model via alternating optimization. First, we learn an initial model by fine-tuning BERT on unlabeled data to distinguish between real sentences and distractors produced by random corruptions like shuffling (Section 5). Then, we refine the model by alternating between (1) producing trees, and (2) maximizing/minimizing the scores of predicted constituents/distituents in those trees (Section 6).

To evaluate the effectiveness of our approach, we compare to existing methods for unsupervised parsing (Section 7). Our refined model achieves 62.8 F1 averaged over four random restarts on the Penn Treebank (PTB) test set, an absolute improvement of 7.6 points over the previous best published result,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4798–4808,
November 16–20, 2020.

showing that constituency tests provide powerful inductive bias. Analyzing our parser (Section 8), we find that despite its strong numbers, it makes some mistakes that we might expect from the parser's reliance on this class of constituency tests, like attaching modifying phrases incorrectly. As one possible solution to these shortcomings, we use our method to induce the unsupervised recurrent neural network grammar (URNNG) (Kim et al., 2019b) following the approach in Kim et al. (2019a), where we use our induced trees as supervision to initialize the RNNG model and then perform unsupervised fine tuning via language modeling. The resulting model achieves 67.9 F1 averaged over four random restarts, approaching the supervised binary tree RNNG with a gap of 4.9 points.

2 Related Work

Grammar induction. There has been a long history of research on grammar induction. Here, we touch on just a couple threads of work most related to our method. Early works focused on building probabilistic context-free grammars (PCFGs) but found that inducing them with expectation-maximization (EM) did not produce meaningful trees (Carroll and Charniak, 1992). We highlight some themes since then that have produced successful unsupervised parsers.

Directly modeling spans rather than mediating structure through a grammar: In contrast with previous work based on probabilistic grammars, the constituent-context model of Klein and Manning (2002) proposed a different probabilistic formulation that modeled the constituency of each span directly, where each span yielded words conditioned on whether or not it was a constituent. Parsing then proceeded via minimum risk decoding (Smith and Eisner, 2006), where they chose the tree containing the maximum expected number of constituents.

Explicitly defining criteria for what it means to be a constituent: Rather than designing a generative model over sentences and trees, Clark (2001) proposed that constituents could be identified based on their span statistics, e.g. the mutual information between the left and right contexts of the span.

Finding external signals of constituency: To perform noun compound bracketings ("[*liver cell*] *line*" vs "*liver* [*cell line*]"), Nakov and Hearst (2005) extracted a series of features from Web text, like the frequency of "*liver-cell line*" vs "*liver cell-line*." With a similar idea of extracting signal from Web text, Spitkovsky et al. (2010) found evidence for constituency from HTML markup, e.g. hyperlinks and italicized phrases.

Designing neural latent variable models: Many works have taken the approach of designing a neural language model with tree-valued latent variables and optimizing it via EM, some of which can also be seen as probabilistic grammars parameterized by neural networks. For example, the compound PCFG (Kim et al., 2019a), found that the original PCFG is sufficient to induce trees if it uses a neural parameterization, and they further enhanced the model via latent sentence vectors to reduce the independence assumptions. Another model, the unsupervised recurrent neural network grammar (URNNG) (Kim et al., 2019b), uses variational inference over latent trees to perform unsupervised optimization of the RNNG (Dyer et al., 2016), an RNN model that defines a joint distribution over sentences and trees via shift and reduce operations. Unlike the PCFG, the URNNG makes no independence assumptions, making it more expressive but also harder to induce from scratch. Shen et al. (2018) proposed the Parsing-Reading-Predict Network (PRPN), where the latent tree structure determines the flow of information in a neural language model, and they found that optimizing for language modeling produced meaningful latent trees. On the other hand, the Deep Inside-Outside Recursive Autoencoder (DIORA) (Drozdov et al., 2019) computes a representation for each node in a tree by recursively combining child representations following the structure of the inside-outside algorithm, and it optimizes an autoencoder objective such that the representation for each leaf in the tree remains unchanged after an inside and outside pass.

Extracting trees from neural language models: The Ordered Neuron (ON) model (Shen et al., 2019) modifies the LSTM to enforce a hierarchy of long- to short-term neurons, with the idea that the forget operation should naturally occur at phrase boundaries. After training on language modeling, they parse by recursively finding splitpoints based on each neuron's decision of where to forget. More recently, Kim et al. (2020) extract trees from pre-trained transformers. Using the model's representations for each word in the sentence, they score fenceposts (positions between words) by computing distance between the two adjacent words, and they parse by recursively splitting the tree at the fencepost with the largest distance.

Name	Applied to "A [B] C"	Example
Clefting	it {is, was} B that A C	*it {is, was} the london market that by midday , was in full retreat*
Coordination	A B and B C	*by midday , the london market and the london market was in full retreat*
Substitution	A {it, ones, did so} C	*by midday , {it, ones, did so} was in full retreat*
Front Movement	B , A C	*the london market , by midday , was in full retreat*
End Movement	A C B	*by midday , was in full retreat the london market*

Table 1: The constituency tests we use in this paper, using the span *"by midday , [the london market] was in full retreat"* as an example.

Name	Description
Shuffle	Choose a random subset of words in the sentence and randomly permute them.
Swap	Choose two words and swap them.
Drop	Choose a random subset of words in the sentence and drop them.
Span Drop	Choose a random contiguous span of words and drop it.
Span Movement	Choose a random contiguous span of words and move it to the front or back.
Bigram	Generate a sentence of the same length using a bigram language model trained on the source corpus.

Table 2: The corruptions we use to train the initial grammaticality model using unlabeled data, where the model must determine whether a given sentence is real or corrupted.

Neural grammaticality models. Pre-training has recently produced large gains on a wide range of tasks, including the task of judging whether a sentence is grammatical (Devlin et al., 2019; Liu et al., 2019). Most works evaluate on the Corpus of Linguistic Acceptability (CoLA) (Warstadt et al., 2018), which compiles acceptable and unacceptable sentences from linguistics publications. The paper also investigates the question of whether grammaticality can be learned from unlabeled data, where fake sentences are generated via either random shuffling or an LSTM language model, and the model must determine whether a given sentence is real or fake. They find that real/fake models perform comparably to supervised models trained on the CoLA training set. Lau et al. (2017) also investigate unsupervised acceptability models, where they instead augment language models with a variety of acceptability measures, e.g. perplexity renormalized to remove the influence of unigram frequency. They find that such models achieve an encouraging level of agreement with crowd-sourced human judgments.

3 Constituency Tests

We begin by specifying a set of constituency tests. The constituency tests we focus on involve transformation functions $c : (\mathtt{sent}, i, j) \mapsto \mathtt{sent}'$ that take in a span and output a new sentence, and a judgment function $g : \mathtt{sent} \mapsto \{0, 1\}$ that judges the resulting transformed sentence. A span $(\mathtt{sent}, i, j)$ passes a constituency test if the judgment function approves of the transformed sentence, or $g(c(\mathtt{sent}, i, j)) = 1$. Then, parsing via constituency tests involves specifying a set of transformation functions (this section), learning the judgment function (Sections 5 and 6), and aggregating these test results to produce a tree (Section 4).

We will focus on constituency tests that are judged via grammaticality because it is feasible to learn a grammaticality model using unlabeled data. We describe the set of transformations in Table 1. As future work, modeling semantic preservation could also prove fruitful as a way to correct some false positives, e.g. *"stock [prices rose after the announcement]"* → *"stock it."*

Because we specify constituency tests, while the parser is unsupervised in that it doesn't use labeled data, it is not tabula rasa in that we provide it with linguistically-inspired inductive bias, in contrast with past methods that may have less inductive bias or encode it more implicitly. To induce more and specify less, another interesting line of future work would involve inducing the tests as well.

4 Parsing Algorithm

With this set of transformations, in this section we describe how to parse sentences using a (potentially noisy) grammaticality model. In the supervised setting, Stern et al. (2017) and Kitaev and Klein (2018) showed that independently scoring each span and then choosing the tree with the best total score produced a very accurate and simple parser, while Klein and Manning (2002) showed a similar result in the unsupervised setting. Therefore, we also use a span-based approach.

We will use $g_\theta : \texttt{sent} \mapsto [0, 1]$ to denote the grammaticality model with parameters θ, which outputs the probability that a given sentence is grammatical. First, we score each span by averaging the grammaticality judgments of its constituency tests, or

$$s_\theta(\texttt{sent}, i, j) = \frac{1}{|C|} \sum_{c \in C} g_\theta(c(\texttt{sent}, i, j)),$$

where C denotes the set of constituency tests. Then, we score each tree by summing the scores of its spans and choose the highest scoring binary tree via CKY, or

$$t^*(\texttt{sent}) = \underset{t \in T(\texttt{len}(\texttt{sent}))}{\arg\max} \sum_{(i,j) \in t} s_\theta(\texttt{sent}, i, j),$$

where $T(\texttt{len}(\texttt{sent}))$ denotes the set of binary trees with $\texttt{len}(\texttt{sent})$ leaves. If we interpret the score $s_\theta(\texttt{sent}, i, j)$ as estimating the probability that the span $(\texttt{sent}, i, j)$ is a constituent, then this formulation corresponds to choosing the tree with the highest expected number of constituents, i.e. minimum risk decoding (Smith and Eisner, 2006). This scoring system accounts for noisy judgments, which lead to false positives and negatives, by allowing some spans to have low probability if the model is confident about the rest of the tree.

If we want $s_\theta(\texttt{sent}, i, j)$ to estimate the posterior probability that the span is a constituent given the judgments of its constituency tests, or

$$\mathbf{P}((\texttt{sent}, i, j) \text{ is a constituent} \mid \{g_\theta(c(\texttt{sent}, i, j)) : c \in C\}),$$

then we might want to do something more sophisticated than taking the average. However, we find that the average performs well while being both parameter-less and simple to interpret, so we leave this avenue of exploration to future work.

5 Initializing the Grammaticality Model

In this section and the next, we describe how we learn the grammaticality model. Given gold trees, we can train the model to accept constituency test transformations of gold constituents and reject those of gold distituents. On the other hand, given model parameters, we can estimate trees using the parsing algorithm in Section 4. Therefore, we first initialize the model (this section), and we then refine it via alternating optimization (Section 6).

Previously, Warstadt et al. (2018) found that LSTM grammaticality models trained with supervision versus those trained on a real/fake task achieved similar correlation with human judgments when evaluating on the Corpus of Linguistic Acceptability (CoLA), a dataset with examples of acceptable and unacceptable taken from linguistic publications. Given an unlabeled corpus of sentences and a set of corruptions, the real/fake task involves predicting whether a given sentence is real or corrupted. Motivated by their result, we train our model via a real/fake task but a wider range of corruptions, as described in Table 2.

Rather than training from scratch, we fine-tune the RoBERTa model (Liu et al., 2019), a BERT variant pre-trained on masked word prediction and next sentence prediction. As our unlabeled sentences, we use 5 million sentences from English Gigaword (Graff and Cieri, 2003), and we do not perform any early stopping. We report optimization hyperparameters in the appendix.

Comparing the real/fake RoBERTa model to a supervised version, we find that the former achieves 0.21 MCC (Matthews Correlation Coefficient) on the CoLA development set, while the latter achieves 0.73 MCC, in contrast with the finding in Warstadt et al. (2018) that real/fake and supervised LSTMs achieved similar accuracy (both around 0.2 to 0.3 MCC).[1] This gap is not totally surprising given how high the supervised RoBERTa numbers are. However, when used for parsing via constituency tests, the real/fake RoBERTa model outperforms the supervised model by about 6 F1 (before refinement), likely because invalid constituency tests look more like random corruptions than examples from the CoLA training set, which are taken from linguistics publications.

6 Refining the Grammaticality Model

While the unrefined grammaticality model achieves 48.2 F1, which is in the range of current methods (Table 3), we further improve accuracy via alternating optimization, which proceeds as follows:

1. Using the span-based algorithm in Section 4, parse a batch B of sentences to produce trees.

---

[1] We did not optimize the corruption set for CoLA MCC.

2. Use these trees as pseudo-gold labels to update the span judgments. Specifically, for each sentence, minimize the loss function

$$\sum_{(i,j)\in t^*(\texttt{sent})} \log(s_\theta(\texttt{sent}, i, j)) + \sum_{(i,j)\notin t^*(\texttt{sent})} \log(1 - s_\theta(\texttt{sent}, i, j)),$$

   i.e. binary cross-entropy on each span with inclusion into the predicted tree as the label, summed over the sentences in the batch.

   Note that the span scores $s_\theta(\texttt{sent}, i, j))$ are derived from grammaticality judgments of constituency tests, so the only parameters are those in the grammaticality model. Therefore, this step can be thought of as increasing the grammaticality judgment of every constituency test applied to every predicted constituent, while decreasing the judgments for predicted distituents.

3. Repeat for the next batch of sentences.

This step can be thought of as encouraging self-consistency between the model's grammaticality judgments and the trees that result from them. For example, CKY might choose a tree where a few of the spans are considered invalid if the model is confident about the other spans in the tree. The refinement procedure would then increase the probability of these initially invalid spans, which might help the model catch spans that it initially missed. We see evidence of this effect in Section 8. In addition, there is an inherent mismatch between the real/fake task that the model was trained on and the constituency test judgment task it is being used for. For example, many of the sentences resulting from constituency tests are far out of distribution from sentences seen during training. Therefore, this step can also be thought of as helping the grammar model adapt to its new setting.

One problem, however, is that the loss function takes a gradient through the grammaticality judgments of all of the constituency tests for every span in the sentence. This computation takes up too much memory, given that a length-30 sentence has about 400 spans and thus about 3000 constituency tests. Therefore, to reduce memory usage, for every sentence we only take the gradient through 16 of the constituency tests, chosen randomly.

While early stopping would likely improve performance, we instead perform refinement for a fixed number of iterations because we don't have access to labeled data. Specifically, we perform refinement for one epoch on 5000 sentences from the PTB training set (sections 2 to 21), combined with the 2416 sentences in the PTB test set (section 23). We find that the training curve is relatively consistent across runs. We use the same optimization parameters as the ones for the real/fake task, as described in the Appendix.

Model	PTB F1 Mean	PTB F1 Max
PRPN† (Shen et al., 2018)	37.4	38.1
URNNG (Kim et al., 2019b)	–	45.4
ON† (Shen et al., 2019)	47.7	49.4
Neural PCFG† (Kim et al., 2019a)	50.8	52.6
DIORA (Drozdov et al., 2019)	–	58.9
Compound PCFG† (Kim et al., 2019a)	55.2	60.1
Left Branching	8.7	
Balanced	18.5	
Right Branching	39.5	
Ours (before refinement)	48.2	
Ours (after refinement)	**62.8**	**65.9**
Oracle Binary Trees	84.3	

Table 3: Unlabeled sentence-level F1 on the PTB test set without punctuation or unary chains. "Before refinement" denotes the parser using the acceptability model after real/fake training, which we only run once. Starting from this initial model, we report the mean and maximum score out of 4 random restarts of refinement. Baseline numbers are taken from Kim et al. (2019a). After refinement, the parser outperforms the previous best method by 7.6 points.
† denotes models trained without punctuation.

7 Results

7.1 F1 on the Penn Treebank

For evaluation, we report the F1 score with respect to gold trees in the Penn Treebank test set (section 23). Following prior work (Kim et al., 2019a; Shen et al., 2018, 2019), we strip punctuation and collapse unary chains before evaluation, and we calculate F1 ignoring trivial spans. The averaging is sentence-level rather than span-level, meaning that we compute F1 for each sentence and then average over all sentences. Because most unsupervised parsing methods only consider fully binary trees, we include the oracle binary tree ceiling, produced by taking the (often flat) gold trees and binarizing them arbitrarily.

Model	PTB F1 Initial (Max)	 +URNNG
PRPN	47.9	51.6
ON	50.0	55.1
Neural PCFG	52.6	58.7
Compound PCFG	60.1	66.9
Ours (after refinement)	65.9	**71.3**
Supervised Binary RNNG	71.9	72.8

Table 4: Unlabeled sentence-level F1 on the PTB test set without punctuation or unary chains. Following the experimental setup in Kim et al. (2019a), "Initial (Max)" denotes the induced trees resulting from running the method four times and selecting the best result. Next, we use the induced trees as supervision for RNNG and then run unsupervised RNNG fine-tuning, denoted by the "+URNNG" column. "Supervised Binary RNNG" denotes training the RNNG on binarized gold trees. Baseline numbers are taken from Kim et al. (2019a). When selecting the best parser out of four runs, our method combined with URNNG approaches the supervised binary RNNG, with a gap of 1.5 points. Departing from the setup of Kim et al. (2019a), we also induced URNNG three more times using the other three runs, which resulted in a mean score of 67.9 across the four runs and a minimum of 61.1.

	Before refinement	After (best parser)	Best parser + URNNG
SBAR	0.229	0.661	**0.853**
NP	0.604	0.794	**0.843**
VP	0.325	0.682	**0.808**
PP	0.571	**0.862**	0.844
ADJP	**0.664**	0.626	0.556
ADVP	0.620	**0.639**	0.546
F1	48.2	65.9	**71.3**

Table 5: Recall by label, or the fraction of gold constituents predicted to be constituents by each model, along with F1 (calculated over all spans). We report numbers for the parser before refinement, the best parser out of four runs of refinement, and URNNG induced from the best parser. Refinement and URNNG both produce large improvements for all categories except ADJPs and ADVPs.

Table 3 displays the resulting F1 numbers for our method compared to existing unsupervised parsers, where we report mean, maximum, and minimum out of four random restarts. Before refinement, at 48.2 F1, the parser is already in the range of existing methods. After refinement, the parser achieves 62.8 F1 averaged over four runs, outperforming the previous best result by 7.6 points.[2]

7.2 Inducing URNNG

Kim et al. (2019a) found that while URNNG (described in Section 2) fails to outperform right-branching trees on average when trained from scratch, it achieves very good performance when initialized using another method's induced trees. Specifically, they first train RNNG using the induced trees from another method as supervision. Then, they perform unsupervised fine-tuning with a language modeling objective. They find that this procedure produces substantial gains when combined with existing unsupervised parsers.

Following their experimental setup, we use our best parser out of four runs to parse both the PTB training set and test set, and we induce URNNG using these predicted trees. We use the default parameters in the Kim et al. (2019b) github, which we report in the Appendix. Table 4 shows the resulting F1 on the PTB test set. After URNNG, we achieve 71.3 F1, approaching the performance of the supervised binary RNNG + URNNG with a gap of 1.5 points. However, selecting the best parser out of four requires labeled data, so we also induce URNNG from each of the three other parsers. We find that the mean score across the four runs is 67.9. To close the gap between the max and mean across the four runs, ensembling might be an effective approach; we leave this direction to future work.

One possible reason for why URNNG helps is that the URNNG model makes no independence assumptions, making it very expressive but also also difficult to induce from scratch. Therefore, we can think of this method as removing some of the independence assumptions and other biases of the original model once they have sufficiently guided the unsupervised training.

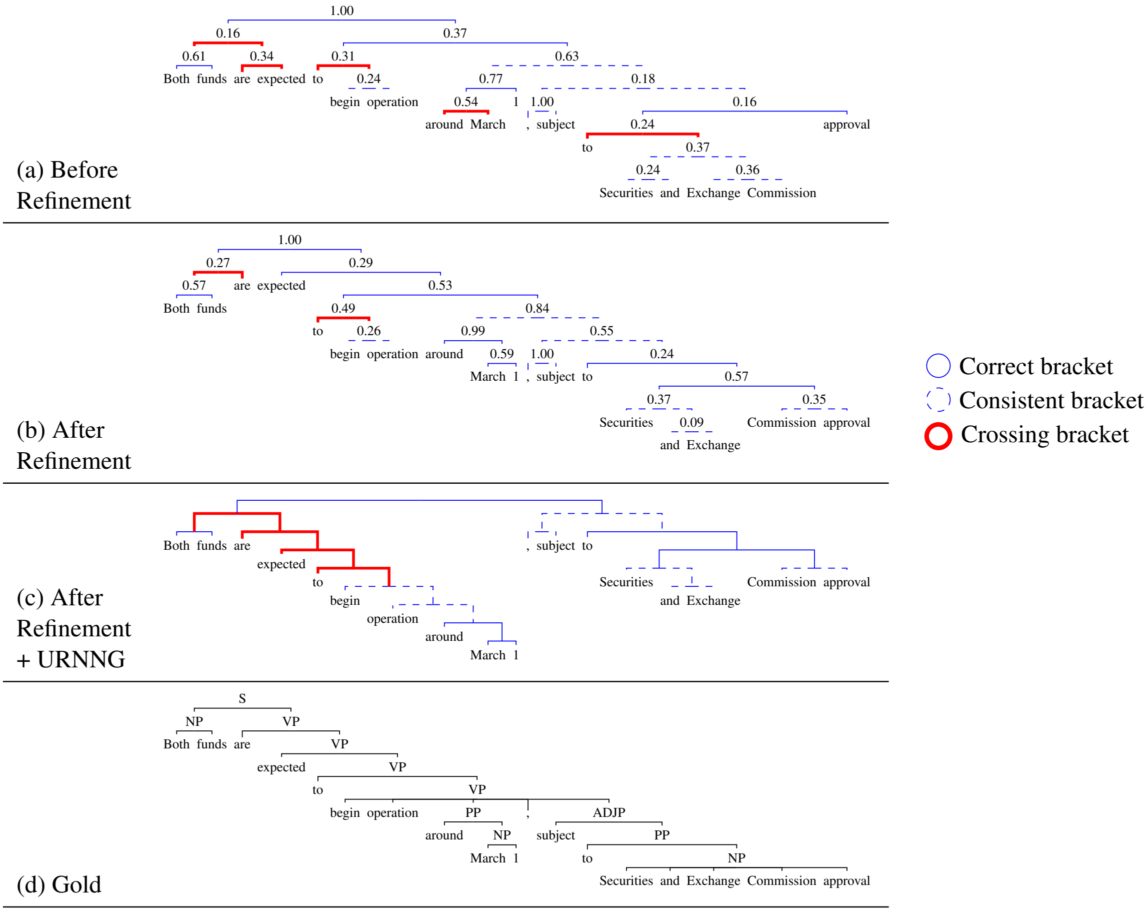
8 Analysis

8.1 Recall by Label

First, we compute recall by label for the parser before refinement, after refinement, and after refinement + URNNG, displayed in Table 5. Before refinement, the parser is strongest in ADJPs and ADVPs and weakest for VPs and SBARs. Refine-

---

[2] While other methods do not report the minimum, our minimum score was 60.4 F1. We also evaluate in the setting where the test set sentences are not available during refinement, and we find similar results (mean: 62.8, max: 64.6, min: 61.5).



(a) Before Refinement

(b) After Refinement

(c) After Refinement + URNNG

(d) Gold

◯ Correct bracket

◌ Consistent bracket

⭕ Crossing bracket

Figure 1: Example trees (a) before refinement, (b) after refinement, (c) after refinement + URNNG, and (d) gold, where we use the first PTB train sentence whose F1 was within 1 of the average. Each non-trivial span is labeled with its score under the model, i.e. the average grammaticality of its constituency tests. Each span is labeled blue if it is present in the gold, dashed blue if it is consistent (ignoring punctuation), and thick red if it is crossing. After refinement (tree b), the parser makes two mistakes: attaching "are" to the subject, and attaching the phrase "around March ... Commission approval" one level too high. After refinement + URNNG (tree c), the only mistake is attaching the phrase "subject to ... Commission approval" at the top level, which produces four crossing brackets.

ment causes all categories except ADJP and ADVP to receive a boost of about 0.3 in recall. Afterward, URNNG produces a boost for SBAR and VP, resulting in the four categories being above 0.8, except with ADJP and ADVP still both around 0.55. In Section 8.3, we analyze the sources of these mistakes in more detail and find that the model is less effective in identifying ADJPs that serve as NP adjuncts (e.g. "[*most recent*] *news*").

8.2 Analyzing the Constituency Tests

To better understand how well each category is covered by constituency tests, in Table 6 we display the recall per phrase type for each test, along with F1 computed over all spans. Using each test, we judge each span in the PTB development set individually by thresholding the grammaticality judgment at 0.5, and for each phrase type we report the fraction that pass the test. Before refinement, the tests behave roughly as expected. Coordination fires consistently for all phrase types but also half the distituents, while the NP and VP proforms fire for NPs and VPs respectively. Clefting and movement are more mixed, with clefting sometimes firing for all phrase types except VP, and movement sometimes firing for SBARs, PPs, and ADVPs. Interestingly, the individual F1 numbers are all quite low at around 10-20 F1, even though the parser achieves 48.1 F1, suggesting that the constraint of outputting a well-formed tree provides substantial information. After refinement, all of the tests have better F1, potentially because refinement allows the grammar model to use the well-formedness constraint to improve its span judgments (see Section 6). In particular, we find that coordination no longer has false positives, and clefting exhibits

	Clefting		Proform Substitution			Movement		Coord-
	is	was	ones	did so	it	front	end	ination
Before Refinement								
SBAR	0.294	0.260	0.113	0.130	0.146	0.279	0.319	0.942
NP	0.353	0.347	0.458	0.178	0.555	0.055	0.048	0.934
VP	0.091	0.089	0.067	0.479	0.127	0.060	0.144	0.944
PP	0.427	0.412	0.238	0.165	0.154	0.308	0.606	0.906
ADJP	0.383	0.361	0.286	0.241	0.346	0.127	0.172	0.911

ADVP	0.565	0.582	0.187	0.627	0.338	0.353	0.292	0.655
Distituent	0.031	0.032	0.052	0.060	0.045	0.012	0.026	0.086
F1	51.1	50.9	29.5	38.6	37.4	18.6	15.0	43.1

Table 6: For each constituency test and each phrase type XP, we report the fraction of XPs in the PTB development set that pass the constituency test, where we judge each span individually and threshold the grammaticality judgment at 0.5. We also report F1 (calculated over all spans). Before refinement, coordination consistently fires for all categories but also for almost half of the distituents. The other tests behave roughly as expected; for example, the NP proforms ("ones" and "it") fire for NPs, while the VP proform ("did so") fires for VPs. After refinement, coordination no longer fires for distituents, and all of the tests have higher F1. In addition, the proforms now fire for a much wider range of phrase types. See the appendix for a grayscale version.

Common mistakes after refinement			
Parts of speech	Example	Percentage of mistakes	Δ in # mistakes after URNNG
PRP VBD/P/Z	[*they 're*] *squaring off*	1.72%	-81.0%
IN NN(S)	[*in letters*] *to the agency*	1.07%	-57.6%
CD NN(S)	*about* [*1,200 cars*]	1.06%	+4.4%
IN DT NN(S)	[*in an effort*] *to streamline*	0.99%	-74.7%
TO VB	[*to work*] *a lot*	0.93%	-95.0%
Common mistakes after refinement + URNNG			
Parts of speech	Example	Percentage of mistakes	Δ in # mistakes after URNNG
CD NN(S)	*about* [*1,200 cars*]	1.51%	+4.4%
JJ NN(S)	*socially* [*responsible companies*]	0.69%	+47.0%
IN NN(S)	[*in letters*] *to the agency*	0.61%	-57.6%
NN(S) IN NN(S)	[*plenty of reasons*] *to stay*	0.57%	-27.3%
NNP VBD/P/Z	*Mr.* [*Lane said*]	0.47%	-21.2%

Table 7: The five most common crossing brackets categorized by part-of-speech, computed on the first 5,000 sentences in the PTB training set. We also report percentage of crossing predicted brackets (i.e. mistakes) that fall under that category, as well as the change in the number of mistakes after adding URNNG. We group (VBD, VBP, VBZ) (past, present, present 3rd-person) and (NN, NNS) (noun, noun plural). We find that the model commonly makes the following mistakes: (1) bracketing the verb with the subject, (2) in a nested PP, attaching the inner PP outside, (3) grouping the cardinal or adjective with the noun instead of with its adverb, and (4) bracketing "to + infinitive." After URNNG, each of the mistakes are corrected except (3).

greatly improved recall. We also see that the proform substitution tests now fire for a wider range of phrase types; for example, "did so" now fires for 70% of SBARs, VPs, PPs, and ADVPs, even though it was originally a VP substitution.

8.3 Common Mistakes

In Table 7, we show the most common crossing brackets predicted by the parser, where for analysis we categorize the brackets by part-of-speech. We find that the model after refinement commonly makes the following mistakes, and we suggest possible explanations for each:

1. Bracketing the verb with the subject:

   [*they 're*] *squaring off*

   As shown in Table 6, there is less support for VPs via consituency tests. This observation is also reflected in the example trees in Figure 1, where the VPs have consistently lower scores. Therefore, while the parser usually chooses to bracket VPs (achieving 0.682 recall, as shown in Table 5), there seem to be cases in which it prefers the [subject verb] bracketing.

2. In a nested PP, attaching the inner PP outside the outer PP:

   [*in letters*] *to the agency*

   The spans resulting from incorrect attachments still tend to produce grammatical constituency tests (e.g. *"they argue* [*in letters*] *to the agency that ..."* → *"in letters , they argue to the agency that ..."*).

3. Grouping cardinals and adjectives with the noun, instead of with the adverb:

   about [*1,200 cars*]

   This span passes some constituency tests, like *"about* {*it, ones*}*,"* while none of the tests except coordination accept *"about 1,200."*

4. Bracketing "to + infinitive":

   they want [*to work*] *a lot*

   Infinitive VPs (e.g. *"work a lot"*) typically don't pass any of our tests except coordination, while "to + infinitive" is often replaceable by a noun proform, like *"they want it a lot."*

After URNNG, the VP errors (1 and 4) are corrected almost completely, while the PP attachment error also decreases in frequency by about half. In contrast, the ADJP error (3) is exacerbated, with [CD NN] and [JJ NN] incorrect bracketings increasing by 4.4% and 47.0% (Table 7). Therefore, URNNG is effective in correcting many but not all of the parser's systematic errors, suggesting paths for future improvement, e.g. by adding tests that fire for currently missing brackets.

8.4 Example Trees

Finally, to qualitatively understand the parser's performance, in Figure 1 we display the trees before refinement, after refinement, and after refinement + URNNG for the sentence *"Both funds are expected to begin operation around March 1 , subject to Securities and Exchange Commission approval."* To produce a representative example, we selected this sentence by choosing the first sentence in PTB train whose F1 was within 1 of the average. Comparing the trees before and after refinement, the parser corrects two mistakes, "[*around March*] *1"* and "[*to Securities and Exchange Commission*] *approval,"* which both involve bracketing the preposition with part of its NP complement. As a result, ignoring punctuation and binarization, the parser after refinement makes only two mistakes: attaching *"are"* to the subject, and attaching the phrases *"around March"* and *"subject to ... Commission approval"* one level too high. After URNNG, the first mistake is corrected, such that the only mistake is in the attachment of *"subject to ... Commission approval"* (but because it attaches this phrase very high, this mistake produces four crossing brackets). This example provides some characterization of each step's improvement to the predicted trees.

9 Conclusion

In this paper, we showed that using constituency tests to parse sentences is an effective approach, achieving strong performance for unsupervised parsing. Furthermore, we used the interpretability of constituency tests to highlight and explain the parser's strengths and shortcomings, like the "[subject verb]" and "adverb [adjective noun]" misbracketings, revealing potential next steps for improvement. Therefore, we see parsing via constituency tests as a promising new approach with both strong results and many open questions.

A Appendix

A.1 Optimization Hyperparameters and Other Training Details

For both real/fake training and refinement, we use a learning rate of 3×10^{-5} with Adam (Kingma and Ba, 2015) hyperparameters $\beta = (0.9, 0.999)$, $\epsilon = 10^{-6}$ and linear learning rate warmup for the first 10% of the training data. For real/fake training, each batch contains 32 real and 32 fake sentences, while for refinement we parse a batch of 32 sentences for each gradient step. We did not perform any hyperparameter search.

We fine-tuned the RoBERTa base model, which has 125M parameters, and we performed classification for sentences by applying a linear layer and softmax to the `[CLS]` embedding.

For real/fake training, we used a single Nvidia K80 with 12GB RAM, which took about 3 days to run for 5 million sentences. For refinement, we either used a single Quadro 8000 with 48GB RAM, which took about 1 day to run, or a single Nvidia K80, which took about 6 days to run.

For URNNG, we used the default hyperparameters in the Kim et al. (2019b) github. Specifically, we used a batch size of 16, and we performed 18 epochs of supervised RNNG training with a learning rate of 0.0001, and 10 epochs of unsupervised fine-tuning with a learning rate of 0.1. Other optimization details can be found in the original paper (Kim et al., 2019b). We used a single Quadro 6000 with 24GB RAM, which took about 3 days.

As our data, we used the first 5M sentences from the English Gigaword corpus (Graff and Cieri, 2003) for real/fake training, and we used the standard train/development/test splits (sections 02-21, 22, 23) of the Penn Treebank for parsing (Marcus et al., 1993), which have 39832, 1700, and 2416 examples, respectively. Both datasets are already tokenized. For preprocessing, we converted all letters to lowercase and removed quotation marks and any ending punctuation.

A.2 Some Ablations of the Refinement Procedure

Having analyzed the output of our parser, next we describe some ablations to determine how much of the performance is due to constituency tests versus the refinement procedure.

First, if we ablate the refinement procedure (Table 3), the initial parser still performs quite well – it is much better than right-branching and relatively close in performance to current methods. We can also try ablating the constituency tests. Specifically, following the suggestion of an anonymous reviewer, we randomly initialized a Roberta-based span classification parser and performed refinement of the span scores (Section 6). The resulting parser did not achieve very high accuracy (initial F1: 11.95, final F1: 12.33; F1 is computed including punctuation). These ablations suggest that constituency tests are the main driving force behind our method. We discuss a few possible reasons below.

	Clefting		Proform Substitution			Movement		Coord-
	is	was	ones	did so	it	front	end	ination

F1	51.1	50.9	29.5	38.6	37.4	18.6	15.0	43.1

Table 8: A grayscale version of Table 6, where higher numbers are shaded with darker shades of gray.

First, because the refinement method has the effect of enforcing self-consistency, the initialization is important, and constituency tests are important for the initialization.

Next, the refinement procedure itself also relies heavily on constituency tests because the gradient step involves maximizing the grammaticality of constituency tests for spans within the imputed trees. In particular, all span judgments originate from grammaticality judgments, and the only parameters are those in the grammaticality model. Therefore, the procedure exploits the fact that grammaticality and constituency are linked.

Please Mind the Root: Decoding Arborescences for Dependency Parsing

Abstract

The connection between dependency trees and spanning trees is exploited by the NLP community to train and to decode graph-based dependency parsers. However, the NLP literature has missed an important difference between the two structures: only *one* edge may emanate from the root in a dependency tree. We analyzed the output of state-of-the-art parsers on many languages from the Universal Dependency Treebank: although these parsers are often able to learn that trees which violate the constraint should be assigned lower probabilities, their ability to do so unsurprisingly degrades as the size of the training set decreases. In fact, the worst constraint-violation rate we observe is 24%. Prior work has proposed an inefficient algorithm to enforce the constraint, which adds a factor of n to the decoding runtime. We adapt an algorithm due to Gabow and Tarjan (1984) to dependency parsing, which satisfies the constraint without compromising the original runtime.[1]

1 Introduction

Developing probabilistic models of dependency trees requires efficient exploration over a set of possible dependency trees, which grows exponentially with the length of the input sentence n.

Under an edge-factored model (McDonald et al., 2005; Ma and Hovy, 2017; Dozat and Manning, 2017), finding the maximum-a-posteriori dependency tree is equivalent to finding the maximum weight spanning tree in a weighted directed graph. More precisely, spanning trees in *directed* graphs are known as arborescences. The maximum-weight arborescence can be found in $\mathcal{O}(n^2)$ (Tarjan, 1977; Camerini et al., 1979).[2]

However, an oversight in the relationship between dependency trees and arborescences has gone largely unnoticed in the dependency parsing literature. Most dependency annotation standards enforce a **root constraint**: Exactly one edge may emanate from the root node.[3] For example, the Universal Dependency Treebank (UD; Nivre et al. (2018)), a large-scale multilingual syntactic annotation effort, states in their documentation (UD Contributors):

> There should be just one node with the root dependency relation in every tree.

This oversight implies that parsers may return *malformed* dependency trees. Indeed, we examined the output of a state-of-the-art parser (Qi et al., 2020) for 63 UD treebanks. We saw that decoding without a root constraint resulted in 1.80% (on average) of the decoded dependency trees being malformed. This increased to 6.21% on languages that contain less than one thousand training instances with the worst case of 24% on Kurmanji.

The NLP literature has proposed two solutions to enforce the root constraint: (1) Allow invalid dependency trees—hoping that the model can learn to assign them low probabilities and decode singly rooted trees, or (2) return the best of n runs of the CLE each with a fixed edge emanating from the root (Dozat et al., 2017).[4] The first solution is clearly problematic as it may allow parsers to predict malformed dependency trees. This issue is further swept under the rug with "forgiving" evaluation metrics, such as attachment scores, which give

---

[1] Our Python library is available at `https://github.com/rycolab/spanningtrees`.

[2] Several authors (e.g., Qi et al. (2020); McDonald et al. (2005)) opt for the simpler CLE algorithm (Chu and Liu, 1965; Bock, 1971; Edmonds, 1967), which has a worst-case bound of $\mathcal{O}(n^3)$, but is often fast in practice.

[3] A notable exception is the Prague Dependency Treebank (Bejček et al., 2013), which allows for multi-rooted trees.

[4] In practice, if constraint violations are infrequent, this strategy should be used as a fallback for when the *unconstrained* solution fails. However, this will not necessarily be the case, and is rarely the case during model training.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4809–4819,
November 16–20, 2020.

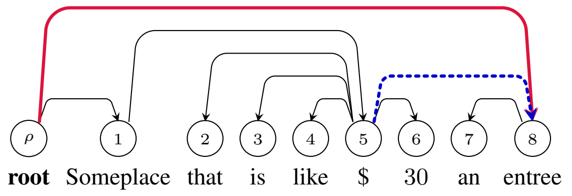

Figure 1: A malformed dependency tree from our experiment. Shown are the incorrect (highlighted) and correct (highlighted) dependency relations for token 8.

partial credit for malformed output.[5] The second solution, while correct, adds an unnecessary factor of n to the runtime of root-constrained decoding.

In this paper, we identify a much more efficient solution than (2). We do so by unearthing an $\mathcal{O}(n^2)$ algorithm due to Gabow and Tarjan (1984) from the theoretical computer science literature. This algorithm appears to have gone unnoticed in NLP literature;[6] we adapt the algorithm to correctly and efficiently handle the root constraint during decoding in edge-factored non-projective dependency parsing.[7]

2 Approach

In this section, the marker ✍ indicates that a recently introduced concept is illustrated the worked example in Fig. 2. Let $G = (\rho, V, E)$ be a **rooted weighted directed graph** where V is a set of nodes, E is a set of weighted edges, $E \subseteq \{(i \xrightarrow{w} j) \mid i, j \in V,\ w \in \mathbb{R}\}$,[8] and $\rho \in V$ is a designated root node with no incoming edges. In terms of dependency parsing, each non-ρ node corresponds to a token in the sentence, and ρ represents the special root token that is not a token in the sentence. Edges represent possible dependency relations between tokens. The edge weights are scores from a model (e.g., linear (McDonald et al., 2005), or neural network (Dozat et al., 2017)). Fig. 1 shows an example. We allow G to be a **multi-graph**, i.e., we allow multiple edges between pairs of nodes. Multi-graphs are a natural encoding of *labeled* dependency relations where possible labels between words are captured by multiple edges between nodes in the graph. Multi-graphs pose no difficulty as only the highest-weight edge between two nodes may be selected in the returned tree.

An **arborescence** of G is a subgraph $A = (\rho, V, E')$ where $E' \subseteq E$ such that:

(C1) Each non-root node has exactly one incoming edge (thus, $|E'| = |V| - 1$);

(C2) A has no cycles.

A **dependency tree** of G is an arborescence that additionally satisfies

(C3) $|\{(\rho \rightarrow \_) \in E'\}| = 1$

In words, (C3) says A contains exactly one out-edge from ρ. Let $\mathcal{A}(G)$ and $\mathcal{A}^\dagger(G)$ denote the sets of arborescences and dependency trees, respectively.

The weight of a graph or subgraph is defined as

$$\overline{w}(G) \overset{\text{def}}{=} \sum_{(i \xrightarrow{w} j) \in G} w \tag{1}$$

In §2.1, we describe an efficient algorithm for finding the best (highest-weight) arborescence

$$G^* = \operatorname*{argmax}_{A \in \mathcal{A}(G)} \overline{w}(A) \tag{2}$$

and, in §2.2, the best dependency tree.[9]

$$G^\dagger = \operatorname*{argmax}_{A \in \mathcal{A}^\dagger(G)} \overline{w}(A) \tag{3}$$

2.1 Finding the best arborescence

A first stab at finding G^* would be to select the best (non-self-loop) incoming edge for each node. Although, this satisfies (C1), it does not (necessarily) satisfy (C2). We call this subgraph the **greedy graph**, denoted $\overrightarrow{G}$.✍ Clearly, $\overline{w}(\overrightarrow{G}) \geq \overline{w}(G^*)$ since it is subject to fewer restrictions. Furthermore, if $\overrightarrow{G}$ happens to be acyclic, it is clearly equal to G^*. What are we to do in the event of a cycle? That answer has two parts.

Part 1: We call any cycle C in $\overrightarrow{G}$ a **critical cycle**.✍ Naturally, (C2) implies that critical cycles can never be part of an arborescence. However, they help us identify optimal arborescences for certain *subproblems*. Specifically, if we were to "break" the cycle at any node $j \in C$ by removing its (unique) incoming edge, we would have an opti-

---

[5] We note exact match metrics, which consider the entire arborescence, do penalize root constraint violations

[6] There is one exception: Corro et al. (2016) mention Gabow and Tarjan (1984)'s algorithm in a footnote.

[7] Much like this paper, efficient root-constrained marginal inference is also possible without picking up an extra factor of n, but it requires some attention to detail (Koo et al., 2007; Zmigrod et al., 2020).

[8] When there is no ambiguity, we may abuse notation using G to refer to either its node or edge set, e.g., we may write $(i \rightarrow j) \in G$ to mean $(i \rightarrow j) \in E$, and $i \in G$ to mean $i \in V$.

[9] Probabilistic models of arborescences (e.g., Koo et al. (2007); Dozat and Manning (2017)) typically seek the maximum a posteriori structure, $\operatorname{argmax}_A \prod_{e \in A} p_e = \operatorname{argmax}_A \sum_{e \in A} \log p_e$. This case can be solved as (1) by taking the weight of e to be $\log p_e$ because $p_e \geq 0$.

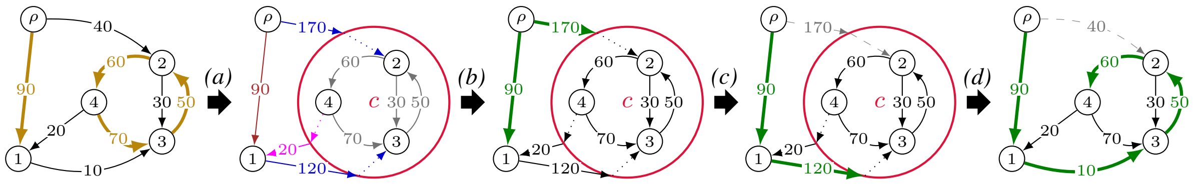

Figure 2: Worked example of finding the best dependency tree. Let G be the graph in the left-most figure, the greedy graph $\overrightarrow{G}$ (highlighted) contains a critical cycle C, ②→④→③→②. Step *(a)* shows the contraction $G_{/C}$ where C is replaced by ⓒ, and edges are cast as **enter**, **exit**, **external**, or **dead** edges in $G_{/C}$. We see the bookkeeping function π (as ····►), e.g., $\pi(c \xrightarrow{20} 1) = (4 \xrightarrow{20} 1)$ and $\pi(\rho \xrightarrow{170} c) = (\rho \xrightarrow{40} 2)$. Step *(b)* takes the greedy (sub)graph of $G_{/C}$ and since it contains no cycles, it is $(G_{/C})^*$ as (highlighted). Note that if we did not require a dependency tree, we could now use Theorem 1 to break C at ②. Step *(c)* takes $(G_{/C})^*$, which has *two* root edges, $(\rho \xrightarrow{90} 1)$ and $(\rho \xrightarrow{170} c)$, and removes the edge with minimal consequence: removing $(\rho \xrightarrow{90} 1)$ leads to $\overline{w} = 190$, while removing $(\rho \xrightarrow{170} c)$ leads to $\overline{w} = 210$. We pick the latter. As deleting $(\rho \xrightarrow{170} c)$ does not lead to a critical cycle (*optimization case*), we remove it from the graph (shown as - - ►) and so we get $(G_{/C})^\dagger$ (highlighted). Step *(d)* stitches $(G_{/C})^\dagger \looparrowright C^{(3)}$ yielding $G^\dagger$ (highlighted).

mal arborescence rooted at j for the subgraph over the nodes in C. Let $C^{(j)}$ be a subgraph of C rooted at j that denotes the broken cycle at j. Let $G_C^{(j)}$ be the subgraph rooted at j where G_C contains all the nodes in C and all edges between them from G. Since C is a critical cycle, $C^{(j)}$ is the greedy graph of $G_C^{(j)}$. Moreover, as it is acyclic, we have that $C^{(j)} = (G_C^{(j)})^*$. The key to finding the best arborescence of the entire graph is, thus, determining where to break critical cycles.

Part 2: Breaking cycles is done with a recursive algorithm that solves the "outer problem" of fitting the (unbroken) cycle into an optimal arborescence. The algorithm treats the cycle as a single *contracted* node. Formally, a **cycle contraction** takes a graph G and a (not necessarily critical) cycle C, and creates a new graph denoted $G_{/C}$ with the same root, nodes $(V \setminus C \cup \{c\})$ where $c \notin V$ is a new node that represents the cycle, and contains the following set of edges: For any $(i \xrightarrow{w} j) \in G$

- **enter**: if $i \notin C, j \in C$, then $(i \xrightarrow{w'} c) \in G_{/C}$ where $w' = w + \overline{w}(C^{(j)})$. Akin to dynamic programming, this choice edge weight (due to Georgiadis (2003)) gives the best "cost-to-go" for breaking the cycle at j.
- **exit**: if $i \in C, j \notin C$, then $(c \xrightarrow{w} j) \in G_{/C}$
- **external**: if $i \notin C, j \notin C$, then $(i \xrightarrow{w} j) \in G_{/C}$
- **dead**: if $i \in C, j \in C$, then no edge related to $(i \xrightarrow{w} j)$ is in $G_{/C}$. This is because such an edge $(c \rightarrow c)$ would be a self-cycle, which can never be part of an arborescence.

Additionally, we define a **bookkeeping function**, π, which maps the nodes and edges of $G_{/C}$ to their counterparts in G. We overload $\pi(G)$ to apply point-wise to the constituent nodes and edges.✍

By (C1), we have that for any $A_C \in \mathcal{A}(G_{/C})$, there exists exactly one incoming edge $(i \rightarrow c)$ to the cycle node c. We can use π to infer where the cycle was broken with $\pi(i \rightarrow c) = (i \rightarrow j)$. We call j the **entrance site** of A_C. Consequently, we can stitch together an arborescence as $\pi(A_C) \cup C^{(j)}$. We use the shorthand $A_C \looparrowright C^{(j)}$ for this operation due to its visual similarity to unraveling a cycle.✍

$G_{/C}$ may also have a critical cycle, so we have to apply this reasoning recursively. This is captured by Karp (1971)'s Theorem 1.[10]

Theorem 1. *For any graph G, either $G^* = \overrightarrow{G}$ or G contains a critical cycle C and $G^* = (G_{/C})^* \looparrowright C^{(j)}$ where j is the entrance site of $(G_{/C})^*$. Furthermore, $\overline{w}((G_{/C})^*) = \overline{w}(G^*)$.*

Theorem 1 suggests a recursive strategy for finding G^*, which is the basis of many efficient algorithms (Tarjan, 1977; Camerini et al., 1979; Georgiadis, 2003; Chu and Liu, 1965; Bock, 1971; Edmonds, 1967). We detail one such algorithm in Alg 1. Alg 1 can be made to run in $\mathcal{O}(n^2)$ time for dense with the appropriate implementation choices, such as Union-Find (Hopcroft and Ullman, 1973) to maintain membership of nodes to contracted nodes, as well as radix sort (Knuth, 1973) to sort incoming edges to contracted nodes; using a regular sort would add a factor of $\log n$ to the runtime.

---

[10] We have lightly modified the original theorem. For completeness, App. A provides a proof in our notation.

Algorithm 1

```
1: def opt$(G)$ :    ▷ Find $G^* \in \mathcal{A}(G)$ or $G^\dagger \in \mathcal{A}^\dagger(G)$
2:     if $\overrightarrow{G}$ has a cycle $C$ :    ▷ Recursive case
3:         return opt$\left(G_{/C}\right) \hookleftarrow C^{(j)}$
4:     else    ▷ Base case
5:         if we require a dependency tree (§2.2) :
6:             return constrain$(G)$
7:         else
8:             return $\overrightarrow{G}$
9: def constrain$(G)$ :  ▷ Find $G^\dagger \in \mathcal{A}^\dagger(G)$; $\overrightarrow{G} \in \mathcal{A}(G)$.
10:     $\sigma \leftarrow$ set of $\rho$'s outgoing edges in $\overrightarrow{G}$
11:     if $|\sigma| = 1$ : return $\overrightarrow{G}$    ▷ Root constraint satisfied
12:     $G' \leftarrow \underset{e\in\sigma:G''=G\backslash\backslash e}{\text{argmax}}\ \overline{w}(\overrightarrow{G''})$    ▷ Find best edge removal
13:     if $\overrightarrow{G'}$ has cycle $C$ :    ▷ Reduction case
14:         return constrain$(G_{/C}) \hookleftarrow C^{(j)}$
15:     else    ▷ Optimization case
16:         return constrain$(G')$
```

2.2 Finding the best dependency tree

Gabow and Tarjan (1984) propose an algorithm that does additional recursion at the base case of opt(G) (the additional if-statement at Line 5) to recover $G^\dagger$ instead of G^*.

Suppose that the set of edges emanating from the root in $\overrightarrow{G}$ is given by σ and $|\sigma| > 1$. We consider removing each edge in $(\rho \rightarrow j) \in \sigma$ from G. Since G may have *multiple* edges from ρ to j, we write $G\backslash\backslash e$ to mean deleting *all* edges with the same edge points as e. Let G' be the graph $G\backslash\backslash e'$ where $e' \in \sigma$ is chosen greedily to maximize $\overline{w}(\overrightarrow{G'})$. Consider the two possible cases:

Optimization case. If G' has no critical cycles, then $\overrightarrow{G'}$ must be the best arborescence with one fewer edges emanating from the root than $\overrightarrow{G}$ by our greedy choice of e'.✍

Reduction case. If G' has a critical cycle C, then all edges in C that do not point to j are in $\overrightarrow{G}$. If $e' \notin G^\dagger$, then C is critical cycle in the context of constrained problem and so we can apply Theorem 1 to recover $G^\dagger$. Otherwise, $e \in G^\dagger$ and we can break C at j to get $C^{(j)}$, which is comprised of edges in $\overrightarrow{G}$. Therefore, we can find $(G_{/C})^\dagger$ to retrieve $G^\dagger$. This notion is formalized in the following theorem.[11]

Theorem 2. *For any graph G with* $G^* = \overrightarrow{G}$*, let* σ *be the set of outgoing edges from* ρ *in* G^**. If* $|\sigma| = 1$*, then* $G^\dagger = G^*$*. Otherwise, let* $G' = G\backslash\backslash e'$ *for* $e' \in \sigma$ *that maximizes* $\overline{w}(\overrightarrow{G'})$*, then either* $G^\dagger = G'^\dagger$ *or there exists a critical cycle* C *in* G' *such that* $G^\dagger = (G_{/C})^\dagger \hookleftarrow C^{(j)}$ *where* j *is the entrance site of* $(G_{/C})^\dagger$.

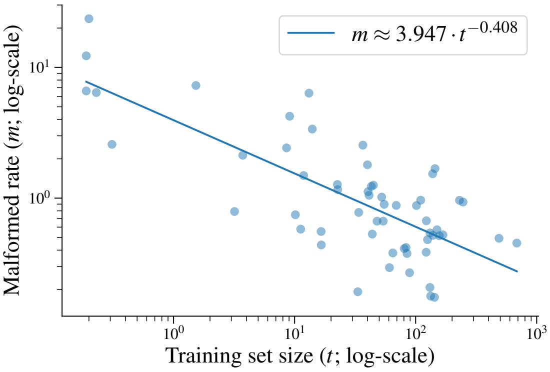

Figure 3: Proportion of malformed trees when decoding pre-trained models (Qi et al., 2020) for languages with varying training set sizes.

Theorem 2 suggests a recursive strategy constrain (Alg 1) for finding $G^\dagger$ given G^*. Gabow and Tarjan (1984, Theorem 7.1) prove that such a strategy will execute in $\mathcal{O}(n^2)$ and so when combined with opt(G) (Alg 1) leads to a $\mathcal{O}(n^2)$ runtime for finding $G^\dagger$ given a graph G. The efficiency of the algorithm amounts to requiring a bound of $\mathcal{O}(n)$ calls to constrain that will lead to the *reduction case* in order to obtain any number *optimization cases*. Each recursive call does a linear amount of work to search for the edge to remove and to stitch together the results of recursion. Rather than computing the greedy graph from scratch, implementations should exploit that each edge removal will only change one element of the greedy graph. Thus, we can find $\overline{w}(\overrightarrow{G\backslash\backslash e'})$ in constant time.

3 Experiment

How often do state-of-the-art parsers generate malformed dependency trees? We examined 63 Universal Dependency Treebanks (Nivre et al., 2018) and computed the rate of malformed trees when decoding using edge weights generated by pre-trained models supplied by Qi et al. (2020). On average, we observed that 1.80% of trees are malformed. We were surprised to see that—although the edge-factored model used is not expressive enough to capture the root constraint *exactly*—there are useful correlates of the root constraint in the surface form of the sentence, which the model appears to use to workaround this limitation. This becomes further evident when we examine the relative change[12] in UAS (0.0083%) and exact match scores (0.60%)

---

[11] For completeness, App. B provides a proof of Theorem 2.

[12] The relative difference is computed with respect to the unconstrained algorithm's scores.

Setting	# Languages	Malformed rate	Rel. Δ UAS	Rel. Δ Exact Match
High	20	0.63%	0.0041%	0.15%
Medium	32	1.02%	0.0012%	0.22%
Low	11	6.21%	0.0368%	2.91%

Table 1: Average malformed rate, relative UAS change, and relative exact match score change for different data settings. The 63 languages are split by their training set size $|\text{train}|$ into high ($|\text{train}| \geq 10,000$), medium ($1,000 \leq |\text{train}| < 10,000$), and low ($|\text{train}| < 1,000$).

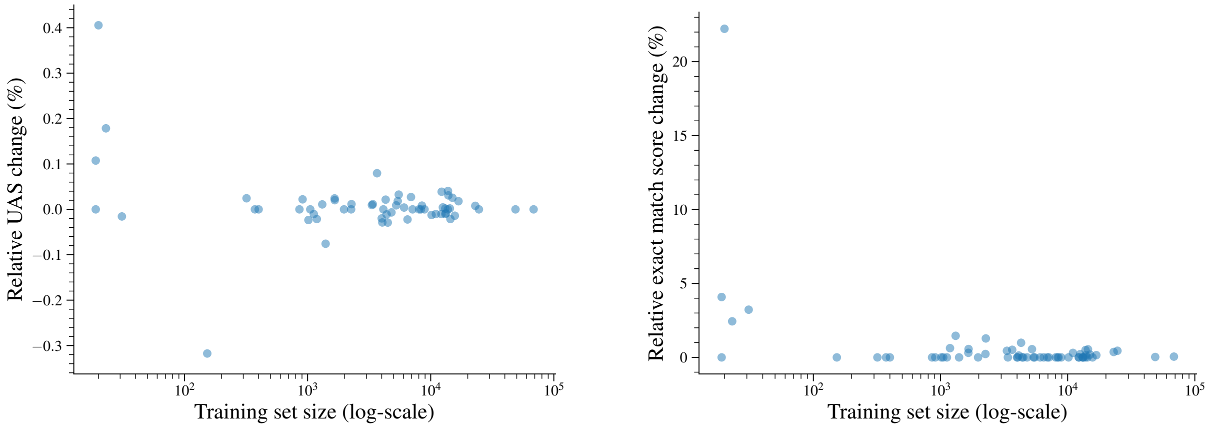

Figure 4: Relative change in UAS and exact match score when using the unconstrained and constrained algorithms for languages with varying training set sizes.

when using the constrained algorithm as opposed to the unconstrained algorithm.

Nevertheless, given less data, it is harder to learn to exploit the surface correlates; thus, we see an increasing average rate of violation, 6.21%, when examining languages with training set sizes of less than $1,000$ sentences. Similarly, the relative change in UAS and exact match score increases to 0.0368% and 2.91% respectively. Indeed, the worst violation rate was 24% was seen for Kurmanji which only contains 20 sentences in the training set. Kurmanji consequently had the largest relative changes to both UAS and exact match scores of 0.41% and 22.22%. We break down the malformed rate and accuracy changes by training size in Tab. 1. Furthermore, the correlation between training size and malformed tree rate can be seen in Fig. 3 while the correlation between training size and relative accuracy change can be seen in Fig. 4. We provide a full table of the results in App. C.

4 Conclusion

In this paper, we have bridged the gap between the graph-theory and dependency parsing literature. We presented an efficient $\mathcal{O}(n^2)$ for finding the maximum arborescence of a graph. Furthermore, we highlighted an important distinction between dependency trees and arborescences, namely that dependency trees are arborescences subject to a *root constraint*. Previous work uses inefficient algorithms to enforce this constraint. We provide a solution which runs in $\mathcal{O}(n^2)$. Our hope is that this paper will remind future research in dependency parsing to please mind the root.

A Proof of Theorem 1

To prove Theorem 1, we note a correspondence between graphs and contracted graphs.

Proposition 1. *Given a rooted graph G and a (not necessarily critical) cycle C in G. For any $A \in \mathcal{A}(G)$ that has a single edge $e = (i \xrightarrow{w} j) \in A$ such that $i \notin C$ and $j \in C$, there exists $A_C \in \mathcal{A}(G_{/C})$ and $A' \in \mathcal{A}(G_C^{(j)})$ such that $A = A_C \looparrowright A'$. Furthermore,*

$$\overline{w}(A) = \overline{w}(A_C) - \overline{w}(C^{(j)}) + \overline{w}(A') \tag{4}$$

Proof. Since e is the only edge in A from a non-cycle node to a cycle node (**enter**), every edge $e' \in G_{/C}$ such that $\pi(e') \in A$ forms an arborescence $A_C \in \mathcal{A}(G_{/C})$. Note that the set of edges in A for which there is no corresponding edge in $G_{/C}$ are **dead** edges. In fact, as A satisfies (C1), these edges form an arborescence $A' \in \mathcal{A}(G_C^{(j)})$. Therefore, $A = A_C \looparrowright A'$.
Furthermore, consider the weight of A:

$$\begin{aligned}
\overline{w}(A) &= \sum_{(i' \xrightarrow{w'} j') \in \pi(A_C)} w' + \overline{w}(A') && (5)\\
&= \sum_{(i' \xrightarrow{w'} j') \in \pi(A_C \smallsetminus \{e\})} w' + w + \overline{w}(A') && (6)\\
&= \sum_{(i' \xrightarrow{w'} j') \in A_C \smallsetminus \{e\}} w' + w + \overline{w}(A') && (7)\\
&= \sum_{(i' \xrightarrow{w'} j') \in A_C} w' - \overline{w}(C^{(j)}) + \overline{w}(A') && (8)\\
&= \overline{w}(A_C) - \overline{w}(C^{(j)}) + \overline{w}(A') && (9)
\end{aligned}$$

Note that (7) follows because e is the only edge in A from a non-cycle node to a cycle node, and (8) follows by the construction of **enter** edges in $G_{/C}$. ☐

As a corollary, we also have that every arborescence in the contracted graph $G_{/C}$ can be expanded into an arborescence in G.

Corollary 1 (Expansion lemma)**.** *Given a rooted graph G with a cycle C, every arborescence $A_C \in \mathcal{A}(G_{/C})$ is related to an arborescence $A \in \mathcal{A}(G)$ by $A = A_C \looparrowright C^{(j)}$ where j is the entrance site of A_C. Furthermore $\overline{w}(A) = \overline{w}(A_C)$.*

Proof. Let j be the entrance site of A_C into C. As $A_C \in \mathcal{A}(G_{/C})$ and $C^{(j)} \in \mathcal{A}(G_C^{(j)})$, Proposition 1 constructs $A \in \mathcal{A}_\rho(G)$ as desired. Furthermore, $\overline{w}(A) = \overline{w}(A_C) - \overline{w}(C^{(j)}) + \overline{w}(C^{(j)}) = \overline{w}(A_C)$. ☐

Note that Proposition 1 does not account for all arborescences in $\mathcal{A}(G)$. We next show that such arborescences which cannot be constructed using Proposition 1 will never be G^*.

Lemma 1. *Given a rooted graph G with a critical cycle C. We have that for all $j \in C$*

$$G_C^{(j)^*} = C^{(j)} \tag{10}$$

Proof. Since $G_C^{(j)}$ is a subgraph of G it must be that $\overrightarrow{G_C^{(j)}}$ is also a subgraph of $\overrightarrow{G}$. Since C is a critical cycle, $C^{(j)}$ does not have cycles and equals $\overrightarrow{G_C^{(j)}}$. Therefore $C^{(j)} = G_C^{(j)^*}$. ☐

Lemma 2. *Given a rooted graph G with a critical cycle C and $A \in \mathcal{A}(G)$. If $e = (i \rightarrow j) \in A$ and $e' = (i' \rightarrow j')$ such that $i, i' \notin C$ and $j, j' \in C$, then there exists a $A' \in \mathcal{A}(G)$ with $e \in A'$ and $e' \notin A'$ such that $\overline{w}(A) \leq \overline{w}(A')$.*

Proof. Construct A' such that for every edge $e'' = (i'' \rightarrow j'') \in G_{/C}$, if $j'' \neq c$ and $\pi(e'') \in A$, then $\pi(e'') \in A'$. Additionally, let e be in A' as well as the edges in $C^{(j)}$. Then A' has no cycles and each non-root node contains a single incoming edge, so $A' \in \mathcal{A}(G)$. Since A and A' contain identical edges except for those pointing to nodes in $C \setminus \{j\}$, by Lemma 1, $\overline{w}(A) \leq \overline{w}(A')$. $\square$

Theorem 1. For any graph G, either $G^* = \overrightarrow{G}$ or G contains a critical cycle C and $G^* = (G_{/C})^* \looparrowright C^{(j)}$ where j is the entrance site of $(G_{/C})^*$. Furthermore, $\overline{w}({G_{/C}}^*) = \overline{w}(G^*)$.

Proof. There are two cases to consider.

Case 1: G does not contain a critical cycle. Trivially, $G^* = \overrightarrow{G}$.

Case 2: G contains a critical cycle C. By Corollary 1, we can construct an arborescence $A = (G_{/C})^* \looparrowright C^{(j)} \in \mathcal{A}(G)$, we now prove that no other $A' \in \mathcal{A}(G)$ can have a higher weight. Firstly, by Lemma 2, we only need to consider A' that satisfy Proposition 1. Therefore, A' must be decomposable into an arborescence $A_C \in \mathcal{A}(G_{/C})$ and an arborescence in $\mathcal{A}(G_C^{(j')})$ where j' is the entrance site of A_C. Then since $(G_{/C})^*$ is optimal, we have that $A_C = (G_{/C})^*$ and $j' = j$. As $C^{(j)}$ is optimal (by Lemma 1), A must also be optimal and so $G^* = (G_{/C})^* \looparrowright C^{(j)}$. $\square$

B Proof of Theorem 2

We prove Theorem 2 by showing that both the *optimization* and *reduction* cases described in the main text lead to progress towards finding $G^\dagger$.

Lemma 3. *For any graph G with $G^* = \overrightarrow{G}$, let σ be the set of outgoing edges from ρ in $\overrightarrow{G}$. If $|\sigma| > 1$, let $G' = G \backslash\backslash e'$ for $e' \in \sigma$ that maximizes $\overline{w}(\overrightarrow{G'})$. If there exists a critical cycle C in G', then $G^\dagger = (G_{/C})^\dagger \looparrowright C^{(j)}$ where j is the entrance site of $(G_{/C})^\dagger$.*

Proof. Let $e' = (\rho \rightarrow i)$ and $e \in G_{/C}$ such that $\pi(e) = e'$. We know that e always exists as e' emanates from the root. By Corollary 1, we know that $A = (G_{/C})^\dagger \looparrowright C^{(j)} \in \mathcal{A}(G)$ where j is the entrance site of $(G_{/C})^\dagger$. Furthermore, As C has no edges emanating from the root, $A \in \mathcal{A}^\dagger(G)$. There are two cases to consider:

Case 1 ($e \in (G_{/C})^\dagger$): As $C^{(j)}$ is a subgraph of $\overrightarrow{G}$, A must have the highest weight in $\mathcal{A}^\dagger(G)$, so $G^\dagger = A$.

Case 2 ($e \notin (G_{/C})^\dagger$): Then e' cannot be in $G^\dagger$, and the edge pointing to i in C is the next best possible edge incoming to j. Therefore, whichever way we break C in A, we will get a set of edges with maximal weight and so $G^\dagger = A$. $\square$

Lemma 4. *For any graph G with $G^* = \overrightarrow{G}$, let σ be the set of outgoing edges from ρ in $\overrightarrow{G}$. If $|\sigma| > 1$, let $G' = G \backslash\backslash e'$ for $e' \in \sigma$ that maximizes $\overline{w}(\overrightarrow{G'})$. Either $G^\dagger = G'^\dagger$ or there exists a critical cycle C in G' such that $G^\dagger = (G_{/C})^\dagger \looparrowright C^{(j)}$ where j is the entrance site of $(G_{/C})^\dagger$.*

Proof. Let j be the entrance site of $(G_{/C})^\dagger$. Proof by induction on $r = |\sigma|$.

Base case ($r = 2$): If G' does not contain a critical cycle, then clearly $G'^\dagger = G'^*$. Since we choose e' to maximize $\overrightarrow{G'}$ and G' is a subgraph of G, $G^\dagger = G'^\dagger$. Otherwise, G' has a critical cycle C. Then by Lemma 3, $G^\dagger = (G_{/C})^\dagger \looparrowright C^{(j)}$.

Inductive case ($r > 2$): Let σ' be the set of outgoing edge from ρ in $\overrightarrow{G'}$. Then clearly $|\sigma'| = r - 1 > 1$. If G' does not contain a critical cycle, then $G'^* = \overrightarrow{G'}$ and we satisfy the induction hypothesis. Otherwise, G' has a critical cycle C. Then by Lemma 3, $G^\dagger = (G_{/C})^\dagger \looparrowright C^{(j)}$. $\square$

Theorem 2. For any graph G with $G^* = \overrightarrow{G}$, let σ be the set of outgoing edges from ρ in G^*. If $|\sigma| = 1$, then $G^\dagger = G^*$, otherwise if $G' = G \backslash\backslash e'$ for $e' \in \sigma$ that maximizes $\overline{w}(\overrightarrow{G'})$, then either $G^\dagger = G'^\dagger$ or there exists a critical cycle C in G' such that $G^\dagger = (G_{/C})^\dagger \looparrowright C^{(j)}$ where j is the entrance site of $(G_{/C})^\dagger$.

Proof. There are two cases to consider.

Case 1 ($|\sigma| = 1$): Then G^* has one edge emanating from the root so clearly $G^\dagger = G^*$.

Case 2 ($|\sigma| > 1$). This is immediate from Lemma 4. $\square$

Abstract

We describe a fully unsupervised cross-lingual transfer approach for part-of-speech (POS) tagging under a truly low resource scenario. We assume access to parallel translations between the target language and one or more source languages for which POS taggers are available. We use the Bible as parallel data in our experiments: small size, out-of-domain and covering many diverse languages. Our approach innovates in three ways: 1) a robust approach of selecting training instances via cross-lingual annotation projection that exploits best practices of unsupervised type and token constraints, word-alignment confidence and density of projected POS, 2) a Bi-LSTM architecture that uses contextualized word embeddings, affix embeddings and hierarchical Brown clusters, and 3) an evaluation on 12 diverse languages in terms of language family and morphological typology. In spite of the use of limited and out-of-domain parallel data, our experiments demonstrate significant improvements in accuracy over previous work. In addition, we show that using multi-source information, either via projection or output combination, improves the performance for most target languages.

1 Introduction

Majority of world's languages do not have annotated datasets even for the most simple NLP tasks such as part-of-speech (POS) tagging. However, efforts in documenting low-resource languages often contain translations, usually of religious text, into other high-resource languages. One such parallel corpus is the Bible (Mayer and Cysouw, 2014): 484 languages have a complete Bible translation, while 2551 have a part of the Bible translated. Our goal is to learn POS taggers for a diverse set of target languages in a truly low-resource scenario, where only a limited and possibly out-of-domain set of translations into one or more high-resource languages is available (e.g., the Bible), together with supervised POS taggers for the high-resource source language(s).

Unsupervised cross-lingual POS tagging via annotation projection has a long research history (Yarowsky et al., 2001; Fossum and Abney, 2005; Das and Petrov, 2011; Duong et al., 2013; Agić et al., 2015, 2016; Buys and Botha, 2016). In contrast to our work, these approaches either use large and/or in-domain parallel data or rely on a large number of source languages for projection. However, since projection could suffer from bad translation, alignment mistakes or wrong assumptions, a key consideration for all these approaches is how to obtain high-quality training instances for the target language (i.e., sentences with accurate POS tags projected from the source-language(s)). Coupling token and type constraints (Das and Petrov, 2011; Täckström et al., 2013; Buys and Botha, 2016), word-alignment confidence (Duong et al., 2013), multi-source projection (Agić et al., 2016) and coverage (percentage of tokens covered by multi-source projection) (Plank and Agić, 2018) have shown to lead to training instances of better quality. However, only one or two of these have been usually employed.

Our first contribution is a robust approach for selecting training instances via cross-lingual annotation projection that exploits and expands all these best practices: coupling type and token constraints obtained in an unsupervised way, word-alignment confidence *together* with the density of the projected POS, and (optionally) multi-source projection (Sub-section 2.1).

Our second contribution is a BiLSTM (Hochreiter and Schmidhuber, 1997) neural architecture that uses pre-trained contextualized word embeddings, affix embeddings and hierarchical Brown clusters (Brown et al., 1992). As contextualized embeddings, we show gains by exploiting the mul-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4820–4831,
November 16–20, 2020.

tilingual *XML-R* model (Conneau et al., 2019), while affix embeddings are particularly useful for morphologically-rich languages, and word clusters have been shown to be useful for non-neural POS tagging (Kupiec, 1992; Täckström et al., 2013; Owoputi et al., 2012). Moreover, in addition to the single-source setups, we propose an approach that utilizes multiple source languages by combining the outputs of single-source taggers via weighted voting at the token level (Sub-section 2.2).

Our third contribution is an extensive experimental setup, with 12 diverse target languages in terms of language family and morphological typology and six high-resource source languages (Section 3). While projecting from a single source language can be efficient, we show that using multiple sources, either via projection or output combination, further improves the tagging accuracy for most target languages. Our experiments, using limited and out-of-domain parallel data, demonstrate significant improvements over previous work (both unsupervised and semi-supervised), even when comparing our single-source setups to other multi-source ones. We also investigate how much gold data is needed to develop supervised taggers comparable to our best unsupervised models. In addition, we show that cross-lingual annotation projection generalizes across languages of different typologies better than the zero-shot model-transfer approach by Pires et al. (2019). Finally, our tagging scripts and models are made publicly available [1].

2 Approach

Our goal is to induce a neural POS tagger for a target language of interest without any direct supervision. Instead, we rely on parallel translations between the target and one or more source languages for which POS taggers are accessible. This section describes our approach: 1) cross-lingual annotation projection via word alignments to prepare the training instances of the target language, and 2) neural POS tagging for the target language.

2.1 Cross-Lingual Projection via Word Alignments

Given sentence-aligned parallel data, we align the text of the source and target sides at the word level using GIZA++ (Och and Ney, 2003), while sentences of more than 80 tokens are eliminated. We construct bidirectional word alignments, by only considering the intersecting source-to-target and target-to-source alignments, and exclude the alignment points where the average of the alignment probabilities in the two directions is below some threshold α.

Tagging of Source Languages. Since cross-lingual projection requires a common POS tagset for all languages, we use the universal POS tagset of the Universal Dependencies (UD) project [2], which consists of 17 universal POS tags. We rely on off-the-shelf taggers to tag the source text prior to projecting the annotations as described next.

POS Projection using Token and Type Constraints. To project the POS tags from the source to the target language, we use token and type constraints based on the mapping induced by the word-level alignments. The idea of using both token and type constraints was first introduced by Täckström et al. (2013). Type constraints define the set of POS tags a word type can receive. In a semi-supervised leaning setup, type constraints can be obtained from an annotated corpus (Banko and Moore, 2004) or from a resource that serves as a POS lookup such as the Wiktionary [3] (Li et al., 2012; Täckström et al., 2013). For the extraction of type constraints in an unsupervised fashion, we follow the approach of (Buys and Botha, 2016), where we define a tag distribution for each word type on the target side by accumulating the counts of the different POS tags of the source-side tokens that align with the target-side tokens of that word type. The POS tags whose probability is equal to or greater than some threshold β constitute the type constraints of the underlying word type. As token constraint, every aligned token on the target side gets assigned the POS tag of its corresponding source-side token.

We combine both token and type constraints in a slightly different way than Täckström et al. (2013) and Buys and Botha (2016). If a token is not aligned, or its token constraint does not exist in the underlying type constraints, the token becomes unconstrained (i.e., receives a NULL tag). Otherwise, the token constraint is applied. Those applied token constraints represent the projected tags.

In contrast to the previous work, we do not use the type constraints to impose restrictions when training the model as they restrict the performance of our neural architecture.

[2] https://universaldependencies.org/

[3] https://wiktionary.org/

Multilingual Projection. In addition to projecting the POS tags from one language to another, we experiment with a multilingual setup in which we follow Agić et al. (2016) by projecting the tags from multiple source languages prior to training the model ($Multi_{proj}$). The intuition is that the projection from a single source might suffer from inaccurate translation or wrong induced alignments. Moreover, the POS tags of two correctly aligned sentences might differ because of language-dependent specifications. Such problems can be resolved by inducing the tags from multiple sources.

For each target token T, we assign the projected tag that receives the maximum voting, weighted by the alignment confidence for each source.

$$tag(T) = \arg\max_{tag} \sum_{i,s} p(l_s|T) \times P(tag_{i,s}|T)$$

where $p(l_s|T)$ is in $\{0, 1\}$ to represent whether target token T is assigned a tag under the projection from language ls, while $P(tag_{i,s}|T)$ is the probability of the alignment resulting in the assignment of tag_i to target token T when projecting from language ls.

Selection of Training Instances. Prior to training a POS tagger using the projected tags as labels, we score the target sentences based on their "annotation" quality and exclude the ones whose scores are below a threshold γ. We define sentence score as the harmonic mean of density d_S and alignment confidence a_S, where d_S is the percentage of tokens with projected tags, and a_S is the average alignment probability of those tokens.

$$Score(S) = \frac{2\times(d_S \times a_S)}{(d_S + a_S)}$$

Filtering out sentences of low density and alignment confidence is crucial for training the model. While choosing the sentences with top alignment scores has proved successful in previous research (Duong et al., 2013), we add the density factor as our Bi-LSTM model benefits from longer contiguous labeled sequences.

2.2 Neural POS Tagging

The architecture of our POS tagger is a bidirectional long short-term memory (BiLSTM) neural-network model (Hochreiter and Schmidhuber, 1997). BiLSTMs have been widely used for POS tagging (Huang et al., 2015; Wang et al., 2015; Plank et al., 2016; Ma and Hovy, 2016; Cotterell and Heigold, 2017) and other sequence-labeling tasks. The input to our BiLSTM model is a labeled sentence where the word representation is the concatenation of word and sub-word information, namely pre-trained and randomly initialized word embeddings, affix embeddings and word clusters. Figure 1 shows the complete structure of our neural architecture. [4].

Word and Affix Embeddings We use two types of word-embedding features: pre-trained contextualized embeddings (*PT*) and randomly initialized embeddings (*RI*). For the pre-trained contextualized embeddings, we use the final layer of the multilingual *XLM-RoBERTa* model, *XLM-R* (Conneau et al., 2019) [5] *XLM-R* is a transformer-based multilingual masked language model that is pre-trained on texts of 100 languages, and its performance is competitive with strong monolingual models when tested on a variety of NLP tasks. It also shows better performance than multilingual *BERT*, *mBERT* (Devlin et al., 2019), particularly for low-resource languages. We use the average of the embedding vectors of the first and last sub-tokens of each word to represent its pre-trained embeddings.

It is worth noting that when using our architecture for a target language that is not present in the *XLM-R* model, one can consider training a custom *XLM* transformer-based model [6] given the availability of monolingual data and suitable computational resources, and thus our architecture is not limited to the languages available in the *XLM-R* model.

The randomly initialized embeddings are learned as part of training the model. Coupling both the randomly initialized embeddings and the pre-trained ones is essential when the domain of the training data is different from the one of the pre-trained embeddings, which is the case in our learning setup, where we use the Bible data for training, while the *XLM-R* model is trained on text from Wikipedia [7] and a CommonCrawl corpus (See Conneau et al. (2019) for more details).

In addition to word embeddings, we use randomly initialized prefix and suffix n-gram character embeddings, where n is in $\{1, 2, 3, 4\}$, as the use of affix information has proved effective in POS tagging (Ratnaparkhi, 1996; Martins and Kreutzer,

---

[4] We also experimented with BiLSTM+CRF, but the CRF layer did not improve the model, which is in line with previous research (Yang et al., 2018; Plank and Agić, 2018).

[5] We get better results when using the XLM-R embeddings as features as opposed to performing fine tuning, where the latter is more suitable to sentence-level predictions.

[6] https://github.com/facebookresearch/XLM

[7] https://wikipedia.org

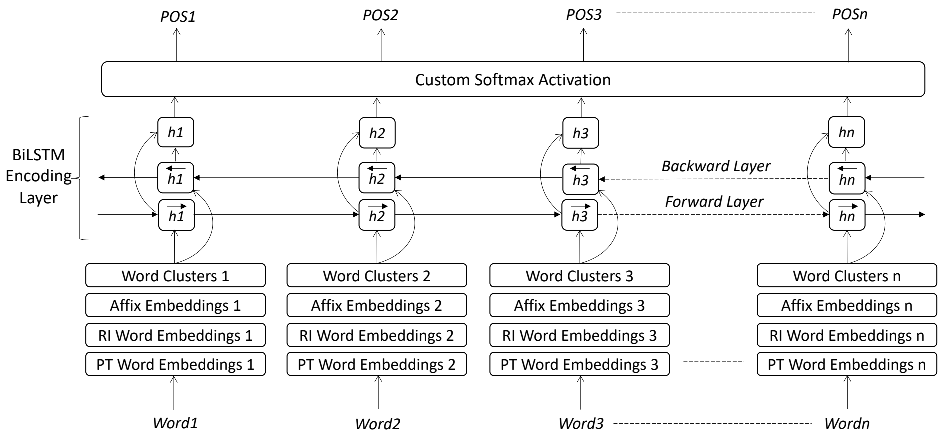

Figure 1: The architecture of our BiLSTM neural-network model. *PT* = pre-trained, *RI* = randomly initialized.

2017).

Word Clusters. The use of word clusters for POS tagging was first proposed by Kupiec (1992) in a supervised tagging setup, and has then proved efficient for unsupervised learning (Täckström et al., 2013; Buys and Botha, 2016). In this work, we follow Owoputi et al. (2012) by utilizing hierarchical Brown clustering (Brown et al., 1992), which is an HMM-based clustering of a binary merging criterion based on the logarithmic probability of a context under a class-based language model, where the objectives is to reduce the loss in adjusted mutual information (AMI).

The output of hierarchical Brown clustering is a binary tree of n leaf nodes that represent n word clusters, where each word in the vocabulary belongs to a single leaf cluster. Leaf clusters are recursively grouped into parent ones (interior nodes) until a super cluster of the entire vocabulary is reached (the root).

We produce hierarchical brown clusters for each target language by applying Percy Liang's implementation of Brown clustering [8] (Liang, 2005) on monolingual text that is a combination of the Wikipedia and Bible texts of the target language.

For each word, we use the main cluster (the binary representation of the corresponding leaf node) and all of its ancestors (the prefixes of the binary representation) as features. This allows us to use the hierarchical clustering information and thus avoid the commitment to a specific granularity level, where high-level clusters may be insufficient, while the lower ones may represent over-clustering.

Custom Softmax Activation. We use softmax activation on top of the BiLSTM encoding layer for the computation of the final output. However, since some words have NULL tags as a result of missing alignments or non-intersecting token and type constraints (Sub-section 2.1), we set the value of the output neuron corresponding to the NULL tag to $-\infty$ so that it does not contribute to the calculation of the softmax probabilities and thus prohibit the model from decoding NULL. Moreover, we mask the words with NULL tags when computing the cross-entropy network loss.

Multilingual Decoding. In addition to the Mul_{proj} setup presented in Sub-section 2.1, we conduct another multilingual setup where we combine the outputs of the single-source taggers through weighted maximum voting at the token level (Mul_{out}). The weight of a language pair, $w(l_s, l_t)$, is measured as a softmax function whose input vector is the average sentence-level alignment probabilities when aligning the source language l_s to the underlying target language l_t.

$$tag(T) = \arg\max_{tag} \sum_{i,s} w(l_s, l_t) \times P(tag_{i,s}|T)$$

Where $P(tag_{i,s}|T)$ is in $\{0, 1\}$ to represent whether target token T is assigned tag_i by the model trained on the projection from language l_s.

3 Experiments and Evaluation

3.1 Languages and Data

We run our experiments on six source languages and 12 target ones [9] for a total of 72 languages pairs.

---

[8] https://github.com/percyliang/brown-cluster

[9] Although the majority of our target languages are high-resource, we use them in a simulated low-resource scenario.

We choose six widely-spoken source languages as the assumption is that for a low-resource language, a parallel text is highly likely to involve one of them. These languages are English (Indo-European (IE), Germanic), Spanish (IE, Romance), French (IE, Romance), German (IE, Germanic), Russian (IE, Slavic) and Arabic (Afro-Asiatic, Semitic). On the other side, we choose 12 diverse target languages in terms of language family and morphological typology: Afrikaans (IE, Germanic), Amharic (Afro-Asiatic, Semitic), Basque (language isolate), Bulgarian (IE, Slavic), Finnish (Uralic, Finnic), Hindi (IE, Hindi), Indonesian (Austronesian, Malayo-Sumbawan), Lithuanian (IE, Baltic), Persian (IE, Iranian), Portuguese (IE, Romance), Telugu (Dravidian, South Central) and Turkish (Turkic, Southwestern).

We use the multilingual parallel Bible corpus [10] (Christodouloupoulos and Steedman, 2015) as the source of our parallel data, where we perform the alignment on the verse and word levels. The Bible text is available in full for our source and target languages except Basque, where only the new testament is available.

We use Stanza [11] (Qi et al., 2020) to tag the source-side text of the source languages except for Arabic, for which we apply MADAMIRA (Pasha et al., 2014) for performance gain. However, since MADAMIRA was trained on PTB tags and was not designed to follow the UD guidelines, we mapped the Arabic PTB tags into their UD cognates and manually corrected the analyses of the most frequent 2,500 Arabic POS and lemma pairs by selecting the most likely analysis for each.

We evaluate our models in terms of POS accuracy on the test sets of the Universal Dependencies, UD v2.5 (Zeman et al., 2019) [12]. We also report our results on older versions in order to compare to the state-of-the-art systems, whenever needed.

3.2 Experimental Settings

The alignment and projection thresholds as well as the hyperparameters of the model are manually tuned on Bulgarian, Basque, Finnish and Indonesian when projecting from English using the UD development sets. We set the alignment threshold α to 0.1 and the threshold γ for the selection of training instances to 0.5. The POS type distribution threshold β is set to 0.3 as this has proved effective by Banko and Moore (2004) and Buys and Botha (2016). Table 1 lists the number of training sentences per target language based on the tuned thresholds.

Language	Number of Training Sentences	
	One-Source Average	Mul_{proj}
Afrikaans	23,800	30,900
Amharic	10,000	26,700
Basque	7,200	7,900
Bulgarian	21,600	30,400
Finnish	24,000	30,900
Hindi	16,100	30,900
Indonesian	9,600	28,900
Lithuanian	25,700	31,100
Persian	17,500	30,900
Portuguese	26,800	31,100
Telugu	10,100	30,000
Turkish	16,000	30,100

Table 1: Number of training sentences per language (rounded to the nearest 100)

Our BiLSTM networks are one layer deep with 128 nodes, while the size of all the randomly initialized word and affix embeddings is 64, and the number of Brown clusters is set to 128. We use Adam for optimization (Kingma and Ba, 2014) with a learning rate of 0.0001 and a learning decay rate of 0.1 at each epoch for a total of 12 epochs. To avoid overfitting, we apply L2 regularization and two dropout layers, before and after the BiLSTM encoder, with a dropout rate of 0.7. The training rate is approximately 2,500 sentences per hour when utilizing a single 2.00 GHz CPU.

3.3 Results

Table 2 reports the accuracy of our POS taggers for all 72 language pairs, in addition to the two multi-source setups Mul_{out} and Mul_{proj}, based on the average of three runs. As upper bound, we report the state-of-the-art supervised results when training on the UD training sets [13] using Stanza [14] (Qi et al., 2020).

There is a noticeable variance in the performance of the different taggers. However, languages of the same families transfer best across each other. For instance, English and German transfer best to Afrikaans (IE, Germanic), while Spanish yields the best results for Portuguese (IE, Romance), and Russian is the best source for Bulgarian (IE, Slavic).

Table 2: POS tagging results (accuracy) when evaluating on the test sets of UD v2.5. The best unsupervised result for each target language is in **bold**, while statistically significant multilingual improvements are marked by *. The last column reports the supervised performance by Stanza

One exception is the case of transferring from Arabic to Amharic (Afro-Asiatic, Semitic). One possible reason is that the Arabic analyzer does not follow the UD guidelines (Sub-section 2.1), which also affects the performance of all the taggers that use Arabic as the source.

Since English is the most vital language, where its morphological-annotation guidelines were the basis for those of other languages, transferring from English yields the best performance for seven target languages. On the target side, the Basque taggers suffer from the lowest performance since the parallel data is only available for the New Testament of the Bible, along with the fact that Basque is a language isolate, which is challenging for cross-lingual transfer learning.

Multi-Source Performance. As expected, the multi-source setups achieve the best on-average results and the best tagging performance for eight target languages. In addition, Mul_{proj} outperforms Mul_{output} in seven occasions, which highlights the importance of producing projected tags of high quality prior to training the taggers. As shown in Table 1, Mul_{proj} results in a significant increase in the number of training sentences, which, along with the quality of the projected tags, gives the best overall performance.

Per-Tag accuracy. Table 3 reports the accuracy of nouns, verbs and adjectives for each target language in the Mul_{proj} setup. The accuracy of adjectives is the lowest across all target languages. The only exception is Persian, where the performance of verbs is lower than that of nouns and adjectives, and it is the lowest among all target languages. In contrast, the accuracy on nouns is the highest on average and across nine languages, where it exceeds 90% in Afrikaans, Bulgarian and Portuguese, while verbs achieve the highest accuracy in Amharic, Indonesian and Telugu. Each of the three tags is ranked second to the lowest in Basque, an isolate with the least available data.

Languages	NOUN	VERB	ADJ
Afrikaans	91.5	85.0	83.6
Amharic	78.1	81.1	43.6
Basque	70.1	61.0	24.9
Bulgarian	92.5	87.8	71.0
Finnish	84.7	79.7	63.1
Hindi	75.2	63.6	53.5
Indonesian	80.2	84.3	56.0
Lithuanian	88.7	86.0	56.2
Persian	85.4	49.0	54.9
Portuguese	92.2	89.0	76.6
Telugu	68.0	80.5	15.0
Turkish	77.2	80.5	44.2
Average	82.0	77.3	53.6

Table 3: Accuracies of nouns, verbs and adjectives for each target language in the Mul_{proj} setup

Ablation Experiments. We conduct two ablation experiments: 1) no XLM-R embeddings (i.e., the target language is not present in the XLM-R model, and no computational resources are available to train one), denoted by *No_XLM*, and 2) no XML-R embeddings and no word clusters (i.e., no monolingual data is available for the target language), denoted by *No_Mono*.

When testing the *No_XLM* and *No_Mono* setups on all 72 language pairs [15], the average accuracy

---

[15] We double the learning rate as the complexity decreases.

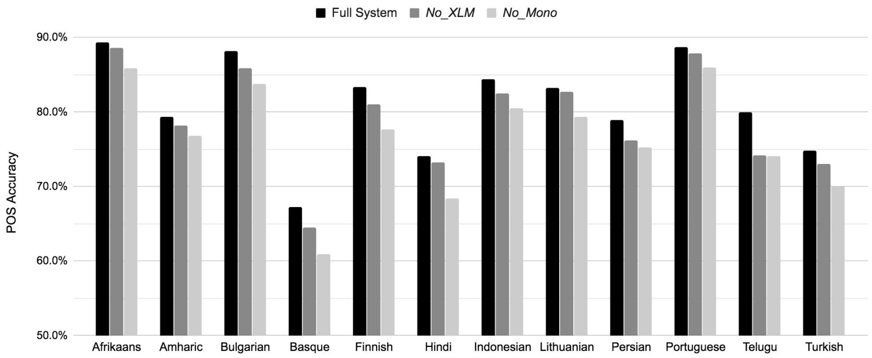

Figure 2: The best performance of each target language in three settings: full system (black), *No_XLM* (dark gray) and *No_Mono* (light gray)

decreases by absolute 2.2% and 5.1%, respectively. However, when projecting from multiple sources in the Mul_{proj} setup, this is reduced to only 1.8% and 4.1%, respectively.

Figure 2 reports the best performance for each target language in three setups: no ablation (full system), *No_XLM* and *No_Mono*. The impact of eliminating the XLM embeddings is most noticeable in Telugu, while it is negligible in Lithuanian, with absolute reduction of 5.8% and 0.6% in POS accuracy, respectively. On the other hand, Hindi benefits most from word clustering, where the *No_Mono* performance is 4.9% below that of *No_XLM*.

The performance drop in the *No_Mono* setup highlights the importance of monolingual data, which is key to the competitive performance of our taggers, especially when compared to other systems that utilize linguistic resources. However, the performance of the system in the absence of only the *XLM-R* embeddings decreases by a small percent, which provides a relatively good compromise when one lacks adequate computational resources.

3.4 Comparison w.r.t. State-of-the-Art

Next, we show that our system outperforms the state-of-the-art unsupervised and semi-supervised cross-lingual POS taggers, where the robust selection of training instances and the rich word representation in the neural architecture are more efficient than using larger and/or domain-appropriate parallel data, some labeled data or off-the-shelf resources encapsulating linguistic knowledge.

We first compare our models to two state-of-the-art systems that perform fully unsupervised cross-lingual POS tagging via annotation projection: AGIC (Agić et al., 2016) and BUYS (Buys and Botha, 2016). AGIC is a multilingual annotation-projection system that is the basis of our Mul_{proj} setup and uses a TnT POS tagger (Brants, 2000) for training. BUYS is a neural model that is based on the Wsabie algorithm (Weston et al., 2011) and utilizes morphological tags projected via coupling token and type constraints.

We report the performance of our system versus AGIC and BUYS on the test sets of UD v1.2 in Table 4. Our taggers outperform both AGIC and BUYS on all the common language pairs with error reduction of 49.1% and 9.0%, respectively, despite the use of smaller and out-of-domain parallel data and only six source languages in the multi-source setup. In contrast, AGIC has the advantage of utilizing 21 source languages for projection, while BUYS uses large-size parallel data, taken from Europarl [16], that is up to 2M tokens whose domain is similar to the one of the UD test sets.

Target	Source	AGIC	Our System
Bulgarian	Multilingual	70.0	**85.6**
Finnish	Multilingual	69.6	**81.2**
Hindi	Multilingual	50.5	**72.9**
Indonesian	Multilingual	75.5	**84.8**
Persian	Multilingual	33.7	**76.7**
Portuguese	Multilingual	84.2	**88.7**

Target	Source	BUYS	Our System
Bulgarian	English	81.8	**83.3**
Finnish	English	77.1	**80.4**
Portuguese	English	84.3	**84.6**
Portuguese	Spanish	88.0	**89.1**

Table 4: Comparison to AGIC and BUYS

Next, we compare our system to two semi-supervised cross-lingual POS tagging systems: CTRL (Cotterell and Heigold, 2017) and DsDs

---

[16] http://www.statmt.org/europarl/

(Plank and Agić, 2018). CTRL is a character-level RNN tagger that jointly learns the morphological tags of a high-resource language and the target one, where it has two experimental setups that utilize 100 and 1000 manually annotated target tokens, denoted by D100 and D1000, respectively. DsDs is a BiLSTM tagger that follows the annotation-projection approach by Agić et al. (2016) and utilizes the Polyglot embeddings (Al-Rfou' et al., 2013) and lexical information from the Wiktionary.

Table 5 reports the performance of our system versus CTRL on the test sets of UD v2, and versus DsDs on the development sets of UD v2.1 using the 12 universal tags of Petrov et al. (2012) (only Basque is evaluated on the test set). Our system outperforms CTRL except in the D1000 setup of Portuguese, where our results are still comparable. Our system also outperforms DsDs when evaluated on four language pairs out of six, with an overall error reduction of 43.7%.

Target	Source	CTRL	Our System
Bulgarian	Russian-D100	68.8	**87.2**
Bulgarian	Russian-D1000	83.1	**87.2**
Portuguese	Spanish-D100	81.8	**88.7**
Portuguese	Spanish-D1000	**88.9**	88.7

Target	Source	DsDs	Our System
Basque	Multilingual	62.7	**76.5**
Bulgarian	Multilingual	**89.7**	89.3
Finnish	Multilingual	82.4	**85.6**
Hindi	Multilingual	66.2	**84.0**
Persian	Multilingual	43.8	**80.6**
Portuguese	Multilingual	**92.2**	**92.2**

Table 5: Comparison to CTRL and DsDs

3.5 Annotation Projection vs. Supervision

The comparison to the upper-bound supervised results in Table 2 shows that the unsupervised Afrikaans, Indonesian and Portuguese taggers successfully predict at least 90% of the correct decisions made by their corresponding supervised ones. The impact of such small gaps could be tolerable when utilizing the taggers as part of downstream tasks, and thus the trade-off between developing an unsupervised tagger versus an expensive supervised one (if possible) should be considered.

Next, for each target language, except Amharic, we estimate the amount of manual annotations needed to develop a supervised tagger that approximates the performance of the unsupervised one. We do so by iteratively training [17] and evaluating POS taggers in increments of 100 words until the target performance is reached. We list the results in Table 6 with respect to the best unsupervised results in Table 2. On average, it is required to annotate 3,773 words to develop an equivalent supervised tagger, where the training sizes range from 1,200 words, for Basque and Telugu, to 9,000 words, for Lithuanian.

Languages	Annotation Size	POS Acc.
Afrikaans	5,700	89.3
Basque	1,200	67.3
Bulgarian	2,400	88.2
Finnish	5,600	83.4
Hindi	1,800	74.1
Indonesian	2,900	84.4
Lithuanian	9,000	83.3
Persian	2,200	79.0
Portuguese	6,900	88.7
Telugu	1,200	80.0
Turkish	2,600	74.9
Average	3,773	81.2

Table 6: Training sizes of equivalent supervised taggers

3.6 Annotation Projection vs. Model Transfer

One approach of zero-shot cross-lingual POS tagging is to apply a tagging model trained for a related language. Pires et al. (2019) investigate zero-shot model transfer by fine-tuning the multilingual *BERT* language model, *mBERT* (Devlin et al., 2019), for the POS tagging of some language and applying the fine-tuned model to another. While the approach does not require any translation or annotations on the source side, the pre-trained models do not generalize well across languages of different typologies.

We compare our approach versus zero-shot model transfer when transferring from English to Japanese (different language families and morphological typologies). We utilize the Bible translation, where we use *mBERT* instead of *XLM-R* and train our model for only three epochs in order to replicate the experimental settings by Pires et al. (2019). As shown in Table 7, our approach achieves relative error reduction of 27.6% when evaluated on the Japanese test set from the CoNLL 2017 shared task (Zeman et al., 2017), This result suggests that annotation projection is less sensitive to the relatedness between the source and target languages (which is in line with the results in Table 2), and thus can better generalize across languages of different typologies.

---

[17] We use the UD training data and the same parameters of the unsupervised setting but for 100 epochs instead of 12.

Target	Source	PIRES	Our System
Japanese	English	49.4	**65.4**

Table 7: Comparison to Pires et al. (2019)

Table 8 reports the macro-average POS accuracies when transferring between languages depending on their typological features: Subject/Object/Verb order (SVO and SOV) and Adjective/Noun order (AN and NA) [18]. In the work of Pires et al. (2019), the best performance is achieved when transferring from a language with similar typological features. In contrast, our system is less sensitive to typological similarities, where the performance of transferring from SVO languages is comparable to that of SOV sources, while both AN and NA targets equally benefit from NA sources. This could be explained since the typological features of the source only contribute to the alignment and projection phases, while training the POS model is fully conducted in the target space after eliminating erroneous annotations.

PIRES	SVO	SOV
SVO	**81.6**	66.5
SOV	64.0	**64.2**

Our System	SVO	SOV
SVO	**82.5**	72.4
SOV	**81.3**	71.3

PIRES	AN	NA
AN	**73.3**	70.9
NA	75.1	**79.6**

Our System	AN	NA
AN	**77.5**	76.8
NA	74.3	**74.4**

Table 8: Macro-average POS accuracies when transferring between SVO/SOV languages and AN/NA languages. Rows = sources, columns = targets

4 Related Work

Unsupervised POS tagging through annotation projection was first proposed by Yarowsky et al. (2001), where they transferred POS tags from English to French and Chinese. The work was then extended by Fossum and Abney (2005), where they combined the outputs of single-source taggers based on different source languages. The multilingual setups were then further explored by Agić et al. (2015) and Agić et al. (2016).

In efforts to increase the coverage of the projected data, Das and Petrov (2011) proposed graph-based label propagation to expand the projected tags on the target side, while Duong et al. (2013) and Agić et al. (2015) applied self-training and revision, where they performed the projection and training in iterations. On another side, Täckström et al. (2013) and Buys and Botha (2016) organized the projection process through the use of token and type constraints, which we adapt in our approach.

Semi-supervised setups have been explored by either restricting the type constraints through the use of a POS dictionary (Täckström et al., 2013) or by adding additional signals in training, either by using a POS dictionary (Kirov et al., 2018; Plank and Agić, 2018) or by combining manual and projected annotations (Fang and Cohn, 2016). In contrast, our system is fully unsupervised, where we show that the robust construction of the training data can surpass the use of external resources.

While most prior work does tagging for several target languages, and so is our work, some research focuses on specific language pairs such as projecting from German to Hittite (Sukhareva et al., 2017) and from Russian to Ukrainian (Huck et al., 2019).

5 Conclusion and Future Work

We presented a fully unsupervised cross-lingual POS tagger that does annotation projection by utilizing translation from one or more source languages into the target one. We showed that despite the use of limited and out-of-domain parallel data, our models outperform the state-of-the-art systems. We also showed that the robust selection of training instances and the rich word representation in our neural architecture are more efficient than utilizing some labeled data or external linguistic resources.

In the future, we plan to enhance the system for handling morphologically complex languages trough unsupervised morphological segmentation. One approach is to perform the alignment and projection on the stem and morpheme levels. In addition, stem and morpheme information can be utilized as additional signals in training.

---

[18] Strictly speaking, the numbers are not comparable as the languages are different. However, they provide insight into how the two approaches perform across languages of different typological features.

Abstract

The deep inside-outside recursive autoencoder (DIORA; Drozdov et al. 2019a) is a self-supervised neural model that learns to induce syntactic tree structures for input sentences *without access to labeled training data*. In this paper, we discover that while DIORA exhaustively encodes all possible binary trees of a sentence with a soft dynamic program, its vector averaging approach is locally greedy and cannot recover from errors when computing the highest scoring parse tree in bottom-up chart parsing. To fix this issue, we introduce S-DIORA, an improved variant of DIORA that encodes a single tree rather than a softly-weighted mixture of trees by employing a hard argmax operation and a beam at each cell in the chart. Our experiments show that through *fine-tuning* a pre-trained DIORA with our new algorithm, we improve the state of the art in *unsupervised* constituency parsing on the English WSJ Penn Treebank by $\mathbf{2.2-6}\%$ F1, depending on the data used for fine-tuning.

1 Introduction

Syntactic parse trees are valuable intermediate features for many NLP pipelines (He et al., 2018; Strubell et al., 2018), as a soft constraint (Rush and Collins, 2012), a hard constraint (Lee et al., 2019b), or in multi-task learning with syntactic scaffolds (Swayamdipta et al., 2018). Syntactic inductive bias can also improve generalization of deep learning models (Kuncoro et al., 2020). These results have motivated researchers to pursue unsupervised parsing, with the hope of training syntax-dependent models on large amounts of data without annotation (Klein and Manning, 2002; Bod, 2006; Ponvert et al., 2011; Shen et al., 2019; Kim et al., 2019, inter alia).

Of these models, we focus on the deep inside-outside recursive autoencoder (DIORA; Drozdov et al. 2019a). DIORA encodes sentences in a procedure resembling the inside-outside algorithm (Baker, 1979), which allows it to induce syntactic tree structures for input sentences *without access to labeled training data*, and achieves near state-of-the-art results on *unsupervised* constituency parsing. DIORA resembles pre-trained language models, such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019), in that it is trained with a self-supervised blank-filling objective on large amounts of unlabeled data.

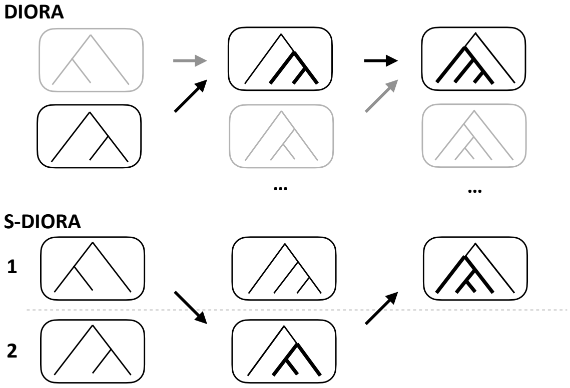

Figure 1: DIORA (top row) is sensitive to locally non-optimal decisions. By assigning a low weight to a potentially important subtree when recursively computing the vector for a target tree, it is difficult or impossible to recover and the important subtree is *washed out* (represented in light gray). Our method, S-DIORA (bottom row) can recover from errors, and the desired tree ends up at the top of the beam in the right-most column.

DIORA is a strong unsupervised parser *in spite of* its locally greedy nature. DIORA works by encoding all subtrees covering a particular span as separate vectors, and then computing a weighted average of these vectors — DIORA uses this averaged vector later in the dynamic program to represent the entire forest of trees covering a span. DIORA computes a score for each subtree; intuitively, a subtree's score affects how strongly it is

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4832–4845,
November 16–20, 2020.

represented in the averaged vector. The representations are computed recursively, and when a tree that looks locally not important is given a weak score, as shown in Figure 1, it will be *washed out*. This weakness in local decision making is similar to the *label bias problem* (Lafferty et al., 2001) in sequence prediction.

In this paper, we extend DIORA so that it can easily recover from local errors (§3). We replace the weight assignment used for vector averaging with a sparse operator equivalent to a one-hot argmax function, ensuring that each representation accurately encodes a **single tree** (hence, we call our method S-DIORA). In S-DIORA, it is not possible for a subtree to be *washed out*, although it is still possible to make an error by ignoring a potentially important subtree. Fortunately, this can be alleviated by adding a beam to each cell of the chart, allowing multiple subtrees over any span to be considered. The key benefit of our modification is that error recovery is easily possible, where previously the vector serves as a bottleneck that makes error recovery difficult or impossible.

We initialize an instance of S-DIORA using the previously released DIORA model, then finetune before evaluating on the target domain, constituency parse trees from the English WSJ Treebank (PTB, Marcus et al. 1993). In one experimental setting, we assume no access to the evaluation domain and use a subset of DIORA's training data, a concatenation of the SNLI (Bowman et al., 2015) and Multi-NLI (Williams et al., 2018b) corpora (hereinafter NLI). In the other setting, we assume access to raw text in the target domain, parse tree labels excluded. In both cases, we see S-DIORA improves on the original DIORA performance by at least **4** F1, and training on the PTB raw text leads to more than **3** F1 over the previous state of the art in constituency parsing.

In summary, the main contributions in this paper are: (a) An extension to DIORA called S-DIORA that allows for easy recovery from local errors; (b) New results in unsupervised constituency parsing, improving over the previous state of the art by $\mathbf{2.2}-\mathbf{6}\%$ F1 depending on the data used for fine-tuning; and (c) Thorough error analysis of the parse tree output revealing useful insights of why S-DIORA improves over baselines, for example, capturing marginally less prepositional phrases in the parse tree output yet making half the PP-attachment errors.

2 DIORA (Drozdov et al., 2019a)

Drozdov et al. (2019a) introduced DIORA, an unsupervised model that learns to 'reconstruct the input by discovering and exploiting syntactic regularities of the text.' It operates much like a masked language model or denoising autoencoder — first it encodes all-but-one of the words from the input sentence as a vector representation, then it decodes from this vector the missing word. DIORA encodes the sentence in the shape of a constituency tree, yet the model is trained using raw text only and without access to tree annotations. The 'ground truth' tree is unknown, so all valid trees are considered simultaneously using an efficient dynamic program with soft vector weighting.

Here is a sketch for how this approach works. Consider the hypothetical sentence with tokens: $x_0 x_1 x_2 x_3$. Although the 'ground truth' tree is unknown, one valid tree is $\tau = ((x_0(x_1 x_2))x_3)$. For each span of token $x_{i:j}$ DIORA computes an *inside* vector $\boldsymbol{h}^{in}_{i,j}$, summarizing the information in that span. Additionally, DIORA computes an *outside* vector $\boldsymbol{h}^{out}_{i,j}$ representing the tokens not in $x_{i:j}$. Assume that x_2 is the target token to predict, then for the parse tree τ the token x_1 is in the *inside* context for x_2 because x_1 is the immediate sibling of x_2 in the subtree capturing both tokens. The tokens x_0 and x_3 are not captured in this subtree and are considered to be in the *outside* context of x_2. DIORA represents the *inside* context as $\boldsymbol{h}^{in}_{1,1}$ and the *outside* context as $\boldsymbol{h}^{out}_{1,2}$ to compute $\boldsymbol{h}^{out}_{2,2,k}$. The k in the subscript indicates that this is only one of many possible valid trees for the hypothetical sentence. DIORA assigns a weight to each valid tree $s_{2,2,k}$ where higher weight values indicate the tree is more helpful for predicting the target token. The vector used to predict the target token is a weighted summation of all the tree representations $\boldsymbol{h}^{out}_{2,2} = \sum_k q_{2,2,k} \boldsymbol{h}^{out}_{2,2,k}$ where $q_{i,j,k}$ is a weight DIORA assigns to each subtree.

The rest of this section covers in more technical detail how to recursively compute the inside and outside vectors and weights for DIORA. The recursive computation is done efficiently using a chart data structure and dynamic program similar to the inside-outside algorithm (Baker, 1979). Part of this computation involves a softly weighted summation, which is an efficient way to encode all valid trees, yet has some downsides (§2.3).

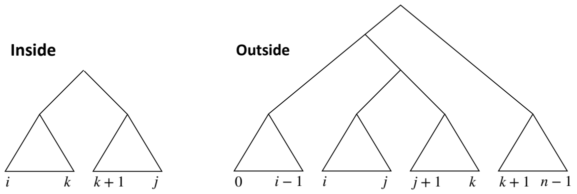

Figure 2: In the inside pass (left) DIORA composes two neighboring vectors. In the outside pass (right) DIORA computes the values for a target span (i, j) recursively from its sibling *inside* span $(j+1, k)$ and outside spans $(0, i-1)$ and $(k+1, n-1)$. The sibling span on the outside pass can appear to the left of the target span, in which case the indexing is adjusted.

2.1 Scoring and Composition

To fill the chart, DIORA learns to compose vectors using a multi-layer neural network (referred to as MLP), and to score vectors using a bi-linear function. In this section, we describe the chart-filling procedure from Drozdov et al. (2019a) using the indexing scheme as demonstrated by Figure 2. The exact equations used to fill the inside chart are:

$$
\begin{aligned}
\boldsymbol{h}^{in}_{i,j,k} &= \mathrm{MLP}^{in}(\boldsymbol{h}^{in}_{i,k}; \boldsymbol{h}^{in}_{k+1,j}) \\
s^{in}_{i,j,k} &= (\boldsymbol{h}^{in}_{i,k})^{\top} W \boldsymbol{h}^{in}_{k+1,j} + s^{in}_{i,k} + s^{in}_{k+1,j}
\end{aligned}
$$

In the inside chart, when $i = j$ the scalars s^{in} equal 0, the matrix W is learned, and the vectors $\boldsymbol{h}^{in}$ are equal to the embedding of the token for the i-th position in the sentence x.

The equations for filling the outside chart are:

$$
\boldsymbol{h}^{out}_{i,j,k} = \begin{cases} \mathrm{MLP}^{out}(\boldsymbol{h}^{in}_{j+1,k}; \boldsymbol{h}^{out}_{i,k}), & \text{if } k > j \\ \mathrm{MLP}^{out}(\boldsymbol{h}^{in}_{k,i-1}; \boldsymbol{h}^{out}_{k,j}), & \text{else} \end{cases}
$$

$$
s^{out}_{i,j,k} = \begin{cases} (\boldsymbol{h}^{in}_{j+1,k})^{\top} U \boldsymbol{h}^{out}_{i,k} + s^{in}_{j+1,k}, & \text{if } k > j \\ \qquad + s^{out}_{i,k} & \\ (\boldsymbol{h}^{in}_{k,i-1})^{\top} U \boldsymbol{h}^{out}_{k,j} + s^{in}_{k,i-1}, & \text{else} \\ \qquad + s^{out}_{k,j} & \end{cases}
$$

In the outside chart, when $i = 0$ and $j = |S| - 1$ the scalars s^{out} equal 0, the matrix U is learned, and the vector $\boldsymbol{h}^{out}$ is learned independent of the sentence (analogous to the initial hidden state in a recurrent neural network).

For a given span (i, j) there may be multiple valid split points or parent-sibling contexts. If each was considered separately, this would lead to a combinatorial explosion of paths to explore. Instead, DIORA averages the scalars and vectors that share the same (i, j) values. This is identical for the outside or inside pass, taking the following form:

$$
\begin{aligned}
q_{i,j,k} &= \frac{s_{i,j,k}}{\sum_{k'} s_{i,j,k'}} \\
\boldsymbol{h}_{i,j} &= \sum_{k} q_{i,j,k} \boldsymbol{h}_{i,j,k} \\
s_{i,j} &= \sum_{k} q_{i,j,k} s_{i,j,k}
\end{aligned}
$$

2.2 Learning

DIORA is trained end to end via word prediction. The bottom-most vectors in the outside chart represent the entire sentence x except for a single token. By predicting this missing token x_i from the outside vector $\boldsymbol{h}^{out}_{i,i}$, we may update the model's parameters without any parse tree labels.[1] The training objective for a single sentence is:

$$
J_{rec} = -\frac{1}{|x|} \sum_{i \in |x|} \log P(x_i | \{x\}_{-i}) \qquad (1)
$$

2.3 Parse Tree Inference

Although DIORA is not trained with any parse tree annotations, its chart filling procedure can be used to extract binary unlabeled parse trees. First, fill the inside chart following §2.1. Afterwards, use the CKY algorithm to find $\hat{y}$ the maximal scoring tree where the score for a tree y is $S(y) = \sum_{(i,j,k) \in y} s^{in}_{i,j,k}$. This approach demonstrated impressive results for unsupervised constituency parsing (Drozdov et al., 2019a).

To understand better the effectiveness decoding parse trees with DIORA, we train DIORA for *supervised* parsing using a binarized version of the 'ground truth' parse trees from the English Penn Treebank (Marcus et al., 1993). The training procedure is done by optimizing the structured SVM loss:

$$
J^{sup}_{tree} = \max(0, S(\hat{y}) - S(y) + 1),
$$

where $S(\hat{y})$ is the score of the maximal tree and $S(y)$ is the score of the 'ground truth'.

---

[1] Since the outside vector is used for word prediction, tricks associated with the inside-outside algorithm using only backpropagation of the inside-pass (Eisner, 2016) are not obviously applicable, if at all.

We use the off-the-shelf parser from Kitaev and Klein (2018) as a baseline and the results are shown in Table 1. Although DIORA is strong in unsupervised parsing, the supervised parsing results are not as competitive with the baseline as we had expected, and lead us to consider deeply why this might be the case.

We posit the low performance in supervised parsing is due to DIORA's inability to effectively recover from local errors. Predicting trees in DIORA is exact — you are guaranteed to find the highest scoring tree given the scalar values associated with each span, but there is a weakness when assigning the scalar values. Specifically, the scalar values are assigned using local information, and may assign a low weight to a subtree which, when given more information, deserves to be given higher weight. Said plainly, this might occur when the sentence has *structural ambiguity* that requires context to resolve. For instance, the clause *'We saw the dog with my phone,'* has a more likely parse tree depending on the context.[2,3] In the next section we present our extension to DIORA that addresses this downside.

	$n \leq 20$		$n \leq 40$	
Model	Binary	N-ary	Binary	N-ary
Kitaev and Klein (2018)	87.5	84.0	85.9	83.6
DIORA	86.0	73.9	81.7	69.1
S-DIORA	89.9	77.5	84.8	73.2

Table 1: Supervised parsing results on the validation set of PTB using parsing F1 with binarized trees. DIORA does not do well because of its inherent weakness, and the best setting from S-DIORA (Table 2) is superior.

3 S-DIORA: Single Tree Encoding

We improve DIORA by making it more robust to local errors. DIORA is sensitive to errors because its vector averaging approach makes it difficult or impossible to recover when important subtrees have been *washed out*. The first modification we present prevents trees from being *washed out* by replacing the weights q with a sparse operator q' equivalent to a one-hot argmax. This effectively replaces vector averaging with selection of the highest scoring subtree for each span.

$$q'_{i,j,k} = \arg\max_{k'}[s_{i,j,k'}][k]$$

$$\boldsymbol{h}_{i,j} = \sum_{k} q'_{i,j,k}\boldsymbol{h}_{i,j,k}$$

$$s_{i,j} = \sum_{k} q'_{i,j,k}s_{i,j,k}$$

This change alone is not sufficient. If using only a single highest-scoring tree, S-DIORA would remain as vulnerable, or more so, to local errors that are inevitable when using the context-free approach of the inside-outside algorithm. Instead, at each cell in the chart we record up to β values corresponding to the highest scoring subtrees. We refer to β as beam-size, and our experiments demonstrate that using a beam-size of 2 already gives a great improvement in results, although any size of β can be used at test time regardless what was used during training.

In the popular K-means algorithm, each point minimizes its distance to only one centroid. Using this as motivation, we train S-DIORA s.t. each sentence is only drawn towards one tree. We implement this change using a variant of the structured SVM loss:

$$J^{unsup}_{tree}(x) = \min(0, S(y_1) - S(y_0) + 1),$$

where $S(y_i)$ is the score for the i-th tree represented on the beam and $S(y) = \sum_{(i,j,k)\in y} s^{in}_{i,j,k}$. S-DIORA trains with this loss in addition to the reconstruction loss (the original DIORA objective):

$$J_{\text{S-DIORA}} = J_{rec} + J^{unsup}_{tree}$$

A natural question to ask is whether S-DIORA is difficult to train given $\arg\max$ is relatively non-smooth. To help train S-DIORA, we employed different tricks. During our unsupervised parsing experiments, we used gumbel-top-k (Kool et al., 2019) for q' to ensure the model would sufficiently explore multiple parse trees. We also added regularization via mixout (Lee et al., 2019a) or L2 regularization for the initial parameters so that the model would not diverge drastically from its initialization and suffer catastrophic forgetting. Empirically, we found that none of these additions were necessary, and that fine-tuning with the $J_{\text{S-DIORA}}$ objective was sufficient. One possible explanation for why this is so is that training with $\beta > 1$ already lets S-DIORA explore multiple subtrees for each span during training.

---

[2] In this particular example, we assume the rest of the sentence serves as sufficient context rather than unavailable information (i.e. world knowledge).

[3] Two valid parses for this clause are: *'(We (saw the dog) (with my phone))'* and *'(We (saw (the dog (with my phone)))).'*

4 Experiments and Results

The model and approach in this paper are motivated mainly by *wash out* in DIORA with respect to its vector averaging. In this section we experimentally test the following hypotheses:

- There are often multiple valid parse trees for a clause (in other words, phrases can have structural ambiguity), therefore we expect that S-DIORA with a beam should be more effective at supervised parsing than DIORA.
- Word prediction benefits from parsing sentences with their most likely constituency tree, therefore S-DIORA, which is trained via word prediction, should be more effective at unsupervised parsing than DIORA because it can recover from local errors.
- Parsers are sensitive to their training domain. Although we expect training with S-DIORA to be helpful for unsupervised parsing, we expect an even bigger benefit when training on the same domain as used for evaluation.

4.1 Preliminaries: Constituency Parsing

We measure the performance of our changes via unsupervised and supervised parsing on the test set of the WSJ Penn Treebank (Marcus et al., 1993).[4] All models (S-DIORA and baselines) output unlabeled binary trees[5] and are evaluated via sentence level F1 (S-F1).

- **True Positives (TP)** are the spans in both parse trees (inferred and ground truth).
- **False Positives (FP)** are spans predicted but not in the ground truth.
- **False Negatives (FN)** are spans in the ground truth but not the predicted tree.
- **Sentence F1** $= \frac{1}{|\mathcal{X}|} \sum_{x \in \mathcal{X}} \frac{2 \times \mathbf{TP}(x)}{2 \times \mathbf{TP}(x) + \mathbf{FP}(x) + \mathbf{FN}(x)}$

Following previous work, we consider only non-trivial spans (covering 2 or more words, and ignoring spans covering the entire sentence). For pre-processing we remove punctuation.

4.2 Supervised Parsing

For supervised constituency parsing we use the off-the-shelf parser from Kitaev and Klein (2018) as a baseline to compare against DIORA and S-DIORA. For training we use the parse trees from training split of PTB and evaluate using the validation data. We binarize the ground truth using the Stanford parser (Manning et al., 2014) and train for 10 epochs. Results against the binary trees and original n-ary (ingoring labels in both cases) is shown in Table 1. Both DIORA and S-DIORA are trained from random initialization using the structured SVM loss from Kitaev and Klein (2018).

We see that DIORA is not competitive with the Kitaev and Klein (2018) parser, and attribute this to *wash out* and its inability to recover from errors.

For S-DIORA we train and evaluate with $\beta \in \{1, 2, 3, 4\}$ and results are shown in Table 2. We see, unsurprisingly, that regardless of the beam-size at training, when $\beta = 1$ at test time the performance is worse than DIORA. This is because even though S-DIORA does not suffer from *wash out*, when the beam is too small it can not recover from errors. As the beam-size increases, so does performance, surpassing DIORA by 3 F1 in the best case ($\beta = 3$ for training; $\beta = 4$ at test time).

	$n \leq 20$				$n \leq 40$			
β	1	2	3	4	1	2	3	4
1	84.6	87.8	88	88.2	77.7	81.5	82.3	82.6
2	85.1	88.8	89.4	89.7	78.6	83	83.9	84.4
3	85.7	88.9	89.7	**89.9**	79.4	83.3	84.5	**84.8**
4	84.7	88.7	89.3	89.5	78.4	82.8	83.8	84.2

Table 2: Supervised parsing results on the validation set of PTB using binarized trees for S-DIORA. The grid represents parsing F1 with different values of β at train time (rows) and test time (columns). The model is not effective when β at test time is 1 because it can not recover from errors. Increasing β for both training and test test time is helpful, with the best performance for $\beta_{train} = 3$ and $\beta_{test} = 4$. Beam search benefits short sentences (length $n \leq 20$) and long ones ($n \leq 40$).

4.3 Unsupervised Parsing

We explored two settings in unsupervised parsing. In the first, the zero-shot case, we assume no access to the evaluation domain. Instead, we sample a subset from the NLI data used to train DIORA and use this to fine-tune S-DIORA. The subset includes the same number of sentences as the train-

---

[4] We evaluate all models using the eval script from Kim et al. (2019). We noticed a small bug in the eval script where some spans covering the entire sentence were not being ignored. This lead to a very small change in the numbers, but for this reason, our numbers for baselines may appear slightly different from previous work.

[5] Although models output binary trees, the ground truth has n-ary trees. This establishes an upper bound on the highest possible F1 since each model has an unavoidable penalty to precision.

ing data from PTB and the same sentence length distribution. The results are shown in Table 3 with the model name S-DIORA$_{NLI}$. This model does substantially better than the original DIORA (and improvement of more than 5 F1) and is even competitive with the state-of-the-art model C-PCFG (Kim et al., 2019).

In the other experimental setting we assume access to raw text in the target domain is available but annotations are not. We fine-tune using the training data from PTB (about 40k sentences) and results are shown in Table 3 with the model name S-DIORA$_{PTB}$. This improves upon S-DIORA$_{PTB}$ by a full 2 F1 points and is also substantially better than the previous state of the art by 3.5 F1.

S-DIORA sees a large improvement in WSJ-10. These sentences are length 10 or less and previously DIORA was on-par with ON-LSTM (Shen et al., 2019). When we bucket F1 by sentence length, we see that S-DIORA improves not only short sentences but on all sentence lengths.

To determine whether fine-tuning is necessary, we initialize S-DIORA from DIORA and evaluate it immediately. In this setting DIORA$_{None}$ performs 5 F1 less than DIORA, confirming the importance of fine-tuning.

To further determine if the extra training data was the main factor in the improved performance, we train DIORA with the an equivalent amount of data and see no improvement. This is not surprising given that the pre-trained DIORA was trained initially until convergence on relatively more data.

Model	**F1**$_{max}$	**F1**$_{\mu}$	**F1**$_{n\leq10}$
ON-LSTM (Shen et al., 2019)	50.21	48.1†	61.02
C-PCFG (Kim et al., 2019)	60.32	55.2†	68.82
DIORA (Drozdov et al., 2019a)	56.75	-	60.55
S-DIORA$_{None}$ (Ours)	51.56	-	59.36
S-DIORA$_{NLI}$ (Ours)	61.68	54.8	70.41
S-DIORA$_{PTB}$ (Ours)	**63.96**	57.6	**71.80**

Table 3: Unsupervised parsing results. We evaluate each model on the full PTB test set using the evaluation script provided by Kim et al. (2019). The average across random seeds is F1$_\mu$[6]and the best model's F1 is reported as F1$_{max}$. We take the best model and also evaluate it on sentences of length of 10 or less and report the value in F1$_{n\leq10}$. Values with a † are copied from Kim et al. (2019). We only had access to a single DIORA model so no F1$_\mu$ is reported.

4.4 Training and Implementation Details

When applicable, we use the MLP with 'softmax loss' model checkpoint provided by Drozdov et al. (2019a). S-DIORA makes an impactful change to DIORA, but its parameters are exactly the same, making it easy to load a pretrained DIORA model for S-DIORA. Our implementation of S-DIORA, checkpoints of best models, training scripts, and all parsing output are available online.[7] Additional training details are covered in the Appendix A.1.

5 Discussion and Analysis

In this section we examine the parse tree output of the models in our experimental setup with more fine-grained detail than parsing F1. Given the prevalence of pre-trained language models in NLP tasks, we also include in our analysis recent results using transformers for unsupervised parsing. In addition, we present a new baseline demonstrating that pretrained language models are better at unsupervised parsing than previously known.

5.1 Linguistic Error Analysis

Parsing F1 is useful to quickly compare performance between parsers, and previous work in unsupervised parsing often also report segment recall to give a sense of which phrases are most often captured in the output. To provide an even more thorough treatment of linguistic errors we add labels to the parse trees using the parser from Kitaev and Klein (2018) and then run the Berkeley parser analyzer (Kummerfeld et al., 2012). This latter tool classifies mistakes for each predicted tree by the type of phrases (or patterns like coordination) involved in the error, allowing analysis of the types of errors being made by a model. In Table 4 we show the parsing F1, segment recall, and error counts as determined by the analyzer.

By segment recall, we see that C-PCFG outperforms DIORA in segment recall for NP and PP, explaining its high S-F1. The linguistic analysis tells a slightly different story — *C-PCFG makes less errors associated with NP internal structure and clause attachment, but substantially more errors associated with PP attachment.*

---

[7] https://github.com/iesl/s-diora

[7] S-DIORA F1$_\mu$ is reported across 5 random seeds with the same hyperparameters. S-DIORA$_{None}$ is evaluated after initialization, so F1$_\mu$ = F1$_{max}$. Since we use early stopping it is not possible for the best model to be worse than initialization, hence S-DIORA performance is strictly $\geq$ performance of S-DIORA$_{None}$.

Table 4: To better understand the difference between models, displayed above are the segment recall on the WSJ validation set separated by phrase type (the left columns). For a more informative look at linguistic phenomenon, we use the Berkeley parser analyzer (Kummerfeld et al., 2012) and display error counts (the right columns). Since the unsupervised parsing models do not provide labels, we use high performing supervised constituency parser (Kitaev and Klein, 2018) to label the trees. β is beam size. The frequency of each label in the validation set is ADJP=428, ADVP=262, NP=10350, PP=3877, SBAR=1091, VP=5407. The error types are: Modifier Attachment (Mod.), NP Internal Structure (NP-I), NP Attachment (NP-A), PP Attachment (PP-A), Clause Attachment (Clause), and Coordination (Coord).

5.2 Unsupervised Parsing with Large Pre-trained LMs

We introduce a new unsupervised parsing baseline using ELMo (Peters et al., 2018), so that we may compare S-DIORA with large pre-trained LMs, a class of models that have recently proven very effective across NLP tasks. To extract a parse tree from ELMo, we first compute vector similarity between phrase embeddings in the output, then use these scalar values as input to the CKY algorithm.[8]

Compared to ELMo we see that S-DIORA captures less ADVP phrases yet also makes less NP-I errors. Although S-DIORA has a strong affinity for VP phrases ELMo makes less VP-A errors.

For further comparison we include the best models from Kim et al. (2020). We see that XLNet$_{\lambda=0}$ is the worst of all models in S-F1 and VP segment recall, but also has the fewest VP-A errors. This suggests that errors related to segment recall are likely folded into a different category such as PP attachment. The right-skewed model XLNet$_{\lambda=1.5}$ substantially improves over XLNet$_{\lambda=0}$ in SBAR recall and is comparable in this category with S-DIORA.

Interestingly, although increasing the size of β in S-DIORA results in a *near monotonic improvement in all categories* (with some minor exceptions), S-DIORA shows a very different error profile when compared to pre-trained LMs, despite having a better S-F1. For instance, the pre-trained LMs make fewer coordinations errors, and perform better with adverbial phrases (ADVP), than any version of S-DIORA. In future work, it may be useful to understand why parser performance does not increase monotonically. Perhaps this is an artifact of the current state of unsupervised parsing research and will change once parsers improve beyond some threshold.

5.3 The Benefit of Error Recovery

5.3.1 DIORA versus S-DIORA

It is not sufficient to initialize S-DIORA from DIORA without fine-tuning. DIORA$_{None}$ does worse than DIORA in nearly every category. Furthermore, the biggest benefit is gained when using S-DIORA with $\beta > 1$, otherwise error recovery is not possible (see Figure 3).

DIORA is trained on NLI and it is not surprising it incurs so many errors in coordination and clause attachment, which are frequently observed in domain mis-match (Kummerfeld et al., 2012). We used the same checkpoint for finetuning with the original formulation of DIORA — any improvements would be from exposure to more training data. When using NLI for finetuning, across 5

---

[8] To compute phrase embeddings, we follow the procedure from (Kitaev and Klein, 2018) which concatenates the forward and backward LSTM vectors at the beginning and end of each phrase. To compute vector similarity we follow the procedure in Kobayashi et al. (2019) which uses ELMo sentence embeddings for RST parsing — rather than document level parsing, our work pertains to sentence level parsing.

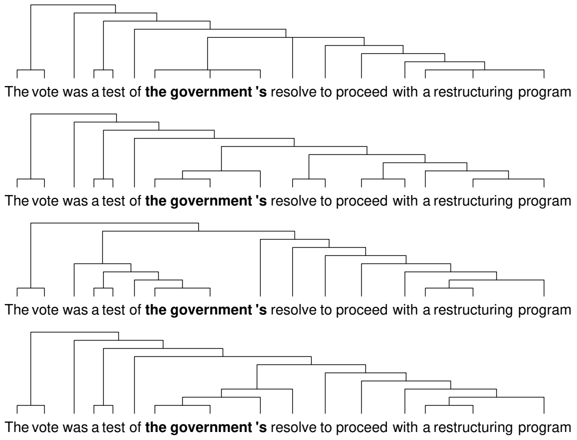

Figure 3: In this example, a beam-size of 1 is not sufficient for S-DIORA to improve upon DIORA — error recovery is only achieved with larger β. The trees from top to bottom are from PTB, DIORA, then S-DIORA$_{PTB}$ with $\beta = 1, 3$. Although larger β can lead to more errors in certain situations (specifically clausal attachment), here they decrease.

random seeds there was no improvement over the pre-trained model. This is not surprising given the original models were trained until convergence with relatively large amounts of training data.

Training on NLI provides S-DIORA with a substantial advantage in segment recall for VP and PP. S-DIORA does much worse in capturing the low frequency ADVP category. This does not incur much penalty in S-F1 but is reflected in NP-I.[9]

5.3.2 Effects of Beam Size

Performance improves across the board as we increase beam size β, and S-DIORA$_{PTB}$ improves over DIORA suggesting that single tree encoding already provided some benefit (recall that we fine-tuned DIORA on both NLI and PTB with no improvements in unsupervised parsing). Most benefit is achieved using $\beta = 3$, although in some cases it helps to increase it further (see Figure 5). Increasing the beam also helps with different classes of errors. In Figure 4 we see the benefit in sentences with tricky coordination.

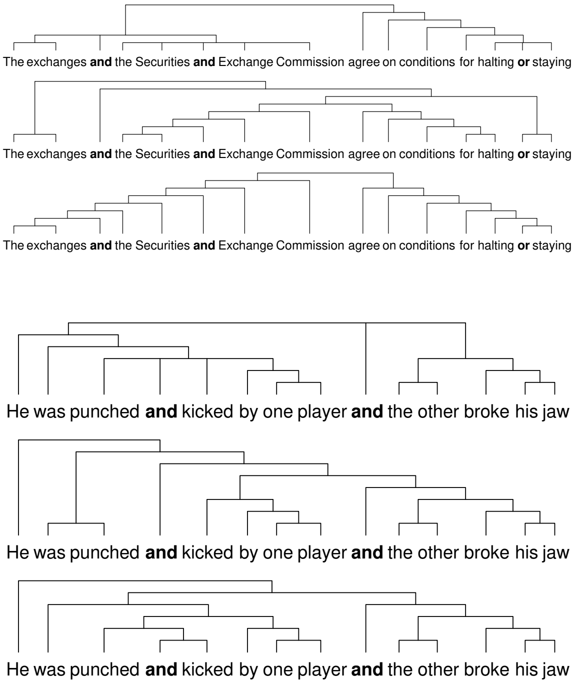

Figure 4: Two sentences where beam-search helps with ambiguous coordination structures, correctly nesting noun phrases (top) and getting better coordination of verb phrases (bottom). The displayed parse tree output, top to bottom, are from PTB, then S-DIORA$_{PTB}$ with $\beta = 1, 3$ respectively.

5.4 Labeled Parsing

We evaluate the labeled trees from §5.1, and the best performing S-DIORA model achieves 80.7 *labeled* parsing F1 on the validation data (72.3 recall, 91.2 precision, and 11.7 complete match) when evaluated this way. *This suggests that unsupervised parsers are closer to supervised parsers than previously realized*, and although deciding which phrases are in the tree is the harder task (Klein and Manning, 2002), it may be worth pursuing unsupervised labeling[10] for more informative error analysis (Bisk and Hockenmaier, 2015).

6 Related Work

Avoiding errors by using rich feature models. The nature of *unsupervised* parsing is that good performance is a result of strong inductive bias, explaining why DIORA and S-DIORA are so effective, yet their context-free approach to chart parsing is also the cause of local errors. S-DIORA employees a beam at each cell to recover from local errors, but this would be less helpful if errors were less frequent. Top performing *super-*

---

[9] The NP-I category covers missed gold phrases within large noun phrases. In general, much of NP structure in PTB is not annotated, and in future work it is worth using the data provided by Vadas and Curran (2011) to investigate NP structure, as determined by unsupervised parsers, more thoroughly.

[10] Typically unsupervised constituency parsing is purely evaluated by its structure, although recent work from Drozdov et al. (2019b) shows that a simple approach to induce labels with DIORA can be done by clustering the inside and outside phrase vectors.

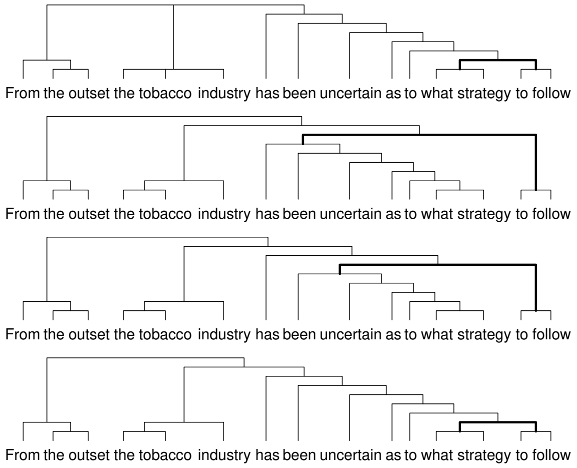

Figure 5: As the beam-size increases, S-DIORA's output tends to match the ground truth more closely. The displayed output, top to bottom, are from PTB, then S-DIORA$_{PTB}$ with $\beta = 1, 3, 5$ respectively.

vised parsers do not need error recovery because they use models with rich features and model each span score independently (Cross and Huang, 2016; Stern et al., 2017; Kitaev and Klein, 2018; Mrini et al., 2019). Previous research has attempted to achieve the "best of both worlds" by distilling a strong model for *supervised* parsing via an *unsupervised* model's output (Le and Zuidema, 2015).

These approaches are closely related to **fast and accurate parsing**. More accurate models tend to use richer features that are more expensive to compute, influencing researchers to find efficient techniques to offset the loss in speed (Vieira and Eisner, 2017). In this paper, we use the most simple approach to learn to parse with the capability to recover from local errors by maintaining a beam of size β at each cell in the chart. S-DIORA is often faster and discovers better trees than DIORA, but there are other methods for extracting lists of best or plausible parses (Resnik, 1992; Roark and Johnson, 1999; Charniak and Johnson, 2005; Huang and Chiang, 2005; Bouchard-côté et al., 2009) that might further improve performance.

Sparse structured inference. Various work has explored sparse alternatives to soft-weighting. Sparsemax (Martins and Astudillo, 2016) is a deterministic sparse alternative to the softmax, and Gumbel-Softmax (Jang et al., 2017) uses the categorical reparameterization trick to sample a discrete value during training. Both have attractive properties but alone would not be sufficient for overcoming local errors in S-DIORA. Nonetheless, these options would be worth exploring for unsupervised parsing when training with more data or when the ground truth parse trees are very different than the ones in S-DIORA's output frontier after initialization. Other work has explored methods for differentiable structured inference (Niculae et al., 2018; Mensch and Blondel, 2018; Corro and Titov, 2019a,b), which may also be suitable. It's worth noting that PCFGs are not graphical models (Liang et al., 2009), and marginal inference is often not tractable,[11] which is why these approximate methods may be helpful.

Grammar induction. There is a rich research history in grammar induction and unsupervised parsing (Fu and Booth, 1975; Angluin, 1980; Carroll and Charniak, 1992). We cover notable work not already mentioned in Appendix A.2.

7 Conclusion

We introduce S-DIORA, an extension to DIORA that enables for easy recovery from local errors and is not subject to *wash out* from vector averaging. Our experiments in supervised parsing verify S-DIORA improves upon the representational power of DIORA. Unsupervised fine-tuning with S-DIORA leads to new impressive results in unsupervised constituency parsing, improving upon the previous state of the art by $\mathbf{2.2-6\%}$ F1, depending on the data used.

---

[11] Although marginal inference is effectively leveraged in C-PCFG (Kim et al., 2019), the recursive vector composition in DIORA and S-DIORA makes this intractable. McAllester et al. (2008) propose case-factor diagrams which can efficiently encode PCFGs and compute the normalizing partition function, although it is not clear how to leverage them for self-supervised training with neural networks.

A Appendices

A.1 Training Details

All key details for training and evaluating our method, S-DIORA, are described in the main text. In this Appendix section we repeat those details and provide an organized reference to aid reproducibility.

A.1.1 Supervised Parsing Loss and Training

In supervised parsing, we assume access to binary non-projective constituency trees y for each sentence x. Predicting a tree $\hat{y}$ with DIORA can be done using the CKY method described in Drozdov et al. (2019a). Similarly, backtracking the various max operations from the inside-pass in S-DIORA can be used to decode $\hat{y}$.[12] The conditional probability of a tree given a sentence is proportional to the sum of scalar values for each span and split (i, j, k) in the tree, depicted in Eq. 2.

$$P(y|x) \propto S(y) = \sum_{(i,j,k) \in y} s^{in}_{i,j,k} \tag{2}$$

To train DIORA or S-DIORA to predict the most likely tree for an input sentence, we use the structured SVM loss employed by multiple other work in supervised parsing (Stern et al., 2017; Kitaev and Klein, 2018) with a margin of 1 and do not use loss augment inference, depicted in Eq. 3.

$$J^{sup}_{tree} = \max(0, S(\hat{y}) - S(y) + 1) \tag{3}$$

In our experiments, we train DIORA and S-DIORA on the training from PTB (roughly 40k sentences). Both models are trained from random initialization and using the same hyperparameters. Early stopping is done by evaluating against the validation data each epoch. S-DIORA is trained with different beam-size $\beta = \{1, 2, 3, 4\}$.

This paper is primarily concerned with *unsupervised* parsing, and we only explored one hyperparameter setting as supervised parsing is used primarily to verify the benefit of beam search in S-DIORA and its improvement over DIORA. Those hyperparameters are listed here:

Learning Rate (η):	2^{-3}
Model Dimension:	400
Max Training Length:	20
Batch Size:	32
Max Epochs:	10
Optimization Algorithm:	Adam
Hardware:	1x1080ti
Training Time:	O(12h)

For both supervised and unsupervised training, each batch is restricted to sentences of uniform length.

A.1.2 Unsupervised Loss and Training

DIORA and S-DIORA are models especially effective for unsupervised parsing. In this setting we assume no access to parse tree labels, only raw text. The models are trained end-to-end by reconstructing the input sentence from the outside vectors. Reconstruction is defined as predicting a word x_i given its context $\{x\}_{-i}$ which are the words in the rest of the sentence. Unlike Drozdov et al. (2019a), we use a fixed vocabulary instead of sampling, which includes the 10k most frequent words from the training data.[13] The objective for a single sentence is depicted in Eq. 4.

$$J_{rec} = -\frac{1}{|x|} \sum_{i \in |x|} \log P(x_i | \{x\}_{-i}) \tag{4}$$

As mentioned in §3, we also train S-DIORA to increase the confidence gap between its highest-scoring tree on the beam and other trees. To accomplish this we use the same structured SVM from supervised parsing, but instead of the ground truth y, we include the highest-scoring tree on the beam y_0 and the second highest y_1. This loss is depicted in Eq. 5, and the total loss for S-DIORA is simply the sum of the reconstruction and 'tree' losses (Eq. 6).

$$J^{unsup}_{tree} = \max(0, S(y_1) - S(y_0) + 1) \tag{5}$$

$$J_{\text{S-DIORA}} = J_{rec} + J^{unsup}_{tree} \tag{6}$$

For S-DIORA$_{NLI}$ we train using a subset of NLI.[14] The subset is sampled once from NLI and

---

[12] Each value save on the beam in S-DIORA represents a unique tree — duplicate trees can not appear on the beam.

[13] The vocabulary is different between NLI and PTB.

[14] A concatenation of the training data from SNLI (Bowman et al., 2015) and Multi-NLI (Williams et al., 2018b).

used across all experiments, and consists of the same number of sentences as the training data from PTB and also the same distribution of sentence lengths. For S-DIORA$_{PTB}$ we use the training data from PTB. Early stopping is done by evaluating against the validation data each epoch. We explore various hyperparameter settings, and for S-DIORA we also train with different beam-sizes β. S-DIORA is initialized from the MLP with 'softmax loss' DIORA checkpoint[15] that was released by Drozdov et al. (2019a). The hyperparameters explored are listed below:

Learning Rate (η):	$2^{-3}, 1^{-3}, 6^{-4}, 2^{-4}$
Model Dimension:	400
Beam-size (β):	$2, 3$
Max Training Length (n):	$20, 30$
Batch Size:	32
Max Epochs:	5
Optimization Algorithm:	Adam
Hardware:	1x1080ti
Training Time:	$O(8\text{h})$

We ran each setting for 5 random seeds. The best performing hyperparameter setting was chosen using validation performance, and the best performing setting (η, β, n) for S-DIORA$_{NLI}$ and S-DIORA$_{PTB}$ were $(1^{-3}, 2, 30)$ and $(2^{-3}, 2, 30)$ respectively.

A.2 Other Work in Grammar Induction and Unsupervised Parsing

There is a rich research history in grammar induction and unsupervised parsing. In the main text, we cover the work most relevant to frame our scientific questions and experimental results. Instead, here, we mention loosely related work that would be useful for further analysis and future research. Furthermore, some of the mentioned work might be in dependency parsing rather than constituency parsing, or about measuring syntactic information without parse trees.

A.2.1 Partial Semantic Information

We assume access to no text annotation, but often some might be available (Pereira and Schabes, 1992) and this can be leveraged to constrain induced syntax in a useful way. Naseem and Barzilay (2011) explore syntactic structure of semantic relations, presenting an approach that encourages structural consistency for each occurrence of a specific semantic relation, but also allowing for variation. DIORA and S-DIORA represent spans as vectors, and a simple extension would be to encourage span vectors associated with the same semantic relation to be similar through contrastive estimation (Smith and Eisner, 2005a,b; Gimpel and Bansal, 2014). Rather than encouraging similarity within a relation, Shi et al. (2019) have success encouraging similarity between an image and constituents in its caption.

A.2.2 Multilingual Alignment

Syntactic phrase types do not necessarily translate to the same type across languages (Koehn and Knight, 2003), but can still leverage parallel text to improve unsupervised constituency parsing as a phrase in one language may have less uncertain structure in another (Snyder et al., 2009).

A.2.3 Label Refinement

Similarities across languages can be used to create fine-grained grammar rules that are helpful when applied as soft constraints for grammar induction since they serve as a prior to contradict patterns seen in the data (Naseem et al., 2010). These linguistic priors need not be derived from cross-lingual data (Druck et al., 2009) — using a small set of simple rules (e.g. a determiner followed by a noun is a noun phrase) can be helpful for grammar induction and can be derived from a few positive examples of phrases (Haghighi and Klein, 2006).

A.2.4 Model Consistency

Williams et al. (2018a) measure *self F1* in addition to parsing F1 and find the models that consistently converge to the same grammar were also the ones most different from ground truth, although this was an extreme case as the pertinent model made trivial predictions (nearly always left-branching). Follow up work from Mohananey et al. (2020) shows that self-training is helpful for training PRPN (Shen et al., 2018) and parsing F1 improves with self-agreement, with the biggest benefit for longer sentences.

---

[15] DIORA and S-DIORA have exactly the same parameters, so one can be initialized easily from the other. The number of parameters is the same, but the runtime of S-DIORA is slower by an order of β. Even so, a correctly implemented S-DIORA should be as fast as DIORA or faster since the sparse operator q' can be leveraged to avoid computation when there are many possible subtrees for a span.

Utility is in the Eye of the User: A Critique of NLP Leaderboards

Dan Jurafsky
Stanford University
`jurafsky@stanford.edu`

Abstract

Benchmarks such as GLUE have helped drive advances in NLP by incentivizing the creation of more accurate models. While this leaderboard paradigm has been remarkably successful, a historical focus on performance-based evaluation has been at the expense of other qualities that the NLP community values in models, such as compactness, fairness, and energy efficiency. In this opinion paper, we study the divergence between what is incentivized by leaderboards and what is useful in practice through the lens of microeconomic theory. We frame both the leaderboard and NLP practitioners as *consumers* and the benefit they get from a model as its *utility* to them. With this framing, we formalize how leaderboards – in their current form – can be poor proxies for the NLP community at large. For example, a highly inefficient model would provide less utility to practitioners but not to a leaderboard, since it is a cost that only the former must bear. To allow practitioners to better estimate a model's utility to them, we advocate for more transparency on leaderboards, such as the reporting of statistics that are of practical concern (e.g., model size, energy efficiency, and inference latency).

1 Introduction

The past few years have seen significant progress on a variety of NLP tasks, from question answering to machine translation. These advances have been driven in part by benchmarks such as GLUE (Wang et al., 2018), whose leaderboards rank models by how well they perform on these diverse tasks. Performance-based evaluation on a shared task is not a recent idea either; this sort of shared challenge has been an important driver of progress since MUC (Sundheim, 1995). While this paradigm has been successful at driving the creation of more accurate models, the historical focus on performance-based evaluation has been at the expense of other attributes valued by the NLP community, such as fairness and energy efficiency (Bender and Friedman, 2018; Strubell et al., 2019). For example, a highly inefficient model would have limited use in practical applications, but this would not preclude it from reaching the top of most leaderboards. Similarly, models can reach the top while containing racial and gender biases – and indeed, some have (Bordia and Bowman, 2019; Manzini et al., 2019; Rudinger et al., 2018; Blodgett et al., 2020).

Microeconomics provides a useful lens through which to study the divergence between what is incentivized by leaderboards and what is valued by practitioners. We can frame both the leaderboard and NLP practitioners as *consumers* of models and the benefit they receive from a model as its *utility* to them. Although leaderboards are inanimate, this framing allows us to make an apples-to-apples comparison: if the priorities of leaderboards and practitioners are perfectly aligned, their utility functions should be identical; the less aligned they are, the greater the differences. For example, the utility of both groups is monotonic non-decreasing in accuracy, so a more accurate model is no less preferable to a less accurate one, holding all else constant. However, while the utility of practitioners is also sensitive to the size and efficiency of a model, the utility of leaderboards is not. By studying such differences, we formalize some of the limitations in contemporary leaderboard design:

1. **Non-Smooth Utility**: For a leaderboard, an improvement in model accuracy on a given task only increases utility when it also increases rank. For practitioners, any improvement in accuracy can increase utility.
2. **Prediction Cost**: Leaderboards treat the cost of making predictions (e.g., model size, energy efficiency, latency) as being zero, which does not hold in practice.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4846–4853,
November 16–20, 2020.

3. **Robustness**: Practitioners receive higher utility from a model that is more robust to adversarial perturbations, generalizes better to out-of-distribution data, and that is equally fair to all demographics. However, these benefits would leave leaderboard utility unchanged.

We contextualize these limitations with examples from the ML fairness (Barocas et al., 2017; Hardt et al., 2016), Green AI (Strubell et al., 2019; Schwartz et al., 2019), and robustness literature (Jia and Liang, 2017). These three limitations are not comprehensive – other problems can also arise, which we leave to be discussed in future work.

What changes can we make to leaderboards so that their utility functions better reflect that of the NLP community at large? Given that each practitioner has their own preferences, there is no way to rank models so that everyone is satisfied. Instead, we suggest that leaderboards demand transparency, requiring the reporting of statistics that are of practical concern (e.g., model size, energy efficiency). This is akin to the use of data statements for mitigating bias in NLP systems (Gebru et al., 2018; Mitchell et al., 2019; Bender and Friedman, 2018). This way, practitioners can determine the utility they receive from a given model with relatively little effort. Dodge et al. (2019) have suggested that model creators take it upon themselves to report these statistics, but without leaderboards requiring it, there is little incentive to do so.

2 Utility Functions

In economics, the *utility* of a good denotes the benefit that a consumer receives from it (Mankiw, 2020). We specifically discuss the theory of *cardinal utility*, in which the amount of the good consumed can be mapped to a numerical value that quantifies its utility in *utils* (Mankiw, 2020). For example, a consumer might assign a value of 10 utils to two apples and 8 utils to one orange; we can infer both the direction and magnitude of the preference.

Leaderboards We use the term *leaderboard* to refer to any ranking of models or systems using performance-based evaluation on a shared benchmark. In NLP, this includes both longstanding benchmarks such as GLUE (Wang et al., 2018) and one-off challenges such as the annual SemEval STS tasks (Agirre et al., 2013, 2014, 2015). This is not a recent idea either; this paradigm has been a driver of progress since MUC (Sundheim, 1995). All we assume is that all models are evaluated on the same held-out test data.

In our framework, leaderboards are consumers whose utility is solely derived from the rank of a model. Framing leaderboards as consumers is unorthodox, given that they are inanimate – in fact, it might seem more intuitive to say that leaderboards are another kind of product that is also consumed by practitioners. While that perspective is valid, what we ultimately care about is how good of a proxy leaderboards are for practitioner preferences. Framing both leaderboards and practitioners as consumers permits an apples-to-apples comparison using their utility functions. If a leaderboard were only thought of as a product, it would not have such a function, precluding such a comparison.

Unlike most kinds of consumers, a leaderboard is a consumer whose preferences are perfectly revealed through its rankings: the state-of-the-art (SOTA) model is preferred to all others, the second ranking model is preferred to all those below it, and so on. Put more formally, leaderboard utility is monotonic non-decreasing in rank. Still, because each consumer is unique, we cannot know the exact shape of a leaderboard utility function – only that it possesses this monotonicity.

NLP Practitioners Practitioners are also consumers, but they derive utility from multiple properties of the model being consumed (e.g., accuracy, energy efficiency, latency). Each input into their utility function is some desideratum, but since each practitioner applies the model differently, the functions can be different. For example, someone may assign higher utility to BERT-Large (Devlin et al., 2019) and its 95% accuracy on some task, while another may assign higher utility to the smaller BERT-Base and its 90% accuracy. As with leaderboards, although the exact shapes of practitioner utility functions are unknown, we can infer that they are monotonic non-decreasing in each desideratum. For example, more compact models are more desirable, so increasing compactness while holding all else constant will never decrease utility.

3 Utilitarian Critiques

Our criticisms apply regardless of the shape taken by practitioner utility functions – a necessity, given that the exact shapes are unknown. However, not every criticism applies to every leaderboard. StereoSet (Nadeem et al., 2020) is a leaderboard that ranks language models by how unbiased they are,

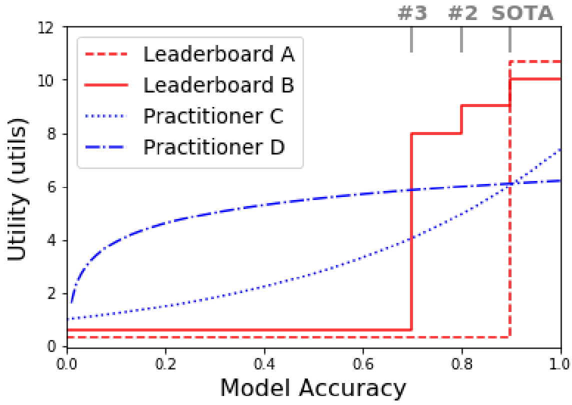

Figure 1: A contrast of possible utility functions for leaderboards and NLP practitioners. Note that for leaderboards, utility is not smooth with respect to accuracy; there is only an increase if the model is SOTA / #2 / #3 on the leaderboard. For practitioners, utility is smooth – any improvement in accuracy yields more utility. The utility functions can take on a variety of shapes but are always monotonic non-decreasing.

so fairness-related criticisms would not apply as much to StereoSet. Similarly, the SNLI leaderboard (Bowman et al., 2015) reports the model size – a cost of making predictions – even if it does not factor this cost into the model ranking. Still, most of our criticisms apply to most leaderboards in NLP, and we provide examples of well-known leaderboards that embody each limitation.

3.1 Non-Smoothness of Utility

Leaderboards only gain utility from an increase in accuracy when it improves the model's rank. This is because, by definition, the leaderboard's preferences are perfectly revealed through its ranking – there is no model that can be preferred to another while having a lower rank. Since an increase in accuracy does not necessarily trigger an increase in rank, it does not necessarily trigger an increase in leaderboard utility either.

Put another way, the utility of leaderboards takes the form of a step function, meaning that it is not smooth with respect to accuracy. In contrast, the utility of practitioners is smooth with respect to accuracy. Holding all else constant, an increase in accuracy will yield some increase in utility, however small. Why this difference? The utility of leaderboards is a function of rank – it is only indirectly related to accuracy. On the other hand, the utility of practitioners is a direct function of accuracy, among other desiderata. To illustrate this difference, we contrast possible practitioner and leaderboard utility functions in Figure 1.

This difference means that practitioners who are content with a less-than-SOTA model – as long as it is lightweight, perhaps – are under-served, while practitioners who want competitive-with-SOTA models are over-served. For example, on a given task, say that an n-gram baseline obtains an accuracy of 78%, an LSTM baseline obtains 81%, and a BERT-based SOTA obtains 92%. The leaderboard does not incentivize the creation of lightweight models that are $\sim 85\%$ accurate, and as a result, few such models will be created. This is indeed the case with the SNLI leaderboard (Bowman et al., 2015), where most submitted models are highly-parameterized and over 85% accurate.

This incentive structure leaves those looking for a lightweight model with limited options. This lack of smaller, more energy-efficient models has been an impediment to the adoption of Green AI (Schwartz et al., 2019; Strubell et al., 2019). Although there are increasingly more lightweight and faster-to-train models – such as ELECTRA, on which accuracy and training time can be easily traded off (Clark et al., 2020) – their creation was not incentivized by a leaderboard, despite there being a demand for such models in the NLP community. A similar problem exists with incentivizing the creation of fair models, though the introduction of leaderboards such as StereoSet (Nadeem et al., 2020) are helping bridge this divide.

3.2 Prediction Cost

Leaderboards of NLP benchmarks rank models by taking the average accuracy, F1 score, or exact match rate (Wang et al., 2018, 2019; McCann et al., 2018). In other words, they rank models purely by the value of their predictions; no consideration is given to the cost of making those predictions. We define 'cost' here chiefly as model size, energy-efficiency, training time, and inference latency – essentially any sacrifice that needs to be made in order to use the model. In reality, no model is costless, yet leaderboards are cost-ignorant.

This means that a SOTA model can simultaneously provide high utility to a leaderboard and zero utility to a practitioner, by virtue of being too impractical to use. For some time, this was true of the 175 billion parameter GPT-3 (Brown et al., 2020), which achieved SOTA on several few-shot tasks, but whose sheer size precludes it from being fully reproduced by researchers. Even today, practitioners can only use GPT-3 through an API, access to which is restricted. The cost-ignorance of leaderboards disproportionately affects practitioners with fewer resources (e.g., independent researchers) (Rogers, 2019), since the resource demands would dwarf any utility from the model.

It should be noted that this limitation of leaderboards has not precluded the creation of cheaper models, given the real-world benefit of lower costs. For example, ELECTRA (Clark et al., 2020) can be trained up to several hundred times faster than traditional BERT-based models while performing comparably on GLUE. Similarly, DistilBERT is a distilled variant of BERT that is 40% smaller and 60% faster while retaining 97% of the language understanding (Sanh et al., 2019). There are many others like it as well (Zadeh and Moshovos, 2020; Hou et al., 2020; Mao et al., 2020). More efficiency and fewer parameters translate to lower costs.

Our point is not that there is no incentive at all to build cheaper models, but rather that this incentive is not baked into leaderboards, which are an important artefact of the NLP community. Because lower prediction costs improve practitioner utility, practitioners build them *despite* the lack of incentive from leaderboards. If lower prediction costs also improved leaderboard utility, then there would be more interest in creating them (Linzen, 2020; Rogers, 2019; Dodge et al., 2019). At the very least, making prediction costs publicly available would allow users to better estimate the utility that they will get from a model, given that the leaderboard's cost-ignorant ranking may be a poor proxy for their preferences.

3.3 Robustness

Leaderboard utility only depends on model rank, which in turn only depends on the model's performance on the test data. A typical leaderboard would gain no additional utility from a model that was robust to adversarial examples, generalized well to out-of-distribution data (Linzen, 2020), or was fair in a Rawlsian sense (i.e., by maximizing the welfare of the worst-off group) (Rawls, 2001; Hashimoto et al., 2018). In contrast, these are all attributes that NLP practitioners care about, particularly those who deploy systems in real-world applications. In fact, the literature on the lack of robustness in many SOTA models is extensive (Jia and Liang, 2017; Zhang et al., 2020).

There are many examples of state-of-the-art NLP models that were found to be brittle or biased. The question-answering dataset SQuAD 2.0 was created in response to the observation that existing systems could not reliably demur when presented with an unanswerable question (Rajpurkar et al., 2016, 2018). The perplexity of language models rises when given out-of-domain text (Oren et al., 2019). Many types of bias have also been found in NLP systems, with models performing better on gender-stereotypical inputs (Rudinger et al., 2018; Ethayarajh, 2020) and racial stereotypes being captured in embedding space (Manzini et al., 2019; Ethayarajh et al., 2019a,b; Ethayarajh, 2019). Moreover, repeated resubmissions allow for a model's hyperparameters to be tuned to maximize performance, even on a private test set (Hardt, 2017).

Note that leaderboards do not necessarily incentivize the creation of brittle and biased models; rather, because leaderboard utility is so parochial, these unintended consequences are relatively common. Some recent work has addressed the problem of brittleness by offering certificates of performance against adversarial examples (Raghunathan et al., 2018a,b; Jia et al., 2019). To tackle gender bias, the SuperGLUE leaderboard considers accuracy on the WinoBias task (Wang et al., 2019; Zhao et al., 2018). Other work has proposed changes to prevent over-fitting via multiple resubmissions (Hardt and Blum, 2015; Hardt, 2017) while some have argued that this issue is overblown, given that question-answering systems submitted to the SQuAD leaderboard do not over-fit to the original test set (Miller et al., 2020). A novel approach even proposes using a dynamic benchmark instead of a static one, creating a moving target that is harder for models to overfit to (Nie et al., 2019).

4 The Future of Leaderboards

4.1 A Leaderboard for Every User

Given that each practitioner has their own utility function, models cannot be ranked in a way that satisfies everyone. Drawing inspiration from data statements (Bender and Friedman, 2018; Mitchell et al., 2019; Gebru et al., 2018), we instead recommend that leaderboards demand transparency and require the reporting of metrics that are relevant to practitioners, such as training time, model size, inference latency, and energy efficiency. Dodge et al. (2019) have suggested that model creators submit these statistics of their own accord, but without leaderboards requiring it, there would be no explicit incentive to do so. Although NLP workshops and conferences could also require this, their purview is limited: (1) models are often submitted to leaderboards before conferences; (2) leaderboards make these statistics easily accessible in one place.

Giving practitioners easy access to these statistics would permit them to estimate each model's utility to them and then re-rank accordingly. This could be made even easier by offering an interface that allows the user to change the weighting on each metric and then using the chosen weights to dynamically re-rank the models. In effect, every user would have their own leaderboard. Ideally, users would even have the option of filtering out models that do not meet their criteria (e.g., those above a certain parameter count).

This would have beneficial second-order effects as well. For example, reporting the costs of making predictions would put large institutions and poorly-resourced model creators on more equal footing (Rogers, 2019). This might motivate the creation of simpler methods whose ease-of-use makes up for weaker performance, such as weighted-average sentence embeddings (Arora et al., 2019; Ethayarajh, 2018). Even if a poorly-resourced creator could not afford to train the SOTA model *du jour*, they could at least compete on the basis of efficiency or create a minimally viable system that meets some desired threshold (Dodge et al., 2019; Dorr, 2011). Reporting the performance on the worst-off group, in the spirit of Rawlsian fairness (Rawls, 2001; Hashimoto et al., 2018), would also incentivize creators to improve worst-case performance.

4.2 A Leaderboard for Every *Type* of User

While each practitioner may have their own utility function, groups of practitioners – characterized by a shared goal – can be modelled with a single function. For example, programmers working on low latency applications (e.g., multiplayer games) will place more value on latency than others. In contrast, researchers submitting their work to a conference may place more value on accuracy, given that a potential reviewer may reject a model that is not SOTA (Rogers, 2020). Although there is variance within any group, this approach is tractable when there are many points of consensus.

How might we go about creating a leaderboard for a specific type of user? As proposed in the previous subsection, one option is to offer an interface that allows the user to change the utility function dynamically. If we wanted to create a static leaderboard for a group of users, however, we would need to estimate their utility function. This could be done explicitly or implicitly. The explicit way would be to ask questions that use the dollar value as a proxy for cardinal utility: e.g., *Given a 100M parameter sentiment classifier with 200ms latency, how much would you pay per 1000 API calls?* One could also try to estimate the derivative of the utility function with questions such as: *How much would you pay to improve the latency from 200ms to 100ms, holding all else constant?* When there are multiple metrics to consider, some assumptions would be needed to tractably estimate the function.

The implicit alternative to estimating this function is to record which models practitioners actually use and then fit a utility function that maximizes the utility of the observed models. This approach is rooted in *revealed preference theory* (Samuelson, 1948) – we assume that what practitioners use reveals their latent preferences. Exploiting revealed preferences may be difficult in practice, however, given that usage statistics for models are not often made public and the decision to use a model might not be made with complete information.

5 Conclusion

In this work, we offered several criticisms of leaderboard design in NLP. While it has helped create more accurate models, we argued that this has been at the expense of fairness, efficiency, and robustness, among other desiderata. We were not the first to criticize NLP leaderboards (Rogers, 2019; Crane, 2018; Linzen, 2020), but we were the first to do so under a framework of *utility*, which we used to study the divergence between what is incentivized by leaderboards and what is valued by practitioners. Given the diversity of NLP practitioners, there is no one-size-fits-all solution; rather, leaderboards should demand transparency, requiring the reporting of statistics that may be of practical concern. Equipped with these statistics, each user could then estimate the utility that each model provides to them and then re-rank accordingly, effectively creating a custom leaderboard for everyone.

An Empirical Investigation Towards Efficient Multi-Domain Language Model Pre-training

`{arumae, qinsun, parmib}@amazon.com`

Abstract

Pre-training large language models has become a standard in the natural language processing community. Such models are pre-trained on generic data (e.g. BookCorpus and English Wikipedia) and often fine-tuned on tasks in the same domain. However, in order to achieve state-of-the-art performance on out of domain tasks such as clinical named entity recognition and relation extraction, additional in domain pre-training is required. In practice, staged multi-domain pre-training presents performance deterioration in the form of *catastrophic forgetting* (CF) when evaluated on a generic benchmark such as GLUE. In this paper we conduct an empirical investigation into known methods to mitigate CF. We find that elastic weight consolidation provides best overall scores yielding only a 0.33% drop in performance across seven generic tasks while remaining competitive in bio-medical tasks. Furthermore, we explore gradient and latent clustering based data selection techniques to improve coverage when using elastic weight consolidation and experience replay methods.

1 Introduction

Transformer (Vaswani et al., 2017) based language modeling has taken over many previous pre-training and initialization approaches (Devlin et al., 2019; Radford et al., 2019; Yang et al., 2019; Liu et al., 2019). Fine-tuning using these architectures yields state-of-the-art results in the order of a few hours. The caveat to these models is that the initial training can be on the scale of many days if not weeks, distributed across multiple GPUs (Strubell et al., 2019), a costly endeavour.

Pre-trained language models are adapted to perform strongly in more specific domains as well. For example, while the original BERT models (Devlin et al., 2019) were trained on English Wikipedia articles and BooksCorpus (Zhu et al., 2015), the same masked language modeling was continued on bio-medical data. BioBERT (Lee et al., 2019) was trained using Pubmed abstracts and full articles, meanwhile Clinical BERT (Alsentzer et al., 2019) was further refined using MIMIC-III clinical notes (Johnson et al., 2016). Evidence suggest that understanding the syntactic structure of scientific literature and clinical data from pre-training boosts performance in their respective downstream tasks (Peng et al., 2019). Pre-training is performed with the expectation of building robust, high capacity generalized language models which continue to absorb new domain knowledge.

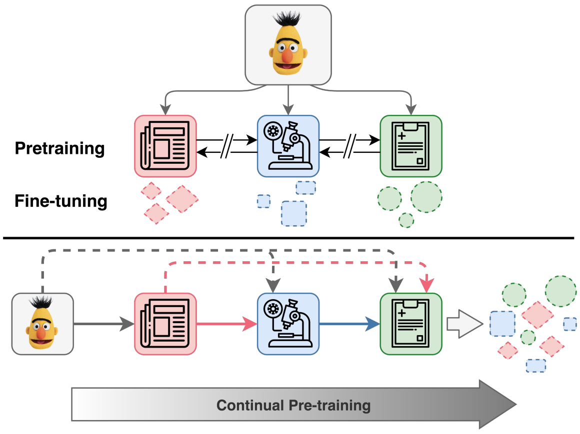

Figure 1: Traditional approaches (top) train independent domain specific language models (newswire, bio-medical, and clinical) which share no cross domain knowledge. They are further fine-tuned on their respective in-domain tasks. Our approach (bottom) shows how several domains are introduced in sequence, with knowledge retention using mitigation techniques across all domains. Here the final model has the capability to properly fine-tune on any domain specific task.

Unfortunately, continual learning (Ring, 1997) suffers from catastrophic forgetting (McCloskey and Cohen, 1989; Ratcliff, 1990) when incorporating domain data in a sequential manner. Parameters shift towards capturing the current task (or domain) and if previous data is no longer available the model will lose representation of it. For

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4854–4864,
November 16–20, 2020.

many tasks the straightforward solution is to combine datasets during training and approach this as a multi-task learning (MTL) (Ruder, 2017) problem. Mixing data has the desired effect of constraining parameters to find a space where both tasks reach close to optimal performance.

We argue that these expensive pre-trained models are an example where MTL is not feasible in practice for several reasons. Time and hardware accessibility are the largest constraints for developing such systems. Access to large scale training data is generally not possible (Radford et al., 2019; Devlin et al., 2019), and exact training configurations are equally difficult to gather with results being arduous to reproduce. Resource usage has recently been criticized from another perspective as well. Strubell et al. (2019) show that as deep neural architectures in the natural language community grow we increasingly trade results for carbon emissions.

Our work conducts an empirical investigation into suitable methods for multi-domain pre-training in a continual learning setting. We focus our efforts towards three methods: (i) elastic weight consolidation (EWC), (ii) learning rate control (LRC), and (iii) experience replay (ER). EWC (Kirkpatrick et al., 2017) is a parameter constraining method, an upgrade to vanilla regularization (e.g. L_2). LRC is borrowed from stage two of ULMFiT (Howard and Ruder, 2018) pre-training as a data independent method. Finally, as a scaled back version of MTL we investigate experience replay (ER), reintroducing data at a fixed scale from previous domains during pre-training. Furthermore we explore data selection approaches to improve efficiency for both ER, and EWC.

Our goal is to understand the trade-offs across these models in terms of resources and setup. To this end we conduct experiments across multiple domain shifts while pre-training. To evaluate the efficacy of the methods we use downstream fine-tuning tasks in the domains we study. To better understand how knowledge across domains is transferred, we perform layer-wise analysis and observe that outer layer are the most transferable.

Our contributions are as follows [1]:

- We provide empirical evidence of catastrophic forgetting mitigation with experience replay, learning rate control, and elastic weight consolidation, applied towards large scale language model pre-training. To this we add multiple domain shifts into bio-medical, and clinical data.
- We explore various data selection approaches for both elastic weight consolidation and replay based models.
- We investigate layer-wise understanding for continual pre-training across several domains to understand how best to mitigate forgetting and transfer knowledge understanding.

2 Continual Learning

We empirically study three forms of mitigation for catastrophic forgetting. Constraint based training in the form of EWC and learning rate control, and experience replay.

2.1 Elastic Weight Consolidation

EWC makes use of a simple Bayesian factorization of model representation (Kirkpatrick et al., 2017). This isolates the posterior of a learned task (A) while maintaining the objective of a current task (B). Due to the intractability of the true posterior, EWC makes use of a Fisher information (Frieden, 2004) matrix diagonal to approximate the effect of Task A on the parameters of a model. Intuitively speaking, if a parameter had a large effect on task A the Fisher value would be small yielding low variance to adapt to task B. This holds true inversely for when the Fisher value is large.

In practice, we initialize the Fisher matrix using gradients calculated with data sampled from Task A, which has already converged (Spall, 2005). This is demonstrated in Eq. 1 where i and j index parameters and data samples respectively.

$$F_{i,i} = \frac{1}{N}\sum_{j=1}^{N}\left(\frac{\partial \mathcal{L}_A^{(j)}}{\partial \theta_i}\right)^2 \tag{1}$$

$$\mathcal{L}(\theta) = \mathcal{L}_B(\theta) + \sum_i \lambda F_{i,i}(\theta_i - \theta^*_{A,i})^2 \tag{2}$$

The full objective for task B is given in Eq. 2 where $\mathcal{L}_B(\theta)$ is the loss function of Task B, and EWC is represented as the second term regularizing model parameters. Specifically by weighting the shift of model parameters while training on Task B (here θ_i and $\theta^*_{A,i}$ being the currently updated and frozen Task A parameters at index i respectively). The EWC objective component is further adjusted by the hyperparameter λ.

---

[1] Our code is avaialble at `https://github.com/aws-health-ai/multi_domain_lm`

Model	CoLA	SST-2	MRPC	STS-B	QQP	MNLI	QNLI	RTE	WNLI
$\text{BERT}_{\text{BASE}}$	57.82	92.09	86.74	88.13	87.49	84.01	90.79	64.98	53.52
BioBERT	37.78	89.68	88.44	87.40	86.96	83.19	89.79	60.29	28.17
Delta	20.04	2.41	-1.69	0.73	0.53	0.82	1.01	4.69	25.35

Table 1: Performance drop of BioBERT after further pre-training on Pubmed articles. The last row shows a positive value indicating the degree to which performance has dropped, and a negative value when it has increased.

2.2 Learning rate control

Our approach models the second stage of ULMFiT (Howard and Ruder, 2018), namely target task fine-tuning. We begin with a layer wise modifications by applying a decaying learning rate as a function of layer depth moving from the last layer towards model input.

$$\eta^{(l-1)} = \frac{\eta^{(l)}}{\rho} \tag{3}$$

Here η, l, and ρ denote learning rate, layer index and decay rate respectively. Depth plays a factor in our model since the network consists of 14 layers (i.e. 12 transformer layers, one layer for input, and one for the LM head).

2.3 Experience Replay

Given a replay buffer of a fixed, limited size we empirically investigate sample efficiency over a number of heuristic data selection methods. We focus our attention on how best to select data for this buffer, hypothesizing that domain coverage will increase performance. Recent work (de Masson d'Autume et al., 2019) has shown how this is crucial in strict lifelong learning when updating a fixed buffer size.

3 Catastrophic Forgetting in Language Modeling

We motivate our own experiments by first exploring off-the-shelf models to get a sense of the problem. To this end we fine tuned a $\text{BERT}_{\text{BASE}}$ architecture on all nine GLUE (Wang et al., 2018) tasks. These were compared directly against BioBERT, which has been further trained on full Pubmed articles. As reported in Table 1 an overall trend of performance deterioration is apparent with a relative increased error of 7.64% in the bio-medical model. Furthermore, we observed that on tasks which BERT struggles with, such as CoLA and WNLI, the performance decrease is amplified when switching pre-training domains.

4 Experimental Details

We first cover the data domains, fine-tuning tasks, and general modeling setup used in both our heuristic search as well as our main experiments in Section 6.2.2.

4.1 Pre-training Data

We processed publicly available bio-medical and non-bio-medical corpora for pre-training our models. For non-bio-medical data, we use BookCorpus and English Wikipedia data, CommonCrawl Stories (Trinh and Le, 2018), and OpenWebText (Gokaslan and Cohen, 2019). This combined corpus contains roughly 18B tokens. For bio-medical data, we use full Pubmed[2] articles which we processed to remove all tables, references, equations, and figures. This yields a dataset of over 4B tokens. For all datasets we retain training, validation, and test splits sampled at the document level with a respective ratio of 8:1:1.

4.2 Evaluation Data

We report the average accuracy across GLUE (Wang et al., 2018) tasks to track the performance of the model on generic natural language understanding. For measuring performance on GLUE, we further limit the selection of tasks to be the five most deteriorated (i.e. CoLA (Warstadt et al., 2018), SST-2 (Socher et al., 2013), MNLI (Williams et al., 2018), QNLI (Rajpurkar et al., 2016) and RTE (Giampiccolo et al., 2007)). Tasks such as QQP[3] and MRPC (Dolan and Brockett, 2005) are generally robust against domain change and perform well regardless of initialization. These five tasks reflect our findings from Table 1. Additionally we evaluate on CoNLL-03 (Tjong Kim Sang and De Meulder, 2003) named entity recognition (NER), and SQuAD 1.1 (Rajpurkar et al., 2016) question answering (QA). To demon-

---

[2] https://www.ncbi.nlm.nih.gov/pmc/

[3] https://www.quora.com/q/quoradata/First-Quora-Dataset-Release-Question-Pairs

strate domain shift we evaluate using BC5CDR (Li et al., 2016), Chemprot (Krallinger et al., 2017) and BioASQ (Nentidis et al., 2019) which are biomedical NER, relation extraction (RE), and QA tasks respectively. The first dataset is from the 2015 CDR challenge for identifying chemicals and diseases expertly annotated from Pubmed abstracts [4]. Chemprot contains annotations of chemical-protein reactions, also taken from Pubmed articles. Finally BioASQ appears in our paper using the same format and splits as described by Gu et al. (2020). Namely QA is treated as a binary classification of whether the answer to the query exists in the provided context.

4.3 Modeling

For modeling we use the RoBERTa architecture (Liu et al., 2019), and implement EWC, learning rate control, and experience replay changes directly into the model[5]. This extension of the original BERT removed next sentence prediction and is trained using only masked language modeling using very large batch sizes. We utilize all training hyperparameters as provided by Liu et al. (2019) unless otherwise noted, and use RoBERTa $_{\text{BASE}}$ as parameter initialization for all experiments. As a form of deterioration understanding, we continue to train a model using Pubmed articles (denoted as PMC) with no mitigation techniques.

5 Data Selection Methods

Data selection is an important component of both supervised, and unsupervised training. In our case, there is an abundance of data to build both the Fisher matrix, as well as the replay buffer. To do this efficiently for EWC and ER we need to severely restrict the number of datapoints we utilize. For example a mere 1.0% of generic pre-training data makes up over 400k segments. We require this subset to be comprehensively representative of the domain. Therefore, rather than randomly sampling data, we can use model generated features to induce better coverage of previous domains.

5.1 Gradient Analysis

We begin by treating the sum of squared gradients as a one-dimensional feature for data selection. The generic data is a skewed distribution with a mean at $1.04e^7$ and a standard deviation and max values of $4.89e^8$, and $1.82e^{11}$ respectively. The lower bound is, of course, 0 and arguably the samples closer towards that bound are more representative of the model in its generic state given this long tail.

	Sampling Type	GLUE	SQuAD	Avg.
	RoBERTa $_{\text{BASE}}$	87.56	90.20	88.00
	RoBERTa $_{\text{PMC}}$	83.00	88.73	83.95
ER	Random	84.23	89.43	85.10
	High	84.59	87.99	85.15
	Low	83.99	88.97	84.82
	Uniform	84.69	89.70	**85.53**
EWC	Random	86.93	90.32	87.50
	High	87.08	90.27	**87.61**
	Low	86.64	90.49	87.28
	Uniform	87.03	90.43	87.60

Table 2: Four sampling techniques used for pre-training and evaluated on GLUE and SQuAD 1.1. The results are compared against RoBERTa $_{\text{BASE}}$ and an unmitigated model trained on Pubmed articles (denoted using $_{\text{PMC}}$). The average column takes into account each of the individual GLUE tasks.

To be thorough we sampled data from this domain in four different ways: (i) randomly, (ii) low, (iii) high, and (iv) uniformly. For low and high sampling we order the samples according to this feature value and slice the list from the front or back. For uniform sampling we bin the data according to the gradient value, and sample from the bins uniformly, whereas random sampling is performed by treating all samples equally. For each of these experiments we sample 0.1% of the total corpus (roughly 42k segments). Furthermore in the same way that ER uses data to construct the replay buffer, EWC uses the samples to build the Fisher diagonal. We therefore test each sampling method across both mitigation techniques.

To test the effectiveness of our methods we pretrain RoBERTa $_{\text{BASE}}$ on one epoch of Pubmed data (with and without mitigation) and test retention performance by fine-tuning our models across GLUE and SQuAD 1.1. Looking at Table 2 we see that above all, using low gradients is the least useful signal. For ER, using uniform rather than low value selection has an average performance increase of 0.71 points. The other methods fall in line with uniform sampling indicating that including samples with larger gradients is helpful in representing of the source domain. EWC appears to be more robust

	100	10	**85.39**	87.24

Table 3: GLUE and SQuAD average performance for both ER and EWC when using two pooling techniques.

to data sampling with lower variance (1.8e−2 vs. 6.4e−2 for ER) across all models, with high and uniform selection improving most.

5.2 Sampling Latent Clusters

We further investigate more feature-rich representations in the form of sentence embeddings. Aharoni and Goldberg (2020) have demonstrated that transformer based LMs exhibit a keen ability to distinguish domains via clustering. The pre-training data for RoBERTa also comes from a variety of sources, with variation in prose, diction, and formality. We therefore cluster this data to see both how it is distributed and if uniformly sampling from these groups yields good performance for both EWC and ER.

Aharoni and Goldberg (2020) used average pooling across the last encoder layer to represent each segment, we test this method against using the vector representation of `<s>` (`[CLS]` in BERT) since it is frequently used in practice for sentence labeling. We then use PCA (Wold et al., 1987) to reduce the dimensionality to $d \in \{50, 100\}$ and apply a Gaussian Mixture Model (Reynolds, 2009) using $k \in \{5, 10\}$ as the number of clusters.

The resulting experiments for both ER and EWC can be seen in Table 3. Using PCA at 100 provides higher metrics for both ER and EWC, while the number of clusters for GMM does not give an interpretable signal across the experiments.

We note that from a practical perspective it is much faster to process data using clustering than gradients, largely due to the ability to batch data for clustering. Accumulating gradients for 1MM samples takes roughly five days using an NVIDIA V100, whereas acquiring latent representations from the same amount of data finishes in less than four hours (this does not account for PCA and clustering which takes an additional four to five hours).

6 Mitigation of Catastrophic Forgetting

We provide results for one and two stage domain shifts as given by fine-tuning tasks. Again, we apply mitigation only to pre-training and express our model performance by using them to fine-tune downstream tasks.

6.1 Setup

For a baseline and potential upper bound of performance we train a multi-domain learning (denoted as MDL) model which utilizes the full combined generic and bio-medical training sets as input data. For EWC (+EWC) we tune both λ [0.5, 1.0, 5.0, 10.0], and the size of the data used for fisher initialization [0.1%, 1.0%, 10.0%]; best values are underlined. For experience replay (+ER) we experiment with mixing non-bio-medical data (the same subset used for EWC init.) in each batch with a ratio proportional to their sizes. Additionally we showcase both a gradient based sampling (denoted with a subscript unif), and the GMM-PCA (subscript GMM) ($k = 5$, $d = 100$) for both ER and EWC. We tuned the decay rate, ρ in Eq. 3 [1.3, 1.7, 2.6] for LRC.

6.2 Results

Our experimental results are reported in Table 4. The first two rows contain the off-the-shelf RoBERTa as well as the PMC setting which received no catastrophic forgetting mitigation when further trained on bio-medical data. The lower section lists all mitigation based experimental settings as described above. For all models pre-trained using Pubmed data we fine-tune on tasks after a single epoch of pre-training.

We divide columns by task domain. The first three tasks (i.e. GLUE, SQuAD, and CoNLL) cover generic domain understanding. Just as in Section 5.1 we use the five worst GLUE tasks. For an overall understanding of forgetting we provide the average across all generic tasks. bio-medical tasks are displayed next followed by overall performance weighing the bio-medical and generic tasks equally [6]. NER and RE scores are reported using micro-F_1; all GLUE tasks we report accuracy on

---

[6] We take the mean of the generic and bio-medical average rather than treating each task equally since there are significantly more generic tasks.

Table 4: Single stage domain adaptation. Other than RoBERTa $_{\text{BASE}}$, each model is pre-trained further on one epoch of bio-medical data. We average generic performance across five GLUE tasks, as well as QA (from SQuAD), and NER (CoNLL). The average across generic tasks considers all nine tasks equally. bio-medical performance is for BC5CDR (NER), Chemprot (RE), and BioASQ (QA) with the overall performance being the mean for bio-medical and generic averages.

the development set; SQuAD is evaluated using F_1; BioASQ uses accuracy.

6.2.1 Catastrophic Forgetting

Unsurprisingly among the first two rows RoBERTa $_{\text{BASE}}$ performs best overall on generic tasks with an average performance increase of 4.47% over the unmitigated (PMC) model. Conversely it underperforms on the bio-medical tasks, validating the need to further pre-train on domain specific data. When averaging across the three bio-medical tasks the PMC model has a 1.05 point F_1 edge. It should be noted here that four of the models achieved the same BioASQ F_1 score, this was not reported in error.

6.2.2 Mitigation Based Models

EWC and LRC both respond well during domain shifts, are our best candidates for combating catastrophic forgetting, and average only half a point in deterioration amongst the three of them when compared against RoBERTa $_{\text{BASE}}$. LRC has the benefit of tuning a single hyperparameter, the decay rate (ρ). Due to the depth of the models we found that a high value ($\rho = 2.6$) yields a model which has a negligible drop in performance for generic tasks (with an average of 88.28) but had a more difficult time with later domains.

We observed during hyper-parameter optimization that EWC was quite sensitive to λ values. With higher coefficients ($\lambda > 1.0$) EWC was able to halt deterioration nearly completely but performed quite poorly on bio-medical tasks. To better understand the importance of the Fisher values, we trained EWC with no Fisher (i.e removing $F_{i,i}$ from Eq. 2). We found that this resulted in less competitive bio-medical results (averaging 3.68% worse than the listed bio-medical EWC scores, and having overall the worst scores for both bio-medical tasks across all models), illustrating that giving equal weight to all the parameters results in poor generalization across source and target domains. MDL performed surprisingly average compared to the resource trade-off of the model. While it does produce better results than RoBERTa $_{\text{BASE}}$ in the bio-medical domain, the model struggles to retain generic knowledge. Experience replay grapples most with domain retention and produced the highest mitigated BC5CDR, Chemprot, and BioASQ results coupled with the lowest generic results.

When comparing sampling techniques across a larger number of fine-tuning experiments we echo results from Section 5. Experience replay is stronger when using gradient based sampling, while EWC functions better using clustered latent representations. Therefore, in practice, we would suggest latent representations for better efficiency.

6.2.3 Two Stage Domain Adaptation

To further evaluate mitigation methods we continue pre-training models using clinical data. We chose the clinical domain since although it may appear close to bio-medical text, health records have been shown to differ drastically in prose and diction even when the underlying information may be similar (Gu et al., 2020). We processed 659M tokens of de-identified clinical notes and continued training using the PMC +LRC, PMC +ER $_{\text{unif}}$, and PMC +EWC $_{\text{GMM}}$ from Table 4 (with this stage of model denoted with a subscript 2). RoBERTa $_{\text{BASE}}$ is the untouched model as presented in Table 4, and we continue to train (unmitigated) the PMC model from the same table (now denoted as PMC, clin.). We evaluate models on RE and NER from the i2b2

Model	Generic	bio-medical	i2b2 NER	i2b2 RE	ADE RE	Clin. Avg.	Overall
RoBERTa $_{\text{BASE}}$	88.30	74.69	81.12	77.16	87.82	82.03	81.67
PMC, clin.	82.98	76.53	85.96	79.44	88.96	84.79	81.43
LRC$_2$	**87.47**	74.33	85.03	77.93	86.84	83.26	81.69
ER$_2$	84.51	**75.85**	85.16	79.20	**88.23**	**84.20**	81.52
EWC$_2$	86.99	75.04	**85.43**	**79.59**	86.07	83.47	**81.91**

Table 5: Averaged performance for all generic, and bio-medical tasks (i.e. as seen in Table 4). Clinical average is across i2b2 NER and RE as well as n2c2 ADE RE are given as Micro-F_1

challenge after 5 epochs [7]. Additionally we use the n2c2 adverse drug reaction (ADE) (Henry et al., 2020) RE task.

Stage two results are reported in Table 5. The last column in this table indicates that average overall performance is about the same across models, however, when we take a closer look at the domain breakdown we see this is not the case. As expected the unmitigated model (PMC, clin.) suffers from performance deterioration in generic tasks, with GLUE dropping drastically (an error increase to 6.21% compared to RoBERTa $_{\text{BASE}}$). We find that LRC is still firmly holding onto generic representation, with the smallest drop in average generic performance of 0.83 points, when compared to stage one. Here we found that tuning ρ became more prevalent, with the range of average clinical scores for LRC being 1.49 points. ER, and EWC are the only mitigated models which achieve competitive numbers for clinical tasks, although they both show a drop in generic, and bio-medical results. Both of the latter models outperform the base model in average bio-medical and clinical metrics.

7 Analysis

To further understand learning and forgetting across different mitigation strategies, we conduct analyses to investigate how different layers of the model adapt to in-domain pre-training, whether the adaptation helps in transferring knowledge to downstream tasks, and how knowledge learned from in & out of domain data cooperates together.

7.1 Layer-wise analyses

7.1.1 Weight Similarity

Figure 2 displays layer-wise weight (cosine-) similarity between models before and after pre-training on bio-medical data. We compare RoBERTa $_{\text{BASE}}$ (denoted as Generic) against the PMC model (row 2 in Table 4 and denoted as bio-medical in the Figure). In Figure 2a we discern similarity in layers closer towards the input. By comparing Figures 2b and 2c which illustrate how mitigated models behave compared to one another, we find that ER allows the model parameters to shift much closer towards the bio-medical data while EWC finds a shared space for parameters in both models. This is consistent with what we have observed in Section 6.2.2 where we find EWC is better at mitigating catastrophic forgetting compared to ER. It was important to see how LRC weights behave as well. Intuitively since the learning rate is close to 0 near the model input, these layers will change very little. This is indeed the case with only the last layer showing significant shift.

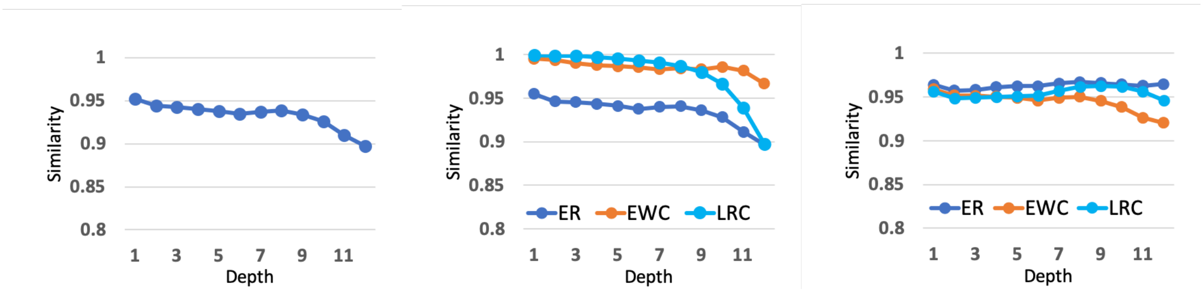
We investigate if constraining the weights to a shared space is enough to produce a good overall model. We observed that without the Fisher matrix, weight similarity between EWC and RoBERTa $_{\text{BASE}}$ is lower than 0.2, which is confirmed by the low F_1 scores noted in Section 6.2.2. This indicates that the Fisher diagonal plays an important role in fluctuating variance.

7.1.2 Transferability via Probing Tasks

To evaluate layer-wise transferability of pre-trained LMs, we use NER as a probing task and limit the capacity of task-specific layers to focus on what information has been learned by the model. We evaluate each layer of pre-trained LMs by extracting the model output as features and only fine-tuning task-specific layers. We observe in Figure 3 that (1) outer layers are most transferable to downstream tasks except for the last layer and (2) the performance of domain specific NER increases much faster than generic NER across layers, which indicates that grammatical understanding occurs in earlier layers, whereas segment level domain spe-

---

[7] To determine an appropriate stopping point we evaluated each epoch using the the clinical NER task until the Micro-F_1 plateaued.



(a) Generic vs. bio-medical (b) Mitigated Models vs. Generic (c) Mitigated Models vs. bio-medical

Figure 2: Weight distance vs. Depth across two domains. We compare RoBERTa BASE (trained on *generic* data) against PMC (denoted as bio-medical) and two mitigated models. Distance is given using cosine similarity.

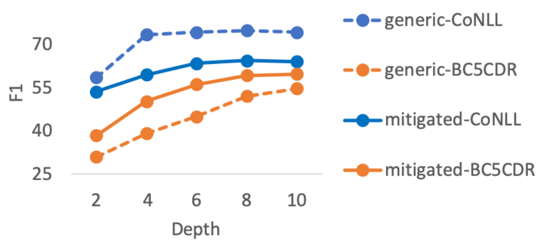


Figure 3: Transferability vs. Depth. Dashed curves denote generic models and solid curves denote mitigated models. After fine-tuning on bio-medical data, the performance of CoNLL drops while the performance of BC5CDR is boosted.

cific perception (i.e. semantics) appears in later layers. Both (1) and (2) are consistent with Figure 2a where weights change more in outer layers. This trend was also observed in previous works Belinkov et al. (2017); Jawahar et al. (2019).

Base on layer-wise analyses in this section, we empirically find that the adaptation in outer layers plays a key role in mitigation, which suggests that a decaying learning rate as a function of layer depth is worth being incorporated into different mitigation strategies.

7.2 Qualitative Examples

We observe that CF mitigation techniques are able to assist in generalization on rare words by composing knowledge from both generic and bio-medical domains. In Figure 4 (i) we observe that “Norilsk” occurs quite rarely in Newswire data, which is used for pre-training generic domain, however, it is frequent in Pubmed but size of pre-training data is small. Combining the two datasets in the form ER and EWC helps generalise the model understanding. We provide additional examples of this phenomenon in Figure 4 (ii) & (iii).

8 Related Work

Current work in catastrophic forgetting mitigation in NLP has been limited. Howard and Ruder (2018) introduced a multi stage training scheme for fine tuning LSTM based universal language models (ULMFiT). The authors proposed that current methods, rather than data, are ineffective and focused on learning rate control across layers, as well as modifying learning rate scheduling. A larger category of work deals with constraining model parameters to a latent space where they continue to capture previous tasks. Initial work focused on model regularization and varying activations (Goodfellow et al., 2013). Kirkpatrick et al. (2017) provided a more sophisticated solution constraining weights individually termed elastic weight consolidation (EWC). We make use of both EWC and ULMFiT and provide further technical detail in this paper. The final approach is focused on experience replay. Using small samples of data from previous tasks coupled with local adaptation de Masson d’Autume et al. (2019) demonstrate improvement in a lifelong learning training scheme. Chaudhry et al. (2019) also explore lifelong learning by experimenting with updating the memory bank for experience replay. Our work focuses on both of these techniques with the major difference being problem scale. Many existing works apply these solutions on small networks whereas we experiment on architectures having several orders of magnitude more parameters.

There has been a recent focus on more effective pre-training which focuses on narrowing the pre-training domain as we move closer towards fine-tuning. STILTs (Phang et al., 2018) and TandA (Garg et al., 2019) use intermediate tasks (in a data rich domain) training to lower variance during target task fine-tuning. This intuition was also covered

in the visio-linguistic domain by Singh et al. (2020). Finally Gururangan et al. (2020) work on MLM pre-training and provide conclusive evidence at scale of the works listed above. This last body of work, although dealing with pre-training is different from our work in that we study mitigation of domain forgetting, rather than reducing variance by adding intermediate domains or tasks to pre-training.

9 Conclusion

In this work, we empirically investigated the existence of catastrophic forgetting in large language model pre-training. We further explored constraint and replay based mitigation techniques to close the performance gap between general and domain specific natural language tasks. We find that training a single model across multiple domains is possible. Due to practical considerations, we would suggest using latent representation for data selection when working with a data dependent model such as ER or EWC. When no previous data is available LRC provides a simple yet powerful solution for retaining prior domain knowledge. In the future work wish to explore more data independent methods such as LRC, for both speed and lack of data dependency, as well as manipulation of the decay w.r.t. what we have discovered from our layer-wise analysis.

Acknowledgments

We would like to thank Byron Wallace, Kevin Small, Ramesh Nallapati, and members of Amazon Comprehend Medical for their help in shaping this work over the last year, as well as the conference reviewers for providing thoughtful feedback.

Abstract

While a lot of analysis has been carried to demonstrate linguistic knowledge captured by the representations learned within deep NLP models, very little attention has been paid towards individual neurons. We carry out a neuron-level analysis using core linguistic tasks of predicting morphology, syntax and semantics, on pre-trained language models, with questions like: i) do individual neurons in pre-trained models capture linguistic information? ii) which parts of the network learn more about certain linguistic phenomena? iii) how distributed or focused is the information? and iv) how do various architectures differ in learning these properties? We found small subsets of neurons to predict linguistic tasks, with lower level tasks (such as morphology) localized in fewer neurons, compared to higher level task of predicting syntax. Our study reveals interesting cross architectural comparisons. For example, we found neurons in XLNet to be more localized and disjoint when predicting properties compared to BERT and others, where they are more distributed and coupled.

1 Introduction

Transformer-based neural language models have constantly pushed the state-of-the-art in downstream NLP tasks such as *Question Answering*, *Textual Entailment*, etc. (Rajpurkar et al., 2016; Wang et al., 2018). Central to this revolution is the contextualized embedding, where each word is assigned a vector based on the entire input sequence, allowing it to capture not only a static semantic meaning but also a contextualized meaning.

Previous work on analyzing neural networks showed that while learning rich NLP tasks such as machine translation and language modeling, these deep models capture fundamental linguistic phenomena such as word morphology, syntax and various other relevant properties of interest (Shi et al., 2016; Adi et al., 2016; Belinkov et al., 2017a,b; Dalvi et al., 2017; Blevins et al., 2018).
More recently Liu et al. (2019) and Tenney et al. (2019) used probing classifiers to analyze pre-trained neural language models on a variety of sequence labeling tasks and demonstrated that contextualized representations encode useful, transferable features of language. While most of the previous studies emphasize and analyze representations as a whole, very little work has been carried to analyze individual neurons in deep NLP models.

Studying individual neurons can facilitate understanding of the inner workings of neural networks (Karpathy et al., 2015; Dalvi et al., 2019; Suau et al., 2020) and have other potential benefits such as controlling bias and manipulating system's behaviour (Bau et al., 2019), model distillation and compression (Rethmeier et al., 2020), efficient feature selection (Dalvi et al., 2020), and guiding architectural search.

In this work, we put the representations learned within pre-trained transformer models under the microscope and carry out a fine-grained neuron level analysis with respect to various linguistic properties. We target questions such as: i) do individual neurons in pretrained models capture linguistic information? ii) which parts of the network learn more about certain linguistic phenomena? iii) how distributed or focused is the information? and iv) how do various architectures differ in learning these properties?

A typical methodology in previous work on analyzing representations trains probing classifiers using the representations learned within a neural model, to predict the understudied task. We also use a probing classifier approach to analyze individual neurons. Since neurons are multivariate in nature and work in groups, we additionally use elastic-net regularization that encourages individual and group of neurons to play a role in the train-

ing of the classifier. Given a trained classifier, we consider the weights assigned to each neuron as a measure of their importance with respect to the understudied linguistic task. We use probes with high *selectivity* (Hewitt and Liang, 2019) to ensure that our results reflect the property of representations and not the probe's capacity to learn.

We choose 4 pre-trained models: ELMo (Peters et al., 2018a), its transformer variant T-ELMo (Peters et al., 2018b), BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019) – covering a varied set of modeling choices, including the building blocks (recurrent networks versus Transformers), optimization objective (auto-regressive versus non-autoregressive), and model depth and width. Our cross architectural analysis yields the following insights:

- Information across networks is distributed, but it is possible to extract a very small subset of neurons to predict a linguistic task with the same accuracy as using the entire network.
- Low level tasks such as predicting morphology require fewer neurons compared to high level tasks such as predicting syntax.
- Some phenomena (e.g. *Verbs*) are distributed across many neurons while others (e.g. *Interjections*) are localized in a fewer neurons.
- Lower layers contain more word-level specialized neurons, and higher layers contain neurons specialized in syntax-level information.
- BERT is the most distributed model with respect to all properties while XLNet exhibits focus with the most disjoint set of neurons and layers designated for different linguistic properties.

2 Methodology

A common approach for probing neural network components against linguistic properties is to train a linear classifier using the activations generated from the trained neural network as static features. The underlying assumption is that if a simple linear model can predict a linguistic property, then the representations implicitly encode this information.

Probe: We go a level deeper and identify neurons within the learned representations to carry out a more fine-grained neuron[1] level analysis. We use a logistic regression classifier with elastic-net regularization (Zou and Hastie, 2005). The weights of the trained classifier serve as a proxy to select the most relevant features[2] within the learned representations, to predict a linguistic property. Formally, consider a pre-trained neural language model $\mathbb{M}$ with L layers: $\{l_1, l_2, \ldots, l_L\}$. Given a dataset $\mathbb{D} = \{w_1, w_2, ..., w_N\}$ with a corresponding set of linguistic annotations $\mathbb{T} = \{t_{w_1}, t_{w_2}, ..., t_{w_N}\}$, we map each word w_i in the data $\mathbb{D}$ to a sequence of latent representations: $\mathbb{D} \overset{\mathbb{M}}{\longmapsto} \mathbf{z} = \{\mathbf{z}_1, \ldots, \mathbf{z}_n\}$. The representations can either be extracted from the entire model or just from an individual layer. The model is trained by minimizing the following loss function:

$$\mathcal{L}(\theta) = -\sum_i \log P_\theta(t_{w_i}|w_i) + \lambda_1 \|\theta\|_1 + \lambda_2 \|\theta\|_2^2$$

where $P_\theta(t_{w_i}|w_i)$ is the probability that word i is assigned property t_{w_i}. The weights $\theta \in \mathbb{R}^{D \times T}$ are learned with gradient descent. Here D is the dimensionality of the latent representations $\mathbf{z}_i$ and T is the number of tags (properties) in the linguistic tag set, which the classifier is predicting. The terms $\lambda_1 \|\theta\|_1$ and $\lambda_2 \|\theta\|_2^2$ correspond to $L1$ and $L2$ regularization. This combination, known as elastic-net, strikes a balance between identifying very focused localized features ($L1$) versus distributed neurons ($L2$). We use a grid search algorithm described in **Search**, to find the most appropriate set of lambda values. But let us describe the neuron ranking algorithm first.

Neuron Ranking Algorithm: Once the classifier has been trained, our goal is to retrieve individual or a group of neurons (some subset of features of the latent representation) that are the most relevant for predicting a particular linguistic property $\mathbb{T}$ of interest. We use the neuron ranking algorithm as described in Dalvi et al. (2019). Given the trained classifier $\theta \in \mathbb{R}^{D \times T}$, the algorithm extracts a ranking of the D neurons in the model $\mathbb{M}$. For each label[3] t in task $\mathbb{T}$, the weights are sorted by their absolute values in descending order. To select N most salient neurons w.r.t. the task $\mathbb{T}$, an iterative process is carried. The algorithm starts with a small

---

[1] In our terminology, a neuron is one dimension in a high-dimensional representation, even when the representation is the output of a complex operation such as a transformer block.

[2] We use features and neurons interchangeably in the paper.

[3] We use label and sub-property interchangeably.

percentage of the total weight mass and selects the most salient neurons for each sub-property (e.g. *Nouns* in POS tagging) until the set reaches the specified size N.

Search: The search criteria is driven through ablation of weights in the trained classifier. Once the classifier is trained, we select M[4] top and bottom features according to our ranked list (obtained using neuron ranking algorithm described above) and zero-out the remaining features. We then compute score for each lambda set (λ_1, λ_2) as:

$$\mathcal{S}(\lambda_1, \lambda_2) = \alpha(A_t - A_b) - \beta(A_z - A_l)$$

where A_t is the accuracy of the classifier retaining top neurons and masking the rest, A_b is the accuracy retaining bottom neurons, A_z is the accuracy of the classifier trained using all neurons but without regularization, and A_l is the accuracy with the current lambda set. The first term ensures that we select a lambda set where accuracies of top and bottom neurons are further apart and the second term ensures that we prefer weights that incur a minimal loss in classifier accuracy due to regularization.[5] We set α and β to be 0.5 in our experiments. This formulation enables the search to be automated, compared to Dalvi et al. (2019) where the lambdas were selected manually, which we found to be cumbersome and error-prone.

Minimal Neuron Selection: Once we have obtained the best regularization lambdas, we follow a 3-step process to extract minimal neurons for any downstream task: i) train a classifier to predict the task using all the neurons (call it *Oracle*), ii) obtain a neuron ranking based on the ranking algorithm described above, iii) choose the top N neurons from the ranked list and retrain a classifier using these, iv) repeat step 3 by increasing the size of N,[6] until the classifier obtains an accuracy close (not less than a specified threshold δ) to the *Oracle*.

Control Tasks: While there is a plethora of work demonstrating that contextualized representations encode a continuous analogue of discrete linguistic information, a question has also been raised recently if the representations actually encode linguistic structure or whether the probe memorizes the understudied task. We use *Selectivity* as a criterion to put a "linguistic task's accuracy in context with the probe's capacity to memorize from word types" (Hewitt and Liang, 2019). It is defined as the difference between linguistic task accuracy and control task accuracy. An effective probe is recommended to achieve high linguistic task accuracy and low control task accuracy. The control tasks for our probing classifiers are defined by mapping each word type x_i to a randomly sampled behavior $C(x_i)$, from a set of numbers $\{1 \ldots T\}$ where T is the size of tag set to be predicted in the linguistic task. The sampling is done using the empirical token distribution of the linguistic task, so the marginal probability of each label is similar. We compute *Selectivity* by training classifiers using all and the selected neurons.

3 Experimental Setup

Pre-trained Neural Language Models: We present results with 4 pre-trained models: ELMo (Peters et al., 2018a), and 3 transformer architectures: Transformer-ELMo (Peters et al., 2018b), BERT (Devlin et al., 2019) and XLNet (Yang et al., 2019). The ELMo model is trained using a bidirectional recurrent neural network (RNN) with 3 layers each of size 1024 dimensions. Its transformer equivalent (T-ELMo) is trained with 7 layers but with the same hidden layer size. The BERT model is trained as an auto-encoder with a dual objective function of predicting masked words and next sentence in auto-encoding fashion. We use base version (13 layers and 768 dimensions). Lastly we included XLNet-base which is trained with the same parameter settings (number and size of hidden layers) as BERT, but with a permutation based auto-regressive objective function.

Language Tasks: We evaluated our method on 4 linguistic tasks: POS-tagging using the Penn TreeBank (Marcus et al., 1993), syntax tagging (CCG supertagging)[7] using CCGBank (Hockenmaier, 2006), syntactic chunking using CoNLL 2000 shared task dataset (Tjong Kim Sang and Buchholz, 2000), and semantic tagging using the Parallel Meaning Bank data (Abzianidze et al., 2017). We used standard splits for training, de-

[4] M is set to 20% of the network in our experiments

[5] For some lambdas, for example with high value of L1, the classifier prefers sparsity, i.e. selects fewer very focused neurons but performs very badly on the task.

[6] We increment by adding 1% neuron at every step.

[7] CCG captures global syntactic information locally at the word level by assigning a label to each word annotating its syntactic role in the sentence. The annotations can be thought of as a function that takes and return syntactic categories (like an NP: Noun phase).

velopment and test data (See Appendix A.1)

Classifier Settings: We used linear probing classifier with elastic-net regularization, using a categorical cross-entropy loss, optimized by Adam (Kingma and Ba, 2014). Training is run with shuffled mini-batches of size 512 and stopped after 10 epochs. The regularization weights are trained using grid-search algorithm.[8] For sub-word based models, we use the last activation value to be the representative of the word as prescribed for the embeddings extracted from Neural MT models (Durrani et al., 2019) and pre-trained Language Models (Liu et al., 2019). Linear classifiers are a popular choice in analyzing deep NLP models due to their better interpretability (Qian et al., 2016; Belinkov et al., 2020). Hewitt and Liang (2019) have also shown linear probes to have higher *Selectivity*, a property deemed desirable for more interpretable probes. Linear probes are particularly important for our method as we use the learned weights as a proxy to measure the importance of each neuron.

4 Evaluation

4.1 Ablation Study

First we evaluate our rankings as obtained by the neuron selection algorithm presented in Section 2. We extract a ranked list of neurons with respect to each property set (linguistic task T) and ablate neurons in the classifier to verify the rankings. This is done by *zeroing-out* all the activations in the test, except for the selected $M\%$ neurons. We select top, random and bottom 20%[9] neurons to evaluate our rankings. Table 1 shows the efficacy of our rankings, with low performance (prediction accuracy) using only the bottom or random neurons versus using only the top neurons. The accuracy of random neurons is high in some cases (for example CCG, a task related to predicting syntax) showing when the underlying task is complex, the information related to it is more distributed across the network causing redundancy.

	BERT	XLNet	T-ELMo	ELMo
